ABOUT THE EDITOR

Gavriel Salvendy is a professor of Industrial Engineering at Purdue University and is the author or coauthor of over 380 research publications, including over 190 journal papers, and the author or editor of 24 books. His publications have appeared in six languages. His main research deals with improving the usability of the network. He is the founding editor of the *International Journal on Human–Computer Interaction, International Journal on Cognitive Ergonomics,* and *Human Factors and Ergonomics in Manufacturing.* Gavriel Salvendy was the founding chair of the International Commission on Human Aspects in Computing, headquartered in Geneva, Switzerland. In 1990 he was the first member of either the Human Factors and Ergonomics Society or the International Ergonomics Association to be elected to the National Academy of Engineering. He was elected ''for fundamental contributions to and professional leadership in human, physical, and cognitive aspects of engineering systems.'' He is the 1991 recipient of the Mikhail Vasilievich Lomonosov Medal (founder medal) of the Russian Academy of Science. This was the first time that this award was presented to a scientist outside the former USSR. In 1995 he received an Honorary Doctorate from the Chinese Academy of Sciences ''for great contributions to the development of science and technology and for the great influence upon the development of science and technology in China.'' He is the fourth person in all fields of science and engineering in the 45-year history of the Academy ever to receive this award. He is an honorary fellow and life member of the Ergonomics Society, a Fellow of the International Ergonomics Association, Human Factors and Ergonomics Society, Institute of Industrial Engineers, and the American Psychological Association. He has advised organizations and corporations in 23 countries on the human side of effective design, implementation, and management of advanced technologies in the workplace. He earned his Ph.D. in engineering production at the University of Birmingham, United Kingdom.

ADVISORY BOARD

CONTRIBUTORS

Mary Elizabeth A. Algeo
Computer Scientist
National Institute of Standards and Technology
Gaithersburg, Maryland
USA
algeo@cme.nist.gov

Susan Archer
Director of Operations

FOREWORD

Many people speculated about what industrial engineering might look like in the 21st century, and now here we are. It is exciting to see how the profession's definition of the work center has broadened to embrace the information age and the global economy. Industrial engineers, with their ever-expanding toolbox, have a greater opportunity to help corporations be successful than ever before.

But while these changes and opportunities are exciting, they presented a challenge to the editor of this handbook. I met with Gavriel Salvendy as he began working to integrate all the thoughtful input he had received from his advisory committee, so I had a firsthand opportunity to observe the energy and creativity required to develop this content-rich edition. This handbook is truly an accomplishment, fully supporting industrial engineers engaged in traditional as well as new facets of the profession.

This edition has stepped up to this multidimensional challenge. The Technology section updates the previous edition, with coverage of topics such as decision support systems, but also delves into information-age topics such as electronic commerce. Look closer and you'll see that attention has been given to the growing services sector, including chapters covering specific application areas.

''Enterprise'' has become a popular way to describe the total system and the broad organizational scope of problem-solving initiatives. I am pleased to see this addressed specifically through topics such as enterprise modeling and enterprise resource planning, as well as globally, as in the Management, Planning, Design, and Control section. This edition truly recognizes that IEs can and do contribute in every phase of the total product life cycle.

The mission of the Institute of Industrial Engineers is to support the professional growth of practicing industrial engineers. This third edition is an all-encompassing Handbook for the IE professional that rises to the task. Students, engineers of all types, and managers will find this a useful and insightful reference.

JOHN POWERS
Executive Director
Institute of Industrial Engineers

PREFACE

Industrial Engineering has evolved as a major engineering and management discipline, the effective utilization of which has contributed to our increased standard of living through increased productivity, quality of work and quality of services, and improvements in the working environments. The *Handbook of Industrial Engineering* provides timely and useful methodologies for achieving increased productivity and quality, competitiveness, globalization of business and for increasing the quality of working life in manufacturing and service industries. This Handbook should be of value to all industrial engineers and managers, whether they are in profit motivated operations or in other nonprofit fields of activity.

The first edition of the *Handbook of Industrial Engineering* was published in 1982. It has been translated into Japanese and published by the Japan Management Association; translated into Spanish and published by Editorial Lemusa; published in a special edition in Taiwan by Southeast Book Company; and translated into Chinese and published by Mechanical Industry Publisher; and adopted by the Macmillan book club. The Handbook was selected by the Association of American Publishers as the Best Professional and Scholarly Publication in 1982 and was widely distributed by the Institute of Industrial Engineers (IIE). The Foreword of the first edition of the Handbook was written by Donald C. Burnham, retired Chairman of Westinghouse Electric Corporation. In this Foreword Burnham wrote, ''The Industrial Engineering principles that are outlines are timeless and basic and should prove useful to corporations, both large and small, both continuous process as well as discrete part manufacturing, and especially to those working in the service industries where most of the jobs are today.'' The second edition of the *Handbook of Industrial Engineering* maintained this thrust.

In the Foreword to the second edition, the former president of NEC Corporation wrote, ''The Second Edition of the Handbook of Industrial Engineering will serve as an extremely powerful tool for both industrial engineers and managers.'' The many contributing authors came through magnificently. I thank them all most sincerely for agreeing so willingly to create this Handbook with me.

Each submitted chapter was carefully reviewed by experts in the field and myself. Much of the reviewing was done by the Advisory Board. In addition, the following individuals have kindly contributed to the review process: Stephan A. Konz, K. Ronald Laughery, Jack Posey, William B. Rouse, Kay M. Stanney, Mark Spearman, and Arnold L. Sweet.

For the third edition of this Handbook, 97 of the 102 chapters were completely revised and new sections added in project management (3 chapters), supply-chain management and logistics (7 chapters) and the number of chapters in

service systems increased from 2 to 11 chapters. The 102 chapters of this third edition of the handbook were authored by 176 professionals with diverse training and professional affiliations from around the world. The Handbook consists of 6441 manuscript pages, 922 figures, 388 tables, and 4139 references that are cited for further in-depth coverage of all aspects of industrial engineering.

The editing of the third edition of the Handbook was made possible through the brilliant, most able, and diligent work of Kim Gilbert, my administrative assistant, who so effectively coordinated and managed all aspects of the Handbook preparation. My sincere thanks and appreciation go to her. It was a true pleasure working on this project with Bob Argentieri, the John Wiley senior editor, who is the very best there is and was a truly outstanding facilitator and editor for this Handbook.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. OVERVIEW

The theme of this chapter is ''achieving full potential.'' We explore how industrial and systems engineering and engineers (ISEs) can achieve full potential and how the ISE function and individual ISEs can assist their organizations in the achievement of full potential. Our fundamental premise is that organizations that desire to achieve full potential can enhance their success by more fully utilizing the potential of their ISEs. This will require holding a different definition for ISE, organizing the function differently, and having a different expectation regarding the ISE value proposition. The practicing ISE will also need to envision the role(s) he or she can play in large-scale transformation. This possibility has implications for the way ISE is organized and positioned in organizations, for higher education, and for the individual ISE.

1.1. Full Potential Introduced

Have you ever experienced being a ''10''? Perhaps you struck a perfect golf shot, had a great day when everything went perfectly, or flawlessly executed a project. We're thinking of something that turned out even better than you expected—when you were in ''flow,'' creating the optimal experience and optimal results (Csikszentmihalyi 1990). Full potential is about realizing personal and organizational possibilities. It's about getting into flow and staying there. It's about creating optimal results from the organizational system.

1.2. Structure of the Chapter

In its simplest form, an organization might be modeled as a complex collection of actions that drive particular results. These actions take place in a context or environment that mediates or moderates the results. Figure 1 illustrates such a model.

This model will be our organizing frame for the chapter. We will discuss the role of ISE in corporate transformation, in the achievement of organizational full potential performance. As you see in Figure 1, there are three roles that the ISE can play in this model:

1. Strategy and positioning (e.g., what is the value proposition? Are we doing the right things? What is the strategic planning process, who is involved, what is the system, how do we ensure it works?)
2. Conditions for success (what are the conditions surrounding the actions that drive results? Is the environment right to support success?)
3. ''Drivers,'' or operations improvement (are we doing the right things right? How are we doing things?)

We will discuss these roles in that order in the chapter. Note that the third role has been the traditional focus of ISE; we will suggest an expansion of the ISE ''domain.'' Rather than cover what is well covered in the rest of this handbook in the three roles for ISE in the future state organization, we will highlight, in each of the three roles, work that we believe ISEs will migrate to in achieving full potential.

1.3. ISE Domain Defined

As James Thompson points out, a domain can be defined by the ''technologies employed,'' the ''diseases treated,'' and/or the ''populations served'' (Thompson 1967).

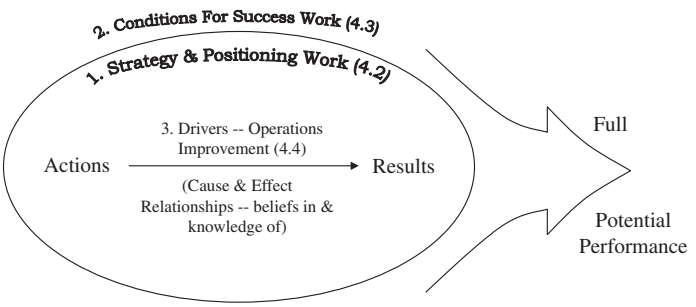

Figure 1 Actions → Results in Context of Conditions for Success.

Consider the remaining sections of this Handbook: Information Technology, Manufacturing and Production Systems, Service Systems, Organization and Work Design, Human Factors and Ergonomics, Project Management, Product Planning, Manpower Resource Planning, Systems and Facilities Design, Planning and Control, Quality, Supply Chain Management and Logistics, Probabilistic Models and Statistics, Economic Evaluation, Computer Simulation, and Optimization. All speak, in one way or another, to technologies employed by ISEs, diseases treated by ISEs, and/or to a lesser extent populations served by ISEs. Again, we will propose expanding the ISE role. Let's begin by examining the traditional definition of ISE and then explore a broader domain definition in the context of full potential performance.

1.4. Operational Definition of ISE

"An Industrial and Systems Engineer is one who is concerned with the design, installation, and improvement of integrated systems of people, material, information, equipment, and energy by drawing upon specialized knowledge and skills in the mathematical, physical, and social sciences, together with the principles and methods of engineering analysis and design to specify, predict, and evaluate the results to be obtained from such systems" (Womack and Jones 1996). This is the current and fairly traditional definition for ISE.

1.5. Applying the Definition

According to Dr. W. Edward Deming, an operational definition is a definition you can "do business with." Let's see if we can do business with the formal definition.

The key word in the definition is "system." It prompts the question "What system is it that ISE's work to optimize?" Our contention is that the ultimate system of interest is the extended enterprise. Ken Wilbur (1996), a challenging author to read and understand, says growth is about "transcending" and "including." To contribute to full potential, ISEs must include and also transcend the subsystem they are working on. ISEs must also transcend and include the roles they play and the work they do. ISEs must see how performance improvement in the target subsystem (warehouse layout, work cell configuration, display/human-equipment interface, queue design, simulation, supply chain, etc.) serves the higher good or works to optimize the performance of the larger system. Jim Tompkins (1999) speaks to this and provides an example in his lectures on the migration from warehouse management to supply chain management to supply chain synthesis. Transcending the ISEs traditional system of interest may be the most profound change facing our profession. Inability or unwillingness to address the larger system may hold a clue to the decline our professional society has experienced in the 1980s and 1990s.

Figure 2 is a portrayal of ISE extracted from the perspective of an academic program.

Notice how in this model ISE builds on a core engineering curriculum foundation and then specializes in four basic areas: human factors engineering, manufacturing systems engineering, operations research, and management systems engineering. Each of these four specialty areas dovetails

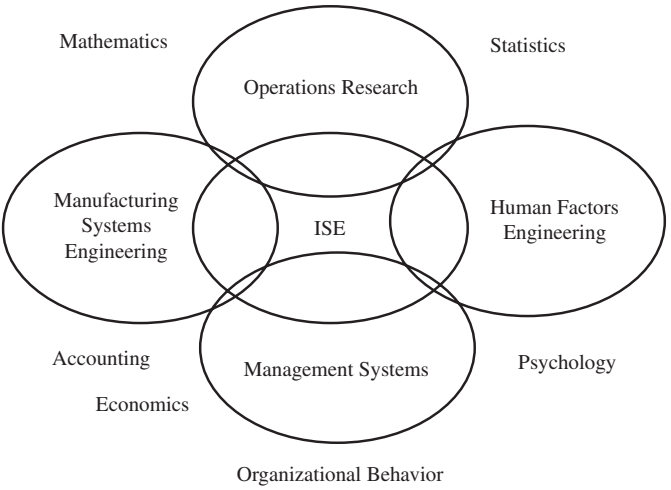

Figure 2 An Academic Portrayal of Part of the "Domain" Definition for ISE.

with basic knowledge areas and/or application areas such as statistics, psychology, mathematics, information sciences, accounting, and economics.

While this model is useful for portraying ISE from a curricular perspective, it is much less useful from an application perspective. Once the ISE begins reduction of theory to practice, the academic distinctions rapidly disappear. The ISE typically migrates to a setting that is defined by business processes rather than subdiscipline. The fledgling ISE is thrown into a system of people and capital that survives and thrives by continuing to enhance customer loyalty while at the same time reducing costs and improving efficiency. Fortunately, the ISE value proposition is so robust that enterprising ISEs find that they can contribute at any point and any level in the enterprise system.

ISEs at work are more accurately portrayed by the potential value contribution or offerings they bring to the enterprise as it migrates to full potential and future state. ISEs at work will increasingly find that they must transcend and include their academic training in order to contribute meaningfully to the quest for full potential. Figure 3 is an example of such a portrayal.

The specific contribution that ISEs make, the true value contribution, is the focus of this model. One example might be creating more effective measurement systems that lead to better information about the connection between improvement interventions and customer behaviors. Others might include optimized supply chain systems or increased safety and reduced lost time injuries. What is important in these examples is their impact on business results rather than their particular tools, techniques, or disciplinary focus. It is the cause-and-effect relationship between the value proposition and the business result that is the emerging emphasis. The disciplinary tool, knowledge, or technique becomes valuable when it is applied and we see its instrumentality for achieving positive business results. The ISE value proposition isn't only knowledge; it is the ability to reduce that knowledge to practice in such a way that it produces positive business results. In the coming decades, ISE practice is going to be very, very focused on creating results that move ISEs and their organizations toward full potential.

1.6. Integrating Work in Strategy and Policy, Conditions for Success, and Operations Improvement Leads to Full Potential

Our point of view is that integrating work done to achieve strategy and positioning, the management of conditions for success, and operations improvement create full potential performance (again, see Figure 1). The role of ISE needs to expand to include more involvement with this integration. ISE work in operations improvement, at minimum, needs to be seen in the context of the other two roles. At the extreme, ISE needs to be active in strategy and positioning and condition for success work. And it is value creation for the organization that is the end in the coming decades. A profession that

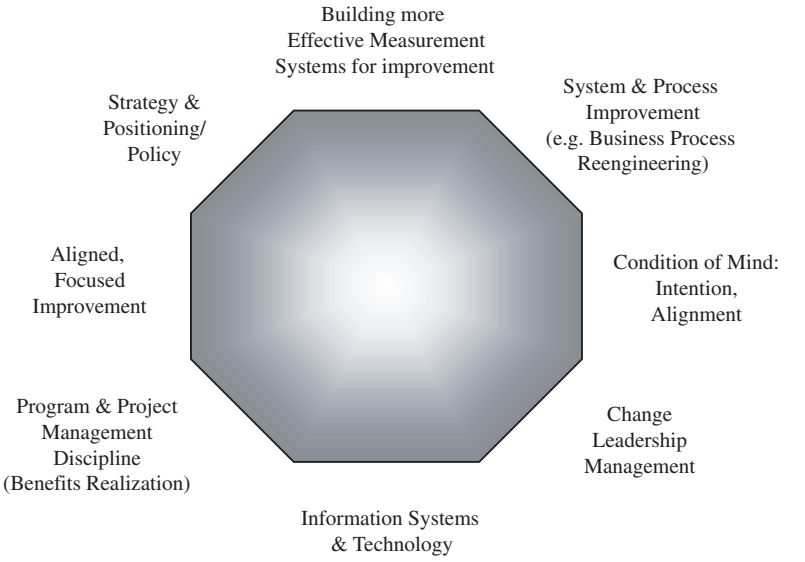

Figure 3 ISE Value Proposition: A Real World Perspective.

is so constrained by the technologies it employs and doesn't focus on the end will continue to struggle. We will explain what we mean further into this chapter.

2. THE FULL POTENTIAL MODEL FOR THE ORGANIZATION

2.1. Overview

Full potential organizations are made up of full potential individuals. We will address individual full potential briefly at the end of the chapter. Our discussion of organizational full potential will be more extensive, including specific examples of full potential for organizations, discussed in the context of the enterprise or business excellence model. We will also explore the implications of the expanded role of the ISE on our profession.

2.2. Examples of Full Potential

Two seminal books come to mind when we think about full-potential organizations: *Built to Last* (Collins and Porras 1994) and *The Living Company* (DeGeus 1997). Collins and Porras portrayed eighteen ''visionary'' companies, companies that are more than successful, more than enduring. They are best of best in their industries and have been that way for decades; in fact, they performed well over some 70 years. The visionary companies were matched with 18 comparison firms* for the analysis. The DeGeus study, commissioned by Dutch Royal Shell, looked at 27 firms that were larger and older than Shell. These ''living companies'' had thrived for 100–200 years. We will review these studies to provide you with a glimpse of the ''full potential'' model (see Figure 4) and to highlight the ''causal variables'' identified by the studies. We will then explore the implications of these studies for the ISE profession.

Collins and Porras's visionary companies attained extraordinary long-term performance. Consider three $1 investments on January 1, 1926: one in a general market stock fund, one in a visionary company, and one in a comparison company. By 1996, $1 in the general market investment would have grown to $415; in the comparison firms, to $955; and in the visionary firms, to $6356 (see Figure 4).

What was full potential? What was possible? The point to be made from these numbers is that there are orders-of-magnitude differences in market performance between the visionary companies and the comparison organizations. One might even contend that ''full potential'' was in fact $10,000 or more! Surviving for 70+ years is an accomplishment in and of itself; we believe that *thriving* over that period begins to describe full potential. Collins and Porras concluded that ''visionary companies display a powerful drive for progress that enables them to change and adapt without compromising their cherished core ideals (1994, 9).

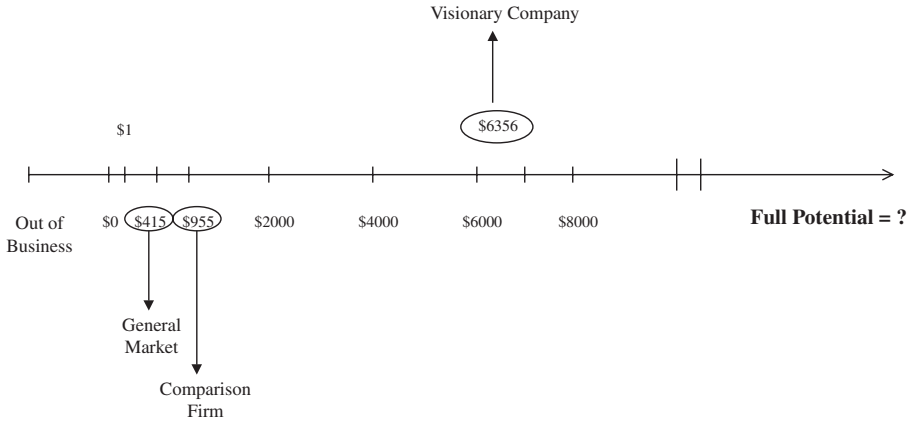

Figure 4 Relative Performance Data from Collins and Porras (1994): What Was Full Potential?

*E.g., 3M the visionary company, Norton the comparison firm; Boeing the visionary company, McDonnell Douglas the comparison firm; Citicorp the visionary company, Chase Manhattan the comparison firm.

What are the attributes of full potential organizations? In living companies, DeGeus found four significant factors:

1. *Sensitivity to the environment:* the ability to learn and adapt (we might add, in a timely fashion)
2. *Cohesion and identity:* the ability to build community and a distinct cultural identity (we might add, that supports full potential performance)
3. *Tolerance and decentralization:* the ability to build constructive relationships with other entities, within and without the primary organization
4. *Conservative financing:* the ability to manage growth and evolution effectively

DeGeus states, ''Like all organisms, the living company exists primarily for its own survival and improvement: to fulfill its potential and to become as great as it can be'' (1997, 11).

Collins and Porras went beyond DeGeus, identifying one distinguishing variable and six ''explanatory'' variables they attributed to performance differences between visionary companies and comparison firms. The distinguishing variable for the visionary firms was ''Leadership during the formative stages.'' The six explanatory variables that they identified were:

1. *Evidence of core ideology:* statements of ideology, historical continuity of ideology, balance in ideology (beyond profits), and consistency between ideology and actions (walk the talk)
2. *Evidence of the use of stretch goals, visioning, defining full potential for a given period of time:* ''bold hairy audacious goals'' (BHAGs); use of BHAGs, audacity of BHAGs, historical pattern of BHAGs.
3. *Evidence of ''cultism'':* building and sustaining a strong culture, seeing culture as an independent variable, not a context variable; indoctrination process, tightness of fit (alignment and attunement)
4. *Evidence of purposeful evolution:* conscious use of evolutionary progress, operational autonomy, and other mechanisms to stimulate and enable variation and innovation
5. *Evidence of management continuity:* internal vs. external CEOs, no ''post-heroic-leader vacuum,'' formal management development programs and mechanisms, careful succession planning and CEO selection mechanisms
6. *Evidence of self-improvement:* long-term investments, investments in human capabilities (recruiting, training and development), early adoption of new technologies and methods and processes, mechanisms to stimulate improvement; effective improvement cycles established and a way of doing business.

We will highlight this last finding particularly as we explore the expanding role for the ISE in the future.

2.3. Enterprise Excellence Models

We find enterprise models or business excellence models to be increasingly relevant to the central message of this chapter. They are a way to portray the lessons from the work of DeGeus and Collins and Porras. For example, the Lean Enterprise Institute is working with MIT to develop a Lean Enterprise Model (LEM) (Womack and Jones 1996). The Malcolm Baldrige Award has created a Performance Excellence Framework (National Institute of Standards and Technology 1999). We believe that the Baldrige model provides valuable insight into the variables and relationships, consistent with the lessons from Collins and Porras.

Figure 5 depicts the Baldrige Criteria for Performance Excellence: (1) leadership; (2) strategic planning; (3) customer and market focus; (4) information and analysis; (5) human resource focus; (6) process management; and (7) business results (overarching—customer- and market-focused strategy and action plans). Compare and contrast these variables to the seven identified in Collins and Porras.

Each of these models prescribes strategies for achieving full potential. Our contention is that this striving for full potential is the context within which ISE will be practiced. ISE will be challenged to present a value proposition in the context of large-scale organizational transformation. Enterprise models of excellence provide insights into how to position our profession and the work of ISE in organizations. With this base, each and every ISE has the potential to be a visionary representative of our profession. This is an excellent way to think about both personal and collective value propositions.

2.4. Implications for ISE

The context shift we describe above for ISE has several specific implications. First, each and every initiative undertaken by an ISE must be causally linked to business results. Let's use a large retail

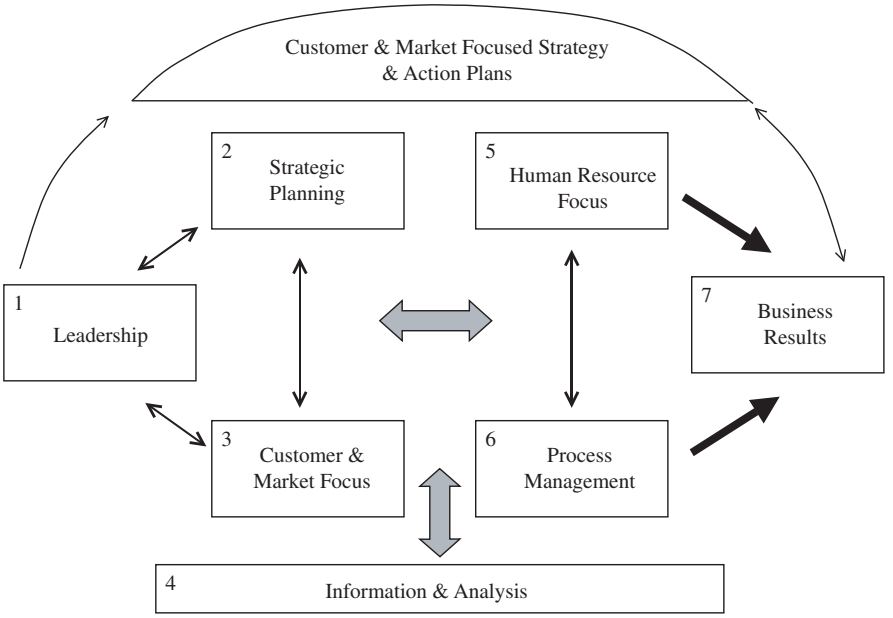

Figure 5 Baldrige Criteria for Performance Excellence.

organization as an example. One of the major business outcomes for this type of business is to fill what we call the ''treasure chest.'' As depicted in Figure 6, the treasure chest's three dimensions are (1) market share, (2) percent spend, and (3) length of relationship or customer loyalty.

Retail businesses want to optimize market share, get their customers to spend more of their disposable income (percent spend) in their stores, and keep their customers (optimize the value stream from customers). How can ISEs help fill the treasure chest?

Consider a profit ratio. Typically, ISEs have worked to reduce the inputs (the denominator) of the profit ratio by driving costs down and increasing efficiency. Focusing ISEs on outcomes (the nu-

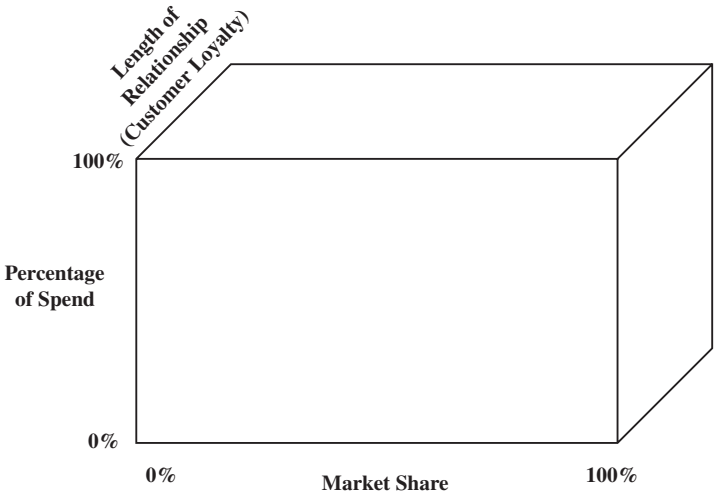

Figure 6 Filling the Treasure Chest as a Major Business Goal: What Does the Treasure Chest Model Look Like in Your Organization?

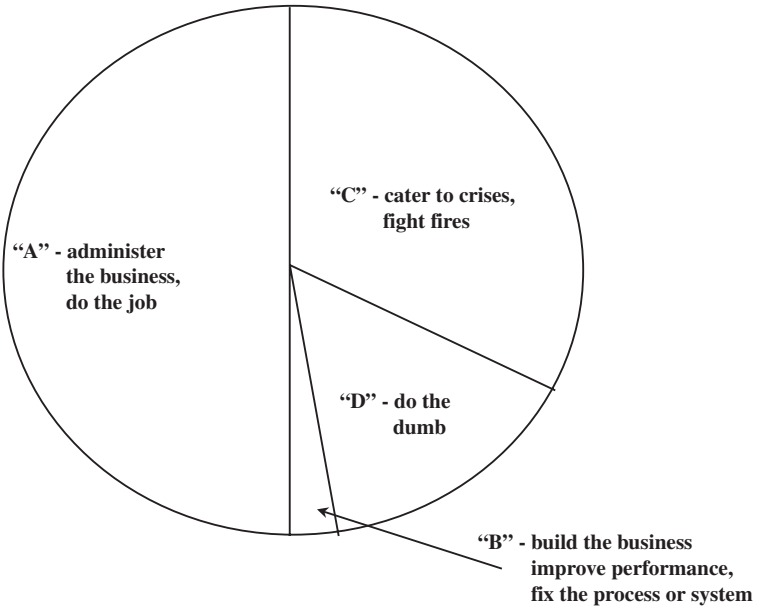

Figure 7 ABCD Model: How We Spend Our Time.

merator) shifts the paradigm about our value contribution. Our contention is that ISEs will be challenged to work on both the numerator and the denominator of the profit equation.

ISEs and the ISE function will be required to explain our contribution in terms of the profit ratio. It won't be enough to say that we improved the efficiency of a process or work cell. We will have to demonstrate how our actions lead to filling the treasure chest.

The seventh variable that Collins and Porras (1994) identified was "evidence of self-improvement." Time is the most critical resource in the knowledge-based organization. People at all levels spend their time doing four things: they **A**dminister the business, that is, do jobs ("A" work); they **B**uild the business, that is, improve performance and fix systems or processes ("B" work); they **C**ater to crises, that is, fight fires, fix problems ("C" work); and they **D**o the dumb, that is, non-value-adding things ("D" work). Figure 7 depicts how we spend our time.

Organizations that intend to achieve full potential will spend more time on B work. They will establish improvement cycles such as the Deming and Shewhart Plan-Do-Study-Act model. Rather than addressing "targets of opportunity," ISEs will deploy improvement cycles that are thought through strategically, comprehensive in scope, and well integrated. Enterprise excellence models clearly indicate this. Systems thinking will be applied at the enterprise level. This has been the clear migratory path for the past 30 years, and it will continue to be. Our profession's value proposition will focus on the special knowledge and skills the ISE brings to the quest for full potential.

In the more traditional model, ISE work is often detached from the work of transformation. ISE improvement efforts tend to be done outside the context of the enterprise improvement cycle, so they lack a clear causal connection to organizational business results (e.g., filling the treasure chest).

So the big implication for ISEs in the next several decades is that they must think enterprise, think total systems, and be connected to the enterprise improvement cycle. ISEs cannot afford to (sub)optimize targeted subsystems at the expense of the larger system, and they cannot afford to be isolated from the large-scale transformation work that characterizes the full potential organization. We might go a bit further and suggest that increasingly ISEs are going to be challenged to prescribe migration paths that move an organizational system toward full potential at a faster rate.

3. THE FUTURE STATE VALUE PROPOSITION FOR ISE

3.1. Overview

On the threshold of the 21st century, Michael Porter is perhaps the best-known researcher, author, teacher, and consultant on the subject of competitive strategy. Porter (1996) makes a distinction

between operating effectiveness and efficiency and positioning and strategy; balance between the two contributes to organizational full potential. Whereas operating effectiveness and efficiency is the traditional core of ISE academic programs, positioning and strategy is rarely, if ever, addressed in ISE academic programs. We believe that our model of full potential depicts that balance. In this section of the chapter, we will approach positioning and strategy from an ISE perspective. Then we'll talk about another subject missing from most academic programs—conditions for success. Finally, we'll make some observations about a more familiar topic, the ISE's role in operations improvement. (For more on this subject, see Sink and Poirier 1999.)

3.2. The Planning System: Position, Strategy, Implementation, and Deployment

The first role in this new model for ISE contribution focuses on the planning system. The planning system includes processes by which high-level strategy and policy are determined and all processes that lead to effective implementation and benefits realization from strategy and policy deployment. In many organizations, this system is not defined, not documented, not systematic, and hence the results it creates are highly variable. We contend that the planning system needs to be reengineered, and we offer this work as a role that ISEs can and should impact. Figures 8, 9(*a*) and 9(*b*) are simple versions of what we mean by this contention.

Figure 8 is a depiction of what we call a ''grand strategy system.'' It is a high-level picture of strategy and policy deployment. Once strategy and policy (positioning) is decided, a transformation plan needs to be developed. The vision and definition of the future state is on the right-hand side of the picture, the current reality is on the left, and the work in front of the organization is in the middle. Conceptually, it will take many improvement cycles (Plan, Do, Study, Adjust/Act) to pull off a large-scale transformation. Figure 9(*a*) depicts the improvement cycle process itself in general terms. It is not important to understand all the details of these figures; it is important that you see that ISE skills of system and process design are being applied at the strategy and policy deployment level. The premise is that more defined and explicit systems and processes for strategy and policy deployment will lead to more consistent results (benefits realization).

Positioning deals with what an organization offers and how that offering is portrayed to the customer. It has to do with whether your value proposition is clear to the customer and whether those propositions are distinctive and attractive. It has to do with whether your customers see your offering

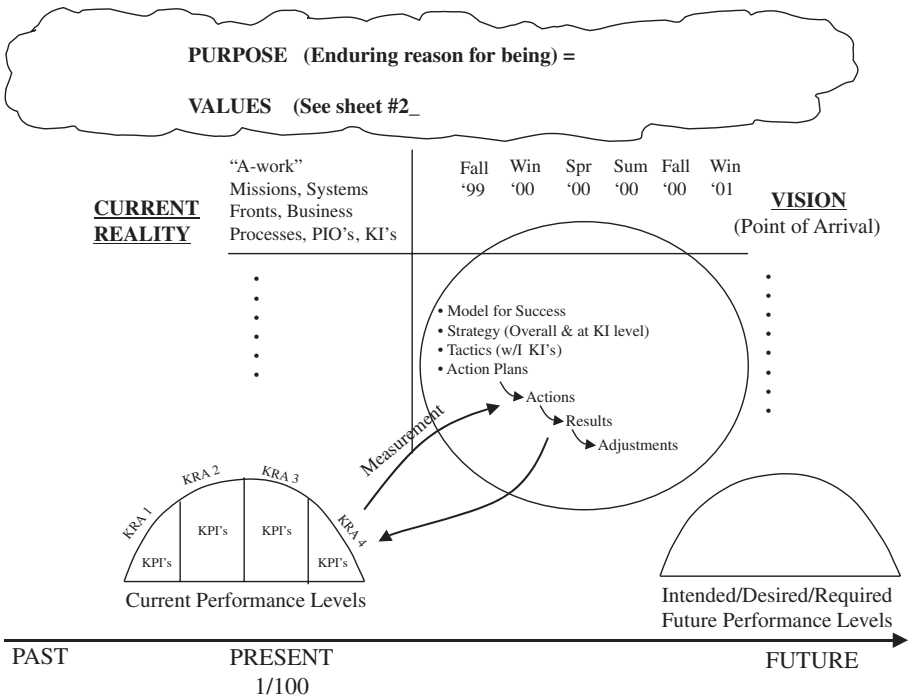

Figure 8 Grand Strategy System.

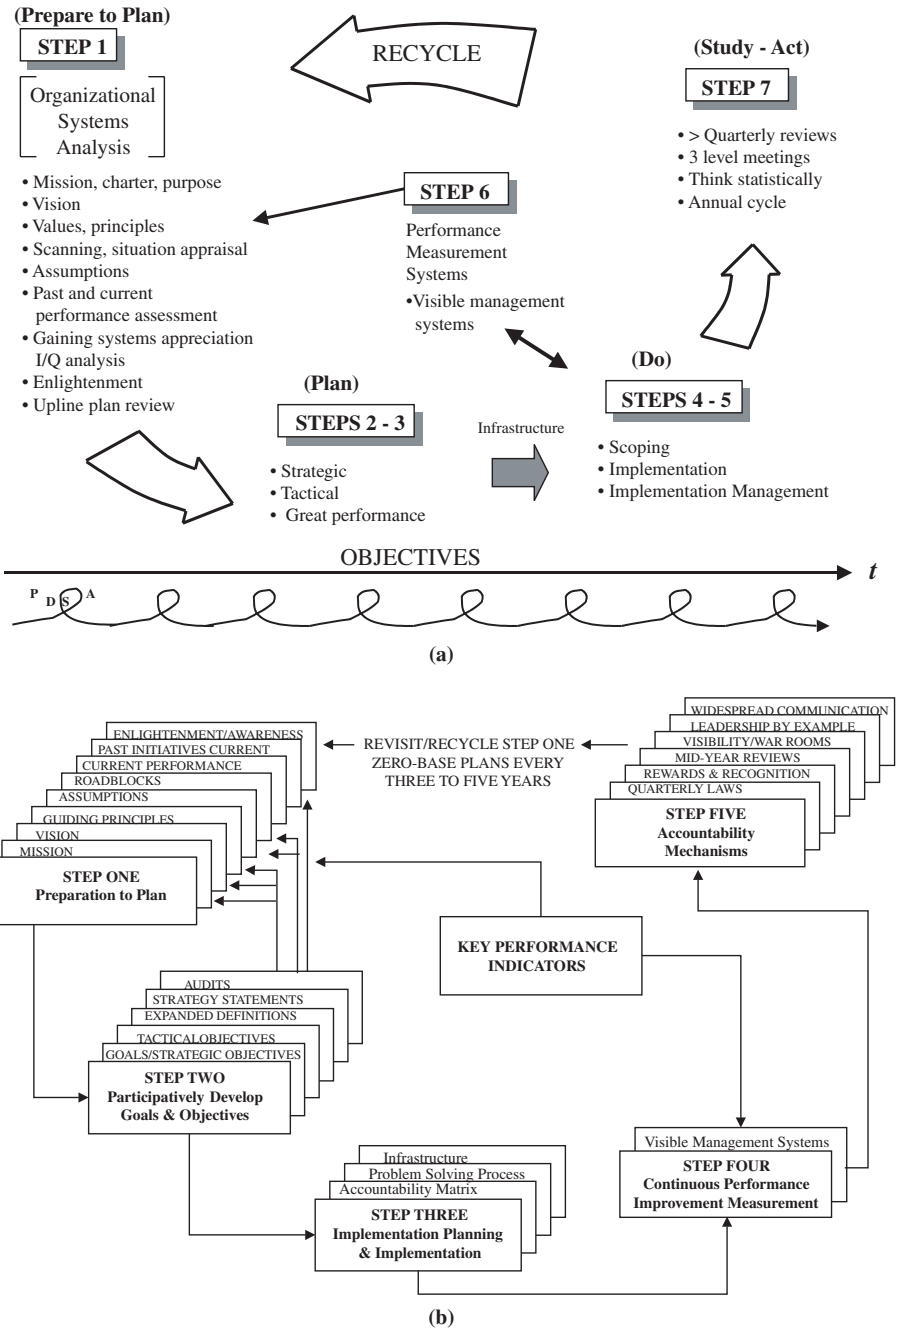

Figure 9 Improvement Cycle Process.

as instrumental to their success. Positioning decisions occur in step 1 of the Improvement Cycle (see Figure 9(*b*)). Positioning decisions end up being articulated and portrayed on the far right side of the transformation plan (see Figure 8). *Strategy*, on the other hand, has to do with how the organization plans to deploy its offering and execute on its position. Strategy ensures that the customer takes up the offering. Success must be operationally defined; you must have a clear vision of what success looks and feels like. *Successfully executing strategy and policy* throughout the organization involves what is called policy deployment. Strategy is reflected in the middle part of the grand strategy plan (Figure 8). Strategy is fleshed out in the improvement cycle (Figures 9(*a*) and 9(*b*) in step 2.

Improvement cycles in context of positioning and strategy are similar to the relationship between a game plan, perfect practice (as Vince Lombardi used to say), and actually playing the game. Strategy and positioning are the game plan; improvement cycles are perfect practice and also playing the game. The key role we see for ISEs in the planning system is in effective implementation and deployment of strategy and policy. This may well be several levels higher in thinking and involvement than many ISEs have traditionally been.

3.2.1. Policy Deployment

Policy deployment involves the successful implementation of the strategy for success (Akao 1991). The Japanese describe it as a ''waterfall-down'' process consisting of communication and ensuing coordination of activities. Effective policy deployment processes and practices ensure alignment and attunement. It is the policy deployment process that causes improvement efforts inside the organization to be aligned with the vision for the organization. Improvement cycles become aligned as a result of the deployment processes and practices. An example of such a practice is what are called three-level meetings. Periodically, leaders and managers and employees from three levels of the business gather for an ''all-hands'' meeting to share progress and performance on key initiatives or performance improvement objectives (PIOs). During these reviews, the dialogue ensures that critical adjustments are made to refine alignment in efforts (pace, focus, resource allocation, etc.). We have found that ISEs can be effective in supporting policy deployment policy and practices; their systems thinking background makes them well suited for this activity.

3.2.2. Relationship Management

In the full potential model of the organization (see Figure 10) are at least four categories of relationships that need to be managed and optimized: (1) customers, (2) employees, (3) stakeholder/stockholders, and (4) business partners (internal and external).

At a micro level, the ISE will be expected to contribute to the conception, design, development, and implementation of improvement initiatives. The extent to which relationships are managed ef-

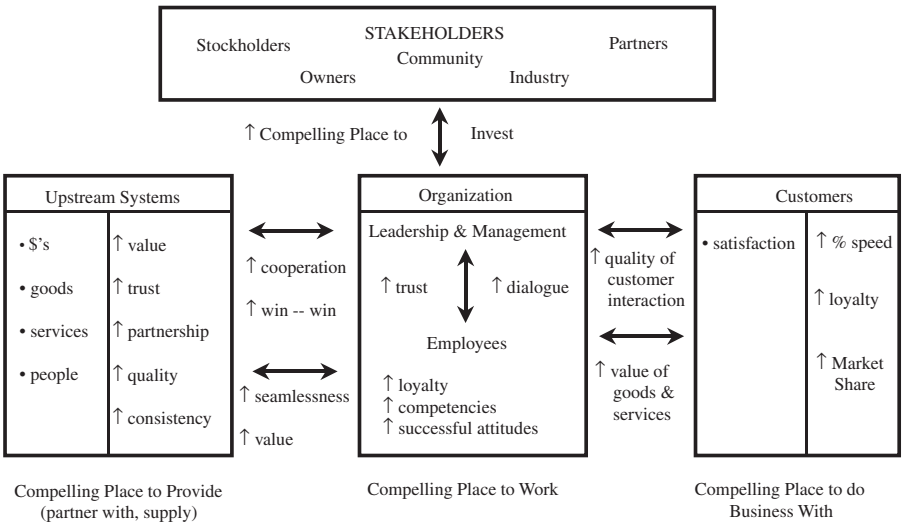

Figure 10 Full-Potential Performance Requires the Optimization of Key Relationships. (↔ represents relationships (or value exchanges) we will optimize in this transformation.)

fectively will ultimately determine the effectiveness of the implementation. At the macro level and with a focus on business results, it will be the relationship with the customer that will determine how well the treasure chest is filled. Acquiring information about the customer, monitoring how that information is used, and helping the customer be successful are all key aspects of customer relationship management (CRM). The role ISE should play is, at a minimum, to be keenly aware of the importance of CRM and to align ISE project work with CRM efforts.

In that larger context and domain, value creation will derive from the ISEs ability to manage our relationship with various partner and customer segments and create results for and with them. In our view there is only one customer, the consumer. The end users or customers are the population we serve. There are no internal customers in our model. Everyone inside the organization should function as a partner on a team working to serve the customer. The ISE is in partnership with others in the enterprise, and all are working to achieve organizational full potential performance. The ISE brings technologies to the enterprise that will facilitate achieving full potential performance.

At the maximum, ISE professionals would be part of the CRM program team. This would involve designing the strategy, working on information systems, and thinking through how to deploy CRM data and information to achieve alignment and optimize the lifetime value of the customer.

Perhaps the most dramatic change for ISEs in the decades to come will be the requirement that they understand the needs of the customers and have a role in managing customer relationships. ISEs understand the process of converting data to information, using information to support decisions and actions. This understanding is sorely needed in organizations today and is a key to unlocking full potential. How will ISE solutions enhance the organization's relationships with its customers? This will be a key area of emphasis for the ISE in the future.

The relationship management aspect of strategy and policy deployment goes well beyond just improved customer relationship management systems and processes. As Figure 10 shows, full potential performance requires that all relationships be managed differently. It has not been uncommon for supplier and vendor relationships to be in transition in the past; what has the role of ISE been in that transition? We contend that relationships with employees must also be managed differently; what is the role of ISE in that? Sears has a well-publicized transformation effort that focuses on being a compelling place to invest, a compelling place to shop, and a compelling place to work. This concept will show up in Figure 10. We would argue that ISEs can and should play a role in the relationship management associated with making the organization compelling from all constituent vantage points. This will lead to full potential performance.

Managing these relationships differently will take different levels of personal mastery. Listening skills will be even more important. How we hold ourselves in relationship to others in the system is foundational; do we see ourselves as partners or as competitors/adversaries to be negotiated with? First we need a different model for full potential. Then we need to develop the skills to work the model effectively.

We have discussed grand strategy, improvement cycle, policy deployment, and relationship management as key elements of planning system (strategy and policy development and execution) transformation. Other changes are required in the planning system in order for an organization to migrate to full potential performance, which we will either mention here and not elaborate on or mention in upcoming sections. The transformation to full potential is a stream of improvement cycles. There are improvement cycles embedded in improvement cycles. There is one for the overall enterprise and then embedded improvement cycles (aligned) for subsystems. Coordinating all these improvement cycles is critical to overall success—yet another natural role for ISEs to play in the future.

Improvement cycles, at all levels, are conceptually a process of Planning, Doing, Studying (progress and performance), and then Adjusting plans based on results. We've addressed the Plan and Do steps. In the third role, operations effectiveness and efficiency, we'll discuss the role of measurement in the Study process and outline how to build more effective measurement systems—yet another key role for ISEs in the work to achieve full potential performance.

All the Planning and Doing and Studying and Adjusting is being done in a context or organizational environment. Figure 1 depicted this. Culture shift is central to creating conditions that will support migration to full potential performance. We would once again contend that ISEs can and should play a role in designing and executing the culture shift to create conditions that will fully support transformation to full potential. This might be a support role to the HR function, team member/collaborator, and so on. We will flesh this out in the next section.

3.2.3. Change Leadership: The IE as Change Master

Pulling off a major shift in the improvement cycle process in organizations will require many, if not most, to get outside their comfort zones. People are going to be asked to do different things differently. One key function of ISE in the context of improvement cycles will be bringing solutions to the business that help fill the treasure chest. Ensuring that the benefits of improvement are actually realized is a three-ball juggling challenge. The first ball is solution design and development. Solutions

must be thought through in the context of strategy and policy of the larger system. The second ball is project leadership and management: delivering the solution. The third ball, and often the most critical, is change leadership and management (Sink 1998). It is the ISEs smooth juggling of these three balls that creates effective change. Clearly there is a science and an art to this, and ISEs can become its foremost practitioners. In large-scale transformation, the three-ball challenge becomes the three^{nth}-ball challenge. Full potential will require that many (n) solutions be delivered concurrently. The challenge is to manage multiple projects rather than a single project. We find that as ISEs gain experience they become excellent candidates for this challenge due to their training in dealing with system interactions and complexity.

Here is a model that is especially useful for understanding change leadership and management:

$$\text{Readiness for change } (R) = V \times BP \times A$$

Change will occur if $R > C$, where:

V = vision, i.e., people's connection to success, their clarity on what success looks like and feels like, an operationally defined desired point of arrival

BP = burning platform, i.e., sense of urgency, level of dissatisfaction with the status quo

A = approach, i.e., clear and pragmatic first steps, knowing what to do next to move in direction of vision

C = Perceived cost and/or risk associated with change, i.e., level of discomfort associated with moving outside the comfort zone

We believe that in the new environment the power of creation will supplant problem solving. It is easier to get people motivated to deal with an uncertain future if they are clear on the vision and they choose for it. (However, in fairness to problem solving, you don't need a vision to fix a broken window.) So we suggest strongly that ISEs work on developing creation skills to complement their highly developed problem-solving skills (Fritz 1991). Once people are in the creation mode, there will be little resistance to change and change leadership will be quite natural and almost easy.

3.3. Conditions for Success

We will now turn from the planning system to look at what we call *conditions for success.* Recall the action-results and conditions for success model (see Figure 1). Much of the work of ISE tends to be in the domain of action to results; working on what we call drivers of change that directly result in improved business results. Often the effectiveness of efforts to influence drivers is diminished because the conditions for enabling the efforts to be effective are not present. So we identify "enablers" that are collectively constitute conditions for success. We will introduce four enablers that are central to conditions for success:

1. *Culture system:* shaping values/attitudes/behaviors that will support full potential performance
2. *Infrastructure:* how we are organized to do B and implications that B work will have on the A work infrastructure
3. *Communication system:* sharing information necessary to ensure that people are informed as we migrate to full potential performance
4. *Learning system:* ensuring that knowledge and skills keep pace to support the transformation

3.3.1. Culture System

Culture is "a pattern of shared basic assumptions that the group learned as it solved its problems of external adaptation and internal integration, that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel in relation to those problems" (Schein 1992).

The fundamental question for organizations aspiring to reach full potential (or should we say leaders who wish to lead groups to full potential?) is, "What is the full potential culture?" Figure 11 is a pictorial we use to describe our answer. The descriptors on the right side reflect values, attitudes, and behaviors that we believe are consistent with achieving full potential. Listed on the left are commonly experienced values, attitudes, and behaviors typical of underperforming organizations. We believe that most people inherently have core values that match those on the right: serving, learning, integrity, and excellence. Unfortunately, we have found that when individuals come together in organizations, things conspire to cause their attitudes and behaviors to migrate to the left. By raising consciousness about personal choices and what motivates those choices, it is possible to induce a shift to the right. We might more accurately say it is possible to create conditions that will naturally bring people back to their core values and to the attitudes and behaviors that are so critical to full

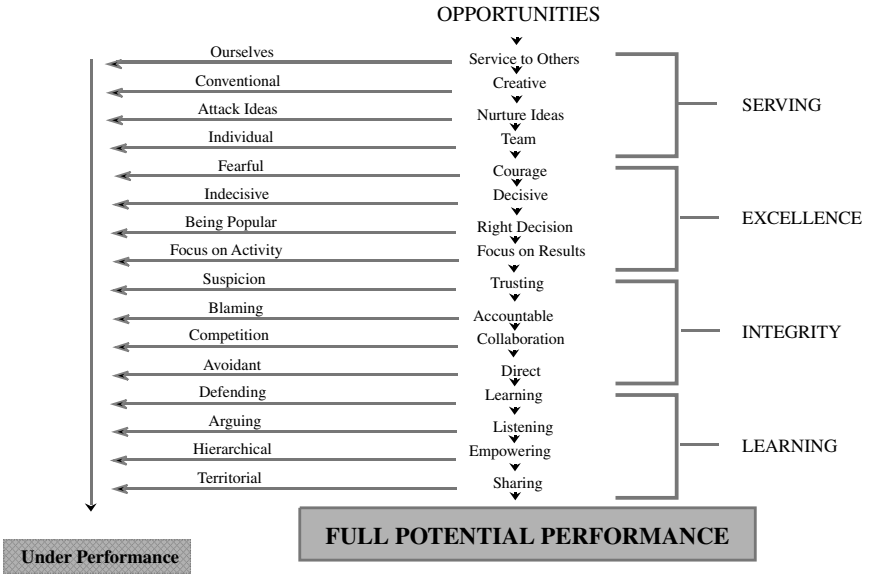

Figure 11 Leadership Values Model.

potential performance. Whether the ISE is an active or a passive player in this process, there still must be an awareness of the role culture plays in performance improvement. Having said this, we are convinced that there can be no passive players. Everyone's behavior must reflect full-potential values. (i.e., ''walk the talk.'') The ISE function is too important to be ignored. The ISEs must model these core values in order to be effective as individuals and as a collective force for improvement.

Note that we entitled the section ''Culture System.'' The implication is that culture is the product of a system. If we want/need the culture to be different in order to achieve full potential, then we need to change the system that shapes culture. This is an active rather than passive approach to culture. We are consciously shifting culture toward what is natural (in our view) and toward values-attitudes-behaviors that support achievement of full potential. Because ISEs are about integrating systems to optimize performance, recognizing that culture is a subsystem that needs to be led and managed is integral to our work—yet another area of potential work for ISEs in the future.

3.3.2. Infrastructure for Improvement

Earlier we alluded to the ABCD model (Figure 7) depicting how we spend our time. Spear and Bowen (1999) highlight the importance of integrating administering the business (A work) with building the business. What are the roles and rules in the context of A and ''B?'' Toyota manages to demand rigid performance specifications while at the same time ensuring flexibility and creativity. This seeming paradox is the ''DNA'' or essence of their success. Disciplined execution of A makes it possible to also do B. The infrastructure for this is supported by culture, discipline, learning, role clarity, and rules.

The potential ISE role in this regard is tremendous. Many organizations lack discipline and specification relative to A work, leading to a great deal of variation and unpredictability. This variability in performance is a source of D and ineffective management of C. Established methods and procedures are central to gaining control of A-work and freeing up more time for B. It is important for ISEs to reestablish their role in the continued ''rationalization'' of A. As Spear and Bowen (1999) mention, rationalizing A involves using experimentation and the scientific method to improve things. A word of caution: things will get worse before they get better. If the experiments are well designed and carefully thought through, the loss in performance will be manageable and the final results will be well worth the cost. Ideally, one could create a system that would perform and improve simultaneously. How to organize this and make it happen is clearly an important domain of activity for ISEs.

How is your organization organized to do B, and what role should ISE play in the infrastructure piece? We have found that the infrastructure for B will determine how effective and efficient the B work is. ISEs can play an important role in this design variable.

3.3.3. Communication System

Noted organizational authority Dr. Edward Lawler (1986) recommends that organizations first share information, then knowledge, then power, and only then share rewards. Communication is sharing information. The theory is that better-informed people perform better. Our experience and a host of research results confirm that hypothesis. Sharing information leads to better coordination, and better coordination creates the conditions for realizing full potential. The communication system needs to be thought through and well designed for effective and efficient implementation and deployment. We have found that ISEs can help improve the information sharing system. We see this as a key area of ISE contribution in the future.

Remember the sequence Lawler recommends: Reengineer the communication system before addressing the learning system, then create the involvement system, and finally, put into place the reward and recognition system. Taken in order, these four steps produce an integrated system that can benefit from key capabilities of the ISE. Taken randomly, as is too often the case, valuable resources are wasted and the value proposition to the enterprise gets diluted and disappears.

3.3.4. Learning System

Full-potential organizations are also learning organizations. Learning organizations must be made up of learning individuals. Each of us is a product of our experience. For the better part of 16–20+ years we participate in a particular educational process. The curriculum and the syllabi are provided for us. The goals, the things to be learned, the sequence, the practice, and so on are all prescribed. And then, suddenly, teachers are no longer part of the process, and we must make choices: either drift away from learning and growth or take charge of our own learning. Unfortunately, most people drift, and as a result their value proposition—their ability to continue to add value—diminishes over time. In the 1990s, as technology, competition, and complexity increased, organizational leaders began to stress the importance of learning and growth as part of the personnel development process. However, stressing importance typically has little or no effect. Lifelong learning is something that must be ''chosen for'' if we are to continue to contribute.

Clearly, the ISEs can play at least two roles in the learning process. First, ISEs of the future will need to be more systematic and more disciplined about continuing education and development. Our professional society—in this case, the Institute of Industrial Engineers—will play an increasingly important role through its conferences and seminars. Additionally, many companies and agencies provide formal programs to support the learning process. Second, the ISE can and should play a role in assisting the organization with the design and execution of the learning (education, training, and development) process. Learning is a key business process. Improving the competencies and capabilities of the human resource requires a well-designed and executed process. Business process reengineering is often required if an organization is to move beyond the minimally effective training systems of the past to the learning systems that support the creation of positive business results and keep employees vital.

We are proposing that learning is the result of a process. The education, training, development process in most organizations is not effective. A work knowledge and skills as well as B work knowledge and skills are needed. This will require being a team member with the HR function. Our experience is that the HR personnel have welcomed the contribution that ISEs can make to rethinking how to spark and sustain learning. The migration to full potential performance will require a tremendous amount of new learning. This will require, first, recognition that this is important, and second, willingness and desire to learn. We believe that creating a learning orientation is part of the culture shift work. People have a natural tendency and desire to learn and grow. When you change the condition within which people are working, this natural tendency will reappear. Then it is just a matter of directing the learning toward the knowledge and skills that support performance improvement. Much of this will be quality and productivity and improvement related, and this is where the ISE comes in. Changing the culture and then changing the system for learning are central to creating conditions that support full potential performance. ISEs can and should play a role in this shift.

3.3.5. Summary

The involvement of ISE in strategy and positioning and in conditions for success occurs too infrequently. Full potential, as we have posited, requires an integration of work in the three areas. We asserted earlier that for ISE to be positioned differently, to adopt a broader domain, a senior champion or sponsor is often required. This will be someone who is an ISE or understands the value proposition of ISE and is constantly looking for effective pieces of work to involve them in, ways to use ISE to migrate to full potential. Each month, *Industrial Management* features ISEs who are in these roles.*

* An outstanding example of an executive champion of ISE is our coauthor and colleague, David Poirier. His story appears in the May/June 1998 issue of *Industrial Management*.

The true impact of leadership in achieving and sustaining full potential performance is most often seen in the work they do in establishing conditions for success. All ISEs would be well served to consider the role they play in establishing and sustaining the proper conditions or environment to support full potential performance.

We believe that ISE modes of thinking will be valuable in the challenging strategy and positioning work of the organizations of the future and in creating optimal conditions for success. A perspective built on systems thinking is ideally suited for the type of planning and analysis required as organizations work to enhance positioning and strategy and creating positive internal conditions in the ever-changing markets.

The challenge to practicing ISEs is to understand the connection between their work and organizational attainment of its full potential. Seminal questions include ''How does my work support the overall positioning and strategies of the organization?'' ''What are the cause-and-effect linkages between my work and 'filling the treasure chest'?'' ''How is my work connected to other efforts in the organization, and how can I strengthen the connection and create synergies where they don't currently exist?'' ''What is full potential performance and how is my work moving the organization toward that goal?'' ''How can the ISE role work on key condition for success issues in a way that enables or enhances the success we achieve over time?''

We have offered some examples of what we call ''strategy and positioning'' and ''conditions for success'' and described the roles that ISE can play in these categories of endeavor. Too often the work of ISE gets over- or underemphasized due to a lack of understanding of where they fit in the organization. ISEs need to be aware of the big picture and the leverage points to ensure that their work is contributing in an optimal fashion to the greater good.

To ensure that we are not misunderstood, we would offer the following. We are not calling for ISEs to be all things to all people. We understand the core value proposition of ISE, what it has been, and we have our views on what it will be. We are simply suggesting that if ISEs are to live up to their lofty definition as systems integrators, the future will require us to continue to transcend and include more traditional roles and migrate to enterprise level contributions.

3.4. Operations Improvement Role

3.4.1. Overview

We will now turn to the traditional role of ISE, that of problem solving and operations improvement. We place improvements in efficiency, quality, and technology (e.g., methods, hardware, software, procedures, processes) in this category. Regardless of whether the ISE specializes in operations research, human factors, manufacturing systems, or management systems methodology, the challenge will be to change how things are done such that total system performance is improved.

Traditionally, ISEs have operated at the work center level. Over the past 30+ years the scope of the system of interest has broadened. The word ''system'' in industrial and systems engineering has taken on increased importance. This migration has occurred naturally; it is what was required for the ISE to be more successful. Unfortunately, industrial engineering tended to lag behind other disciplines in the evolutionary process. Our profession has missed opportunities to continue to add value over the past 30 years. The more striking examples include abandoning the quality movement, and missing both the tactic of business process reengineering and the emergence of the balanced scorecard in the measurement domain. We believe that the decades to come will provide opportunities for ISE to reintegrate and reposition itself as a leader and doer in the field of performance improvement. At the risk of being repetitive, this requires rethinking the role and relationship among positioning and strategy, conditions for success, and operations improvement.

We will not duplicate material in the remaining chapters of this Handbook. However, we do want to fill in some blanks by highlighting a couple of areas of operations improvement that we feel might not be represented: systems and process improvement (more specifically, business process reengineering) and measurement systems. Again, our contention is that the bulk of this Handbook focuses on the traditional ISE role in achieving operations effectiveness.

3.4.2. Business Process Improvement

The term *unit of analysis* applies to the scope of the system of interest. When IE first began, the unit of analysis—the scope of the system of interest—was confined to the worker, the work cell, and individual work methods. Over time, the scope of the system of interest to the ISE has increased—for example, from economic lot size to inventory control to warehouse management system to supply chain optimization to enterprise or supply chain synthesis. It is important to keep in mind that this expansion in focus is an ''and,'' not an ''or.'' Attending to larger units of analysis is a ''transcend and include'' strategy. Inventory control remains in the ISE toolkit, but now it is being applied in the context of larger systems. This causes the ISE to rethink what it means to optimize the system of interest. If a system's performance objective is simply to fill customer orders, one might employ a

''just-in-case'' inventory policy that relies on very high inventory levels to ensure satisfied customers. Vendor relationships of one type might drive inventory even higher. If the unit of analysis is shifted to the next-more inclusive system, so that it includes different relationships with vendors, high weighting on holding costs, preference for short lead times, high values placed on shortage costs, and so on, then the outcome could very well be an entirely different strategy for inventory management. It is interesting to note that the ''dot com'' organizations have to reinvent supply chain models in order to thrive in the high-paced and fast-moving environment. The real challenge will be for more traditional organizations with legacy systems to migrate to a dot com pace.

This migration to a larger system of interest also happened to process improvement. Total Quality Management (TQM) revitalized the interest of organizations in quality issues.* The focus on improving embedded processes has shifted to an enterprise-level focus on improving business processes. Once again we see the transcend-and-include principle being required. A business process begins and ends with the customer. Organizations can no longer afford to optimize a subsystem (embedded process) at the expense of the performance of the larger system (business process). So the techniques and methods that were employed to improve smaller processes are being adapted and enhanced with some expertise borrowed from organizational leadership and management of change, creating a whole new line of business for a large group of professionals.

At the time we go to press, our experience is that few ISE undergraduates are being introduced to business process engineering. Our plea is that ISEs embrace this technology. For example, business process reengineering, we believe, is a context within which most ISE improvement efforts will be done in the near future.

Figure 12 is an example of a business process reengineering roadmap to provide insight as to how the ISE might contribute. First, systems thinking is required to do BPR. ISEs are trained to

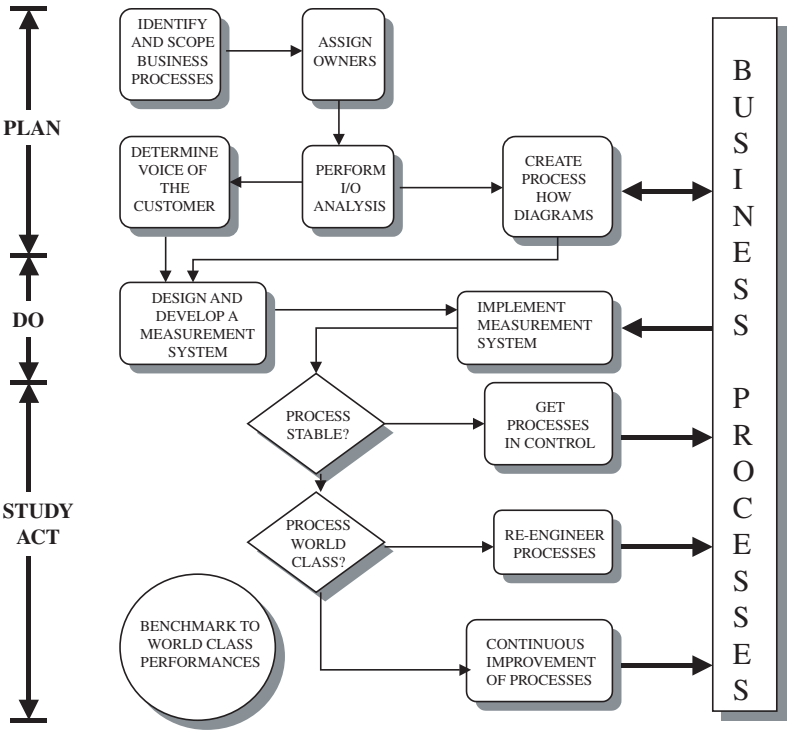

Figure 12 Business Process Reengineering Roadmap: How the ISE Might Contribute.

*Interestingly, quality assurance, control, and sampling, etc. were taught almost exclusively in ISE programs before the 1980s. Now it would be surprising to find an MBA program without TQM coursework.

think systems. Second, many of the substeps in the process (see Figure 12) require specific knowledge and skills that ISEs are grounded in. We understand that ISEs are involved in many BPR efforts in organizations today. We also know that many BPR efforts are information technology-driven and many exclude ISE involvement. We believe this is an error that leads to underperformance.

At several points in the chapter we have mentioned the importance of measurement in transforming to full potential performance. Let's turn our attention to a specific focus on this role and see if we can highlight differences we see in the future in terms of ISE contribution.

3.4.3. Building Effective Measurement Systems

Work measurement and *methods engineering* are terms that have traditionally described actions taken to quantify the performance of a worker or a work unit and to improve the performance of the individual and the unit. The relevant body of knowledge has been developed and preserved through the entire history of ISE. Throughout that history, one principle has served as its unifying force: *an appreciation for and the applied knowledge of systems.* In fact, Frederick Taylor (1856–1915), who is generally recognized as the father of industrial engineering, wrote in 1911, ''The system must be first.'' Methods engineering was pioneered by Frank Gilbreth and his wife Lillian, whose lives were memorialized in the Hollywood film *Cheaper by the Dozen.* Soon after methods engineering began to be practiced, the need for measurement technology became clear. This was inevitable. Once analysts proposed improvements to the way a job was done, natural curiosity led to the question ''How much better is it?'' The ISEs translation of and response to that question led to the development of tools and techniques for measuring work.

More recently, the importance of methods engineering and work measurement was underscored by the late W. Edwards Deming in his legendary seminars. Dr. Deming, when questioned about a system performance deficit, would confront his audience with the challenge ''By what method?'' He virtually browbeat thousands of paying customers into the realization that insufficient thought and planning went into the design of work systems. Dr. Deming believed that workers, by and large, strive to meet our expectations of them. The lack of sufficient high-quality output, he taught, stemmed not from poor worker attitude, but from poor management and poor design of the methods, tools, and systems we provide to the otherwise willing worker.

Dr. Deming also promoted the ISEs contribution through work measurement with an additional challenge. Once a solution to the ''By what method'' question was offered, Deming would ask, ''How would you know?'' This query highlighted his insistence that decisions regarding process improvements be data driven. In practice, this means that effective systems improvement activities require evidence as to whether the changes make any difference. The requirement is that we use our measurement expertise to quantify the results of our efforts to design and implement better systems. The Deming questions—''By what method?'' and ''How would you know?''—articulate the defining concerns of the early ISEs, concerns that continue to this very day.

The ability to measure individual and group performance allowed organizations to anticipate work cycle times, which led to more control over costs and ultimately more profitability and better positioning in the marketplace. Understanding how long it *actually* takes to do a task led to inquiry about how long it *should* take to do work through the application of scientific methods. Standard times became prescriptive rather than descriptive. The next step in the evolution was the integration of production standards into incentive pay systems that encouraged workers to exceed prescribed levels of output. Application of extrinsic rewards became an additional instrument in the ISE toolbox, vestiges of which linger on.

So much for the evolution of the work measurement and methods aspects of traditional ISE practice. The following are some evolutionary enhancements that have become part of the ISE measurement value proposition:

- Statistical thinking plays a more critical role in understanding work performance. Variation is inherent in all processes and systems. Discovering the underlying nature of variation and managing the key variables has become more critical than just establishing a standard.
- The role of production quotas is being reexamined. Should we throw out all standards, quotas, and targets, as Dr. Deming suggested? We think not. We contend that the effective approach is to establish a system within which teams of employees hold themselves and each other accountable for system performance and are encouraged to reduce variation and improve performance on their own. Standards that control and limit employee creativity should be eliminated. The key is understanding performance variation and what causes it and creating a partnership with employees so that they are integral members of the team working to improve it.
- Work measurement and methods improvement became detached, to some extent, from the larger system of improvement efforts. Today, efforts to improve what workers do and how they do it is being tied to overall business strategy and actions. This means that measures of performance at the work unit level will have to be tied to and integrated with measures of performance for

larger units of analysis. Linkages between individual worker and team performance and system-level measures of performance are becoming better understood and managed. Here again, our message is ''transcend and include.'' Efforts to understand how long something does or should take at the employee or work center level will expand to include understanding of how the unit-level systems need to perform in order to fill the treasure chest of the organization.

- Time and quality are no longer the only indicators of organizational performance for which ISEs are being held responsible. This is manifest in a vector of performance indicators, including efficiency, effectiveness, productivity, financial performance, quality of work life, customer satisfaction, and innovation, which are are being made elements in a rich and balanced scorecard on which the organization is being graded (Kaplan and Norton 1996).
- Visibility of measurement systems and portrayal of performance data are being recognized as critical elements in the deployment of enhanced measurement systems. Traditionally, a worker knew the standard and that was it. In the future, employees at every level of the organization will have continual access to their scorecard indicators. Furthermore, they will be aware of how these measures are linked to the performance of more inclusive systems. For example, employees at the checkout counter will understand that their behaviors and attitudes influence whether the store is a compelling place to shop and will have data to tell them how this helps to fill the treasure chest and how that affects them. Store managers will understand that a five-point increase in employee attitudes translates into a 1.3% increase in customer satisfaction, which translates into a 0.5% increase in gross store revenues, and their chart book will portray the data that portray how their unit is performing. As a result, daily, hourly, moment-to-moment decisions will be made on the basis of visible data and facts.

The ISE will be integral to the design, implementation, and maintenance of these comprehensive and very visible measurement systems.

3.4.4. Organizational Systems Performance Measurement

An organizational system is two or more people whose activities are coordinated to accomplish a common purpose. Examples of organizational systems are a work unit, a section, branch, plant, division, company, enterprise.

In Figure 13, the management system is portrayed as consisting of three elements: *who* manages, *what* is managed, and *how* managing is accomplished. In a traditional organization, ''who'' may be

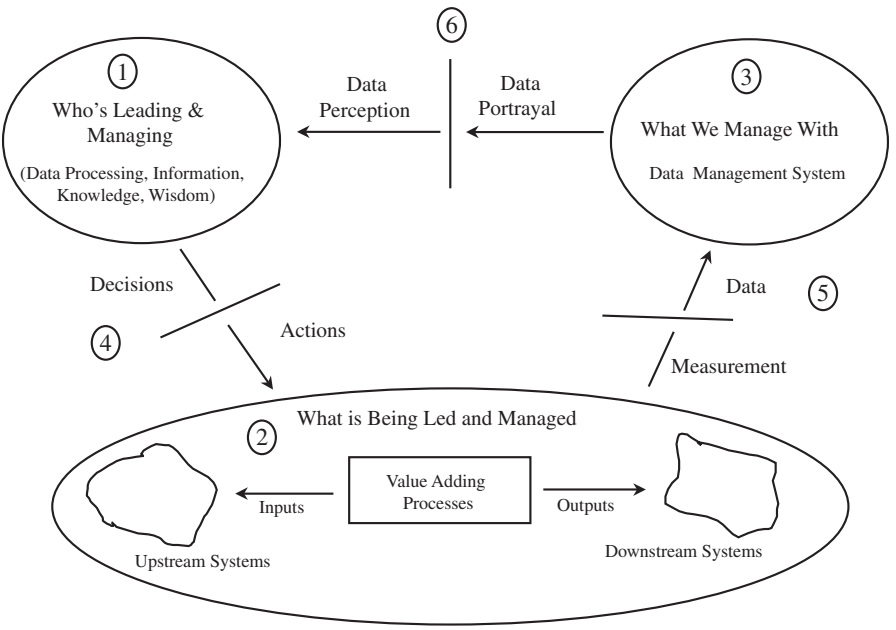

Figure 13 Management System Model.

the manager; but in the contemporary organization, ''Who'' refers to a management team. For the long-range planning horizon, the management team establishes the goals and objectives—the vision—of what the organization is to become. In the short time horizon, levels of system performance must be specified. The ''What'' is the system that is being managed; the organization, system, or process of interest, the object of the management efforts. ''How'' refers to managerial processes and procedures and more specifically to the transformation of data about the performance of the organization (''What'') into information regarding the need for actions or interventions.

The management system model can also be characterized as a feedback or closed-loop control system. In this version, the management team is the controller (who), the process is the system being controlled (what), and the instrumentation (how) monitors the system states and feeds these back to the controller so that deviations between the actual and the desired states can be nulled. The interfaces between each of the elements also represent the management process. Between the ''what'' and the ''how'' elements is the measurement-to-data interface. Between the ''how'' and ''who'' elements is the information portrayal/information perception interface. And between the ''who'' and the ''what'' elements is the decision-to-action interface. Viewed from the perspective of this model, the management of a function would entail:

1. Determining what performance is expected from the system
2. Monitoring the system to determine how well it is performing in light of what is expected
3. Deciding what corrective action is necessary
4. Putting the correction into place

Note that any embedded organizational system is operating in the context of a larger system and the linkages are critical to total system optimization (Sink and Smith 1994).

This model provides the frame and the outline to be followed in building an effective measurement system. The steps one takes to do this are covered in other references we have provided. We will simply restate that understanding what constitutes success for an embedded system must be clearly understood and operationally defined. The model for success must also be operationalized and understood. Senge (1990) and others devote much of their work to helping us understand the tools of systems modeling in this regard. Without a clear, specific, focused understanding of what the key result areas and their related key performance indicators are, it is difficult for workers or managers to assess how they are doing and on what basis to make those assessments. The measurement system allows for effective Study (S) in the Shewhart/Deming PDSA improvement cycle. A modern measurement system will have to be comprehensive, well integrated, and strategic as well as operational. It needs to portray causal linkages from the system of interest to the next-larger system. This assists in ensuring that we do not fall into the trap of optimizing the subsystem at the expense of the larger system.

In our experience, ISEs understand measurement perhaps better than other disciplines, and yet the traditional approach is often reductionist in its orientation. The key to ISE being better integrated to enterprise improvement is that we apply our strengths in a way that avoids suboptimization and clearly ties to the higher organizational good. This is especially true with measurement.

4. ORGANIZING FOR FULL-POTENTIAL ISE CONTRIBUTION

4.1. Overview

We've portrayed what we believe is an extended and expanded value proposition for ISE. To summarize: the ISE is playing a key role in strategy and positioning, planning, change leadership and management, culture, measurement, learning, reengineering, and infrastructure. When you couple this view with the more traditional focus that is discussed in the bulk of the Handbook, we think you will get a flavor of the full potential for ISE and how exciting ISE will be in the decades to come. The issue here is how to position and organize the ISE role such that the potential contribution can be realized. The traditional view is that the ISE function should be located in a dedicated unit that is well connected to positions of power.

An alternative view is emerging. We believe that the environment that made the ISE department or function effective has changed. The challenge is to position the ISE value proposition, not the function. Once again, this transformation requires that there be strong motivation and enlightened executive sponsorship for deploying ISE skills throughout the organization. ISEs will be positioned in ways that were impossible to envision in the past.

4.2. Executive Sponsorship

At the risk of becoming too repetitive, we will reassert that full-potential organizations will have a senior leader (CEO, VP) who champions the ISE contribution. This sponsor will also have a clear mental model of what needs to be done for the organization to migrate toward full potential and how

ISEs can support that. ISEs will be deployed throughout the business in positions of influence and support relative to key initiatives.

This may not seem too different from the current reality, but the major difference will be the extent to which oversight exists. The executive sponsor will own the process of positioning ISEs as their talents are expanded and applied across the enterprise. Review the readiness for change model presented in Section 3.2.3. All the requirements for successful change are present. We've seen executive sponsorship work, and we believe it is the wave of the future.

4.3. Business Partner Relationship Management

Earlier in the chapter we noted that in our conceptual framework, organizations have only one customer. We have abandoned the term *internal customer.* Everyone inside the organization is a partner working on a team dedicated to serving the customer and filling the treasure chest. In this respect the executive sponsor for ISE is in partnership with other key executives working together to migrate the business toward full potential. ISEs are deployed as resources that can support functional and cross-functional efforts to ensure that improvements are well managed and produce the desired results. The model is value based and relationship based. To achieve full potential, it is necessary (but not sufficient) that relationships among employees, internal business partners, stockholders and stakeholders, customers, and suppliers/vendors be effectively managed. This is true for the executive sponsor of the ISE role, for the ISE, and for the partners of ISEs within the enterprise.

4.4. Integration Role

The word ''integration'' is central to the operational definition of ISE. It takes a lot of integration to achieve full potential. It should be clear by now that we view the ISE as a key integrator. Businesses are decentralized or differentiated to reduce span of control and enhance agility, responsiveness, and ownership. Differentiation escalates the need for integration, and integration requires information sharing and cooperation to achieve the higher good. The executive sponsor for ISE should be in a position to understand the higher good, be an integral contributor to organization's senior leadership team, and passionately promote integration. ISEs throughout the organization will have to understand the big picture so that they too can promote integration. To do so, they will be in touch with what is going on across the organization, understand the high level strategy and actions, and share this knowledge when working on their projects throughout the business. This ensures that ISE and their colleagues don't lose sight of the forest for the trees.

5. IIE/CIE/CIEADH RELATIONSHIP MANAGEMENT

5.1. Overview

The leadership in the extended ISE community can be portrayed as consisting of three key constituencies. First is our professional society, the Institute of Industrial Engineers (IIE). Second is the academic institutions that teach and certify competency in the knowledge and skills of their graduates, who then become practitioners. This important group is represented by The Council of Industrial Engineering Academic Department Heads (CIEADH). Third is the Council of Industrial Engineering (CIE), a group of ''executive sponsors'' of ISE in major organizations from around the world. There are other groups in the ISE community; these are three we have chosen for this discussion.

Communication and coordination among these three groups will be essential to our profession achieving full potential. Ideally, from our point of view, CIEADH would view CIE as a focus group of its most influential customers and CIE would view CIEADH as a leadership body representing their supplier organizations. Both CIE and CIEADH would be viewed by IIE as essential customers, suppliers, and stakeholders. IIE would serve both CIE and CIEADH as the organization that encourages and supports lifelong learning and continued personal and professional development for ISE practitioners *and* as their professional society for life. The leaders of all three organizations would accept their roles as stewards of our profession and our professional society.

5.2. Relationship Management

As we've said so many times to this point, much depends on relationships in the context of core values. ISE will achieve full potential in the years to come if and only if those in leadership positions in the three constituencies acknowledge their mutual dependencies and manage their interrelationships. If we truly want our profession to realize its full potential and make the contribution it is capable of, we will opt for improved relationships.

6. MAKING THE FULL-POTENTIAL MODEL WORK FOR YOU: LEADERSHIP AND PERSONAL MASTERY

At the outset we mentioned that it would take full-potential ISEs to create full-potential organizations. We have deferred addressing the issue of personal mastery and making the full-potential model work

for the individual ISE. If ISEs accept personal responsibility for their own growth and development, full potential will be within the grasp of ISEs, our customers, and our organizations. The fundamental questions that make up the process are straightforward:

- What is our purpose in life (our enduring reason for being)? What is our vision (full potential, the look and the feel of success)?
- What will it take for us to be successful?
- What work do we have to do to migrate toward our particular visions?
- What conditions do we have to create for ourselves in order to be successful?
- How will we know how we are doing, on what basis will we make this assessment, and how will we manage our performance over time?

So much good work has been done today to achieve personal and professional mastery that it is difficult to suggest a starting point. Each of us has found Senge's and Covey's work on personal and professional mastery a good place to begin (Senge, 1990; Covey, 1994).

As Dr. Deming used to say, the journey to full potential performance will take a lifetime and that's good because that's all you've got *and* you can begin anytime you want as long as you start now!

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. DEFINING THE ENTERPRISE

In this chapter we use the term *enterprise* in its classical sense: an undertaking, especially one of some scope, complication, and risk. Thus, an enterprise could be a business corporation or partnership, a government agency, or a not-for-profit organization. The business modeling concepts described herein can be applied to any kind of enterprise.

1.1. The Enterprise as a Complex, Living System

Defining any given enterprise is a difficult endeavor because the enterprise is perceived differently by each individual or group that views it. Furthermore, each enterprise is a complex, living system that is continually changing, so today's view may be very different from yesterday's.

Often people attempt to define an enterprise by its organizational structure and the executives who occupy key positions. But this is only a small part of the picture. The enterprise actually operates as a complex system, with many parts that interact to function as a whole. In addition to organizational structure, an enterprise's system includes its economic and social environment; the customers it serves; other enterprises with which it cooperates to achieve its objectives; and the internal processes that are designed to set strategic direction, identify and satisfy the customers, and acquire and provide the resources necessary to keep the enterprise running. Thus, to define an enterprise properly one must define the system within which it operates. Ultimately, the success of an enterprise depends on the strength of its intra- and interconnections—the couplings among the organization's internal processes and between the organization and its external economic agents.

1.2. The Impact of the Global Business Environment

In recent years, technological advances in communications have paved the way for enterprises to operate effectively in a global, rather than just a local, environment. The foundation for this globalization was set by the technological advances in transportation experienced during the twentieth century. As a result, global expansion—often through mergers, acquisitions, and alliances—is now commonplace. Indeed, in some industries globalization has become a requisite for survival.

But globalization brings a whole new level of complexity to the enterprise. When an enterprise seeks to operate in a new environment, markets, competition, regulations, economies, and human resources can be very different from what an enterprise has experienced. Accommodating such differences requires understanding them and how they will affect the strategies and processes of the enterprise.

1.3. Increasing and Changing Business Risks

Another aspect of globalization is that it significantly increases the enterprise's business risks—that is, risks that threaten achievement of the enterprise's objectives. Traditionally, management of risks has been focused on the local external environment, including such areas as the nature and size of direct competition, the labor market, the cost of capital, customer and supplier relationships, and competitor innovations.

But in a global operation the business risks become greater and are not always well defined. For example, regulatory environments in foreign countries may favor local enterprises; vying for limited resources—both natural and human—may be problematic; and the foreign work ethic may not be conducive to productive operation and delivery of quality products and services. The business risks in a foreign environment need to be identified, defined, and managed if the enterprise is to be successful.

Even the business risks of local enterprises are affected by globalization. For example, new market entrants from foreign countries can provide unexpected, lower-priced competition, or product innovations originating in another country can become direct product substitutes. As a result, even local enterprises must anticipate new business risks brought on by the strategies of global organizations.

1.4. The Business Model and Its Purpose

An enterprise business model is designed to compile, integrate, and convey information about an enterprise's business and industry. Ideally, it depicts the entire system within which the enterprise operates—both internal and external to the organization. Not only does the construction of a model help enterprise management better understand the structure, nature, and direction of their business, but it provides the basis for communicating such information to employees and other interested stakeholders. The model can be the catalyst for developing a shared understanding of what the business is today and what needs to be done to move the enterprise to some desired future state.

A business model can be as detailed as the users deem necessary to fit their needs. Other factors regarding level of detail include the availability of information and the capabilities and availability of the business analysts who will ''build'' the model.

1.5. The Business Model as the IE's Context

The business model is a tool that helps the industrial engineer develop an understanding of the effectiveness of the design and management of the enterprise's business, as well as the critical performance-related issues it faces, to evaluate opportunities and manage risk better.

One of the industrial engineer's key roles is to improve the productivity of enterprise business processes. Often he or she is assigned to analyze a particular process or subprocess and make rec-

ommendations for changes that will enhance product/service quality, increase throughput, and/or reduce cycle time and cost. But in today's environment, a given process is not a stand-alone operation; rather, it is an integral part of an entire enterprise system. Changes made to one process may very well affect the performance of other processes in the system—sometimes adversely.

A comprehensive business model can provide the enterprise context within which the engineer conducts his or her process analysis. Specifically, the model displays how and where the process fits into the enterprise system, what other processes are affected by it, and what business and information systems must support it. This context helps the engineer make sure that proposed process changes will not degrade the performance of other processes and systems.

2. A COMPREHENSIVE BUSINESS MODEL FRAMEWORK

2.1. Looking at the Entire Enterprise System

The comprehensive business model paints a picture of the entire enterprise system. It depicts not only the internal operations of the enterprise, but the external forces that act upon it. Strategies, business objectives, business risks, and management controls are reflected, as well. Because of its comprehensiveness, the model helps management address key questions about the enterprise:

- Do the enterprise's strategy and the business relationships it has formed address the external forces in the industry?
- Does the design of the business processes established by the enterprise support its strategic objectives?
- Has management gained a complete perception of the business risks that could affect achievement of the strategic and business process objectives?
- Does the design of the management control framework adequately address the business risks?
- Does management monitor and measure those factors that are critical to the achievement of its significant business objectives?

An industrial engineer who is responsible for answering and resolving such questions within an enterprise clearly is in a very strategic position.

2.2. Overview of Business Model Elements and Structure

Figure 1 shows the basic framework for the comprehensive enterprise business model. Six components comprise the model:

- *External forces:* political, economic, social, and technological factors, pressures, and forces from outside the entity that threaten the attainment of the entity's business objectives
- *Markets:* the domains in which the enterprise may choose to operate

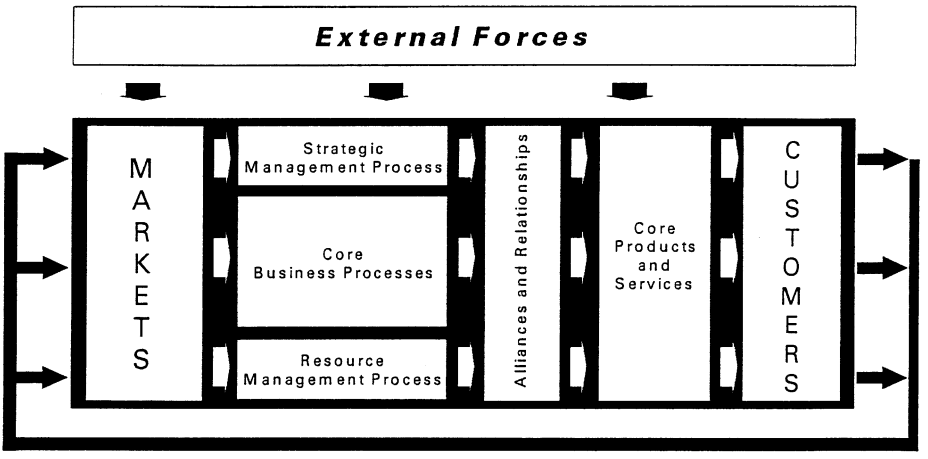

Figure 1 Enterprise Business Model Framework. (From Bell et al. 1997)

- *Business processes*, including:
  - Strategic management processes: the processes by which
    - the enterprise's mission is developed
    - business objectives are defined
    - business risks that threaten attainment of the business objectives are identified
    - business risk management processes are established
    - progress toward meeting business objectives is monitored
  - Core business processes: the processes that develop, produce, market, and distribute the enterprise's products and services.
  - Resource management processes: the processes by which resources are acquired, developed, and allocated to the core business activities
- *Alliances:* the relationships established by the enterprise to attain business objectives, expand business opportunities, and/or reduce or transfer business risk
- *Core products and services:* The value that the enterprise brings to the market
- *Customers:* the individuals and organizations who purchase the enterprise's output

Each of these components is discussed more fully later in this chapter.

2.3. The IE's Use of the Business Model

The business model can be used by the industrial engineer in a number of ways, depending on his or her placement and role in the enterprise. Following are several important potential uses. A more detailed discussion of how the industrial engineer might apply the business model is provided later in the chapter.

2.3.1. Gaining an Understanding of the Whole Business

Regardless of a person's placement and role, a good understanding of the whole business will help the individual see how he or she fits in, both operationally and strategically. This should help the person ensure that his or her objectives are consistent with and supportive of those of the enterprise, improving the potential for advancement within the organization.

2.3.2. Facilitating a Common Understanding of the Business by Others

Each person in an enterprise has an individual view of the business, and this view is often limited in scope and parochial in nature. Variations among viewpoints can cause considerable misunderstanding among individuals and groups about the purposes and direction of the enterprise. A well-documented, comprehensive business model can facilitate a common understanding of the business, both internally and externally.

2.3.3. Identifying Opportunities for Process Improvements

As noted earlier, process improvement is at the heart of the industrial engineer's purpose, regardless of where and at what level he or she is placed in the enterprise. The business model provides the framework for assessing process performance and interrelationships with other processes. Such assessment can lead directly to the identification and design of process changes that will improve the performance of the process as well as the enterprise as a whole.

2.3.4. Identifying and Mitigating Business Risks

Critical to the success of any enterprise is effective management of business risk. The business modeling process provides the basis for identifying the most significant risks, both internal and external, and developing means for mitigating those risks.

2.3.5. Developing the Basis for Process Performance Measurement

Performance measurement is fundamental to continuous improvement. Development of a comprehensive business model includes the identification or establishment of specific performance objectives for each business process. The performance objectives then provide the basis for an ongoing process performance measurement program.

2.3.6. Facilitating the Development of the Enterprise's Directional Course

The comprehensive business model can provide the basis for painting a future picture of the enterprise and determining the course of action to get there. This is done by developing a vision of what leadership wants the enterprise to be at some future point—for example, in three years. This vision is translated into a model of what the enterprise needs to look like to support the vision (the ''to be'' model). The ''to be'' model then is compared with today's ''as is'' model, and a migration plan is

developed to transform the business to the new vision. This use of the model is for the industrial engineer who is placed at the highest levels of the enterprise.

3. BUILDING THE BUSINESS MODEL

The enterprise business model depicts a complex system, and building it can be a major effort. Accordingly, the effort should be planned and managed like any complex business project. The major steps in a model-building project plan follow.

3.1. Obtain a Committed Sponsor at the Appropriate Level of the Enterprise

Developing a comprehensive business model can involve considerable information gathering and analysis. Substantial time and cost may be involved. Accordingly, there must be a sponsor for the effort, at the appropriate level of the enterprise, who will back the model design team and ensure that the necessary funding and other resources are provided. In essence, the sponsor will legitimize the effort and be responsible for making sure that the finished model meets its design objectives.

3.2. Set out the Purpose and Scope of the Model

The sponsor and others, as appropriate, clearly articulate the purposes and expected uses of the model. The purpose and use statement provides the basis for determining the scope of the model (e.g., in terms of geographic coverage, business unit coverage, and ''as is'' vs. ''to be'' views of the enterprise). The purpose, use, and scope statements then are translated into model-development time and cost objectives for the design team.

3.3. Gather and Orient the Model-Building Team

The team that will develop the enterprise business model is assembled and briefed on the purpose, scope, and framework of the model. The team members may be from various parts of the enterprise, typically including representatives from the key business processes (strategic, core, and resource management). The internal team may be supplemented by outside resources, as necessary (e.g., information specialists, process facilitators, and the like). A skilled project manager is appointed whose role is to ensure that the model-development effort is properly planned and completed on time and within budget.

3.4. Determine Information Requirements for Each Element of the Model

Each element of the model requires the development of information. In most cases the information will be readily available within the enterprise, but, particularly in the external forces area, the information may have to be developed with the assistance of outside information providers. Determining the information requirements for each element will highlight those areas that will be problematic and require special attention.

3.5. Construct the Business Model

The team gathers, compiles, and integrates the information to develop a draft of the business model. The model is depicted graphically and supported by textual material, as necessary. Reviews are conducted to ensure that the model is developed to an appropriate level of detail and that the various elements are properly integrated.

3.6. Build Consensus for the Model

Consensus for the model is built best through involvement. Such involvement can come through participating directly as a member of the design team, participating as a member of a project ''steering committee,'' or acting as a reviewer of the draft business model. The key is knowing who needs to be involved and in what ways they can participate most effectively.

4. BUSINESS MODEL CONTENT

4.1. Developing the Business Model Content

As previously mentioned, the business model is a tool that helps the industrial engineer develop an understanding of the effectiveness of the design and management of the enterprise's business, as well as the critical performance-related issues it faces, to evaluate opportunities and manage risk better. When completed, the business model is a strategic-systems decision frame that describes (a) the interlinking activities carried out within a business entity, (b) the external forces that bear upon the entity, and (c) the business relationships with persons and other organizations outside of the entity.

In the initial stage of developing the business model, pertinent background information is gathered to gain a full understanding of the industry structure, profitability, and operating environment. This industry background information and preliminary analysis then is used to determine the impact on

the enterprise's business. Each of the elements of the business model provides a summary of information that is pertinent to developing an understanding of the competitive environment and the enterprise's relative strengths and weaknesses in the marketplace.

The processes the engineer uses to assimilate the acquired knowledge will be unique for each enterprise and each engineer and therefore cannot and should not be reduced to highly structured formats, such as templates, checklists, and mathematical models.

A thorough understanding of five key business principles—strategic analysis, business process analysis, business measurement, risk management, and continuous improvement—will be necessary as the engineer seeks to acquire knowledge about the company's business and industry for the purpose of developing the full business model. These business principles and their interrelationships are depicted in Figure 2.

Throughout the model-building process, the engineer is working toward the ultimate goal of integrating the knowledge he or she obtains about the enterprise's systems dynamics and the congruence between strategy and the environment. He or she may use mental processes or more formal business simulation and systems thinking tools, or some combination of both, to structure his or her thinking about the dynamics of the enterprise's strategic systems.

4.2. Model Element 1: External Forces and Agents

External forces and agents encompass the environment in which an enterprise operates. They are the forces that shape the enterprise's competitive marketplace and provide new opportunities, as well as areas of risk to be managed.

Continuous monitoring and assessment of external forces is critical to the future of any business. The environment plays a critical role in shaping the destinies of entire industries, as well as those of individual enterprises. Perhaps the most basic tenet of strategic management is that managers must adjust their strategies to reflect the environment in which their businesses operate.

To begin understanding what makes a successful business, one must first consider the environment in which the enterprise operates and the alignment of its strategy with that environment. "Environment" covers a lot of territory—essentially everything outside the organization's control. The analysis of external forces and agents includes an assessment of both the general environment and the competitive environment. To be practical, one must focus attention on those parts of the general and competitive environments that will most affect the business. Figure 3 provides an example of a framework that can be used in assessing the general environment.

The general environment consists of factors external to the industry that may have a significant impact on the enterprise's strategies. These factors often overlap, and developments in one area may influence those in another. The general environment usually holds both opportunities for and threats to expansion.

The competitive environment, generally referred to as the "industry environment," is the situation facing an organization within its specific competitive arena. The competitive environment combines

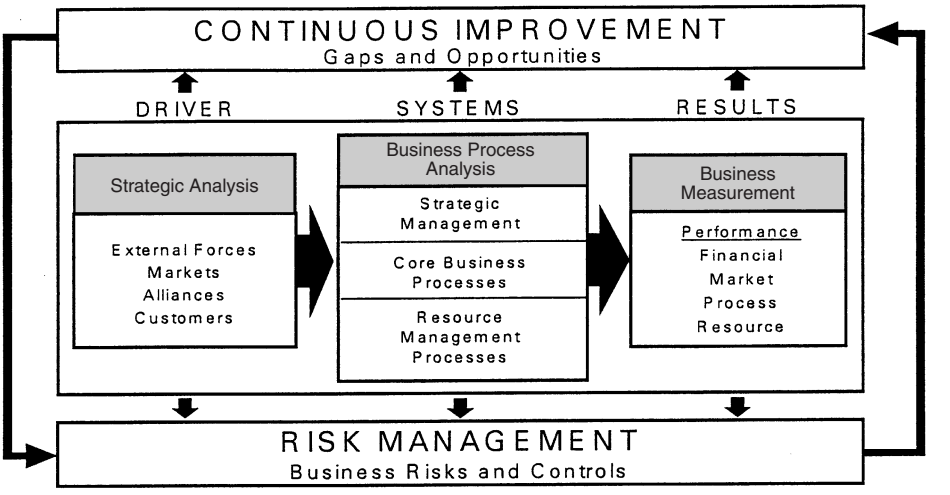

Figure 2 Business Improvement Principles. (From Bell et al. 1997)

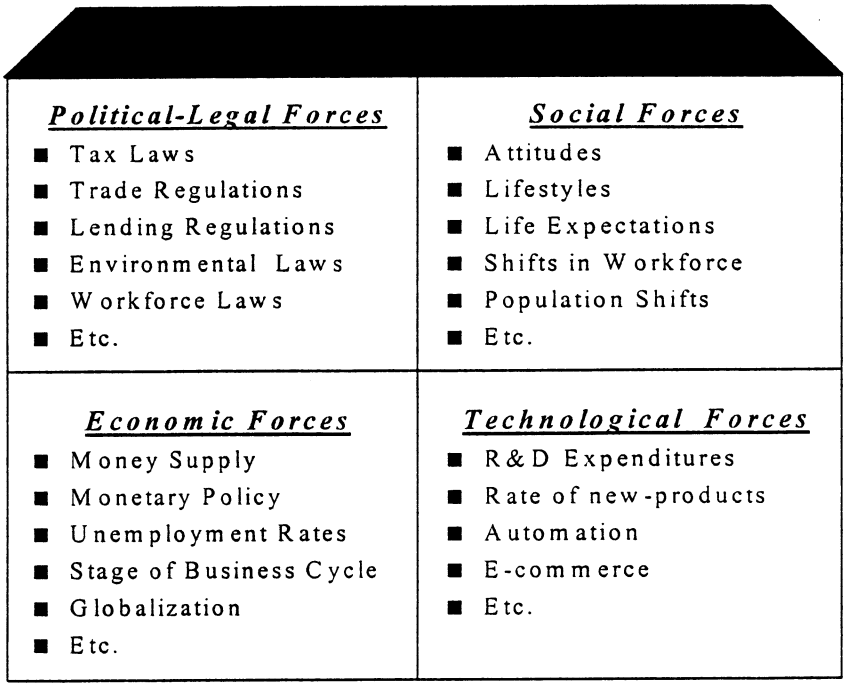

Figure 3 Dimensions in General Environment Assessment. (From Risk Management Partners, Inc.)

forces that are particularly relevant to an enterprise's strategy, including competitors (existing and potential), customers, and suppliers. The five forces model developed by Michael Porter, probably the most commonly utilized analytical tool for examining the competitive environment, broadens thinking about how forces in the competitive environment shape strategies and affect performance. Figure 4 is a graphic depiction of the five basic forces.

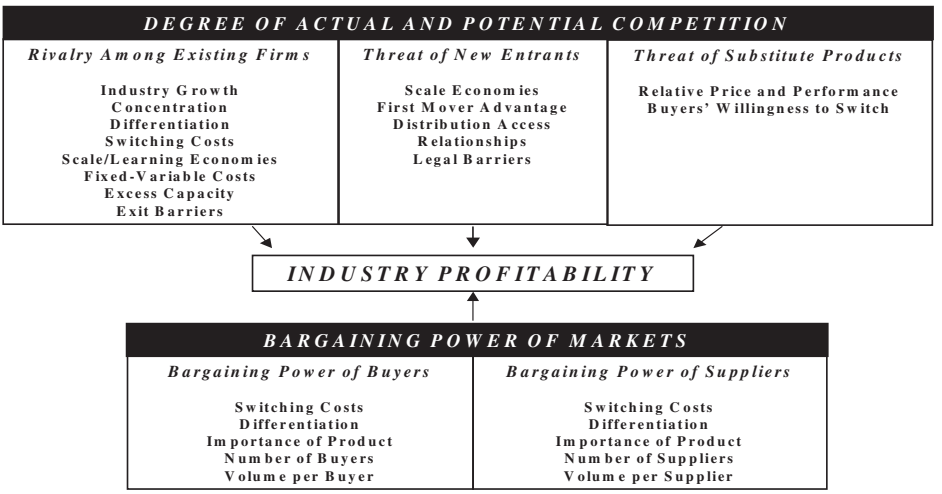

Figure 4 Five Forces Model of Competition. (Adapted from Porter 1985)

4.3. Model Element 2: Markets

Understanding the markets in which the enterprise competes is critical in developing the knowledge base for the business model. The extent to which an enterprise concentrates on a narrowly defined niche or segment of the market is referred to as *focus*. The engineer should understand the relevant advantages and disadvantages of particular levels of focus in terms of their impact on competitive advantage. For example, a differentiation strategy is often associated with focusing on a narrowly defined market niche. In contrast, a cost leadership strategy is often associated with a broadly defined target market.

Markets are not static—they emerge, grow, mature, and decline. As a market moves from one life cycle stage to another, changes occur in its strategic considerations, from innovation rates to customer price-sensitivity to intensity of competitive rivalry and beyond. The market life cycle provides a useful framework for studying markets and their impact on the enterprise's value proposition.

4.4. Model Element 3: Business Processes

In the enterprise, work gets done through a complex network of business processes. Work processes are the vehicles of business life. If properly configured and aligned and if properly coordinated by an integrated set of goals and measures, they produce a constant flow of value creation.

Process view of the business involves elements of structure, focus, measurement, ownership, and customers. A process is a set of activities designed to produce a specified output for a particular customer or market. It implies a strong emphasis on *how* work is done rather than *what* is done. Thus, a process is a structured set of work activities with clearly defined inputs and outputs. Understanding the structural elements of the process is key to understanding workflow, measuring process performance, and recommending process improvements.

4.5. Model Element 4: Alliances and Relationships

Financial pressures and time constraints continually squeeze managers who do not have the resources to fill the resource gaps through internal development. Acquisitions have not always been the most effective way to fill these resource gaps. They have proved expensive and brought not only the capabilities needed, but also many that were not desired. As a result, an increasing number of global enterprises recognize that strategic alliances can provide growth at a fraction of the cost of going it alone. In addition to sharing risks and investment, a well-structured, well-managed approach to alliance formation can support other goals, such as quality and productivity improvement. Alliances provide a way for organizations to leverage resources.

The rapid emergence of strategic collaborations as alternatives to the usual go-it-alone entrepreneurial ventures is evident everywhere, from the growing collaborative efforts of large multinationals to the continuing use of alliances to help maintain competitive advantage.

4.6. Model Element 5: Core Products and Services

Intense global competition, rapid technological change, and shifting patterns of world market opportunities compel firms to develop new products and services continually. Superior and differentiated products—those that deliver unique benefits and superior value to the customer—are the key to business success. Understanding the enterprise's core products and services and the value they bring to the customer is essential in developing a business model.

The importance and benefits of measuring new product success and failure cannot be overstated. Measuring new product performance has several benefits. Measurement (a) facilitates organizational learning and process improvements, (b) fulfills the need for consensus on new product outcomes and determinants, and (c) leads to observable benefits, such as improved cycle times, improved new product success rates, and an enhanced ability to assess changes to the new product development process.

4.7. Model Element 6: Customers

An organization cannot survive and prosper in today's world without customers. Customers allow organizations to exist, and yet customer capital is a mismanaged intangible asset. In many cases, companies are providing the wrong products and services for the markets they serve. Such organizations focus on pushing products onto the customer, rather than involving the customer in the design and development activities. Only mismanagement of customer capital can explain why U.S. companies, on average, lose half their customers every five years.

In a knowledge economy, information is more valuable than ever, and generally speaking, customers have more knowledge than the enterprise. As information and the economic power it conveys move downstream, it is vital that businesses manage customer relationships in new ways. Enterprises that learn with their customers, simultaneously teaching them and learning from them, form dependencies with them. Their people and systems—human and structural capital—mesh better than before.

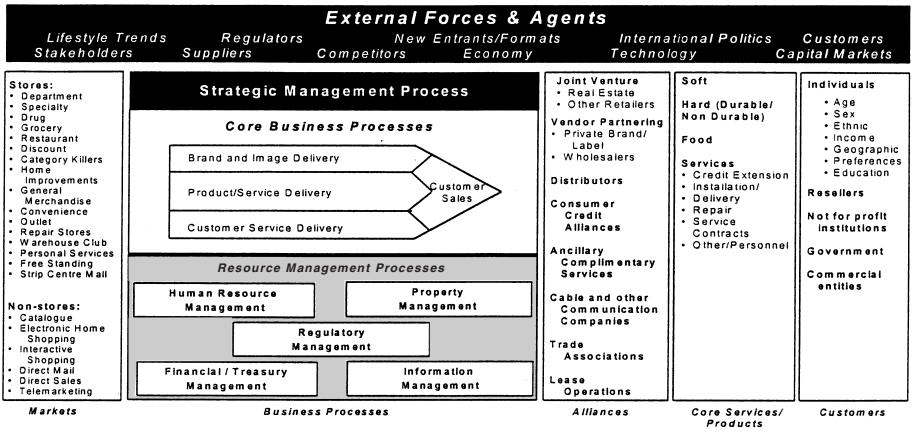

Figure 5 Example Entity-Level Model—Retail Company. (From Bell et al. 1997)

Understanding the power of the enterprise's customers, their needs and expectations, and the manner in which they are integrated into the enterprise's value proposition is critical in developing a knowledge-based business model.

4.8. Summary

Figure 5 provides an example of the major elements of a hypothetical retail company's business model. Each of the six business model elements is discussed more fully in the following sections.

5. ELEMENT 1: EXTERNAL FORCES AND AGENTS

5.1. The Multiplicity of External Forces and Their Relative Impact on the Business

The general environment consists of many factors external to the industry that may have a significant impact on the strategies of the enterprise. Systematic analysis of the factors making up the general environment can identify major trends in various industry segments. The framework shown in Figure 6 provides insight into the factors that should be understood when the enterprise engages in an analysis of its general, competitive, and internal environments.

In today's world, distance is no longer a barrier to market entry, technologies are rapidly replicated by competitors, and information and communications technologies are shaping a new economic order. To manage their business operations effectively, organizations must now view their playing field as

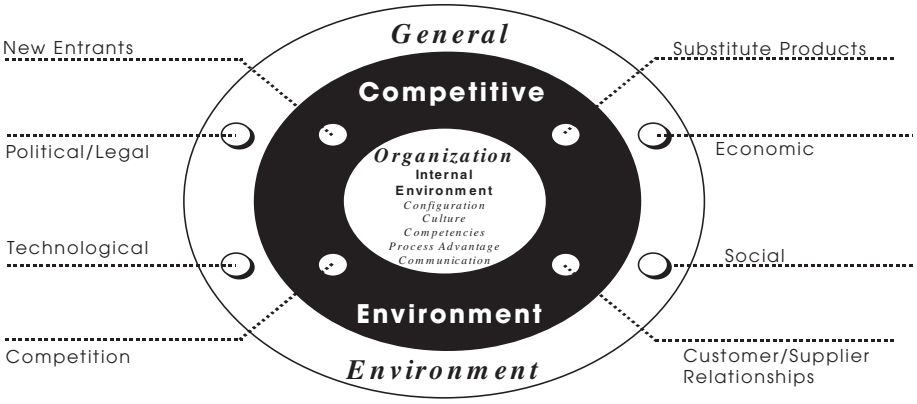

Figure 6 External/Internal Analysis—A Global Perspective. (Adapted from Bell et al. 1997)

the whole global economy. Prudent managers continually scan these environments for indications of the emergence of business opportunities and risks. They understand current trends and the relevant implications for their business.

Many trends are impacting the way business will be conducted in the future, but the New Economy is taking shape at the intersection of three very significant long-term trends that will continue to gather momentum in the decades ahead: the *globalization of business,* the *revolution in information technology*, and the *growth of knowledge work.* These trends are undermining the old order, forcing businesses to restructure and dramatically change their business models. In the following paragraphs, we discuss these trends and other significant social, demographic, political, and business reporting trends.

5.1.1. Globalization of Business

Simply put, capitalism is spreading around the world—if not full-blown capitalism, at least the introduction of market forces, freer trade, and widespread deregulation. It's happening in the former Communist countries, in the developing world of Latin American and Asia, and even in the industrialized West, with economic union in Europe and the Free Trade agreement in North America.

The number of foreign companies operating in the United States is growing rapidly, at about 2% per year. They now total more than 40,000 and account for about 7% of all corporate assets in the United States. These foreign firms bring to bear the financial and production resources of their home countries on almost any emerging market opportunity in the United States and can quickly take market share with products manufactured less expensively abroad. Foreign competition has arisen not just in large industrial enterprises—automobiles, trucks, aircraft, and computers—but even in some traditional natural monopolies, such as telecommunications and satellite broadcasting.

International trade and investment will play a much larger role in the U.S. economy in the future. Exports and imports already constitute over 25% of the economy.

Increasingly porous national borders, changing corporate cultures, and continuing labor shortages are contributing to the emergence of a global workforce. As regions develop into pockets of specific talent, more workers will relocate to them. In other cases, companies will go to workers, hiring them where they live. Technology will enable the efficient execution of tasks regardless of proximity to home office. This fluid interchange of individuals and information will bring together people of disparate backgrounds. Individuals with dual nationalities will be commonplace.

5.1.2. Revolution in Information Technology

The foundation of the New Economy is the revolutionary explosion of computer processing power. Computing power doubles every 18 months. In addition, we have seen a 22-fold increase in the speed of data transmission obtained over ordinary telephone lines during the past two decades. This wave of innovation in data communications has promoted the extraordinary build-out of the world's computer networks. Over 60 million computers are connected via the Internet. The network phenomenon is just as remarkable as the explosion in computing power. As information technology reduces the trade-off between the depth and quality of information and its access, the economics that underlie industry and organizational structures will be transformed. As more individuals and businesses connect electronically, the economics of scope will change organizational relationships, competition, and make vs. buy decisions.

Technology is likely to continue on its path of being smaller, faster, cheaper, and less visible in the everyday world. The intersection of computing and telecommunications will bring about a fundamental change in the perception of distance and time. At the same time, the traditional interface that has existed between humans and technology will rapidly disappear. Remote sensing, data collection systems, cameras, and adjuncts to sensing abilities are among the major new applications in this field.

More significantly, information technology is transforming the global business environment. Housing and autos used to drive the U.S. economy. Now information technology accounts for a quarter to a third of economic growth.

5.1.3. Growth of Knowledge Work

Increasingly, knowledge has become more valuable and more powerful than natural resources and physical facilities. Value propositions are based on information and ideas, rather than on the mere physical attributes of products. This phenomenon is true in both service businesses and in businesses that have historically focused heavily on tangible products. Knowledge is being used to enhance greatly the value of all physical products. The result is that much of our economic growth in recent years has been intangible. As value creation shifts from the mere economics of physical products to the economics of information, managing information, knowledge, and innovation will become a business imperative.

Information and knowledge have become the sources of competitive advantage. In industry after industry, success comes to those enterprises that manage knowledge and information more effectively than their competitors. Companies like Wal-Mart, Microsoft, and Toyota became great companies because they had intellectual capital—knowledge, information, intellectual property, and experience—and used it to achieve competitive advantage. Knowledge and information have become the New Economy's primary raw materials and the source of its most important products.

5.1.4. Data Access Transforms Business Reporting

The demand for data from users, including employees, capital suppliers, customers, regulators, and the like, will continue to accelerate rapidly. This will require the use of massive databases and network technologies that will provide customized information to users—anyplace, anytime.

In addition, highly networked environments will increase user needs for instantaneous information. Information on demand will be a requirement of all network participants. Users won't be satisfied with paging through static report images; they will need to analyze data—within the scope of the reporting system—from multiple perspectives in order to answer critical business questions involving all aspects of the value chain.

Data access will replace traditional forms of reporting. Companies will employ complex, multifaceted, client/server report-processing environments that include intelligent report viewers, tiered report processors, flexible report schedulers, report distribution schemes, user flexibility, and administration and control mechanisms. Content agents that allow users to customize their reports and receive data in real time will support these databases.

5.1.5. Other Social, Demographic, and Political Changes

The following social, demographic, and political trends have been obtained from various research studies. They are illustrative examples of current trends and their related business implications. Many government agencies and private research firms continuously analyze and monitor trends that affect the way business is conducted. The enterprise and the engineer should cultivate and become familiar with these resources and monitor current trends during the design and development of the full business model.

5.1.5.1. Birth Rates The significant changes in birth rates during the past half century continue to affect the marketplace in subtle ways. New births have now become part of a much larger population base and are not as likely to have the major impact that the "baby boomers" have had. Markets will be smaller and enterprises will have to spend more time and resources to tap into them.

5.1.5.2. Immigration As births fall in the next decade, immigration will have even more of an effect on the composition of the market. Immigrants bring a diverse set of skills and attitudes to the United States, the most prominent being their enthusiasm and desire to partake in the U.S. experience.

Immigrants expand the labor pool in the workplace at both ends, as unskilled workers and as high-end workers with specialized talent and training. Business will find that the foreign-born make up an increasing share of their markets, especially in the four largest and most dynamic states: California, Texas, New York, and Florida. Companies will have to learn about the cultures of these groups as they become both customers and employees.

5.1.5.3. Household Growth Households are of particular importance to future markets because they are the fundamental purchasing unit. Virtually all consumer-spending decisions are made within the context of household needs and budgets. Thus, new households create new sales opportunities.

One of the most important longer-term consequences of the aging baby boomers is that household formation is slowing down. For companies that sell products and services to new households (housing, home furnishings, new cars, insurance), the days of growing with the market are over. Opportunities will now have to come from understanding the composition of the household, more than sheer growth in numbers. More and more sales will be driven by increasing the provision of value-added goods and services to households.

5.1.5.4. Families Continue to Change The composition of the household is changing. The share of households made up of married couples with children declined from 40% in 1970 to 25% in 1995. That share will continue to go down. The households with the most dynamic growth rates will be married couples without children.

Business will make more sales to smaller households, and the sales will demand more one-on-one interaction. This is because needs and tastes will no longer be driven by family imperatives, which tend to be similar to each other, but by those of adults, which tend to be more personal. This means much wider swings in the purchasing patterns of households.

5.1.5.5. Income Mobility of Workers Increasing immigration rates, the growing importance of education, and changing systems of compensation that reward high performers have contributed to a

disturbing trend in the United States: a growing inequality in income between the rich and the poor. In the last three decades, the number of households with incomes under $15,000 (in constant 1996 dollars) has grown from 14 million to 21 million, while the number with incomes over $75,000 (in constant 1996 dollars) has grown from 4 million to 17 million. The good news is that every year about one third of adults of working age move out of their income quintile. In five years, almost half move.

Consumers' purchasing behavior is driven by household resources. But access to credit means that consumer purchases may not always be limited by current earnings. Many household purchases are based on expected changes in future income. The fact that as many as 50% of adults can expect to find themselves in a different income quintile in the next five years suggests that payment flexibility will be a critical tool for enterprises trying to meet the ever-more elusive needs of the 21st century consumer.

5.1.5.6. The Virtual Workforce Technology and changing organizational cultures are enabling more people to work wherever they choose to live. In the next five years, the number of telecommuters is expected to reach 20 million or more. Some predict that half the workforce will be telecommuting from home, office, or shared facilities within the next decade.

At the same time, the number of temporary workers, freelancers, independent contractors, and the like exceeds 25 million by some estimates. Virtual partnerships/alliances between independent contractors are expected to flourish as sophisticated telecommunications capabilities enable people to link up with anyone, anywhere.

5.1.5.7. Political and Regulatory Changes The regulation of commerce and industry is being adapted to meet the needs of the new consumer. The United States spent almost a century building a regulatory network to protect citizens from the complex risks of a rich, urbanized, industrialized society. Now a more sophisticated consumer, new technologies, and a much more competitive global market are gradually creating an environment more self-regulating and open to consumer discretion, in which it is easier to spread throughout the marketplace the risk that the government formerly took on. As a result, regulatory barriers are coming down.

Sophisticated consumers, one of the key drivers of the move toward deregulation, will become a roadblock if they feel that their fundamental birthrights are threatened: (a) affordable and accessible health care choices, (b) safety and security of the financial system, (c) quality of life that environmental regulations protect; and (4) any issue that seems to lead to an unwanted invasion of privacy.

5.1.5.8. Privatization The transformation of state-owned or controlled enterprises into privately owned or managed enterprises is sweeping the world for the second decade. This phenomenon indicates expanding confidence in the benefits of market forces the world over.

While privatization initiatives have been common all over the world, Europe has felt the largest impact. Almost 60% of the private money raised in the last few years has been in Europe. The flow of public enterprises into the private sector will continue in the 21st century, though probably at a slower rate. Privatization has increased competition and lowered prices, given consumers more choices, increased the rate of innovation, ended subsidies to state-run enterprises, provided new investment opportunities, and replaced monopolies with new players.

5.1.5.9. Key Trends to Follow The New Economy will be affected largely by future developments in three key areas:

1. *Information technology*, providing refinements of computer technologies to optimize the possibilities of electronic commerce
2. *Biotechnology*, where the manipulation of genes will allow new control over diseases and health possibilities
3. *Nanotechnology*, the development of miniaturized systems so that everyday instruments such as mobile phones and calculators can be used in extraordinary ways

5.2. Customers

In the New Economy, the companies with the smartest customers win. The richness and reach of information created by the network economy has moved the power downstream to the customer. With more timely, accurate, and relevant information, customers will be in the driver's seat as existing products are improved and new products are introduced. Their power in the New Economy cannot be overemphasized. The extent to which customers are integrated into the design, development, and improvement of products and services will determine competitive advantage. Knowledge is the driver of the New Economy, and customers generally have much more of it than the producers of products and services.

5.3. Competitors

As the richness and reach of information improve, traditional barriers to entry in most markets will be reduced substantially. Enterprises can no longer focus most of their efforts on analyzing existing competition. New market entrants will appear at an ever-increasing rate, and value propositions will be challenged continuously.

5.4. Regulators

The regulation of commerce and industry is being adapted to meet the needs of the new consumer. The competitive global market is gradually creating an environment that is more self-regulating and open to consumer discretion. As a result, sophisticated consumers are driving deregulation; however, markets will deregulate at varying speeds around the world, some much more slowly than others. In-depth understanding of local regulations will be important as enterprises expand into an ever-increasing number of new markets.

While many regulatory barriers will disappear over time, new regulations will emerge regarding the environment, safety of the financial system, access to health care, and other areas that are considered important to the new generation.

5.5. The Community

The networked economy will ensure that an enterprise's stakeholders, including the local communities that it serves, have a breadth of information to help them make choices. Managing the brand image will become even more important as companies realize the importance of providing information to their stakeholders about social and environmental performance.

5.6. Alliances

Alliances are fraught with uncertain risks and opportunities. Uncertainty brings ambiguity, and ambiguity can lead to business failures. Alliances are most advisable when conditions are right within both the enterprise and the target industry. When alliances are considered, there is a range of strategic options that should be measured in terms of their related risks and rewards.

Rewards can be measured in a variety of ways: market share, cash flow, depth of product line, and growth, to name a few. Risks generally include political, monetary, technological, partner, and market risks, among others.

The architecture of alliances is composed of a number of critical elements, including common language; principles and practices; strategies; structure, roles, and responsibilities; processes and systems design; interrelationships and interfaces; early warning signals; and performance management.

5.7. Stakeholders and Owners

Stockholders are only one of several possible stakeholder groups. Obligations to a firm's stockholders are generally referred to as the firm's fiscal responsibility, while obligations to its stakeholders—parties that have an interest, or stake, in the success or performance of the company—are referred to as the firm's social responsibility.

Sweeping trends in corporate governance are placing more oversight responsibility on boards of directors, audit committees, and other corporate committees to improve fiscal and social performance, as well as stakeholder communication. In addition, stockholders are demanding board of director independence and accountability.

5.8. Suppliers

In many industries, the cost of purchased supplies accounts for 60–80% of production costs, so suppliers can have an important impact on an industry's profit potential. When the number of suppliers in a market is limited and substitute products are lacking, suppliers can exercise considerable power over their customers because the switching costs can be problematic and costly.

The relative importance of the suppliers' products to the buyer, and conversely the relative lack of importance of the buyer to the supplier group, give significant power to suppliers. Other factors that increase the bargaining power of suppliers include high switching costs and a credible threat of suppliers to move into various stages of the value chain as direct competitors.

5.9. Capital Markets

The changes in capital markets in Europe and North America are spreading throughout the world. China is already entering the commercial capital markets in Europe and the United States, and Russia will follow. The West is investing in rising and maturing stock exchanges throughout the world as it seeks market positions and greater return on capital. Major new enterprises in developing economies,

created through privatization, are entering the world's capital markets. But as companies tap capital sources outside their home countries, capital suppliers are likely to demand representation on their boards of directors.

5.10. The Economy

Macroeconomic developments, such as interest rate fluctuations, the rate of inflation, and exchange rate variations, are extremely difficult to predict on a medium- or long-term basis. Unpredictable movements of these macroeconomic indicators cannot only affect a company's reported quarterly earnings, but even determine whether a company survives. There is general agreement that the financial environment, characterized by increased volatility in financial markets, is more risky today than in the past. Growing uncertainty about inflation has been followed quickly by uncertainty about foreign exchange rates, interest rates, and commodity prices.

The increased economic uncertainty has altered the way financial markets function. Companies have discovered that their value is subject to various financial price risks in addition to the risk inherent in their core business. New risk management instruments and hybrid securities have proliferated in the market, enabling companies to manage financial risk actively rather than try to predict price movements.

6. ELEMENT 2: MARKETS

6.1. "Market" Defined

In simple terms, a market is a group of customers who have a specific unsatisfied need or want and are able to purchase a product or service to satisfy that need. For example, the market for automobiles consists of anyone older than the legal driving age with a need for transportation, access to roads, and enough money to purchase or make a payment on a car.

Markets can be broken down in numerous ways as marketers try to find distinctive groups of consumers within the total market. Market segmentation allows marketers to allocate promotional expenses to the most profitable segments within the total market and develop specific ad campaigns for each one. Segmentation produces a better match between what a marketer offers and what the consumer wants, so customers don't have to make compromises when they purchase a product.

6.2. Market Domains Served

The served market is the portion of a market that the enterprise decides to pursue. For example, a company that manufactures video games defines the market as anyone who owns a television. The *potential market* is defined as households with children and a television. The *available market* is limited to households with children, a television, enough income to make the purchase, and a store nearby that carries the game. The *served market* consists of households with a television, access to a toy store, sufficient income to buy the product, and children within a specific age range.

7. ELEMENT 3: BUSINESS PROCESSES

7.1. Categories of Business Processes

Considerable controversy revolves around the number of processes appropriate to a given organization. The difficulty derives from the fact that processes are almost infinitely divisible; the activities involved in taking and fulfilling a customer order, for example, can be viewed as one process or hundreds. Process identification is key to making process definitions and determining their implications. If the objective is incremental improvement, working with many narrowly defined processes is sufficient because the risk of failure is relatively low, particularly if those responsible for improving a process are also responsible for managing and executing it. But when the objective is radical process change, a process must be defined as broadly as possible.

Before we explain the major business process categories, the following definitions may be useful:

- A *business process* is a logical, related, sequential—connected—set of activities that takes an input from a supplier, adds value to it, and produces an output to a customer.
- A *key business process* is a process that usually involves more than one function within the organizational structure, and its operation has a significant impact on the way the organization functions.
- A *subprocess* is a portion of a major process that accomplishes a specific objective in support of that major process.
- *Activities* are work elements that go on within a process or subprocess. They may be performed by one person or a team of people.
- *Tasks* are individual elements and/or subsets of an activity. Normally, tasks relate to how an individual performs a specific assignment.

For purposes of understanding the business and documenting the business model, it is useful to organize the business processes into categories:

1. *Strategic management processes:* those processes that develop the value proposition of the enterprise and define the business objectives
2. *Core business processes:* those processes that develop, produce, sell, and distribute products and services (i.e., the value chain)
3. *Resource management processes:* those processes that support and provide appropriate resources to the value-creating processes of the enterprise

Most enterprises can define their business in terms of 10–15 key processes: one to three strategic management processes, 5–7 core business processes, and 3–5 resource management processes. Figure 7 is an illustrative example of process definitions in the industrial products industry.

Identifying and selecting processes for the business model is an important prerequisite to understanding the enterprise and its competitive strengths and weaknesses. Without some focus on critical processes, an organization's energies, resources, and time will not be focused appropriately. The appendix to this chapter provides a list of key generic business processes and their related subprocesses that should be useful as a guide in identifying and selecting processes in any organization.

7.1.1. Strategic Management Processes

Strategic management is the name given to the most important, difficult, and encompassing challenge that confronts any private or public organization. The conflict between the demands of the present and the requirements of the future lies at the heart of strategic management. Change is the central concern and focus of strategic management: change in the environment, change inside the enterprise, and change in how the enterprise links strategy and structure. Strategic management is the process of identifying opportunities to achieve tangible and sustainable success in the marketplace and understanding the risks that threaten achievement of that success. Figure 8 shows one view of the major components of a strategic management process.

Information technology (IT) has introduced new challenges and opportunities for business. Businesses are forced to adopt IT strategies that provide for connectivity to everyone in the business network—stakeholders, suppliers, customers, alliance partners, and others—and react strategically and operationally in real time. The external forces affecting business are changing so rapidly that organizational structures must be designed so they can respond quickly to changes in the business environment. In addition, IT investments must be leveraged by the adoption of open systems and standards that allow rapid changes in those systems that support the execution of key business processes.

Figure 7 Process Definitions—Industrial Products Example. (From Risk Management Partners, Inc.)

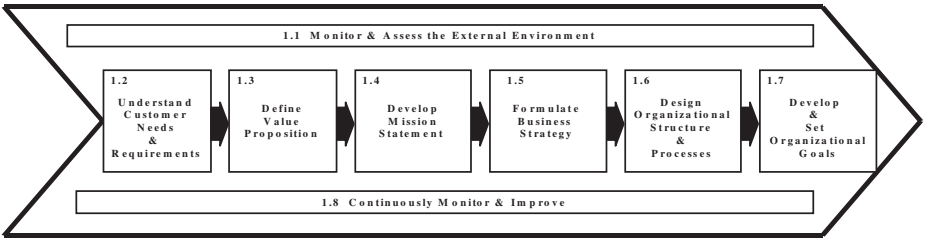

Figure 8 Illustrative Strategic Management Process (From Risk Management Partners, Inc.)

Strategic management principles in the New Economy must recognize the importance of knowledge and information to all value propositions and the need for structures that can adapt quickly and continuously improve in real time. Figure 9 provides an example of the important components of strategy in a connected world.

In the ''Enterprise Business Model'' block in Figure 9:

- ''Knowledge Networks'' means capturing and managing knowledge as a strategic asset.
- ''Process Excellence'' means designing and managing processes to achieve competitive advantage.
- ''Core Competencies'' means focusing on those things that the enterprise does best and using alliance partners to supplement those skills.

In particular, strategy involves continuously reconceiving the business and the role that business can play in the marketplace. The new business model is a real-time structure that can change continually and adapt more quickly and better than the competition.

The traditional approach to strategy development relied upon a set of powerful analytic tools that allowed executives to make fact-based decisions about strategic alternatives. The goal of such analysis was to discuss and test alternative scenarios to find the most likely outcome and create a strategy based on it. This approach served companies well in relatively stable business environments; however, fact-based decisions in the rapidly changing New Economy will be largely replaced by imagination and vision.

Rapidly changing business environments with ever-increasing uncertainty require new approaches to strategy development and deployment. While traditional approaches are at best marginally helpful and at worst very dangerous, misjudging uncertainty can lead to strategies that do not identify the business opportunities and business risks. However, making systematically sound strategic decisions will continue to be important in the future. Even in the most uncertain environments, executives can generally identify a range of potential scenarios. The key will be to design business models that can

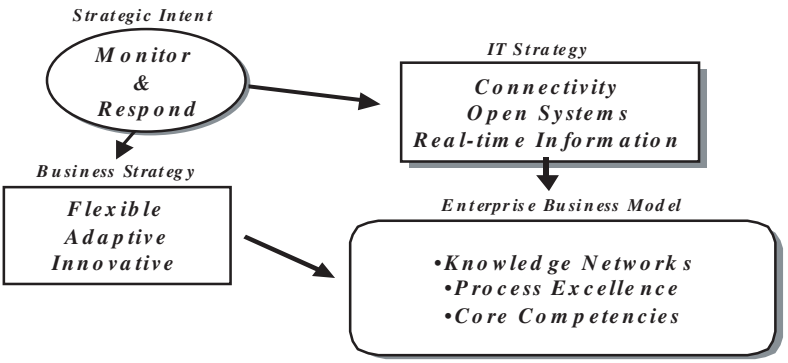

Figure 9 A New Economy Strategy. (From Risk Management Partners, Inc.)

respond quickly as economic realities change. Understanding competitive environments, external forces, and the levels of uncertainty in the marketplace will lead to more informed and confident strategic decisions. The design and development of a real-time business model can provide an invaluable tool to support the strategic management process.

7.1.2. Core Business Processes

Core business processes develop, produce, sell, and distribute an entity's products and services; they are the entity's value chain. These processes do not follow traditional organizational or functional lines, but reflect the grouping of related business activities.

The management of core business processes is about execution of the enterprise's value proposition. Significant changes are taking place in the New Economy that will have profound impacts on core business processes and the way they are managed in the future.

IT is driving the transformation of core business processes by creating a new competitive dynamic that rewards institutional agility. Business processes will no longer be viewed within the boundaries of the organization. Multiple partners will be involved in key activities of many organizations' key business processes.

Historically, the fundamental disposition of core business processes is to prepackage and shrink-wrap as much product as possible, take advantage of economies of scale, and then persuasively offer these products. Service is viewed as a way of enhancing the attractiveness of products. The New Economy enterprise, on the other hand, will design core processes that concentrate on assembling modular elements into a customized response to a specific customer's specific request.

The evolution of extranets and content standards alters the bases of competitive advantage by increasing the quality of information and its access. These technologies diminish the value of established business processes and relationships because most buyers can easily find suppliers—worldwide—who offer the best product. Higher-quality information will allow companies to improve business processes by supplementing internal capabilities with the needed skills and technologies from others—worldwide.

The opportunities to radically change traditional business processes and take advantage of network externalities, multiple strategic and alliance partners, and the richness and reach of information cannot be overstated. Using business process excellence to obtain competitive advantage will be more important than ever before. Deconstructing value/supply chains for the purpose of exploiting market opportunities and reducing transaction costs will be the norm for most successful businesses in the New Economy.

The ultimate challenge posed by deconstructing value chains will be to the traditional hierarchical organization, with its static business processes. Core business process improvement will be both challenging and exciting as opportunities are unleashed to create value in new ways. Outsourcing will flourish as organizations design core processes that emphasize their strengths and supplement them with the outstanding capabilities of other firms that can add significant value to their products and services.

7.1.3. Resource Management Processes

Resource management processes are the processes by which organizations allocate resources and monitor their use. They provide appropriate resources to support the other business processes. Resource management processes can be placed into three basic categories: information, people, and capital. They are focused on serving the needs of internal customers, principally those in the enterprise's core business processes who are externally focused on serving customers outside the organization. Without appropriate resources—information, people, and capital—the core processes cannot offer the value customers need and will cease to provide an effective source of competitive advantage.

7.2. Process Analysis Components

Figure 10 displays a framework for process analysis. The process analysis components in this framework are discussed in this section.

7.2.1. Process Objectives

Processes are established to serve specific customer needs. The customers may be internal, such as another process, or external to the enterprise. The process objectives define what value will be supplied to the customer. One can look at them as the whole purpose for which the organization has put together this set of resources and activities. Process objectives need to be specific, measurable, attainable, and realistic and to have a sense of time. Business process objectives may differ significantly between enterprises within an industry or industry segment, being shaped by the organization's strategic objectives and related critical success factors. For example, the business objectives for the ''materials procurement process'' in a consumer products company might be as follows:

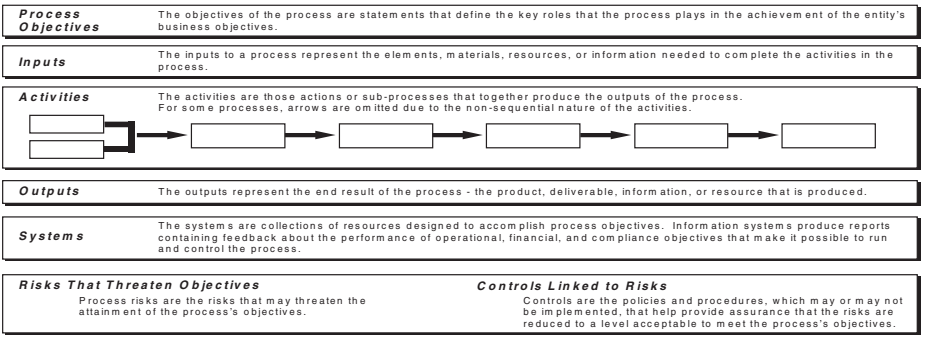

Figure 10 Process Analysis Framework. (Adapted from Bell et al. 1997)

- Effectively manage supplier relationships to ensure the highest quality materials at the lowest cost.
- Provide accurate, real-time production information to suppliers to minimize inventory levels.

7.2.2. Inputs

The inputs to a process represent the elements, materials, resources, or information needed to complete the activities in the process. Examples of inputs for the aforementioned materials procurement process could be the following:

- Material requirements, supply requisitions, negotiated prices;
- Material specifications, bills of material, capital authorizations
- Supply base, production reports, lead times

7.2.3. Activities

Almost everything that we do or are involved in is a process. Some processes are highly complex, involving thousands of people, and some are very simple, requiring only seconds of time. Therefore, a process hierarchy is necessary to understand processes and their key activities. From a macro view, processes are the key activities required to manage and/or run an organization. Any key business process—a strategic management process, a core business process, or a resource management process—can be subdivided into subprocesses that are logically related and contribute to the objectives of the key business process. For example, Figure 11 provides an example of the subprocess components of a new product planning process for a consulting firm.

Every key business process or subprocess is made up of a number of activities. As the name implies, activities are the actions required to produce a particular result. Furthermore, each activity is made up of a number of tasks that are performed by an individual or by small teams. Taken together, tasks form a microview of the process.

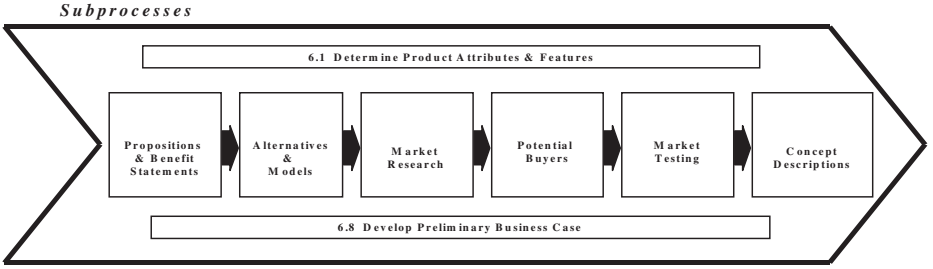

Figure 11 Example: New Product Planning Process—Consulting. (From Risk Management Partners, Inc.)

7.2.4. Outputs

Outputs represent the end result of a process; they are the products, deliverables, information, or resources that are produced.

7.2.5. Supporting Systems

Supporting systems include the hardware, software, information, and communications capabilities that the organization requires to fulfill its mission and achieve its business objectives.

7.2.6. Risks That Threaten Objectives

Business risk is the threat that an event or action will adversely affect an entity's ability to achieve its business objectives and execute its strategies successfully. A business risk is always related to one or more business objectives and can be described as the antithesis of those objectives.

Business risks can be categorized as:

- *External:* strategic risks that threaten an enterprise's marketplace objectives and are mitigated by an effective strategic management process
- *Internal:* process risks that threaten an enterprise's ability to execute its strategy effectively and are mitigated by effective process controls

Figure 12 shows examples of generic risks that could affect the achievement of core process objectives. Similarly, Figure 13 provides examples of generic risks that could affect the achievement of resource management process objectives.

7.2.7. Controls Linked to Risks

A new business risk control paradigm is changing the way organizations manage their business risks. Over the years, businesses have used a variety of practices to control risk. In many organizations, however, control is a misunderstood and misapplied concept. Control all too often means inflexible and unimaginative budgets, seemingly endless management reporting requirements, and an overburdening and often irrelevant stream of information up and down the corporate hierarchy. The new control paradigm is illustrated in Figure 14.

Fast-moving markets, flattening corporate hierarchies, and the need for an expanding scope of authority at the local level are making salient the costs of misunderstanding and misapplying control. In response, managers are rethinking fundamental definitions of control and how business risks should be identified and mitigated.

Empowerment will increasingly blur lines of authority, and increasingly flat organizations will provide fewer opportunities for segregation of duties. Traditional notions of control (such as segregation of duties and functions, proper authorization for expenditures, controlled access to assets, and proper recording of transactions) that define the procedural checks and balances that safeguard assets

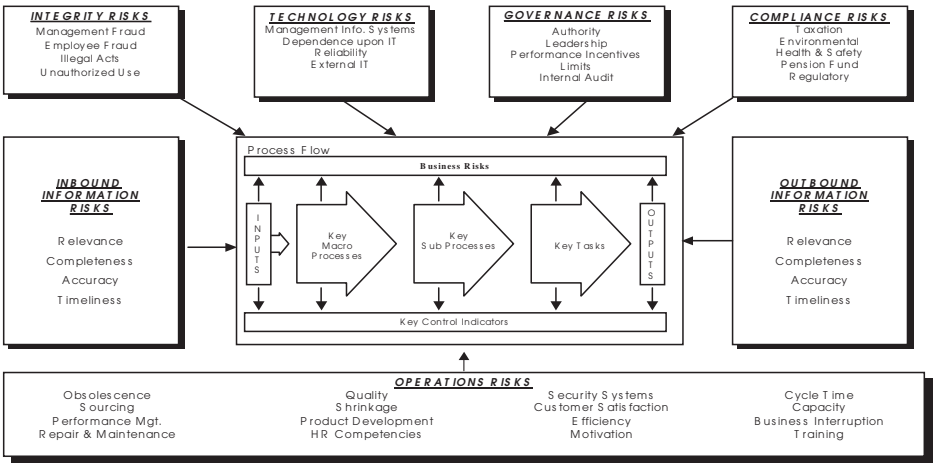

Figure 12 Illustrative Process Risks for Core Processes. (From Risk Management Partners, Inc.)

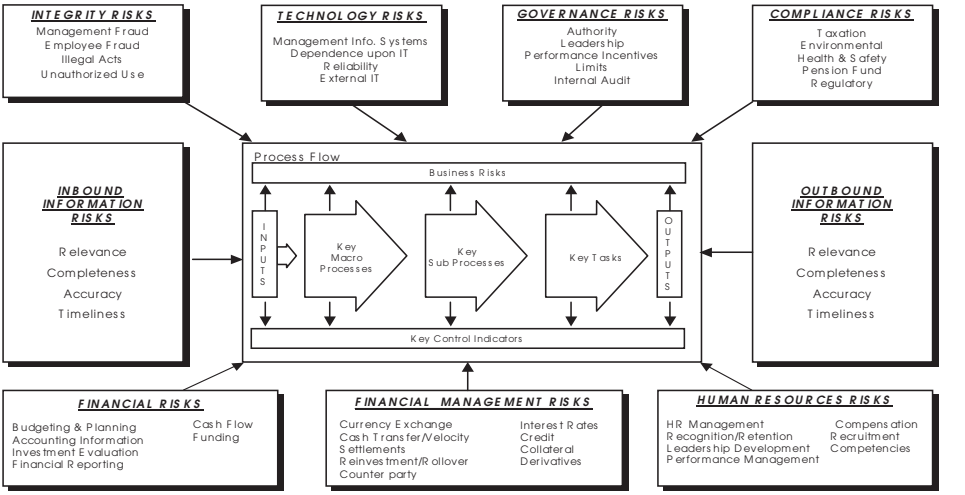

Figure 13 Illustrative Process Risks for Resource Management Processes. (From Risk Management Partners, Inc.)

and assure integrity of data must be recognized as only one aspect of the contemporary organization's control structure.

Other components of the control structure include diagnostic control systems, belief systems, boundary systems, and incentives. Diagnostic control systems, for example, recognize that empowerment requires a change in what is controlled. Consistently, empowered individuals are being asked to take risks and there must be commensurate rewards for the risk taking and achievement of superior performance. Such rewards, which can be either monetary or nonmonetary, are made on the basis of tangible performance consistent with the organization's mission.

The evolving organizational controls structure consists of strategic controls, management controls, and business process controls. A brief description of these elements follows:

- *Strategic controls* are designed to assess continuously the effect of changes in environment risks on the business, formulate business risk control strategies, and align the organization with those strategies.
- *Management controls* drive business risk assessment and control throughout the organization.
- *Process controls* are designed to assess continuously the risk that business processes do not achieve what they were designed to achieve. Embedded in process risk is information processing/technology risk, which arises when the information technologies used in the process are not operating as intended or are compromising the availability, security, integrity, relevance, and credibility of information produced.

Figure 15 provides examples of these types of controls.

8. ELEMENT 4: ALLIANCES AND RELATIONSHIPS

8.1. "Alliance" Defined

Several types of alliances exist, each with a specific purpose. The following are three of the more common types:

- *Transactional alliances* are established for a specific purpose, typically to improve each participant's ability to conduct its business. Cross-licensing in the pharmaceutical industry is an example. Open-ended purchase orders for specific products would be another.
- *Strategic sourcing* involves a longer-term commitment. It is a partnership between buyer and seller that can reduce the cost and friction between supplier and buyer by sharing product development plans, jointly programming production, sharing confidential information, or otherwise working together much more closely than do typical suppliers and customers. Wal-Mart and Home Depot are examples of companies with substantial capabilities in strategic sourcing.

Figure 14 The Old and New Business Risk Control Paradigms. (From Risk Management Partners, Inc.)

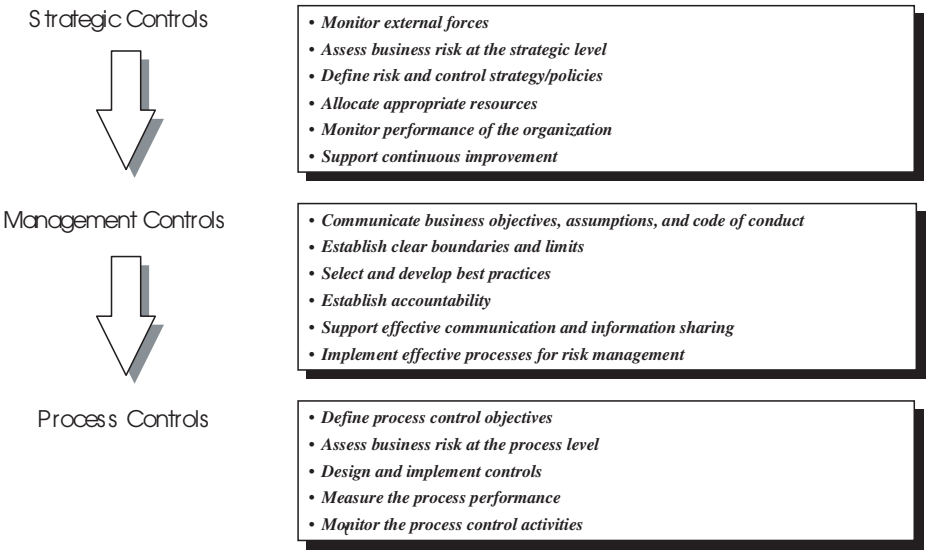

Figure 15 Illustrative Examples of Controls. (From Risk Management Partners, Inc.)

- *Strategic alliances* involve two enterprises pulling together to share resources, funding, or even equity in a new enterprise on a long-term basis. For example, Motorola, Apple, and IBM pooled research programs and made financial commitments to develop a new-generation engine for personal computers—the Power PC.

8.2. Strategic Alliances in the Value/Supply Chain

The move toward strategic alliances is very strong because of increased global competition and industry convergence. For example, in banking, insurance, mutual funds, financial planning, and credit cards, industry boundaries are beginning to blur.

Strategic alliances form when one enterprise alone can't fill the gap in serving the needs of the marketplace. Financial pressures and time constraints have squeezed managers without resources to fill the gaps through internal development. Also, acquisitions have proved expensive and have not always brought the needed capabilities.

An increasing number of global enterprises recognize that strategic alliances can provide growth at a fraction of the cost of going it alone. In addition to sharing risks and investment, a well-structured, well-managed approach to alliance formation can support other goals, such as quality and productivity improvement. Alliances provide a way for organizations to leverage resources. In the future, many organizations will be nothing more than "boxes of contracts," with substantially all of the traditional value/supply chain components outsourced to business partners in the form of alliances or other strategic relationships.

In addition to the more obvious reasons to focus on a company's "core competencies," the new economics of information will dramatically dismantle traditional business structures and processes. New business structures will reform based on the separate economics of information and physical products. Over the next few years, many relationships throughout the business world will change. The dismantling and reformulation of traditional business structures will include value chains, supply chains, and business models. This will result from the separation of the economics of information from the economics of physical products. In addition, the explosion of networks and content standards will allow informational value chains to separate from the physical chain. This will create enormous opportunities to use information innovatively and create new knowledge for competitive advantage. As value chains deconstruct to create new market opportunities, more and more alliances and new relationships will be formed to maximize opportunities and fill the gaps that will exist in traditional business processes.

8.3. Performance Management

While the promise of alliances is very bright, managing a myriad of different and sometimes very complex relationships will be a significant challenge for most enterprises. Improper guidelines, poor

communications between the enterprise and its partners (suppliers, customers, manufacturers, outsourcers, etc.), and unrealistic expectations can lay the groundwork for failure.

The significant shift from hierarchies to alliance networks will require a high level of competency in IT and relationship management. The enterprise and its partners must develop relationships at multiple levels throughout the organization to gain the trust and understanding required for long-term success. That includes making senior managers of the network well acquainted with one another.

Although multiple relationships are beneficial, consistent communication must take place between the partners at various levels within the respective organizations. Partners can receive confusing and conflicting direction from multiple sources within the enterprise. All parties must be connected to a database that tracks commitments and instructions made for their respective staffs.

To achieve success in these complex relationships, enterprises and their partners should speak a common business language. All parties will need to coordinate standards (such as software and network protocols) and business process elements (such as procurement, production, logistics, and customer service). In addition, all parties should participate in joint budgeting in order to understand the key cost drivers inherent in the network's infrastructure.

It is critical for the parties in the network to have access to detailed cost and performance information associated with each partner's respective services. Alliances typically are described by agreements that represent long-term relationships in which unforeseen opportunities, technologies, and business conditions will need to be addressed. The agreements should be flexible in order to accommodate changes in technologies and technology costs. Without careful planning and management, the network can get out of control, producing disastrous results.

The needs of all parties should be addressed in the contractual agreements. These contracts may be inexpensive to enter but extremely expensive to exit. Contracts should define intermediate consequences—generally penalties—for poor behavior and performance, with termination of the contract only as a last resort. Additional payments should be provided to reward superior performance that provides a measurable benefit.

Measurement becomes a major issue in managing alliance relationships. If performance cannot be measured effectively on a real-time basis, failure will likely occur. Service-level agreements must be defined in detail and allow for the addition of service levels that reflect changing business requirements and service levels. Partners should agree to measure and benchmark their cost structures against others on a regular basis for performance goal-setting and ongoing performance evaluation.

Effective day-to-day management of a complex network of relationships begins with planning. Management on both sides of an alliance must be committed to the communication and flexibility required for the relationship to shape and reshape itself as needs and opportunities arise. Well-designed management structures and processes enhance the probability of success for all parties.

9. ELEMENT 5: CORE PRODUCTS AND SERVICES

9.1. "Core Product and Service" Defined

The general goal of a product is to fill customers' specific needs. Core products are the product offerings that are most closely associated with the enterprise's brand image and generate the largest share of product revenue. The enterprise's core products and services are generally the basis for its marketplace strategy and value proposition.

9.2. Categories of Products and Services

A product family is a set of products based on a common platform. A platform includes design components that can be shared by products in the family. These shared design components allow for variations in product functions and features to meet different customer needs. As product strategies change and new technologies are introduced, new platforms are created. The automobile industry, for example, uses product platforms extensively to reduce costs and leverage technologies.

Derivative products are the products that are designed around a platform product. For example, Sony designed over 200 Walkman products, based on three platforms, to meet the specific needs of global markets. The economic proposition for derivative products is to reduce cost by reducing features (low-cost products), or to add features without changing the price significantly (line extensions), or to add features to increase the value to the customer (superior products).

9.3. Measuring Product Performance

Measurements of product performance should exist along four dimensions:

- *Market performance:* How does the marketplace view the company's products?
- *Process performance:* How well does the product development process work?
- *Resource performance:* How well do cross-functional teams perform?
- *Financial performance:* How profitable are the products/services?

Key Performance Indicator	Short-Term	Long-Term
Market Performance		
Customer Acceptance	X	X
Customer Satisfaction	X	X
Market Share		X
Unit Sales Growth		X
Brand Image		X
Process Performance		
Time-to-market	X	X
Quality Standards	X	X
Unique Benefits	X	X
Technology Enablers	X	X
Resource Performance		
Cross-functional Teaming	X	X
Performance Against Goals	X	X
Financial Performance		
Margin Goals		X
Profitability Goals		X
Return on Investment		X
New Product Sales/total Sales	X	X

Figure 16 Core Products/Services Measurement Framework. (From Risk Management Partners, Inc.)

The measurement framework in Figure 16 provides an example of the product dimensions that should be continuously monitored and improved.

10. ELEMENT 6: CUSTOMERS

10.1. "Customer" Defined

Customers are the reason that organizations exist—they are the most valuable assets. They are consumers or other businesses that utilize the enterprise's products and services. Large customers and/or groups of customers can exert significant influence over an organization. The business model is a framework for analyzing the contributions of individual activities in a business to the overall level of customer value that an enterprise produces, and ultimately to its financial performance.

10.2. Categories of Customers

An organization's customer base is made up of customers with many different attributes. They may be categorized along many different dimensions, depending on the purpose for which the segmentation is performed. Possible segmentation criteria include size, market, profitability, geographic location, customer preferences, influence or bargaining power, and intellectual capital. Segmentation gets the enterprise closer to the customer and allows the enterprise to understand customer needs in a very deep way. This closeness gives the enterprise access to information that is critical to strategy formulation and implementation. In addition, the enterprise and/or engineer can utilize customer segmentation techniques for various improvement initiatives.

10.3. Product and Services and Customer Linkages

Products and services and customers are inextricably linked. An enterprise's value proposition is expressed in the value—the products and services—it delivers to its customers. In the New Economy, these linkages will become more formalized as organizations innovate and produce new products *with* their customers. Customer capital will grow when the enterprise and its customers learn from each other. Collaborative innovation will be in everyone's best interest.

10.4. Relationship of Customers to Markets

Markets are made up of customers that have some common interests. Markets can be divided into finer and finer segments (customer groups), with each segment having its own issues. Market seg-

mentation allows an organization to pursue the acquisition of those customers that are most attractive to its value proposition. Segmenting markets also provides the basis for tailoring products more specifically to the customers' needs.

11. APPLYING THE BUSINESS MODEL

The engineer can apply the enterprise business model to his or her work in a number of ways, including:

- Communication of the nature of the business
- Strategic analysis
- Business process analysis
- Business performance measurement
- Risk assessment

In this section, we will discuss each of the above applications.

11.1. Communicating the Nature of the Business

Throughout the design and development of the business model, the engineer should review findings and conclusions with management. The review could take the form of overhead slides or other visual aids, discussions, or a written document. During a review with the enterprise's management, the engineer should confirm that his or her understanding of the business is accurate and complete and provide management with potential new perspectives that may assist in organizational improvement. Once adopted by management, the model can be used as the basis for communicating the nature and structure of the business to employees and other interested stakeholders.

11.2. Improving the Business

As discussed in prior sections, the business model should be designed and developed with an objective of improving the business. The improvement model shown earlier in Figure 2 includes five key business principles that will guide the engineer as he or she achieves that stated objective.

11.2.1. Strategic Analysis

The business model focuses the engineer's attention on whether managers have designed effective strategies for reshaping patterns of behavior. The strategic analysis is intended to provide the engineer with a deep understanding of the broad environment in which the enterprise operates, and it focuses on the organization's strategic orientation and potential for reorientation. Included therein are both the industry and global environs of the organization. Also included is the engineer's understanding of the enterprise's strategy for achieving a sustainable competitive advantage within the industry context. The business risks that threaten achievement of this strategy are consistently identified, along with the enterprise's responses to such risks.

As part of the strategic analysis, the engineer will obtain or update an understanding of the organization's history, management's business strategy and objectives, the business risks faced by the organization, management's planned responses to such business risks, and the business processes that management has implemented. The strategic analysis is also focused on the articulation between the business strategy and the supporting business processes, as well as the articulation between the identified business risks and management's responses or controls.

During strategic analysis, the engineer may first obtain general industry information, including that which is available from trade associations, periodicals, and the like. Then he or she will consider obtaining information about the structure of the industry, including its segmentation, the dynamics among the various organizations that comprise the industry, the critical business issues facing entities in the industry, and significant industry risks.

At the conclusion of the strategic analysis, the engineer will have learned the "directional course" the management has set in response to the environment, taking into consideration:

- The relationship between the broad economic environment and the industry segment(s) in which the enterprise competes
- The enterprise's position and role within its respective industry segment(s)
- Threats to maintaining or improving the current position
- The needs and wants of the enterprise's chosen market segment(s)
- The total productive capacity of the enterprise and its competitors for each niche

- Management's vision of how to satisfy the market needs better than its rivals
- Management's specific strategies and plans for achieving that vision

Also, the engineer will have obtained an understanding of how and to what extent management steers the business and attains a fit between its strategy and the range of environmental forces acting on it. This will have been done through review of:

- The enterprise's strategic management process
- The formalized strategic plan
- The enterprise's approach to ''environmental scanning'' to monitor emerging or changing external threats
- Management's methods for communicating strategies throughout the organization, as well as the clarity of such communications
- The methods and measures used to monitor entity-level performance in terms of the strategic goals

The strategic analysis will provide the engineer with in-depth knowledge of the enterprise's value proposition and insight into opportunities to improve business performance and mitigate the risks that threaten achievement of the established objectives.

11.2.2. Business Process Analysis

Business process analysis is designed to provide the engineer with an in-depth understanding of the key business processes identified earlier during strategic analysis. Through this analysis, the engineer learns how the organization creates value. Specifically, each core business process is studied in depth to discern significant process objectives, the business risks related to these objectives, the controls established to mitigate the risks, and the financial implications of the risks and controls. Likewise, each significant resource management process is examined with the same foci.

Business process analysis adopts a ''value chain'' approach to analyzing the interconnected activities in the business, both domestically and globally. It is consistent with W. Edward Deming's views of business processes and the role of total quality management in monitoring the value of these processes. Core business processes represent the main customer-facing activities of the business. It is the successful combination and execution of the core business processes that creates value in the eyes of customers and therefore results in profitable customer sales. During business process analysis, the engineer recognizes the cross-functional nature of activities in the enterprise's business, that not all activities within and across processes are sequential, and that important linkages exist between processes.

Figure 5, above, provides the context for a process analysis example. Specifically, it depicts the four core business processes of a hypothetical retail company: brand and image delivery, product/service delivery, customer service delivery, and customer sales. Consider the brand and image delivery core business process, which might include the following subprocesses: format development and site selection, brand management, advertising and promotion, visual merchandising, and proprietary credit. Figure 17 presents an example of a completed process analysis template for the format development and site selection subprocess. Such a process analysis template can be used by the engineer to analyze his or her enterprise's core business processes and significant resource management processes. The template is a framework that guides the engineer's collection and integration of information about business processes, using eight components: process objectives, inputs, activities, outputs, systems, risks that threaten objectives, and management controls linked to risks. Refer to Section 7.2 for descriptions of each of these components.

In the retail company, the engineer would address each of the following objectives, which are typical for this process:

1. Provide an environment in which the customer's needs can be met.
2. Deliver a cost-effective and viable shop solution.
3. Inject freshness and maintain a competitive edge.
4. Use the store as a vehicle for differentiation.
5. Open the store on time and stay on budget.
6. Take maximum advantage of available financial incentives.

From a value-chain perspective, and focusing first on process inputs, among the key considerations are historical performance, technology capability, competitor formats, customer profile, and cost constraints.

Continuing the value-chain perspective, the engineer will gather information about process activities such as:

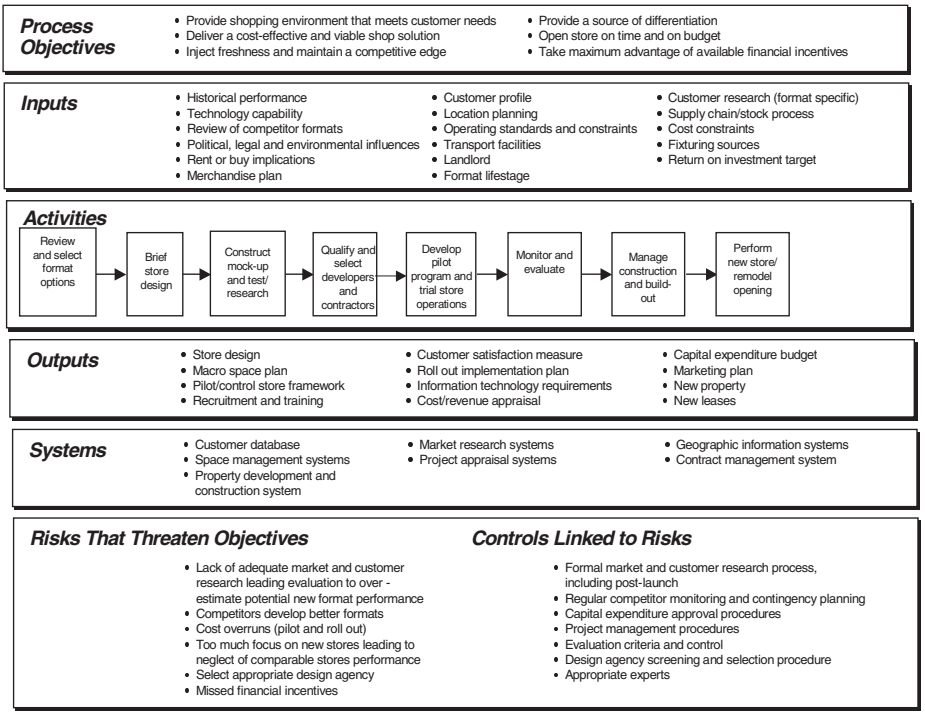

Figure 17 Format Development and Site Selection Subprocess—Retail Company. (Adapted from Bell et al. 1997)

1. Review and selection of format options
2. Store design
3. Store mock-up and research
4. Developer and contract selection

And the engineer will consider outputs like the following:

1. Store design
2. The macrospace plan
3. Recruitment and training
4. Customer satisfaction measures
5. The roll-out implementation plan

The engineer also will recognize that various systems are germane to the format development and site selection subprocess. These systems include the customer database, space management, property development and construction, market research, project appraisal, and contract management systems.

The engineer next considers the risks that threaten achievement of the process objectives and the controls that have been implemented to mitigate such risks. Continuing with the focus on the format development and site selection subprocess, such risks may include the possibility that competitors will develop better store formats, or an overemphasis on new stores relative to existing stores. Controls that could mitigate such risks are regular monitoring of competitors, in concert with contingency planning and usage of appropriate evaluation criteria.

A similar approach is taken by the engineer for the significant resource management processes, which were identified for the retail company in Figure 5 to be financial/treasury management, information management, human resource management, property management, and regulatory man-

agement. Figure 18 presents an example of a completed process analysis template for a retail company's human resource management process.

As shown in Figure 18, the following are among the process objectives of relevance: attract and retain a skilled and motivated workforce; control employee costs while maintaining morale and productivity; comply with regulatory/tax filing requirements; and adhere to the organization's code of conduct. Maintaining a value-chain perspective, the engineer next considers inputs to this process, including the organization's strategic plan, its operating plan, employee regulations, tax regulations, union contracts, industry statistics and market data, and training goals. Activities are then considered, such as developing and maintaining human resource policies and procedures; establishing and maintaining compensation and benefit policies and programs; identifying resource requirements; recruitment and hiring; training and development; performance reviews; compensation and benefit administration; monitoring of union contracts and grievances; and monitoring compliance with regulations.

The engineer then will consider outputs, such as regulatory filings, personnel files, tax filings, and performance reviews. Of course, various systems will be recognized as keys to successful human resource management, such as those related to compensation and benefits, tax compliance, and regulatory compliance.

Subsequently, the engineer considers risks related to the human resource management function, including high levels of staff turnover, noncompliance with regulations, and noncompetitive compensation packages. In turn, the engineer considers the controls that can mitigate the risks, such as implementing growth and opportunity plans for employees; regulatory monitoring; and benchmarking salary costs against industry and other norms.

At the conclusion of business process analysis, the engineer will have updated his/her understanding of (a) how the enterprise creates value, (b) whether the enterprise has effectively aligned the business process activities with the business strategy, (c) what the significant process risks are that threaten the achievement of the enterprise's business objectives, and (d) how effective the processes are at controlling the significant strategic and process risks. This detailed and updated knowledge about the business provides a basis for the engineer's development of recommendations about improvement opportunities and risk management.

11.2.3. Business Performance Measurement

Information-age enterprises succeed by investing in and managing their intellectual assets as well as integrating functional specialization into customer-based business processes. As organizations acquire these new capabilities, their measure of success should not depend solely on a traditional, historical

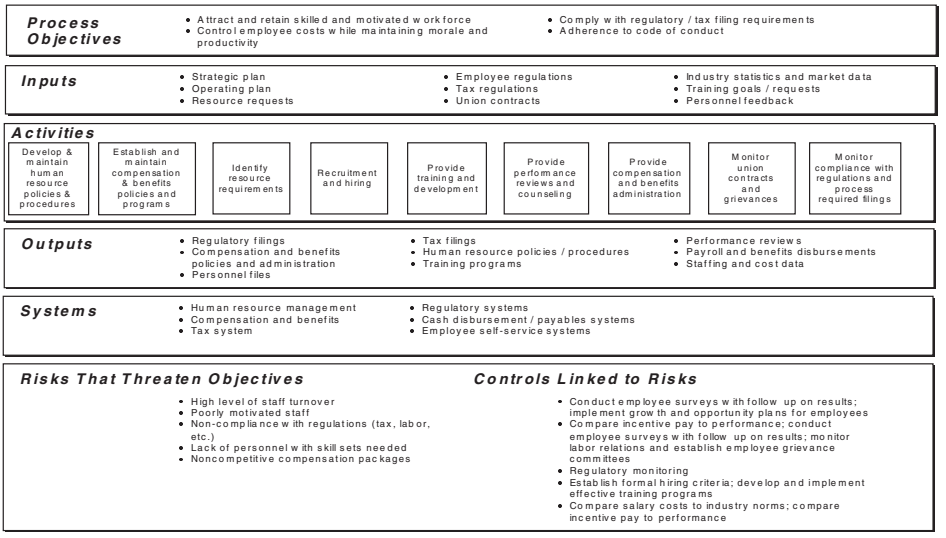

Figure 18 Example Human Resource Management Process—Retail Company. (Adapted from Bell et al. 1997)

financial accounting model. Rather, measurement and management in the information age requires enterprises to become much more competent at identifying and monitoring measures that drive their business performance.

To develop a credible business model, the engineer must gain an understanding of how the enterprise measures and monitors business performance. Financial performance measures are valuable for summarizing the readily measurable economic consequences of actions already taken; however, outcome measures without performance drivers do not communicate how the outcomes have been achieved.

Performance drivers are key indicators of an enterprise's future financial performance. Understanding the cause-and-effect relationships between resource, process, market, and financial performances is essential to understanding the enterprise's strengths and weaknesses.

Figure 19 shows the cause and effect relationships between financial and nonfinancial performance.

Figure 20 provides some illustrative examples of financial and nonfinancial measures for a large management consulting firm, using the measurement framework shown in Figure 19. The performance measures are designed to provide feedback regarding implementation of strategic initiatives.

The strategic analysis provides the engineer with a basis to judge the effectiveness of the enterprise's performance management system. The business measurement approach should include the perspectives mentioned in Figure 19. During the development of the business model, the engineer will be in a unique position to evaluate the cause-and-effect relationships of the major elements of the performance management system. The engineer will review measures of resource performance, process performance, market performance, and financial performance; he or she will determine the business processes and variables that appear to have the greatest impact on the organization. In addition, the engineer will analyze interrelated key performance measures, both financial and nonfinancial, over time and relative to similar organizations. These measurements and assessments are combined with the engineer's knowledge about the business opportunities/risks that are documented in the business model. The updated business model, as well as the mental or more formal simulations performed by the engineer to better understand the organization's strategic-systems dynamics, provide a knowledge-base for development of expectations about the entity's achieved level of overall performance.

During business measurement, the engineer also evaluates the performance of the entity taken as a whole and its key business processes, using key performance indicators (KPIs) and the collective knowledge contained in the business model. KPIs are quantitative measurements, both financial and nonfinancial, collected by an entity or by the engineer, either continuously or periodically, and used by management and the engineer to evaluate performance in terms of the entity's defined business

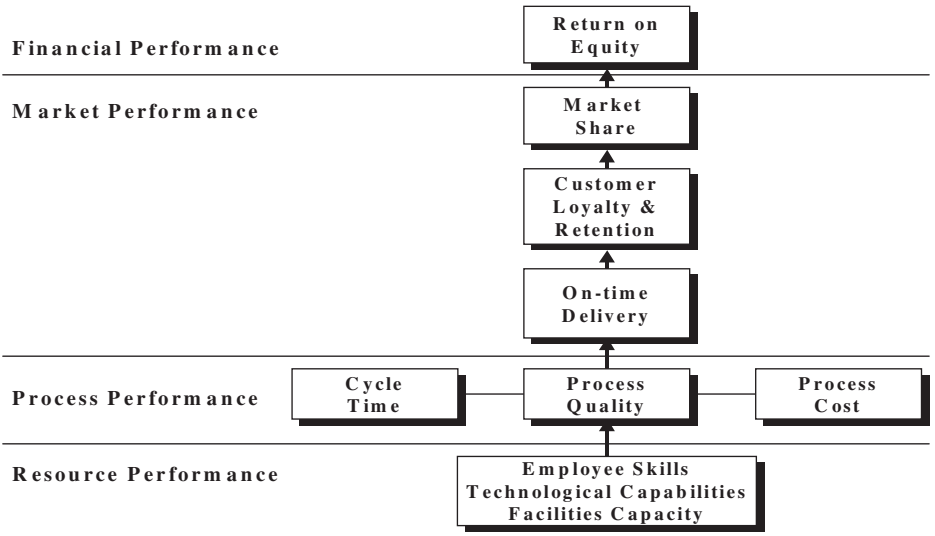

Figure 19 Financial and Nonfinancial Performance Relationships. (From Risk Management Partners, Inc.)

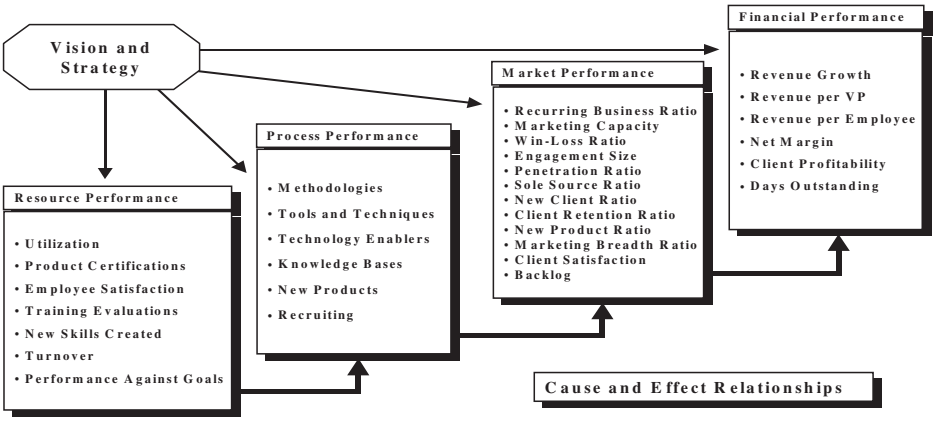

Figure 20 Sample Financial and Nonfinancial Measures—Consulting Firm. (From Risk Management Partners, Inc.)

objectives. KPIs at the process level typically focus on three dimensions of process performance: cycle time, process quality, and process cost. More specifically, management might monitor and control process performance using one or more of the following types of KPIs:

- Waste, rework, and other indicators of process inefficiency
- Backlog of work in process
- Customer response time
- Number of times work is recycled between subprocesses and departments
- Number of document errors
- Customer satisfaction ratings
- Number of routing errors
- Value-adding processing time
- Information processing errors

An integrated performance management system, with the appropriate KPIs, can provide evidence to the engineer that the organization is maintaining the level of process quality required to sustain product demand.

11.2.4. Risk Assessment

Risk assessment is a continuous process performed throughout the design and development of the business model. During strategic analysis and business process analysis, the engineer reviews the processes and procedures that the enterprise has established to identify and manage strategic and process risks.

During the engineer's review of the enterprise's risk management activities, he or she develops an understanding of management's perceptions of business risk, both strategic risks and business process risks, and considers the reasonableness of the assumptions that underlie management's assessments of the potential impacts of these risks. These underlying assumptions may be viewed as a combination of assumptions about the probability of occurrence and assumptions about the magnitude of impact. Also, the engineer uses other information obtained during the strategic and business process analyses to make judgments about coverage (i.e., whether management has considered all significant business risks). And he or she uses this information to make judgments about the extent to which strategic and process risks remain uncontrolled (i.e., to determine the level of residual risk).

Next, the engineer further integrates information about residual business risks by grouping risks based on the particular business model elements to which they relate. He or she will also consider possible interactions among these groups of risks and develop expectations about how they might be manifested in the performance of the business. This integrated knowledge, together with the appropriate business measurements, provides the engineer with a basis for performing a diagnosis of the

business. Furthermore, it guides tactical planning about the type and extent of additional information he or she should obtain in order to make recommendations for improving risk management activities.

By this point, the engineer will have developed a business risk profile of the organization. In the business risk profile, residual business risks are classified as either strategic or process risks. Also, interactions among risks are identified, and the risk classifications and identified interactions are cross-matched with related business performance attributes.

11.3. Continuous Improvement

At the conclusion of the business model design and development effort, the engineer will have constructed a fully integrated business model containing all of the information he or she has collected and integrated through the application of the five business principles shown earlier in Figure 2: strategic analysis, business process analysis, risk assessment, business measurement, and continuous improvement. The engineer will use the completed model as the basis for final review of the recommendations for improving business performance. But it must be remembered that the business model is a living document that must be updated and maintained on a continuous basis to reflect changing market conditions, new or improved value propositions, changes in organization structures, and the like. Continuous improvement applies just as much to the business model as it does to the business itself.

Acknowledgement

The enterprise business modeling concept described in this chapter was developed by KPMG LLP as an integral and fundamental part of its proprietary audit approach called the Business Measurement Process (BMP). The authors, both KPMG LLP retired partners, were involved in the development of the BMP: Frank Marrs led the entire development effort as National Managing Partner, Assurance Services; Barry Mundt was involved in the design of the business modeling concept and facilitated the development of generic enterprise business models for six industries. A large part of this chapter is based on a research monograph published by KPMG LLP, entitled *Auditing Organizations Through a Strategic-Systems Lens.*

APPENDIX
List of Generic Business Processes and Subprocesses

Strategic Management Processes

1.0 Understand Markets and Customers:

- **1.1** Determine customer needs and wants.
- **1.2** Monitor changes in market and customer expectations.

2.0 Develop Vision and Strategy:

- **2.1** Monitor the external environment.
- **2.2** Define value proposition and organizational strategy.
- **2.3** Design organizational structure/processes/relationships.
- **2.4** Develop and set organizational goals.

3.0 Manage Improvement and Change:

- **3.1** Measure organizational performance.
- **3.2** Conduct quality assessments.
- **3.3** Benchmark performance.
- **3.4** Improve processes and systems.

Core Business Processes

4.0 Design Products and Services:

- **4.1** Develop new product/service concepts and plans.
- **4.2** Design, build, and evaluate prototype products/services.
- **4.3** Refine existing products/services.
- **4.4** Test effectiveness of new/revised products or services.
- **4.5** Prepare for production.

5.0 Market and Sell Products/Services:

- **5.1** Market products/services to relevant customers.
- **5.2** Process customer orders.

6.0 Produce and Deliver Goods:

- **6.1** Plan for and acquire necessary resources.
- **6.2** Convert resources or inputs into products.
- **6.3** Deliver products.
- **6.4** Manage production and delivery process.

7.0 Produce and Deliver Services:

- **7.1** Plan for and acquire necessary resources.
- **7.2** Develop human resource skills.

7.3 Deliver service to the customer.
7.4 Ensure quality of service.

8.0 Invoice and Service Customers:
8.1 Bill the customer.
8.2 Provide after-sales service.
8.3 Respond to customer inquiries.

Resource Management Processes

9.0 Develop and Manage Human Resources:
9.1 Create and manage human resource strategies.
9.2 Perform work level analysis and planning.
9.3 Manage deployment of personnel.
9.4 Develop and train employees.
9.5 Manage employee performance, reward, and recognition.
9.6 Ensure employee well-being and satisfaction.
9.7 Ensure employee involvement.
9.8 Manage labor/management relationships.
9.9 Develop human resource information systems.

10.0 Manage Information Resources:
10.1 Plan for information resource management.
10.2 Develop and deploy enterprise support systems.
10.3 Implement systems security and controls.
10.4 Manage information storage and retrieval.
10.5 Manage facilities and network operations.
10.6 Manage information resources.
10.7 Facilitate information sharing and communication.
10.8 Evaluate and audit information quality.

11.0 Manage Financial and Physical Resources:
11.1 Manage financial resources.
11.2 Process finance and accounting transactions.
11.3 Report information.
11.4 Conduct internal audits.
11.5 Manage the tax function.
11.6 Manage physical resources.

12.0 Execute Environmental Management Program:
12.1 Formulate environmental management strategy.
12.2 Ensure compliance with regulations.
12.3 Train and educate employees.
12.4 Implement pollution-prevention program.
12.5 Manage remediation efforts.
12.6 Implement emergency response program.
12.7 Manage government agency and public relations.
12.8 Manage acquisition/divestiture environmental issues.
12.9 Develop/manage environmental information systems.

13.0 Manage External Relationships:
13.1 Establish communication networks and requirements.
13.2 Communicate with stakeholders.
13.3 Manage government relationships.

13.4 Build relationships with network participants.
13.5 Develop public relations program.
13.6 Interface with board of directors.
13.7 Develop community relations.
13.8 Manage legal and ethical issues.

1. INTRODUCTION

Spanning the series of revolutionary changes in computer technology and hardware has been an ongoing evolution of software and methodology. This evolution has been motivated by the intent of harnessing raw computing power as a means for increasing human productivity and enhancing organizations' competitiveness. The result is a vast array of computer systems in today's organizations. These systems are being used on a daily basis to assist managers and operating personnel in all kinds of work environments, ranging from manufacturing to service tasks. Two of the most important types of these computer systems are *information systems* and *decision support systems*. In this chapter we will focus on prominent software tools that can be used in building an information system (IS). Decision support systems are dealt with in Chapter 4.

Progress in the development of information systems has been greatly affected by ongoing advances in hardware, tools, and methods. Many information systems in use today would have been economically or technically infeasible a mere decade ago. Continuous decreases in hardware costs per unit of storage and processing power have increased the ubiquity and size of ISs, making them essential components of even modest-sized organizations. Software tools that greatly improve a developer's leverage in implementing information systems have led to ISs of greater sophistication, having more features and better interfaces. For example, software that makes it easy to store, manipulate, and update data (i.e., database management systems) and that allows development of programs in high-level languages (i.e., fourth-generation languages) provides tools that greatly affect the costs of developing information systems and the capabilities that these systems can provide.

In addition to improvements in tools available for IS development, advances have been made in methodologies for developing information systems. In some instances, automated tools support methodology. A structured development method, commonly referred to as the systems life cycle, is routinely used by professional IS developers when building information systems. In addition, various structured development techniques have been devised to support different phases of the systems life cycle. For example, techniques such as data flow diagrams, structure charts, and decision tables have had positive impacts on systems development. One class of software tools, commonly referred to as computer-aided software engineering tools, facilitates the use of these methods and techniques. This chapter examines both the tools that are used in the actual building of information systems (e.g., database management software) and tools that support methodologies for system development.

1.1. The Nature of Information Systems

The core function of an information system is record keeping. Record keeping is able to represent and process information about some domain of interest such as a job shop, an inventory, suppliers

of parts for a manufacturing operation, customer accounts, and so forth. Regardless of its application domain, an information system is able to store records describing one or more states of that domain (e.g., current state, historical states, and hypothetical states). The manner in which this descriptive knowledge is organized in a computer is a problem of information representation. The way in which information is represented strongly influences how it can be processed (e.g., updated, retrieved for presentation).

The principal value of an information system being able to represent and process large volumes of descriptive knowledge is that it can give engineers, managers, and operating personnel a way of recording, viewing, and monitoring states of an application domain. An information system provides its users with means for invoking any of a variety of standard reports. When an IS is designed, the developer must determine what reports will be allowed. Each type of report has a particular layout by which it presents information gleaned from the stored data. Thus, in implementing an IS, the developer must be concerned not only with record keeping issues, but with devising means for extracting information represented in the records and mapping it into corresponding report layouts.

Often the predefined reports are produced at predefined times. These may be periodic, as in the case of a weekly sales report or monthly expense report, or they may be event-triggered, as in the case of a stockout report or shipment report. In either case, the reports that an IS can produce may enable users to keep abreast of the current (or past) state of affairs pertaining to some aspect of an organization's operations. Such awareness is essential for a manager's ability to control those operations and can furnish a useful background for decision making. However, the ability of a traditional management information system to support decision making is quite limited because its reports are predefined, tend to be unavailable on the spur of the moment, and are based only on descriptive knowledge (Holsapple and Whinston, 1996).

Except in the most structured cases, the situation a decision maker faces can be very dynamic, with information needs arising unexpectedly and changing more rapidly than ISs can be economically revised to produce new kinds of reports. Even when the newly needed information exists in a set of predefined reports, it may be a needle in the haystack, distributed across several reports, or presented in a way not particularly helpful to the decision maker. It may be incomplete or unfocused or require some value-added processing. In contrast, the ideal of a decision support system (DSS) is to provide focused, complete, fully processed knowledge in the desired presentation format.

Periodic or event-triggered reports from an IS can be useful. However, in dynamic or unstructured decision situations, it is important for a decision maker to control the timing of reporting. With an IS, one must wait for the next periodic or triggered report. Beyond scheduled or event-triggered reporting, a DSS tends to allow desired knowledge to be easily and readily requested on an as-needed basis.

Keeping sufficiently up-to-date records of relevant descriptive knowledge is important as a prerequisite for IS report production. However, other kinds of knowledge enter into decision making, such as procedural knowledge and reasoning (Holsapple 1995). Procedural knowledge involves step-by-step specifications of how to do something. For instance, a solver is an algorithm that typically operates on existing descriptive knowledge to yield new descriptive knowledge in the guise of expectations, beliefs, facts, or model solutions. Reasoning knowledge is concerned with what conclusions are valid under some set of circumstances. For instance, a rule indicates what conclusion to draw when a premise is satisfied; a set of rules can be subjected to inference in order to produce diagnoses or recommendations. Traditional ISs have little concern with storing, updating, and manipulating such knowledge representations as solver libraries or rule sets. DSSs are not only concerned with them, but with how to integrate them as well.

Aside from being able to produce any standard report from a predefined portfolio of report types, an IS may be equipped with a query facility to provide greater flexibility in the kinds of reports that can be produced. After an IS has been implemented, it is not unusual for its users to want reports other than those in the predefined portfolio. The usefulness of these kinds of reports may have been overlooked in the original design of the system, or new reports may be needed because of changing conditions in a user's work environment. A query facility provides a nonprocedural way to state what should be in the desired report, allowing a user to specify what is desired without having to specify how to extract data from records in order to produce the report. An information system equipped with a query facility is a step in the direction of a decision support system. It gives the user a way to address some of the ad hoc knowledge needs that arise in the course of decision making.

1.2. Classes of Information Systems

Having characterized information systems and distinguished them from decision support systems, we can now look at classes of ISs. One approach to classification is based on functional application domains: ISs for finance applications, manufacturing applications, human resource applications, accounting applications, sales applications, and so forth. Another classification approach is to differentiate ISs in terms of the underlying technologies used to build them: file management, database

management, data warehouses, Visual Basic, C++, COBOL, HTML, XML, artificial intelligence, and so on. However, it is not uncommon for multiple technologies to be employed in a single IS.

Here, we classify ISs in terms of their intended scopes. Scope can be thought of in two complementary ways: the scope of the records that are kept by the IS and the scope of IS usage. The IS classes form a progression from those of a local scope, to ISs with a functional scope to enterprise-wide ISs to ISs that are transorganizational in scope. Some tools for building information systems are universal in that they can be used for any of these classes. Examples include common programming languages and database management tools. Others are more specialized, being oriented toward a particular class. Representative examples of both universal and specialized tools are presented in this chapter.

1.2.1. Local Information Systems

Local ISs are in wide use today. This is due to such factors as the tremendous rise in computer literacy over the past two decades, the economical availability of increasingly powerful computing devices (desktop and handheld), and the appearance of more convenient, inexpensive development tools. Local ISs are used in both small and large organizations. They are also prominent outside the organizational setting, ranging from electronic calendars and address books to personal finance systems to genealogy systems.

A local IS does record keeping and reporting that relate to a specific task performed by an individual. For instance, a salesperson may have an IS for tracking sales leads. The IS would keep records of the salesperson's current, past, and prospective customers, including contact information, customer characteristics (e.g., size, needs, tastes), history of prior interactions, and schedules of planned interactions. The IS would allow such records to be updated as needed. Reports produced by this IS might include reports showing who to contact at a customer location and how to contact them, a list of all customers having a particular characteristic (e.g., having a need that will be addressed by a new product offering), or a list of prospects in a given locale and a schedule showing who to contact today.

Operation of a local IS tends to be under its user's personal control. The user typically operates the IS directly, assuming responsibility for creating and updating its records and requesting the production of reports. The behavior of a local IS, in terms of what records it can keep and what reports it can produce, may also be under the user's control. This is the case when the IS software is custom-built to meet the particular user's requirements. The user either personally builds the IS software or has it built by a professional IS developer according to his or her specifications. At the opposite extreme, the user may have little control over the behavior of the local IS's software. This is the case when the user obtains off-the-shelf, packaged software that has been designed by a vendor to suit most of the needs of a large class of IS users.

Thus, the user of a local IS has a choice between creating or obtaining custom-built IS software and acquiring ready-made software. Customized construction has the advantage of being tailor-made to suit the user's needs exactly, but it tends to be time-consuming and expensive. Ready-made software is quickly available and relatively inexpensive, but the behavior of an off-the-shelf software package may not match the IS user's needs or desires. Such mismatches range from crippling omissions that render a package unworkable for a particular user to situations where the behavior is adequate in light of cost and time savings.

A middle ground between custom-made and ready-made software is package software that can be configured to behave in a certain way. In principle, this is packaged software that yields a variety of local ISs. The user selects the particular IS behavior that most closely suits his or her needs and, through an interactive process, configures the packaged software to exhibit this behavior. This approach may be somewhat more expensive and time-consuming than strictly ready-made packages, but it also permits some tailoring without the degree of effort required in the custom-made approach.

1.2.2. Functional Information Systems

A functional IS is one that performs record keeping and reporting related to some function of an organization such as production, finance, accounting, marketing, sales, purchasing, logistics, personnel, or research. Such systems include those that give reports on production status, inventory levels, financial positions, accounts (e.g., payable, receivable), sales levels, orders, shipments, fringe benefits, and so forth. These ISs are much broader in scope than local ISs and may be thought of as being more for departmental use than individual use. A functional IS tends to be larger and more complex in terms of records it possesses and processes. Often there are many individuals who use a given functional IS.

Functional ISs are typically administered by IS professionals rather than individual users. It would be even more unusual for an individual user to build his or her own functional IS, as the size and complexity of these systems usually calls for formal system development methodologies. The options for building a functional IS are using customized development, purchasing ready-made software, and

purchasing configurable software. Customized development can be performed by an organization's IS department or contracted out to an external developer. In either case, the developer works closely with prospective users of the system, as well as a functional sponsor (e.g., a department head), to ascertain exactly what the system needs to do. The customized development approach is the most flexible for building a system that closely fits users' needs and departmental requirements.

With ready-made software, building a functional IS becomes largely a matter of using the software to enter the system's initial records (and to update them over time). This software allows production of a predefined set of reports from the IS's records. The resultant functional IS can be constructed much more quickly than its custom-made counterpart, but the users will need to conform to the system rather than having a system specifically designed to conform to their needs.

Configurable software forms a middle ground, offering some options in the nature of records to be stored and processed for a given functional application, as well as various reporting options. After a developer sets up a configuration that sufficiently approximates the desired system's behavior, records are loaded into the system for subsequent updating and reporting.

As functional ISs proliferate within a department and across departments, issues of integration and consistency arise. For instance, information held in two functional ISs may be needed in a single report, which cannot be produced (even with an ad hoc query facility) from either IS on its own. Or two functional ISs may store some of the same kinds of records. If updates to these records in the two systems are not made simultaneously, the inconsistencies between their records can lead to inconsistencies between the reports produced by the two systems. One way to try to address integration and consistency issues is to devise additional systems that recognize interrelationships between functional ISs and serve to link them for update or reporting purposes. A second way is to build information systems at an enterprise scale, encompassing multiple functionality in a single IS.

1.2.3. Enterprise Information Systems

Enterprise ISs cross traditional functional boundaries. They keep records pertinent to multiple organizational functions, maintaining them in a consistent fashion and producing both functional and cross-functional reports. The magnitude and complexity of enterprise ISs far exceed those of functional ISs. The creation and operation of enterprise ISs are strictly in the domain of IS professionals. The earliest examples of these systems were custom-made via very large-scale projects. At the time, no off-the-shelf software solutions were available on an enterprise-wide scale. However, over the past decade several vendors have successfully offered configurable off-the-shelf software that functions as a tool for building enterprise ISs. These are known by such names as enterprise resource planning (ERP) and enterprise asset management (EAM) software. For simplicity, the former term is used here.

In some cases, ERP offerings are industry-specific. For instance, one might be oriented toward record keeping and reporting needs of the oil industry, another toward the automotive industry, and yet another toward retailers. ERP offerings also tend to be functionally modular. For instance, an organization may decide to start with implementations of accounting, finance, and production functions. Later, an integral human resources module may be added. In any case, building an enterprise IS with ERP tools is a matter of configuring the record storage mechanisms and configuring the behavior of ERP software to try to fit specific enterprises. This is by no means a trivial task and often causes a redesign of the organization to fit the IS.

The main attraction of an enterprise IS is the potential for consistency of information and integration of information usage. As an example, when a salesperson enters an order, the records describing it are immediately available to others in the enterprise. The factory receives a report of it and starts production. The logistics function receives reports on production progress, allowing it to schedule shipments. Inventory and procurement receive reports of production, leading to replenishment of raw materials and parts. Accounting receives reports on orders, production, and shipments; accounts records are updated accordingly. The enterprise's senior management receives reports allowing it to monitor sales activity, production progress, and inventory levels.

1.2.4. Transorganizational Information Systems

Transorganizational ISs are those that involve information flows to and from entities beyond an enterprise's boundaries. Information for updating records comes directly from customers, suppliers, partners, regulators, and others. Reports are issued directly to these same entities. All of this transorganizational activity is either linked to various internal ISs (local, functional, or enterprise) or designed as an extension of enterprise ISs. Especially notable examples are so-called supply chain management systems and customer relationship management systems. Configurable off-the-shelf software for building each of these is available, in some cases allowing them to be treated as additional ERP modules.

More broadly, transorganizational ISs form a major element of most organizations' electronic commerce initiatives. The Internet and the World Wide Web have been tremendous facilitators of

transorganizational ISs, which take two main forms: those that involve accepting and reporting information from and to other businesses (B2B electronic commerce) and those that involve accepting and reporting information from and to consumers (B2C electronic commerce). As companions to transorganizational ISs, many examples of Web-oriented decision support systems exist (Holsapple et al. 2000).

1.3. Overview of Information System Development and Tools

Given an application domain and a class of potential users, we are confronted with the problem of how to create a useful information system. The act of creation spans such activities as analysis, design, and implementation. System analysis is concerned with determining what the potential users want the system to do. System design involves transforming analysis results into a plan for achieving those results. Implementation consists of carrying out the plan, transforming the design into a working information system.

IS implementation may involve software tools such as programming-language compilers and database management software. Or it may involve configuring off-the-shelf software packages. The activity of design can be strongly influenced by what tools are to be used for implementation. Both the analysis and design activities can themselves be supported by tools such as data flow diagrams, data dictionaries, HIPO (hierarchical input, process, output) charts, structure charts, and tools for computer-assisted software engineering (CASE).

In the early days of IS development, the principal software tool used by developers was a programming language with its attendant compiler or interpreter. This tool, together with text-editing software, was used to specify all aspects of an information system's behavior in terms of programs. When executed, these programs governed the overall flow of the information system's actions. They accomplished information storage and processing tasks. They also accomplished user interaction tasks, including the interpretation of user requests and production of reports for users. Section 2 provides an overview of programming, accompanied by highlights of two languages widely used for IS implementation: Visual Basic and C++.

Although programming is a valuable way for developers to specify the flow of control (i.e., what should happen and when) in an information system's behavior, its use for specifying the system's data representation and processing behaviors has steadily diminished in concert with the proliferation of database management tools. Today, database management systems are a cornerstone of information system development. Most popular among the various approaches to database management is the relational, which is described in Section 3. In addition to packaging these as separate tools from conventional (so-called third-generation) languages such as COBOL, C, and FORTRAN, various efforts have been made to integrate database management and programming facilities into single facility. The resultant tools are examples of fourth-generation languages.

Programming and database management tools can be used in implementing ISs in any of the four classes discussed in Section 2. There is great variation in off-the-shelf packages available for IS implementation both within and across the IS classes. Section 2.5 considers prominent Web-based tools used for implementing transorganizational information systems. Section 3 provides a brief overview of database management, which forms the foundation for most information systems today. Section 4 focuses on tools for the class of enterprise ISs. Finally, Section 5 considers ancillary tools that can be valuable in the activity of developing information systems. These are examined in the context of the system development life cycle of analysis, design, implementation, and maintenance. We will focus on tools often used by IS professionals during the analysis and design phases.

2. PROGRAMMING LANGUAGES

2.1. Overview

This section describes how programming languages may be used to build information systems. First, a brief historical review of programming languages helps explain how programming tools have become more powerful and easier to use over the years. We characterize today's modern programming languages, such as C++ and Visual Basic, by considering the advantages and disadvantages of each. Then we review some basic programming concepts by showing some typical examples from these languages. Finally, we consider how program development is affected when the World Wide Web is targeted as a platform. This includes a comparison of Internet programming tools, such as HTML, Java, and CGI scripting.

2.2. Historical Review

In the earliest days of program development, programmers worked directly with the computer's own machine language, using a sequence of binary digits. This process was tedious and error-prone, so programmers quickly started to develop tools to assist in making programming easier for the humans involved. The first innovation allowed programmers to use mnemonic codes instead of actual binary

digits. These codes, such as *LOAD, ADD,* and *STORE,* correspond directly to operations in the computer's instruction set but are much easier to remember and use than the sequence of binary digits that the machines required. A programming tool, called an *assembler,* translates mnemonics into machine codes for the computer to execute. This extremely low-level approach to programming is hence referred to as *assembly language* programming. It forces the programmer to think in very small steps because the operations supported by most computers (called *instruction sets*) are very simple tasks, such as reading from a memory location or adding two numbers. A greater problem with this approach is that each computer architecture has its own assembly language, due to differences in each CPU's instruction set. This meant that early programmers had to recreate entire information systems from scratch each time they needed to move a program from one computer to another that had a different architecture.

The next major innovation in computer programming was the introduction of *high-level languages* in the late 1950s. These languages, such as COBOL and FORTRAN, allow a programmer to think in terms of larger, more complex steps than the computer's instructions set allows. In addition, these languages were designed to be portable from machine to machine without regard to the underlying computer architecture. A tool called a *compiler* translates the high-level statements into machine instructions for the computer to execute. The compiler's job is more complex than an assembler's simple task of one-to-one translation. As a result, the machine code that is generated is often less efficient than that produced by a well-trained assembly programmer. For this reason, programming in assembly language is still done today when execution time is absolutely critical. The cost of developing and maintaining high-level code is significantly reduced, however. This is especially important given another trend in computing, towards cheaper and more powerful hardware and more expensive and harder-to-find programmers.

As high-level languages became more prevalent, programmers changed to a new development paradigm, called *structured programming*. This approach, embodied in languages such as Pascal and C from the 1970s and 1980s, emphasizes functional decomposition, that is, breaking large programming tasks into smaller and more manageable blocks, called functions. Data used within a function block is local to that function and may not generally be seen or modified by other blocks of code. This style of programming is better suited to the development of large-scale information systems because different functions can be assigned to different members of a large development team. Each function can be thought of as a black box whose behavior can be described without revealing how the work is actually being done but rather in terms of input and output. This principle of *information hiding* is fundamental to the structured programming approach. Another advantage is *code reuse,* achieved by using the more general-purpose functions developed for one project over again in other systems.

As the information systems being developed became more complex, development with structured programming languages became increasingly difficult. A new paradigm was required to overcome the problem, and it arrived in the late 1980s in the form of *object-oriented programming* (OOP). This continues to play an important role today. In structured programming, functions are the dominant element and data are passed around from one function to another, with each function having a dependency on the structure of the data. If the way the data are represented changes, each function that manipulates the data must, in turn, be modified. In OOP, data are elevated to the same level of importance as the functions. The first principle of object-oriented programming is called *encapsulation*. It involves joining data together with the functions that manipulate that data into an inseparable unit, usually referred to as a *class*. A class is a blueprint for actual *objects* that exist in a program. For example, the class *Clock* would describe how all clocks (objects or instances of the class) in a program will behave. It does not create any clocks; it just describes what one would be like if you built one, much as an architect's blueprint describes what a building would look like if you built one.

The importance of encapsulation is seen when one considers the well-known Year 2000 problem encountered in many programs written with structured languages, such as COBOL. In many of these information systems, literally thousands of functions passed dates around as data, with only two digits reserved for storing the year. When the structure of the data had to be changed to use four digits for the year, each of these functions had to be changed as well. Of course, each function had to be identified as having a dependency on the date. In an OOP language, a single class would exist where the structure of the data representing a date is stored along with the only functions that may manipulate that data directly. Encapsulation, then, makes it easier to isolate the changes required when the structure of data must be modified. It strengthens information hiding by making it difficult to create a data dependency within a function outside a class.

OOP also makes code reuse easier than structured programming allows. In a structured environment, if you need to perform a task that is similar but not identical to an existing function, you must create a new function from scratch. You might copy the code from the original function and use it as a foundation, but the functions will generally be independent. This approach is error-prone and makes long-term program maintenance difficult. In OOP, one may use a principle called *inheritance*

to simplify this process. With this approach, an existing class, called the *base class* or *superclass,* is used to create a new class, called the *derived class* or *subclass*. This new derived class is like its parent base class in all respects except what the programmer chooses to make different. Only the differences are programmed in the new class. Those aspects that remain the same need not be developed from scratch or even through copying and pasting the parent's code. This saves time and reduces errors.

The first OOP languages, such as SmallTalk and Eiffel, were rarely used in real world projects, however, and were relegated to university research settings. As is often the case with easing system development and maintenance, program execution speed suffered. With the advent of C++, an OOP hybrid language, however, performance improved dramatically and OOP took off. Soon thereafter, new development tools appeared that simplified development further. *Rapid Application Development* (RAD) tools speed development further by incorporating a more visual development environment for creating graphical user interface (GUI) programs. These tools rely on wizards and code generators to create frameworks based on a programmer's screen layout, which may be easily modified. Examples include Borland's Delphi (a visual OOP language based on Pascal), Borland's C++ Builder (a visual C++ language), and Microsoft's Visual Basic.

2.3. C++

The C++ language was originally developed by Bjarne Stroustrup (Stroustrup 1994) but is now controlled and standardized by the American National Standards Institute (ANSI). It is an extension (literally, an increment) of the C programming language. C is well known for the speed of its compiled executable code, and Stroustrup strove to make C++ into a similarly efficient object-oriented language (see Stroustrup 1994 for a description of the development of the language). Technically, C++ is a hybrid language in that it supports both structured (from C) and object-oriented development. In order to achieve the speed that earlier OOP languages could not, C++ makes some sacrifices to the purity of the OO model. The tradeoffs required, however, helped make OOP popular with real-world developers and sparked a revolution in modern program development.

Like C before it, C++ is a language with a rich abundance of operators and a large standard library of code for a programmer's use. In its current form, C++ includes the Standard Template Library, which offers most of the important data structures and algorithms required for program development, including stacks, queues, vectors, lists, sets, sorts, and searches (Stroustrup 1997). Programs written using C++'s standard components are easily ported from one platform to another. The language lacks, however, a standard library of graphics routines for creating a graphical user interface program under different operating systems. Instead, each compiler vendor tends to offer its own classes and functions for interacting with a specific operating system's windowing routines. For example, Microsoft offers the Microsoft Foundation Classes (MFC) for developing Windows applications with its compiler, while Borland offers its Object Windows Library (OWL) for the same purpose. This makes it difficult to port GUI programs from one vendor's compiler on one operating system to another vendor's compiler on another operating system.

A simple example (Main and Savitch 1997) is shown below that declares a basic *Clock* class. It is an abstraction of a real-world clock used for telling time.

```
class Clock {
 public:
  Clock();
  void set_time(int hour, int minute, bool morning);
  void advance(int minutes);
  int get_hour() const;
  int get_minute() const;
  bool is_morning() const;
 private:
  int hour_24, // Stores the current hour
  minute_24; // Stores the current minute
};
```

This class is typical of the structure of most classes in C++. It is divided into two sections, *public* and *private*. In keeping with information hiding, the data are normally kept private so that others outside of the class may not examine or modify the values stored. The private data are exclusively manipulated by the class functions, normally referred to as *methods* in OOP. The functions are declared in the public section of the class, so that others may use them. For example, one could ask a clock object its minute by using its *get_minute*() function. This might be written as in the following code fragment:

```
Clock c; // Creates an actual object, c
cout << ``The minute is `` << c.get_minute() ;<< endl;
```

Of course, this simple class provides a method for modifying the time stored. The public method *set_time*() is used for this purpose. By forcing the use of this method, the class designer can ensure that the data are manipulated in accordance with appropriate rules. For example, the *set_time*() method would not allow the storage of an illegal time value. This could not be guaranteed if the data were public and directly available for modification. The implementation of this method is shown below:

```
void Clock::set_time(int hour, int minute, bool morning) {
 assert((hour >= 1) && (hour <= 12));
 assert((minute >= 0) && (minute <= 59));
 minute_24 = minute;
 if ((morning)&&(hour == 12))
  hour_24 = 0;
 else if ((!morning) && (hour < 12))
  hour_24 = hour + 12;
 else
  hour_24 = hour;}
```

Note how the values passed to the method are tested via an *assert*() statement before they are used. Only if the assertion proves true are the values used; otherwise a runtime error message is produced.

To show an example of inheritance, consider extending the *Clock* class to create a new class, *CuckooClock*. The only difference is that this type of clock has a bird that chirps on the hour. In all other respects it is identical to a regular clock.

```
class CuckooClock : public Clock {
 public:
  bool is_cuckooing( ) const;
};

bool CuckooClock::is_cuckooing( ) const {
 return (get_minute( ) == 0);}
```

Note, we declare the new *CuckooClock* class in terms of the existing *Clock* class. The only methods we need to describe and implement are those that are new to or different from the base class. Here there is only one new function, called *is_cuckooing*(), which returns true on the hour. It is important to understand that *CuckooClock* is a *Clock*. In important respects, an instance of *CuckooClock* can do anything that a *Clock* object can do. In fact, the compiler will allow us to send a *CuckooClock* object anywhere a *Clock* object is expected. For example, we might have a function written to compare two *Clock* objects to see if one is "equal to" the other.

```
bool operator ==(const Clock& c1, const Clock& c2) {
 return ((c1.get_hour() == c2.get_hour()) &&
 (c1.get_minute() == c2.get_minute()) &&
 (c1.is_morning() == c2.is_morning())); }
```

We may confidently send a *CuckooClock* to this function even though it is written explicitly to expect *Clock* objects. Because of inheritance, we do not need to write a different version of the function for each class derived from *Clock*—*CuckooClock* is a *Clock.* This simplifies things considerably for the programmer. Another interesting note about this code segment is that C++ allows us to provide definitions for most of its built-in operators in the context of a class. This is referred to as *operator overloading,* and C++ is rare among programming languages in allowing this kind of access to operators. Here we define a meaning for the equality operator (==) for *Clock* objects.

In summary, C++ is a powerful and rich object-oriented programming language. Although widely recognized as difficult to work with, it offers efficient execution times to programmers that can master its ways. If you want portable code, you must stick to creating console applications. If this is not a concern, modern compilers assist in creating GUI applications through wizards, such as in Microsoft's Visual C++. This is still more difficult to accomplish using C++ than a RAD tool such as Visual Basic, which will be discussed next.

2.4. Visual Basic

Visual Basic (VB) is a programming language and development tool from Microsoft designed primarily for rapidly creating graphical user interface applications for Microsoft's Windows operating

system. First introduced in 1991, the language is an extension of BASIC, the Beginners' All-Purpose Symbolic Instruction Code (Eliason and Malarkey, 1999). BASIC has been in use since John Kemeny and Thomas Kurta introduced it in 1965 (Brookshear 1999). Over the years, Visual Basic has evolved more and more towards an object-oriented programming model. In its current version, 6.0, VB provides programmers with the ability to create their own classes using encapsulation, but it does not yet support inheritance. It simplifies the creation of Windows applications by making the enormously complex Windows Application Program Interface (consisting of over 800 functions) available through easy-to-use objects such as forms, labels, command buttons, and menus (Eliason and Malarkey 1999).

As its name suggests, Visual Basic is a highly *visual* tool. This implies not only that the development environment is GUI-based but also that the tool allows you to design a program's user interface by placing components directly onto windows and forms. This significantly reduces development time. Figure 1 provides a snapshot of the Visual Basic development environment.

Another feature that makes Visual Basic into a Rapid Application Development tool is that it supports both interpreted and compiled execution. When VB is used in *interpreted* mode, the tool allows the programmer to quickly see the effects of their code changes without a lengthy compilation directly to machine code. Of course, run-time performance is better when the code is actually compiled, and this can be done before distributing the application.

In Visual Basic, objects encapsulate properties, methods, and events. *Properties* are an object's data, such as a label's caption or a form's background color. *Methods* are an object's functions, as in C++ and other OOP languages. *Events* are typically user-initiated actions, such as clicking a form's button with the mouse or making a selection from a menu, that require a response from the object. Figure 1 shows some of the properties of the highlighted command button object, *Command1*. Here the button's text is set to ''Press Me'' via the *Caption* property. In the code window for the form, the *Click* event's code is displayed for this command button. This is where you would add the code to respond when the user clicks on the form's button. The tool only provides the outline for the code, as seen here. The programmer must add actual VB statements to perform the required action. Visual Basic does provide many wizards, however, to assist in creating different kinds of applications, including forms that are connected back to a database. These wizards can significantly reduce development time and improve reliability.

The fundamental objects that are important to understand in Visual Basic development are *forms* and *controls*. A form serves as a container for controls. It is the ''canvas'' upon which the programmer

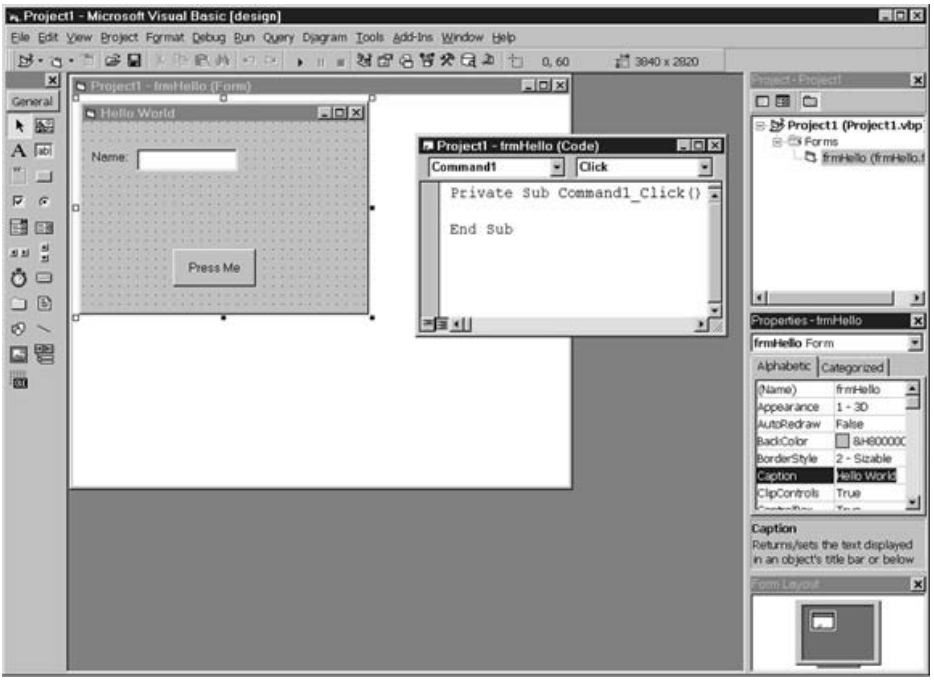

Figure 1 The Visual Basic Development Environment.

"paints" the application's user interface. This is accomplished by placing controls onto the form. *Controls* are primarily GUI components such as command buttons, labels, text boxes, and images. In Figure 1, the standard toolbox of controls is docked on the far left of the screen. These controls are what the user interacts with when using the application. Each control has appropriate properties and events associated with it that affect its appearance and behavior. For example, consider the form shown in Figure 2.

This form shows the ease with which you can create a database-driven application. There are three controls on this form. At the bottom of the form is a *data* control. Its properties allow the programmer to specify a database and table to connect to. In this example, it is attached to a simple customer database. At the top are two *textbox* controls, used for displaying and editing textual information. In this case, these controls are *bound* to the data control, indicating that their text will be coming from the associated database table. The data control allows the user to step through each record in the table by using the left and right arrows. Each time the user advances to another record from the table, the bound controls update the user's text to display that customer's name and address. In the code fragment below, you can see some of the important properties of these controls.

```
Begin VB.Data Data1
 Caption = ''Customer''
 Connect = ''Access''
 DatabaseName = ''C:\VB Example\custdata''
 DefaultCursorType= 0 'DefaultCursor
 DefaultType = 2 'UseODBC
 Exclusive = 0 'False
 ReadOnly = 0 'False
 RecordsetType = 1 'Dynaset
 RecordSource = ''Customer''
End

Begin VB.TextBox Text1
 DataField = ''customer name''
 DataSource = ''Data1''
End

Begin VB.TextBox Text2
 DataField = ''street address''
 DataSource = ''Data1''
End
```

In the data control object, *Data1,* there are several properties to consider. The *Connect* property specifies the type of database being attached, here an Access database. The *DatabaseName* property specifies the name and location of the database. *RecordSource* specifies the table or stored query that will be used by the data control. In this example, we are connecting to the *Customer* table of the example database. For the bound text controls, the programmer need only specify the name of the data control and the field to be used for the text to be displayed. The properties that need to be set for this are *DataSource* and *DataField,* respectively.

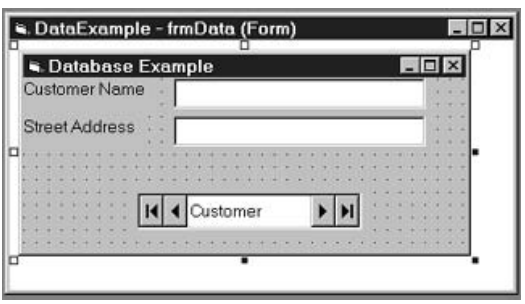

Figure 2 Database Example.

As these examples demonstrate, Visual Basic makes it relatively easy to create complex GUI applications that run exclusively under the Windows operating system. When these programs are compiled into machine code, the performance of these applications is quite acceptable, although not yet as fast as typical C++ programs. The object-oriented model makes development easier, especially since most of the properties can be set visually, with the tool itself writing the necessary code. Unfortunately, VB still does not support inheritance, which limits a programmer's ability to reuse code. Recent additions in the language, however, make it easier to target the Internet as an application platform. By using *Active X controls,* which run under Windows and within Microsoft's Internet Explorer (IE) web browser, and *VBScript* (a subset of VB that runs in IE), you can create applications that may be ported to the World Wide Web. Your choice of controls is somewhat limited and the user must have Microsoft's own web browser, but in a corporate Intranet environment (where the use of IE can be ensured) this might be feasible. For other situations a more flexible solution is required. The next section will explore some of the tools for achieving this.

2.5. Web-Based Programming

Developing applications where the user interface appears in a web browser is an important new skill for programmers. The tools that enable a programmer to accomplish this type of development include HTML, Java, CGI, Perl, ColdFusion, ASP, etc.—a veritable cornucopia of new acronyms. This section explains these terms and shows how these new tools may be used to create web pages that behave more like traditional software applications.

2.5.1. HTML

The HyperText Markup Language (HTML) is *the* current language of the World Wide Web. HTML is a markup language, not a programming language. Very simply, a document is ''marked up'' to define its appearance. This involves placing markup tags (or commands) around text and pictures, sound, and video in a document. The general syntax for HTML tags is:

```
<Tagname [options]>your text here</tagname>
```

These tags indicate how to display portions of the document. Opening tags, along with available options, are enclosed in < and > and closing tags include the / before the tagname. In some instances both opening and closing tags are required to indicate what parts of the documents the tags should affect. In other instances no closing tag is required. The contents of the file (including HTML tags and web page contents) that generates the simple web page shown in Figure 3 are as follows:

```
<html>
<head>
<title>Tools for Building Information Systems</title>
</head>
<body>
<center><h1>Tools for Building Information Systems</h1>
by<p>
Robert L. Barker<br>Brian L. Dos Santos<br>Clyde H.
```

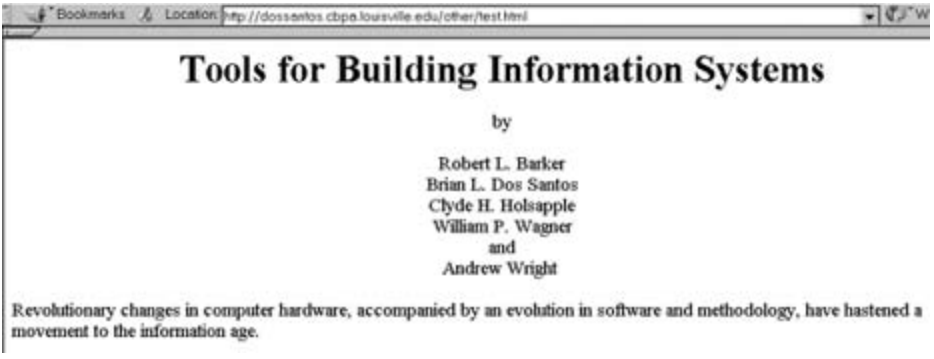

Figure 3 Web Page and HTML Tags.

```
Holsapple<br>William P. Wagner<bR>and<br>Andrew Wright
</center><p>
Revolutionary changes in computer hardware, accompanied by
an evolution in software and methodology, have hastened a
movement to the information age.
</body>
</html>
```

HTML documents may then be processed and displayed using a browser that runs on any number of computer platforms, from UNIX workstations down to cellular telephones. These documents are simple text files that can be created with WYSIWYG tools (such as Microsoft's FrontPage or Netscape's Composer) or even a simple text editor such as the Windows Notepad. HTML relies on *tags,* keywords enclosed in angle brackets, like `<h1>`, `<b>`, `<li>`, etc., to specify what type of content or formatting is intended. HTML standards are controlled by an organization called the World Wide Web Consortium (W3C), and their website (http://www.w3.org/) has the most accurate and up-to-date information about HTML.

The latest version of HTML is 4.0 (http://www.w3.org/MarkUp/), and several of today's browsers support most of its features. In addition, the leading producers of web browsers, Microsoft and Netscape, frequently include support for proprietary features not specified in the W3C's version of HTML. These extensions can make it difficult to create extremely complicated documents that will work on both browsers. This is especially true for *dynamic* HTML documents, or documents whose contents change even after the page is loaded into a browser (Castro, 1999). HTML 4.0 includes support for Cascading Style Sheets (http://www.w3.org/Style/), which gives page designers easier control of large and complicated websites. HTML is essentially a system for formatting documents. It includes both structuring and formatting tags, which makes it difficult to maintain complex websites. The introduction of cascading style sheets allows a designer to separate structuring and formatting tags. Formatting tags are maintained in cascading style sheets so that HTML is used only for structuring documents. Style sheets are very powerful but not as easy to use as basic HTML. The future, however, lies in Extensible Markup Language (XML) (http://www.w3.org/XML/). XML is designed to allow groups to create their own markup languages, like HTML, specifically suited to their needs (Castro, 1999). It is especially important for its ability to put structured data into a text format. This might make it easy to view and edit a spreadsheet or database via the Web, for example. In fact, the W3C is rewriting HTML (as XHTML) and its Cascading Style Sheets (as XSL) using XML (see http://www.w3.org/TR/xhtml1/ and http://www.w3.org/Style/XSL/).

HTML, by itself, does not provide the capabilities required for electronic commerce. For e-commerce, it is necessary to develop applications that are interactive in nature, permitting visitors to dynamically obtain information they need (e.g., search a product catalog) or complete some task (e.g., submit an order). Such capabilities typically require that user-provided data be processed in real time and require interaction with databases. This type of processing may be accomplished via programming languages such as Perl, Visual Basic, and C++. Recently, several tools have emerged that reduce the need for traditional programming while essentially achieving the same results (e.g., ColdFusion and Tango). These capabilities are often achieved via the Common Gateway Interface (CGI).

2.5.2. CGI

To create truly powerful websites, a programmer must be able to access current data, typically from a corporate database. For example, commerce sites need to be able to tell a user whether a product is in stock and record how many items a customer would like to purchase. This cannot be done with static HTML files. Instead, processing is required on the server-side before the contents of a web page are delivered to a user's web browser. One widely used approach is the Common Gateway Interface (CGI). CGI specifies a common method for allowing Web pages to communicate with programs running on a Web server.

A typical CGI transaction begins when a user submits a form that he or she has filled out on a web page. The user may be searching for a book by a certain author at an online bookstore and have just entered the author's name on a search page. The HTML used for displaying the form also specifies where to send the data when the user clicks on the submit button. In this case, the data is sent to a CGI program for processing. Now the bookstore's CGI program searches its database of authors and creates a list of books. In order to return this information to the user, the CGI program must create a response in HTML. Once the HTML is generated, control may once again be returned to the web server to deliver the dynamically created web page. CGI programs may be written in nearly any programming language supported by the operating system but are often written in specialized scripting languages like Perl.

CGI provides a flexible, but inefficient mechanism for creating dynamic responses to Web queries. The major problem is that the web server must start a new program for each request, and that incurs significant overhead processing costs. Several more efficient alternatives are available, such as writing programs directly to the Web server's application program interface. These server APIs, such as Microsoft's ISAPI and Netscape's NSAPI, allow more efficient transactions by reducing overhead through the use of dynamic link libraries, integrated databases, and so on. Writing programs with the server APIs is not always an easy task, however. Other alternatives include using products like Allaire's ColdFusion or Microsoft's Active Server Pages (ASP).

2.5.3. Java

Java is a programming language from Sun Microsystems that is similar to C/C++ in syntax and may be used for general-purpose applications and, more significantly, for embedding programs in web pages (Hall 1998). Although Java is an extremely young language, it has gained widespread acceptance because of its powerful and easy-to-use features. It is not yet a mature product, however, and experiences some stability problems as the language continues to evolve.

Java has a lot in common with C++, so much so that it is often referred to as "C++ Lite" by experienced programmers. It is an object-oriented programming language that was built from the ground up, unlike the hybrid C++. It is designed to be a cross-platform development tool; in other words, the code is easy to port from one computer architecture and operating system to another. It does a better job of this than C++ does by including a standard set of classes for creating graphical user interfaces. This allows a GUI application designed on a Macintosh to be run under Windows or Linux, for example. Extremely complex interfaces may still require tweaking to achieve complete interchangeability of the interface, but new additions to the language (the Swing classes) make this less necessary. Java is widely considered a simpler language to use than C++ because it forgoes some of the more troublesome C++ (though powerful) features. For example, Java does not explicitly use pointers and has automatic memory management, areas where C++ programmers often introduce bugs into their programs. This makes Java much easier to work with and somewhat less error-prone. Java only supports *single inheritance,* which means that a derived class may only have a single parent base class. C++ allows the use of the more powerful form, *multiple inheritance,* which allows several parents for a derived class. Java does not support *templates,* which allow C++ programmers to create functions and classes that work for many different types of data without needing to be implemented separately for each. Java also does not support operator overloading. Like C++, however, Java does have a rich and powerful set of standard libraries. Java's libraries even include components for network programming and database access (through JDBC), which standard C++ lacks. Even with all these improvements to C++, Java would be a footnote in the annals of programming if it were not for its web features.

Java allows the creation of specialized applications called *applets,* which are designed to be run within a web browser. Most modern web browsers support Java in some form, and Sun offers plug-ins that provides the most up-to-date language features. Early applets focused on creating more dynamic web pages through animations and other graphical components easily created in Java but hard to reproduce in pure HTML. Today, applets are used for delivering entire software applications via the Web. This has many advantages over a traditional development and distribution model. For example, programmers do not have to worry about the end-user platform because applets run in a browser. Users don't have to worry about applying patches and bug fixes because they always get the latest version from the Web. Security is an obvious concern for applets because it might be possible to write a malicious Java applet and place it on a web page for unsuspecting users. Luckily, the Java community has created a robust and ever-improving security model to prevent these situations. For example, web browsers generally restrict applets from accessing memory locations outside their own programs and prevent writing to the user's hard drive. For trusted applets, such as those being run from a company's Intranet, the security restrictions can be relaxed by the end user to allow more powerful functionality to be included.

2.5.4. ColdFusion

ColdFusion is a tool for easily creating web pages that connect to a database. Developed by Allaire (http://www.allaire.com), ColdFusion is being used in thousands of Web applications by leading companies, including Reebok, DHL, Casio, and Siemens. The ColdFusion Markup Language (CFML) allows a user to create Web applications that are interactive and interface with databases. The syntax of CFML is similar to HTML, which is what makes it relatively easy to use; it makes ColdFusion appealing to Web designers who do not have a background in programming. ColdFusion encapsulates in a single tag what might take ten or a hundred lines of code in a CGI or ASP program. This allows for more rapid development of applications than competing methods provide. However, if a tag does

not do exactly what you need it to, then you must either change your application or resort to a programmatic approach. Although ColdFusion is not a programming language per se, knowledge of fundamental programming concepts and SQL is essential for sophisticated applications. CFML allows a user to display output based on the results of a query to a database and update databases based on user input. In order to use CFML, a ColdFusion Application Server (CFAS) must be installed. CFAS works in conjunction with a web server. The CFAS can do much more than query/update databases; it interfaces with many different Internet services to provide the functionality that a website designer desires. Figure 4 shows how a ColdFusion Application Server interacts with a web server, databases, and other services it provides.

The following sequence of actions illustrates how ColdFusion functions to produce dynamic results.

1. A user submits a form via a browser. The form is designed to be processed by a file containing CFML code. This file must have a ''cfm'' extension.
2. The web server recognizes the cfm extension and hands the file to the CFAS for processing.
3. The CFAS executes the instructions per the CFML code. This typically results in information from a database to be included in the web page. In addition, it may interact with other Internet services, such as other web servers, e-mail, etc.
4. The web page generated by the CFAS is then returned to the web server.
5. The web server sends this page to the browser.

Allaire offers versions that run under Microsoft Windows NT and the Unix-based operating systems Solaris and HP-UX. ColdFusion programs interface with many different Web server APIs to provide greater efficiency than traditional CGI programs.

2.5.5. ASP

One of Microsoft's methods for creating more dynamic web pages is through its web server's support of Active Server Pages. ASP lets programmers use the VBScript programming language on the server-side to create HTML content on-the-fly. Because ASP is built into the Web server, it is more efficient than other CGI programs. It offers greater flexibility and control than a product like ColdFusion but requires greater programming knowledge to achieve results.

3. DATABASE MANAGEMENT TOOLS

3.1. DBM Concepts

One of the most important functions that an information system must perform is data management (i.e., record keeping). Prior to the advent of true database software, computer data management was characterized by excessive data redundancy (or duplication), large data dependence (or coupling),

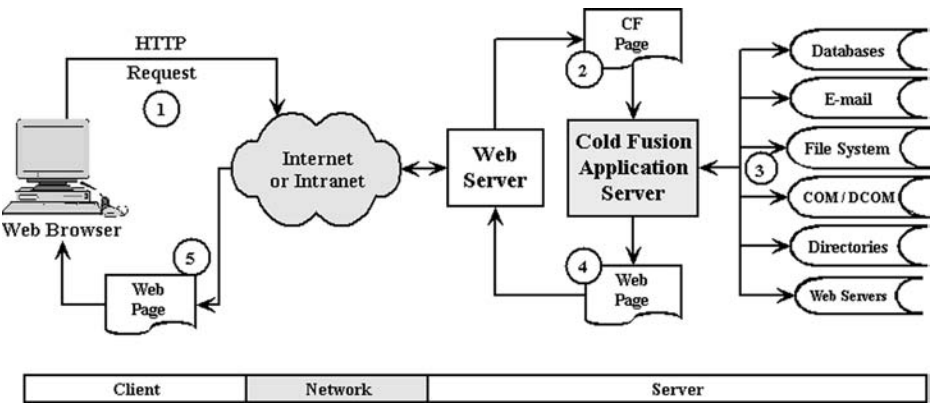

Figure 4 ColdFusion Application Server.

and diffused data ownership (McLeod 1998). In early data processing systems, the data files were often created with ''little thought as to how those files affected other systems. Perhaps much, or even all, of the new data in a new file was already contained in an existing file'' (McLeod 1998). This resulted in significant data redundancy and several associated problems. Obviously, data duplication results in wasted space, but worse than this are synchronization problems. ''Multiple copies of data were often updated on different frequencies. One file would be updated daily, another weekly, and a third monthly. Reports based on one file could conflict with reports based on another, with the user being unaware of the differences'' (McLeod 1998). These early systems also exhibited a high degree of dependence between the data specifications and the programs written to manipulate the data. Every time the representation of the data or the file storage format changed, all of the programs that depended on that data would also need to be changed. Other problems resulted from a lack of agreement on data ownership and standardization. ''This situation of the 1950s and early 1960s may have been the reason why many of the first management information systems failed in the late 1960s. Information specialists appeared unable to deliver systems that provided consistent, accurate, and reliable information'' (McLeod 1998).

Database systems sought to address these issues by separating the *logical* organization of the data from the *physical* organization. The logical organization is how the *user* of the system might view the data. The physical organization, however, is how the *computer* views the data. A database, then, may be defined as ''an integrated collection of computer data, organized and stored in a manner that facilitates easy retrieval'' by the user (McLeod 1998). It seeks to minimize data redundancy and data dependence. A database is often considered to consist of a hierarchy of data: files, records, and fields. A *field* is the smallest organized element of data, consisting of a group of characters that has a specific meaning. For example, a person's last name and telephone number would be common fields. Related fields are collected and stored in a structure referred to as a *record*. A specific person's record might consist of his or her name, address, telephone number, and so on (all values associated with that individual). Related records are grouped into a *file,* such as a file of employees or customers. Keep in mind that the physical representation of the database will be shielded from the user and should not limit the user's ability retrieve information from the system.

A database management system (DBMS) is a ''collection of programs that manage the database structure and controls access to the data stored in the database. The DBMS makes it possible to share the data in the database among multiple applications or users'' (Rob and Coronel 1997). In a sense, it sits between the user and the data, translating the users' requests into the necessary program code needed to accomplish the desired tasks. General Electric's Integrated Data Store (IDS) system, introduced in 1964, is considered by most to be the first generalized DBMS (Elmasri and Navathe 2000).

Database systems are often characterized by their method of data organization. Several popular models have been proposed over the years. Conceptual models focus on the logical nature of the data organization, while implementation models focus on how the data are represented in the database itself. Popular conceptual models include the entity-relationship (E-R) model and the object-oriented model discussed below. These models typically describe relationships or associations among data as one-to-one, one-to-many, or many-to-many. For example, in most organizations an employee is associated with one department only but a department may have several employees. This is a one-to-many relationship between department and employee (*one* department has *many* employees). But the relationship between employee and skills would be many-to-many, as a single employee might possess several skills and a single skill might be possessed by several employees (*many* employees have *many* skills).

Implementation models include the hierarchical model, network model, and relational model. Each model has advantages and disadvantages that made it popular in its day. The relational model is easily understood and has gained widespread acceptance and use. It is currently the dominant model in use by today's database management systems.

3.1.1. Relational DBMS

The relational database model, introduced by E. F. Cod in 1970, is considered a major advance for users and database designers alike. At the time, however, many considered the model impractical because its ''conceptual simplicity was bought at the expense of computer overhead'' (Rob and Coronel 1997). As processing power has increased, the cost of implementing the relational model has dropped rapidly. Now you will find relational DBMS implementations from mainframes down to microcomputers in products like DB2, Oracle, and even Microsoft's Access.

To the user, the relational database consists of a collection of *tables* (or *relations* in the formal language of the model). Each table may be thought of as a matrix of values divided into rows and columns. Each row represents a record and is referred to as a *tuple* in the model. Each column is a field and is called an *attribute* in the model. Below are some simple tables for Employee and Department.

Employee	EmployeeID	EmpName	EmpPhone	DepartmentID
	1234	Jane Smith	5025551234	11
	2111	Robert Adams	8125551212	20
	2525	Karen Johnson	6065553333	11
	3222	Alan Shreve	5025558521	32
	3536	Mary Roberts	8125554131	20

Department	DepartmentID	DeptName
	11	Marketing
	20	Engineering
	32	Accounting

Pay special attention to how relationships between tables are established by sharing a common field value. In this example, there is a one-to-many relationship between the Employee and Department tables established by the common *DepartmentID* field. Here, Robert Adams and Mary Roberts are in the Engineering department (*DepartmentID* = 20). The tables represented here are independent of one another yet easily connected in this manner. It is also important to recognize that the table structure is only a logical structure. How the relational DBMS chooses to represent the data physically is of little concern to the user or database designer. They are shielded from these details by the DBMS.

3.1.2. Processing

One of the main reasons for the relational model's wide acceptance and use is its powerful and flexible ad hoc query capability. Most relational DBMS products on the market today use the same query language, Structured Query Language (SQL). SQL is considered a fourth-generation language (4GL) that ''allows the user to specify *what* must be done *without* specifying *how* it must be done'' (Rob and Coronel 1997). The relational DBMS then translates the SQL request into whatever program actions are needed to fulfill the request. This means far less programming for the user than with other database models or earlier file systems.

SQL statements exist for defining the structure of the database as well as manipulating its data. You may create and drop tables from the database, although many people use tools provided by the DBMS software itself for these tasks. SQL may also be used to insert, update, and delete data from existing tables. The most common task performed by users, however, is data retrieval. For this, the *SELECT* statement is used. The typical syntax for *SELECT* is as follows:

```
SELECT <field(s)>
FROM <table(s)>
WHERE <conditions>;
```

For example, to produce a list of employee names and telephone numbers from the Engineering department using the tables introduced earlier, you would write:

```
SELECT EmpName, EmpPhone
FROM Employee
WHERE DepartmentID = 20;
```

Of course, you may use the typical complement of logical operators, such as *AND, OR,* and *NOT,* to control the information returned by the query.

The *SELECT* statement may also be used to join data from different tables based on their common field values. For example, in order to produce a list of employee names and their departments, you would write:

```
SELECT Employee.EmpName, Department.DeptName
FROM Employee, Department
WHERE Employee.DepartmentID = Department.DepartmentID;
```

In this example, the rows returned by the query are established by matching the common values of *DepartmentID* stored in both the *Employee* and *Department* tables. These joins may be performed across several tables at a time, creating meaningful reports without requiring excessive data duplication.

It is also possible to sort the results returned by a query by adding the *ORDER BY* clause to the *SELECT* statement. For example, to create an alphabetical listing of department names and IDs, you would write:

```
SELECT DeptName, DepartmentID
FROM Department
ORDER BY DeptName;
```

These examples demonstrate the ease with which SQL may be used to perform meaningful ad hoc queries of a relational database. Of course, SQL supports many more operators and statements than those shown here, but these simple examples give a hint of what is possible with the language.

3.2. Object-Oriented Databases

The evolution of database models (from hierarchical to network to relational) is driven by the need to represent and manipulate increasingly complex real-world data (Rob and Coronel 1997). Today's systems must deal with more complex applications that interact with multimedia data. The relational approach now faces a challenge from new systems based on an object-oriented data model (OODM). Just as OO concepts have influenced programming languages, so too are they gaining in popularity with database researchers and vendors.

There is not yet a uniformly accepted definition of what an OODM should consist of. Different systems support different aspects of object orientation. This section will explore some of the similar characteristics shared by most of these new systems. Rob and Coronel (1997) suggest that, at the very least, an OODM

1. Must support the representation of *complex objects*
2. Must be *extensible,* or capable of defining new data types and operations
3. Must support *encapsulation* (as described in Section 2)
4. Must support *inheritance* (as described in Section 2)
5. Must support the concept of *object identity,* which is similar to the notion of a primary key from the relational model that uniquely identifies an object. This object identity is used to relate objects and thus does not need to use *JOIN*s for this purpose.

Consider an example involving data about a *Person* (from Rob and Coronel 1997). In a typical relational system, *Person* might become a table with fields for storing name, address, date of birth, and so on as strings. In an OODM, *Person* would be a class, describing how all instances of the class (*Person* objects) will be represented. Here, additional classes might be used to represent name, address, date of birth, and so on. The *Address* class might store city, state, street, and so on as separate attributes. *Age* might be an attribute of a *Person* object but whose value is controlled by a method, or function of the class. This inclusion of methods makes objects an *active* component in the system. In traditional systems, data are considered *passive* components waiting to be acted upon. In an OODM, we can use inheritance to create specialized classes based on the common characteristics of an existing class, such as the *Person* class. For example, we could create a new class called *Employee* by declaring *Person* as its superclass. An *Employee* object might have additional attributes of salary and social security number. Because of inheritance, an *Employee* is a *Person* and, hence, would also gain the attributes that all *Person* objects share—address, date of birth, name, and so on. *Employee* could be specialized even further to create categories of employees, such as manager, secretary, cashier, and the like, each with its own additional data and methods for manipulating that data.

Rob and Coronel (1997) summarize the advantages and disadvantages of object-oriented database systems well. On the positive side, they state that OO systems allow the inclusion of more semantic information than a traditional database, providing a more natural representation of real-world objects. OO systems are better at representing complex data, such as required in multimedia systems, making them especially popular in CAD/CAM applications. They can provide dramatic performance improvements over relational systems under certain circumstances. Faster application development time can be achieved through the use of inheritance and reuse of classes. These OO systems are not without problems, however. Most of them are based on immature technology, which can lead to product instability. This is exacerbated by the lack of standards and an agreed-upon theoretical foundation. OO database systems especially lack a standard ad hoc query language (like SQL for relational systems). In addition, the initial learning curve is steep, particularly for individuals who are well accustomed to the relational model. On the whole, it seems clear that object-oriented databases are

worth consideration. As standards develop over time and people become more familiar with object-oriented systems in general, OO databases could prove to be the successor to the relational model.

3.3. Data Warehouses

One of the major changes in the information systems area within the past decade is a recognition that there are two fundamentally different types of information systems in all enterprises: *operational systems* and *informational systems*. Operational systems are just what their name implies: they are the systems that help us run the enterprise day-to-day. These are the backbone systems of any enterprise: the order entry, inventory, manufacturing, payroll, and accounting systems. Because of their importance to the organization, operational systems were almost always the first parts of the enterprise to be computerized. Over the years, these operational systems have been enhanced and maintained to the point that they are completely integrated into the organization. Indeed, most large enterprises around the world today couldn't operate without their operational systems and the data that these systems maintain. Operational data normally is current (the present) and is focused on an area within the enterprise.

On the other hand, other functions go on within the enterprise that have to do with planning, forecasting, and managing the organization. These functions are also critical to the survival of the organization, especially in our fast-paced world. Functions like marketing planning, engineering planning, and financial analysis also require information systems to support them. But these functions are different from operational ones, and the types of systems and information required are also different. The information needed to aid such major decisions that will affect how the enterprise will operate, now and in the future, typically is obtained by analyzing operational data over a long time period and covering many different areas within an enterprise.

A data warehouse is a subject-oriented, integrated, time-variant, nonvolatile collection of data to support management decision making. The data in a data warehouse are stored in a manner that will support the information and analytical processing needs of the organization over a long historical time period. They are typically physically separated from the operational databases that an organization must maintain and update to function effectively on a day-to-day basis (Singh 1998; Barquín and Edelstein 1997).

There are many data flows from the operational databases to the data warehouse and from the data warehouse to users. Data must flow from the enterprise's legacy systems to a more compact form, then to the data warehouse storage, and finally out to consumers. The flows necessary to manage the warehouse itself (metaflow) must also be considered (Hackathorn 1995). For each flow, data warehouses require tools to make these processes function effectively (Mattison 1996).

The tools for developing data warehouses can be grouped into three categories, based on their activities: acquisition tools (for inflow), storage tools (for upflow and downflow), and access products (for outflow) (Mattison 1996). Acquisition tools are necessary to perform tasks such as modeling, designing, and populating data warehouses. These tools extract data from various sources (operational databases and external sources) and transform it (i.e., condition it, clean it up, and denormalize it) to make the data usable in the data warehouse. They also establish the metadata, where information about the data in the warehouse is stored (Francett 1994).

Storage is usually managed by relational DBMSs and other special tools in ways that enable the use of data for effective decision support (Mattison 1996). Access to warehouse contents is provided by data mining tools using such methods as neural networks and data discovery mechanisms (Mattison 1996), plus multidimensional analysis software that supports end users in accessing and analyzing the data in the warehouse in various ways (Francett 1994). Data mining is the process of making a discovery from large amounts of detailed data (Barry 1995) by drilling down through detailed data in the warehouse. Data mining tools sift through large volumes of data to find patterns or similarities in the data. Data mining and online analytical processing tools translate warehouse contents into business intelligence by means of a variety of statistical analyses and data visualization methods (Brown 1995; Fogarty 1994). Table 1 provides a list of some of the common terms used within the data warehouse community.

A number of commercial products attempt to fulfill warehousing needs, including the SAS Institute's SAS/Warehouse Administrator, IBM's Visual Warehouse, Cognos's PowerPlay, Red Brick Systems' Red Brick Warehouse, and Information Builders' FOCUS. A discussion of these tools is beyond the scope of this chapter.

4. ENTERPRISE TOOLS

Since the early days of business computing, system designers have envisioned information system architectures that would allow the seamless sharing of information throughout the corporation. Each major advance in information technology spawned a new generation of applications such as CIM or MRP II that claimed to integrate large parts of the typical manufacturing enterprise. With the recent

TABLE 1 Common Terms Used by the Data Warehousing Community

Term	Description
Aggregates	Precalculated and prestored summaries that are stored in the data warehouse to improve query performance. For example, for every VAR there might be a prestored summary detailing the total number of licenses, purchased per VAR, each month.
Business Intelligence Tools	Those client products, which typically reside on a PC, that are the decision support systems (DSS) to the warehouse. These products provide the user with a method of looking and manipulating the data.
Data Extraction, Acquisition	The process of copying data from a legacy or production system in order to load it into a warehouse.
Data Mart	Separate, smaller warehouses typically defined along organization's departmental needs. This selectivity of information results in greater query performance and manageability of data. A collection of data marts (functional warehouses) for each of the organization's business functions can be considered an enterprise warehousing solution.
Data Mining	A collection of powerful analysis techniques for making sense out of very large datasets.
Data Modeling	The process of changing the format of production data to make it usable for heuristic business reporting. It also serves as a roadmap for the integration of data sources into the data warehouse.
Data Staging	The data staging area is the data warehouse workbench. It is the place where raw data are brought in, cleaned, combined, archived, and eventually exported to one or more data marts.
Data Transformation	Performed when data is extracted from the operational systems, including integrating dissimilar data types and processing calculations.
Data Warehouse	Architecture for putting data within reach of business intelligence systems. These are data from a production system that now resides on a different machine, to be used strictly for business analysis and querying, allowing the production machine to handle mostly data input.
Database Gateway	Used to extract or pass data between dissimilar databases or systems. This middleware component is the front-end component prior to the transformation tools.
Drill Down	The process of navigating from a top-level view of overall sales down through the sales territories, down to the individual sales person level. This is a more intuitive way to obtain information at the detail level.
DSS (Decision Support Systems)	Business intelligence tools that utilize data to form the systems that support the business decision-making process of the organization.
EIS (Executive Information Systems)	Business intelligence tools that are aimed at less sophisticated users, who want to look at complex information without the need to have complete manipulative control of the information presented.
Metadata	Data that define or describes the warehouse data. These are separate from the actual warehouse data, which are used to maintain, manage, and support the actual warehouse data.
OLAP (Online Analytical Processing)	Describes the systems used not for application delivery, but for analyzing the business, e.g., sales forecasting, market trends analysis, etc. These systems are also move conducive to heuristic reporting and often involve multidimensional data analysis capabilities.
OLTP (Online Transactional Processing)	Describes the activities and systems associated with a company's day-to-day operational processing and data (order entry, invoicing, general ledger, etc.).
Query Tools and Queries	Queries can either browse the contents of a single table or, using the databases SQL engine, they can perform join conditioned queries that produce result sets involving data from multiple tables that meet specific selection criteria.

TABLE 1 (*Continued*)

Term	Description
Scrubbing/Transformation	The processes of altering data from its original form into a format suitable for business analysis by nontechnical staff.
Star Schema	A method of database design used by relational databases to model multidimensional data. A star schema usually contains two types of tables: fact and dimension. The fact table contains the measurement data, e.g., the salary paid, vacation earned, etc. The dimensions hold descriptive data, e.g., name, address, etc.

growth in client/server applications and more powerful relational databases, a new breed of ''enterprise'' tools has emerged in the last 10 years. These enterprise tools enable the design of information systems, commonly called ''enterprise resource planning'' or ''ERP systems,'' that are truly enterprise-wide. They have become popular in large part because they are replacing older legacy systems that are often complex, redundant, and notoriously inflexible, with a suite of integrated application modules and integrated data that is accessible throughout the enterprise. Another common feature among the various enterprise tools is that they are intended to develop a set of integrated applications, typically for large business enterprises. These business enterprises may be global in nature, and these systems are typically running on a distributed client/server platform with a common, integrated database.

4.1. Enterprise Tools Defined

Today, when software vendors and consultants talk about enterprise tools they are referring to a class of tools that are frequently referred to as enterprise resource planning (ERP) software. *ERP* is a term used by the industry to refer to a collection of applications or modules that can be used to manage the whole business. ERP software describes the class of prepackaged software applications that can be configured and modified for a specific business to create an ERP system. Here we use the term *ERP* interchangeably with the term *enterprise tools*. ERP software or packages are defined here as:

An integrated set of software modules designed to support and automate core business processes that may include logistics, sales, manufacturing, finance, and human resources.

A key point to note in this definition is that the software is integrated around a common user interface and around a shared database so that data can easily be shared between applications such as production and finance. Also of importance is the notion that the software is designed to be modular, so users can implement whichever modules they choose, and that it is oriented towards supporting business processes rather than the traditional functional view of the organization. It is this process view that is often the most misunderstood part of implementing an ERP system, since it can entail substantial reengineering of core business processes.

4.2. Evolution of Enterprise Resource Planning

The idea that a large corporate enterprise could be supported by a completely integrated information system is certainly not new. It has been envisioned since the early days of computers. These visions began to become more concrete in the manufacturing area when computer integrated manufacturing (CIM) systems became popular in the early 1980s. The goal of CIM was to link up the CAD output from the engineering function to marketing personnel so it could be reviewed and also be shared with the production planning and production departments. A part of the product's design was the bill of materials (BOM), which contained the material specifications and quantities to produce a single unit of the particular product. In later versions of CIM, this BOM might also be used create an electronic order and send it to approved vendors via an electronic data interchange (EDI) connection. The basic benefits were that it would decrease product development time and production costs while allowing designs to be changed rapidly and smaller production runs to be made. Because of its inherent complexity, few firms developed these in-house and most chose to purchase generic CIM software. However, CIM did not achieve all the anticipated gains in integration and gave way to another manufacturing integration concept, MRP II.

The lessons learned in trying to implement CIM in the manufacturing environment were used in the development of the newer material requirements planning (MRP) systems in the mid-1980s. The functionality of these new planning systems continued its expansion as companies tried to take a more holistic view of manufacturing processes. Improvements in new relational database technology made it possible to integrate the different departments involved in the manufacturing processed around

a central database. MRP II systems extended the integrated manufacturing concept by linking the production schedule to other organizational systems in finance, marketing, and human resources. For instance, changes in customer demand would have a ripple effect on cash flow planning, and personnel planning, in addition to purchasing. The goals again were to cut costs of production, reduce inventory, improve customer service, and integrate production decisions better with finance and marketing functions.

4.2.1. The Appearance of Enterprise Resource Planning

While MRP II remained focused on shortening the ordering and production cycles in a manufacturing environment, several advances in technology in the late 1980s led to the development of ERP tools and applications. Beyond the manufacturing processes, ERP encompasses business planning, sales planning, forecasting, production planning, master scheduling, material planning, shop floor control, purchasing and financial planning, routing and bill of material management, inventory control, and other functions. As with MRP II, a centralized relational database is key to the success of an ERP application. Other new technologies that enabled the spread of ERP tools include the rapidly maturing client/server distributed architecture and object-oriented programming (OOP) development practices. Both of these factors make the ERP system more scalable both in terms of the hardware and also the modularity of the software. This scalability in turn lends itself to continuous expansion of their functionality, as can be seen by the rise of new ERP modules that extend to supply chain and customer relationship concepts, generating tighter linkages with both the customer's and supplier's own planning systems.

As the scope of these integrated applications has grown, it is clear that the complexity has also grown. Horror stories about runaway ERP implementations appear frequently in the popular press. Two examples occurred in 1999 with the much-publicized problems of Hershey's ERP implementation and also a similar set of problems at Whirlpool. After more than $100 million had been spent on Hershey's ERP implementation, Hershey's inventory system did not work and they reportedly lost more than $100 million during the busy Halloween season (Stedman 1999b). ERP costs for large multinational firms can easily take several years and cost several hundred million dollars. Corning Inc. reported in 1998 that they expected their ERP project to take between five and eight years to roll out to all 10 of its manufacturing divisions (Deutsch 1998). Common complaints about ERP products are that they are inflexible and if anything special is desired, expensive consultants must be hired to design ''tack on'' modules that often must be programmed in some obscure proprietary language. This ''one size fits all'' mentality makes it difficult for smaller companies to justify the expense of an ERP systems. It may be that ERP will not fit with certain types of organizations that require extensive flexibility. Experience has shown that ERP systems seem to work best in those organizations with a strong top-down structure. Also, the very complexity of an ERP implementation frightens off many potential adopters because it may involve shifting to a client/server environment combined with an often painful process of reengineering.

With all the problems and risks associated with ERP, why would anyone even want to consider an ERP system? Despite these problems, from 1995 to 1999 there was a tremendous growth in corporate implementation of ERP systems. Over 70% of the Fortune 500 firms (including computer giants Microsoft, IBM, and Apple) have implemented an ERP system. Though market growth slowed a bit in 1999 due to corporate focus on the Y2K problem, during this same five-year period, ERP vendors averaged about 35% annual growth (Curran and Ladd, 2000). Globally, the ERP market is projected to grow at a compound annual rate of 37% over the next few years, reaching $52 billion by 2002.

The reality is that if a company today wants an enterprise-wide IS, there are few alternatives to ERP tools. Though the risks are very high, the potential benefits include Y2K and Euro compliance, standardization of systems and business processes, and improved ability to analyze data (due to improved data integration and consistency). A vice president at AlliedSignal Turbocharging Systems said the company was replacing 110 old applications with an ERP system and this would help the $1 billion unit do a much better job of filling orders and meeting delivery commitments (Davenport 1998). Prior to the year 2000, the most common expected benefits of implementing an ERP solution cited in interviews of information technology executives included:

- Solved potential Y2K and Euro problems
- Helped standardize their systems across the enterprise
- Improved business processes
- Improved efficiency and lowered costs
- Needed to support growth and market demands
- Global system capabilities
- Ability to integrate data (Bancroft et al., 1998)

4.2.2. The Enterprise Tools Market

Next to electronic commerce, ERP is one of the most dynamic and rapidly growing areas of business computing. The market for ERP tools has grown at an average annual rate of 30–40% since 1994. ERP revenues for 1998 were approximately $23 billion and were expected to grow to $52B by 2002. Because it grew out of the MRP II market, the early focus of ERP tools was on the manufacturing complex, and it expanded from there, to service and even government and educational institutions. Penetration of this market by ERP tools has reached 70%, and it is said that almost all of the remaining companies are considering installing an ERP solution. The ERP tools market was really defined and is still dominated by a German software company, SAP AG, which currently controls 33% of the ERP market. SAP had revenues in 1998 of $5.05 billion, a 41% increase from the year before (Curran and Ladd 2000). Oracle is the next-leading ERP tools vendor, at 10% of the market, then J.D. Edwards Inc. at 7%, PeopleSoft, Inc. at 6%, and Baan, NV rounding out the top 5 ERP vendors at 5%.

Begun in 1972 by four IBM German engineers, SAP virtually defined the ERP tools market. Its early product, R/2, was a mainframe-based extension to MRP II. However, its top leadership made the strategic decision in 1988 to focus all R&D efforts on developing enterprise solutions for the client/server platform. SAP was one of the earliest software vendors to recognize this fundamental shift and is now the leading client/server application software vendor and the fourth-largest software company in the world. The list of their clients includes 9 of the 10 companies with the top market value in the world and includes IBM, Microsoft, and Apple within the computer industry itself. Their product, R/3, is available in 14 languages and is used by over 10,000 customers in more than 90 countries (Curran and Ladd 2000). SAP has expanded beyond its traditional base in manufacturing industries into service industries, education, and governmental agencies. Service industry clients include Burger King, Sothebys, Lufthansa, and Deutsche Banke. Among governments, the Canadian government standardized on SAP and has one of the largest public installations. MIT and several other institutions of higher learning have also implemented SAP to run their fundamental operations.

The cost of SAP's R/3 for a mid-sized company averages about $750,000, but the implementation costs can be many times the software costs. Typical costs for a full-fledged Fortune 500 firm can typically run about $30 million in license fees and $100–200 million in consulting fees (Kirkpatrick 1998). SAP was the first to institute a University Alliance, which fosters the teaching of business courses that use R/3. SAP invests about 20–25% of its revenues in R&D. This represents an amount greater than all the other ERP vendors combined and ensures that it should be able to respond rapidly to changes in the ERP market.

Of the other ERP vendors, Oracle is in the odd position of being the second-largest software company in the world next to Microsoft and being second to SAP in the area of ERP tools. One reason for this is the fact that Oracle is the preferred database engine for SAP and so is often even shipped with R/3 to new clients. However, Oracle has begun to compete more aggressively with SAP with respect to its ERP tools. Initially, it focused on developing financial application modules and targeted the smaller to mid-sized corporate market. In the last several years, it has either developed application modules in-house or purchased smaller software development firms, so that they now can compete with SAP on the entire ERP spectrum. In addition to its enterprise-wide financial applications, Oracle has recently rolled out an Internet Procurement Suite, Oracle Exchange Suite, and the Oracle Customer Relationship Management (CRM) package. Of all the ERP vendors, it was the first to aggressively extend the ERP functions to e-commerce. As such, 19 of the top 20 e-businesses (e.g., Amazon.com, eBay, Barnes & Noble, and CDNow) use Oracle ERP software. One indicator of this strategy is that in 1988 it was the first to allow users to access their enterprise ISs from a standard web browser. Many venture capitalists reportedly refuse to fund an Internet start-up unless Oracle is a part of the business plan (Stroud, 1999).

PeopleSoft Inc. made its niche in the ERP market by being the company that disaffected SAP users could turn to as an alternative. When it was founded in 1987, it was a vendor of software for the human resource (HR) function. It has since focused on this application in the ERP market, while SAP has focused on inventory management and logistics processes. The quality of PeopleSoft's HR modules was such that some companies would adopt SAP for part of their processes and PeopleSoft specifically for their HR processes. Because it was more flexible in its implementations, PeopleSoft won over customers who just wanted a partial ERP installation that they could integrate more easily than with their existing systems. PeopleSoft was perceived as being more flexible and cost-effective because it developed its whole ERP software suite by collaborating with firms like Hyperion, Inc. for data warehousing, data mining, and workflow management applications. Once PeopleSoft got into a company with its HR applications, it then began offering the financial and other ERP software modules. This led to rapid growth; 1992 revenues of $33 million grew to $1.4 billion in 1998 (Kirkpatrick 1998). Along with the rest of the ERP software industry, PeopleSoft has been scrambling to extend its ERP offerings to the Internet. In 1999, it began development of eStore and eProcurement, and it acquired CRM vendor Vantive (Davis 1999).

Baan Software, a Dutch firm, was an early player in the ERP software market, shipping its first product in 1982. It was the first ERP vendor to focus on an open UNIX computing environment in 1987. Its early strengths were in the areas of procurement and supply chain management. Through internal development and acquisitions, Baan offers one of the most complete suites of ERP tools, including accounting, financial, and HR applications in one comprehensive package or separately for functional IS development. Shifting toward an Internet focus, Baan has recently acquired a number of tool development firms and entered into an alliance with Sun for its Java-based software. It is also moving aggressively to integrate XML-based middleware into its next release of BaanERP (Stedman 1999a).

J.D. Edwards began in 1977 as a CASE tool vendor but developed its own suite of ERP applications, primarily for the AS/400 platform. Its modules now include manufacturing, distribution, finance, and human resources. The company emphasizes the flexibility of its tools and has risen quickly to be fourth-largest ERP vendor, with nearly $1 billion in 1998 sales (Kirkpatrick 1998). It has been an aggressive ERP vendor in moving to the ERP Outsourcing model, where firms access the J.D. Edwards software over a secure network link to an offsite computer. This means firms' pay a fixed monthly fee per user and don't have large up-front investments in expensive implementations and software and skills that are rapidly out of date. This network-distribution-based outsourcing model for ERP vendors has yet to be validated, though, and presents many potential technical problems.

4.3. Basic Concepts of Enterprise Tools

As one reads the literature on ERP tools, it quickly becomes apparent that very little academic research has been performed to in this rapidly emerging area. The field, for the most part, is defined by a few case studies, and research consists primarily of industry publications (Brown and Vessey 1999). Articles appearing in industry publications generate many new terms, which the authors seldom define, and they also tend to over-hype new technology. Various ERP-related terms have been put forth, including *ERP tools, ERP integration tools, ERP network tools, ERP security tools, ERP software,* and *ERP system*. Some vendors are also trying to move away from the term *ERP* to the term *enterprise planning* (EP) and even *extended resource planning* (XRP) systems (Jetly, 1999). As mentioned earlier, *enterprise resource planning* (ERP) is a term used by the industry to refer to prepackaged software tools that can be configured and modified for a specific business to create an enterprise IS. Common enterprise-wide processes are integrated around a shared database. Although mainframe versions of ERP tools exist, for the most part ERP tools assume a client/server platform organized around a centralized database or data warehouse. The essential concepts that generally define ERP tools include integration of application modules, standard user interfaces, "process view" support, integrated database with real-time access, and use of an "open" system architecture usually built around a client/server platform.

4.3.1. ERP and the "Process View"

Another common feature of ERP tools/systems is that they usually involve the extensive application of business process reengineering (Curran and Ladd 2000). This process is often very painful because it may require an organization to reexamine all of its core processes and redesign whole departments. The ERP tool chosen actively supports this "process view." In this sense, a process can be thought of specified series of activities or a way of working to accomplish an organizational goal. To be properly supported by an ERP tool, processes have a defined structure and order and identifiable inputs and outputs. This process view is in contrast to the more traditional functional view, where processes are broken down into activities that lack integration. ERP tools offer further support for the process view of an organization by building into the system standard business processes such as order management or shipping scenarios. These scenarios are then used as the basis for configuring and customizing an ERP system for the specific company. Certain vendors go so far as to try and capture the "best practices" within whole industries, such as the pharmaceutical industry, and use these as models for implementing ERP systems within that industry. Benefits include streamlined business processes, better integration among business units, and greater access to real-time information by organizational members. For many organizations, movement to an ERP-based IS is seen as one way to use computer technology to provide substantial gains in productivity and speed of operations, leading to competitive advantage (Davenport 1998).

4.3.2. ERP and the Open Systems Architecture

It is clear that one of the reasons ERP tools became so successful was that they were able to take advantage of improvements in the client/server architecture and in middleware. The general movement to the client/server platform in the late 1980s meant that firms could reduce the cost of a highly centralized configuration in favor of a more flexible client/server setup. The C/S configuration preferred by most ERP vendors is that of the standard three-tier C/S platform, which consists of a presentation server, connected to the application server, which is in turn connected to the database

server. The ''3'' in SAP's R/3 product name even refers to this three-tier platform, as opposed to the old R/2 mainframe product.

ERP systems take advantage of new developments in middleware that make it feasible to distribute applications across multiple, heterogeneous platforms. This means that ERP applications can be running on different operating systems and can be accessing data stored in various formats on different database servers worldwide. The middle-ware built into such ERP packages such as SAP and PeopleSoft contains all the communication and transaction protocols needed to move the data back and forth from the database server to the presentation server. The ultimate goal of this is that the movement of data across the varied platforms be transparent to the user, who comes into the ERP applications via a common graphical user interface or even a standard browser interface for e-commerce extensions to the enterprise ISs.

4.3.3. ERP Application and Data Integration

ERP packages include software for a wide range of applications, ranging from purchase orders to accounting and procurement to warehousing. They grew out of the need to plan, manage, and account for resources in manufacturing environments. In recent years, their functionality has grown in both breadth and depth. As companies integrate business units through consolidation or global operations, their information technology's ability to support these changes is often challenged. The broad functionality of the ERP applications allows companies to replace much of their systems with ERPs, providing better support for new business structures and strategies. The great appeal of ERPs is that employees enter information only once and that information is then available to all applications company-wide. Activities tracked or triggered by the ERP software are also automatically captured in the enterprise's accounting general ledger, without the risk of reentry errors. This means that IS reports throughout a company are based on accurate, real-time information. The value of this is borne out by the large amounts of money that multinational firms are willing to pay to implement ERPs.

An ERP tool provides companies with a standard interface for all of a firm's IS applications, a feature that may be lacking with the older legacy application systems. This has become even more important with rise of CRM and the movement of ERP toward Web-enabled enterprise applications. Although standard, SAP's R/3 interface is famous for some confusing and complicated aspects. Research on an improved user interface is continuing, and the new versions are much improved and more intuitive. For e-commerce extensions to ERP-based ISs, users will soon be able to navigate using a standard web browser such as Microsoft's Internet Explorer. Soon users will also have the option of accessing their ERP-based ISs using wireless, pen-based, hand-held computers (Marion 1999b).

4.4. Standard Enterprise Tool Applications

When companies look to implement an IS with an ERP tool, they typically analyze their functional requirements, technical integration issues, costs, and strategic issues. With respect to analyzing the functional requirements of a company and comparing them to the functionality of the various ERP tools available, this task is clouded somewhat by several factors. First, with the ERP emphasis on supporting core business processes, designers must be more knowledgeable about how all the corporate processes flow into each other, from creating a sales document (i.e., report) all the way to maintaining records of employee profiles. Beyond this, with the new emphasis on business plans that integrate alliance partners and customers more closely, a company must move its focus away from a strictly intraorganizational one to an increasing awareness of transorganizational needs. Both of these needs are further complicated by the fact that each vendor defines the standard business processes in different ways and hence the component architectures of their software reflect a different set of configurable components. Also, within the different vendor packages there are varying degrees of overlap in the functionality of each of the modules. This makes it very difficult to compare the functionality of specific modules from different vendors and how much of them will be able to be integrated into existing systems. The functionality varies, making it difficult to do a proper comparison of the purchase cost and implementation cost of the modules. This problem is further complicated when one considers the different sets of ''industry solutions'' that ERP vendors push as ways of smoothing the implementation process.

One way to get around some of the problems in making comparisons of ERP tool functionality is to try to translate a particular company's needs into a generic set of core processes, such as order management, inventory management, and so forth. Companies may then go through several iterations of attempting to map each vendor's modules to those requirements until the desired level of functionality has been met. In this way, some of the gaps and overlaps will become more apparent. Further requirements, such as those related to technical, cost, support, and data integration can be overlaid onto the matrix to refine the comparison further. This section examines the four standard core business processes that almost all ERP tools are designed to support. These processes include the sales and distribution processes, manufacturing and procurement, financial management, and

human resources. Each ERP package defines these processes slightly differently and has varying degrees of functionality, but all tend to support the basic processes presented here with various combinations of modules.

4.4.1. Sales and Distribution Applications

With the advent of newer, more customer-oriented business models such as Dell's ''build to order'' computer manufacturing model, it is increasingly important for companies to take customer needs into account and to do it in a timely fashion. ERP tools for supporting sales and distribution are designed to give customers a tighter linkage to internal business operations and help to optimize the order management process. The processes that are most typically supported by the sales and distribution (sales logistics) ERP modules include order entry, sales support, shipping, quotation generation, contract management, pricing, delivery, and inquiry processing. Because the data and functional applications are integrated in a single real-time environment, all the downstream processes, such as inventory management and production planning, will also see similar improvements in timeliness and efficiency.

When companies adopt a particular ERP vendor's package, they often begin with the sales and distribution model because this is the beginning of the business cycle. ERP customers are given a variety of different sales scenarios and can choose the ones that most closely mirror how they would like to run their sales processes. Then they can configure that module to reflect more accurately the way they want to support their sales processes. If they need to modify the module more substantially, they will have to employ programmers to customize the module and possibly link it to existing custom packages that they wish to keep. Whichever approach they choose, the generic sales processes that are chosen by the ERP customer can be used as a good starting point from which to conduct user requirements interview sessions with the end users within the company.

One example of a typical sales process that would be supported by an ERP sales and distribution module is the ''standard order processing'' scenario. In the standard scenario, the company must respond to inquiries, enter and modify orders, set up delivery, and generate a customer invoice (Curran and Ladd 2000). The system should also be able to help generate and manage quotes and contracts, do credit and inventory availability checks, and plan shipping and generate optimal transportation routes. One area that does distinguish some of the ERP packages is their level of support for international commerce. For example, SAP is very good in its support for multiple currencies and also international freight regulations. Their sales and distribution module will automatically perform a check of trade embargoes to see if any particular items are blocked or are under other trade limits for different countries. They will also maintain international calendars to check for national holidays when planning shipping schedules. This application is also where customer-related data are entered and corresponding records maintained. Pricing data that is specific to each customer's negotiated terms may also be a part of this module in some ERP packages (Welti 1999).

Other sales processes that might be considered a part of the sales and distribution module (depending on the particular ERP product) include support for direct mailing campaigns, maintenance of customer contact information, and special order scenarios such as third party and consignment orders. With the rapid growth of the newer CRM software packages, much of the support for these processes is now being moved to the Internet. E-mail and Web-based forms enabling customer input mean that ERP sales and distribution modules will have to evolve rapidly along CRM lines. Currently, the most advanced with respect to this type of web integration is the ERP package from Oracle, but the other vendors are moving quickly to enhance their current sales and distribution module functionality (Stroud 1999).

4.4.2. Manufacturing and Procurement Applications

Certainly the most complex of the core business processes supported is the large area generally called manufacturing and procurement. Because ERP tools grew out of MRP II and its precursors, these modules have been around the longest and have been fine-tuned the most. The suite of ERP modules for this application is designed to support processes involved in everything from the procurement of goods used in production to the accounting for the costs of production. These modules are closely integrated with the financial modules for cash flow and asset management and with the sales and distribution modules for demand flow and inventory management. Key records maintained by these application modules include material and vendor information.

Among the supply chain activities, the manufacturing and procurement applications handle material management, purchasing, inventory and warehouse management, vendor evaluation, and invoice verification (Bancroft et al. 1998). These activities are so complex that they are typically divided up among a whole suite of manufacturing modules, such as in SAP's R/3, which consists of materials management (MM), production planning (PP), quality management (QM), plant maintenance (PM), and project management (PM). These various modules can be configured in a wide variety of ways and can accommodate job shop, process-oriented, repetitive, and build-to-order manufacturing envi-

ronments. The PM module is designed to support the management of large, complex projects, such as shipbuilding or special construction projects. Also, despite being oriented more towards large manufacturing enterprises, ERP vendors have made great strides in modifying these modules to accommodate the special needs of service industries such as education and government.

With respect to procurement processes, ERP tools can be used to configure the desired IS in many ways, but they are generally built around a standard procurement scenario. Whether a company must procure subcontract work, consumable goods, or material for their day-to-day production stock, the chain of procurement activities is somewhat similar. These activities involve recognizing a material need, generating a purchase requisition, sending out RFQs to approved vendors, choosing a vendor, receiving and inspecting the goods, and verifying the vendor invoice (Curran and Ladd, 2000). In this area, many companies already use EDI effectively to support their procurement processes, and so most ERP tools are equipped to support standard EDI transactions. The growth of the Internet and extended supply chain management means that ERP tools are increasingly linked directly to their preapproved vendors to further shorten the procurement cycles.

4.4.3. Accounting and Finance Applications

Like the other core business activities, accounting has been undergoing a total reorientation towards a more process-oriented view of the enterprise. Most ERP tools support the accounting and financial processes with another suite of modules and submodules. These include general ledger, AR/AP, asset management, controlling, taxation, and cash flow projection. The more robust ERP packages support accounting for multiple divisions, across multiple currencies, and also support consolidation of financial statements across countries and divisions. Again, because of the integrated nature of all the ERP applications and data, the output from these modules is generated in a much more efficient and timely manner than in the older, legacy systems. The key, of course, is to make sure that the data are highly accurate when it is entered into the system. The downside of data integration is that inaccurate data can be spread through many different applications' reports.

A large part of the accounting and financial activities in an enterprise is the efficient processing of vendor payments and the posting of payments in the correct order into the various ledger accounts. This can be done automatically via EFT or manually in an ERP system, depending on the preferences of the vendor or customer. One of the outputs from the procurement process is a vendor-produced invoice, and this input is the usual starting point for the external accounting activities. Once the invoice is entered either via EDI, manual entry, or even scanning, the invoice is posted to the appropriate account and the amount is verified by matching it with a purchase order and any other partial payments. Once verified, a payment release is issued and payment is issued either electronically or manually. On the customer side, the accounting module also maintains the customer credit records and generates dunning notices (i.e., reports) according to a predefined dunning procedure for each individual customer. The ERP application system will also automatically add on any interest or processing charges that are defined as part of the sales contract for that particular customer. As payments are received and entered into the system, it applies them to the appropriate invoice and moves them to the appropriate GL account.

Most ERP tools also support a variety of management accounting activities. The largest part of these internal accounting activities center on cost management and profitability analysis. Depending on the type of organization, costs can be collected as a byproduct of procurement and production and the system can be configured to generate cost estimates, simultaneous production costing, and also final costs for a period or a project. These costs can be further analyzed and broken down by organizational unit and by specific product or project. Profitability analysis can likewise be conducted at various points in the process and be broken down by organizational unit and product or project. One must bear in mind that with a properly configured suite of ERP financials, the data that are collected and analyzed for these controlling reports are very timely and generating the reports can be done much more efficiently than previously. Analysis can also be conducted across international divisions of the company and whole product lines.

4.4.4. Human Resource Applications

Typically the last set of business processes to be converted to an ERP system, HR applications have recently become very popular as companies look to areas where they might be able to gain a competitive advantage within their respective industries. Because of this, there has been substantial improvement in the HR modules of the leading ERP vendors. This improvement in turn has led to a substantial second wave of ERP implementations among those early adopters, who may have only adopted the financial and manufacturing or sales modules in the first wave of ERP implementations (Caldwell and Stein 1998).

In most organizations, HR too often has become a catchall for those functions that do not seem to fit elsewhere. As a result, HR typically houses such disparate functions as personnel management, recruiting, public relations, benefit plan management, training, and regulatory compliance. In ERP

applications, the HR modules house the employee data and also data about the current organizational structure and the various standard job descriptions. The latest wave of ERP tools now supports most of these activities in a growing suite of HR modules and submodules. For example, personnel management includes the recruitment, training and development, and compensation of the corporate workforce. Typical recruitment activities include realizing the internal need for new personnel, generating a job description, posting advertisements, processing applicants, screening, and selecting the final choice for the position. Once the position has been filled, then training assessments can be done and a benefit and development plan can be implemented. Other core processes in the HR module include payroll processing, benefits, and salary administration; sometimes they include time and travel management to help employees streamline reimbursement for travel expenses.

4.5. Implementing an Enterprise System

Because of the large investment in time and money, the selection of the right enterprise tool has a tremendous impact on the firm's strategy for many years afterward. Choosing a particular ERP package means that a company is entrusting its most intimate core processes to that vendor's software. This is a decision that cannot be easily reversed after it has been made. Some firms have chosen to implement an ERP package not realizing the extent of the commitment involved and then had to stop the project in the middle (Stedman 1999b). This is often because these companies are unwilling to reexamine their core processes to take advantage of the integrated nature of an ERP package.

What makes choosing an ERP package different from other types of organizational computing decisions? As discussed above, the large scale and scope of an ERP system make it even more critical than local or functional IS applications for the well-being of the enterprise, apart from the high-cost issue. It is also different in that it is oriented towards supporting business processes rather than separate islands of automation and so the typical implementation involves business experts more than technology experts as opposed to traditional system implementations. The process-oriented nature of an ERP implementation also means that cross-functional teams are a large part of the design process. Because of the high potential impact on an organization due to the redesign of core business processes and reduction of the labor force needed for these processes, one of the more subtle differences is that end users may fight the changes brought about by an ERP system. Therefore, project leaders must also be skilled in "change management" (Davenport 1998).

4.5.1. Choosing an Enterprise Tool

Given that an ERP implementation is so risky to an enterprise, what should a firm consider when choosing an ERP tool? There are currently a handful of case studies in the academic literature and numerous anecdotal references in the trade literature. From these we can derive some factors that a firm should take into account. Probably the most important criterion is how well the software functionality fits with the requirements of the firm. A firm could develop a matrix of its core business process requirements and then try to map the modules from the various ERP packages to the matrix to see where obvious gaps and overlaps might exist (Jetly 1999). A byproduct of this analysis will be a better understanding of the level of data and application integration that the package offers. Increasingly, the ERP package's support for electronic commerce functions will be a major factor in choosing the right package.

Beyond an analysis of the ERP package functionality, a firm must also take technical factors into consideration. Each package should be evaluated for the flexibility of the architectures that it supports and its scalability. How well will this architecture fit with the existing corporate systems? How many concurrent users will it support and what is the maximum number of transactions? Will the module require extensive modifications to make it fit with our business processes and how difficult will it be to change them again if my business changes? Given the potential complexity of an ERP implementation, potential users should be concerned about the ease of use and amount of training that will be required for end users to get the most out of the new system. ERP vendor-related questions should center on the level of support that is offered and how much of that support can be found locally. They should also look into the overall financial health and stability of their prospective ERP vendors and the scope and frequency of their new product releases and updates.

With respect to cost, several factors should be kept in mind when choosing an ERP package. First is the cost of the software and hardware itself that will be required. Besides the required number of new database and application servers, hardware for backup and archiving may also be required. Software costs are typically on a per-module basis and may vary between modules, but a firm may also have to purchase the submodules in order to get the desired functionality. If these modules need to be customized or special interfaces with existing systems need to be programmed, firms should consider the amount of customization required. This cost is exaggerated for some ERP packages, such as SAP's R/3, which require knowledge of the rather exotic proprietary language ABAP/4 in order do extensive customization. Training and ongoing support for these packages will be a continuing expense that should also be considered.

4.5.2. Enterprise System Implementation Strategies

With the high cost of implementing an enterprise information system, developers are under pressure to build them as quickly as possible. Given that the actual system development costs can typically range from 2–10 times the actual cost of the software and hardware (Doane 1997), many ERP consulting firms have sprung up to service this market. Of course, each of them has its own methodology which it claims to be faster and more efficient than the other's. Most of these methodologies represent some variation of the traditional phased systems implementation, so this will be discussed here. Another current ERP debate is the relative merits of the "big bang" conversion strategy as opposed to a slower, phased conversion (Marion 1999a).

Because of the strategic nature of ERP decisions, they are usually made at the top executive level. To help coordinate an ERP implementation, firms often create a steering committee with some top executives and high-level management from each of the affected divisions of the firm. The committee will determine the initial scope of the ERP implementation and also which area of the firm will act as a test bed for debugging the initial IS, assuming the firm does not choose to do a big bang implementation. As a result, a firm may choose to begin with the sales and distribution module in its marketing department and expand from there. A project team consisting of IS professionals and end users should then be formed. This team will work in conjunction with the steering committee. Studies show that the importance of the project leader cannot be underestimated and that this person should have strong leadership skills and some experience in implementing an ERP-based IS (Bancroft et al. 1998).

It is the project team's job to analyze the current business processes that will be the focus of the ERP-based IS and look at the existing hardware and software along with the existing data and interfaces. In order to explore the ERP software functionality in more detail, firms sometimes map the initial business processes to the chosen ERP package and do a limited test installation. After exploring the ERP package, the project team will come up with a detailed new design of the business processes in question and a prototype system may be developed and tested by users. Once the prototype has been accepted by users, then the complete ERP-based IS application will be developed and implemented and the data migration will take place. Once the IS has been rolled out for the initial application, it will be expanded to include the rest of the enterprise applications that have been identified in the initial scope of the project. It should be noted that most ERP packages support this development process with built-in CASE tools, standard process scenarios and scripts, and possibly a set of recommended "best" practices for specific industries.

As an alternative to this phased approach to ERP implementation, some firms choose the big bang approach, which is riskier but less expensive, in which a firm shifts its entire application for the whole firm from its old legacy system to its new ERP application. This is a high-risk implementation method because the resulting system may have so many bugs that chaos may result, after which it may take months for the firm to recover. An example of the potential problems occurred in the fall of 1999 when Hershey's tried to implement its ERP inventory application using the big bang approach and lost over $100 million due to its failure to manage inventory properly (Stedman 1999b). However, there have been big bang success stories at McDonalds Corp. and Rayovac, and perhaps the benefits of this approach can outweigh the risks (Marion 1999a). Some of the benefits include lower cost because it requires less expensive consultant time. It also reduces the amount of interface development with the old legacy systems because there is no temporary connection to maintain with the new ERP applications. The other problem with the long phased approach is that when one application is ready, updated versions of the ERP software are available for other applications when they are ready to be rolled out, and then developers must deal with a whole new set of compatibility and conversion issues.

4.5.3. Critical Success Factors for ERP Implementations

From the various case studies reported in the trade literature, several key factors have been reported that seem critical for the success of an ERP implementation (Bancroft et al. 1998). These include:

1. Management support for making the hard decisions
2. Capability and readiness of the organization for making changes
3. A balanced project team with strong leadership
4. Reasonable project scope
5. The right ERP package
6. The right implementation method
7. A strong training plan for users and the project team

The most commonly cited of these factors is the importance of management support for the success of the project. This factor has been widely documented for other types of business computing projects, but it is especially important in implementing an ERP system because this may involve a radical redesign of some core processes and resulting major changes in the organization. In a project as complex as an ERP system, problems will occur. Leaders must maintain the strong vision to persevere through all the changes. One study showed that nearly 75% of new implementations resulted in some organizational change, and these changes could be very severe (Boudreau and Robey 1999). Project teams should also be balanced with respect to business area experts and IS professionals. As the software becomes easier to configure and has more complete functionality, it seems clear that the trend of shifting more responsibility away from the IS professionals to the business experts will continue (Bancroft et al., 1998). Because of the cross-functional nature of ERP-based ISs, it is also important that team members be drawn from multiple business units and assigned full-time to the project (Norris et al., 1998).

4.6 Future of Enterprise Tools

The new generation of enterprise tools is beginning to enable large corporations to reap significant gains in efficiency and productivity, but the investment costs of implementing an ERP system can be a huge hurdle for smaller companies. Enterprise tools will continue to improve in overall functionality and ease of use as modules are developed and refined. The functionality will continue to be extended to the customer, supplier, and other business partners in what some call the Extended Resource Planning (XRP) software generation (Jetly 1999). Most of these extensions are based on some form of e-business model using the Internet. A description of some of the principal newer enhancements to ERP systems follows. These are taking enterprise ISs into the transorganizational realm.

4.6.1. Enterprise Tools and Supply Chain Management (SCM)

One logical outgrowth of the increased integration of enterprise-wide data and support for core business processes is the current interest in supply chain management. In the 1980s, much of the focus in manufacturing was on increasing the efficiency of manufacturing processes using JIT, TQM, Kanban, and other such techniques. Given the large investment in these improvements in manufacturing strategies, companies managed to lower the cost of manufacturing goods as far as was practical. These same companies are finding that they can take a system view of the whole supply chain, from suppliers to customers, and leverage their investment in ERP systems to begin to optimize the efficiency of the whole logistics network. In this context, supply chain management is defined as follows:

> A set of approaches utilized to efficiently integrate suppliers, manufacturers, warehouses, and stores, so that merchandise is produced and distributed at the right quantities, to the right locations, and at the right time, in order to minimize system-wide costs while satisfying service level requirements (Simchi-Levi et al. 2000).

Until recently, ERP vendors have focused their efforts on providing real-time support for all the manufacturing transactions that form the backbone of the supply chain and left the more focused decision support applications to software companies such as i^2 Technologies and Manugistics. These companies have produced whole families of decision support systems to help analyze the data produced by the ERP-based IS and make better decisions with respect to the supply chain. The interfaces between the standard ERP tools and the new generation of DSSs is where some of the most interesting and valuable research and development is being conducted. As companies improve their support of specific supply chain activities, they can expand the level of integration to include supporting activities from financial operations and human resources.

When taking a supply chain view of its operations, a company must begin with the notion that there are three basic flows within their enterprise: materials, financials, and information. At defined points in the supply chain, data can be collected and stored. The goal of ERP-based ISs in this view is to enable the enterprise to collect and access this information in a timely fashion. This reduces inventory levels, reduces costs, and improves customer service and satisfaction, and each product produced by the enterprise will also have an accompanying information trail that can be tracked and used for planning and estimating lead times. It must be kept in mind that this integrated information flow is available in real time as a basis for decision making.

Much of the recent interest in supply chain management and ERP stems from the e-business models that have been emerging. These models now call for tighter linkages between suppliers and customers, and the ERP tools must support these linkages. This extended supply chain management makes use of the Internet to link with suppliers and customers via standard browsers and TCP/IP protocols. This means that not only will customers be able to track their orders, but companies will be sharing inventory and BOM information with their suppliers. In fact, one of the major unresolved issues in ERP research is the question of inter-ERP linkage. Most vendors have their own standard

format, and until there is general agreement within the industry, inter-ERP data sharing will require the development of sophisticated middleware to share data between ISs at companies using different vendors' ERP tools (Simchi-Levi et al. 2000).

4.6.2. Enterprise Tools and Customer Relationship Management (CRM)

As ERP vendors continue to extend the functionality of their packages, one area where there has been tremendous growth has been in the ability of the software to support a company's links to its clients. Interest in better supporting these linkages has led to the development of a niche software market called customer relationship management (CRM) software. CRM supports business functions typically performed by marketing, sales, and service. CRM software is designed to support these functions by helping to identify, select, develop and retain customers. With the recent move to e-business, the traditional view of CRM has changed to look to how CRM software can be combined with electronic commerce technology to gain a competitive advantage. This means that new CRM software helps to move existing processes such as order entry to the Internet and supports new processes such as email-based customer support. Companies are now revising their business strategies to take advantage of Web-enabled CRM software to support Web marketing and customer interaction. Besides supporting sales staff, the new breed of CRM software supports a "contact center," which is a focal point of phone, Web, e-mail, ATM, and kiosk customer interactions. These front-office activities then must be linked in real time to back office functions that fall into the domain of the traditional ERP package.

While the predictions for the maturing ERP market indicate that its growth rate is slowing, the market for CRM software is just starting to explode. One industry analyst has predicted that the market will grow at an annual growth rate of 49% over the period from 1999–2003, when it will reach $16.8 billion in sales (Bowen, 1999). Of this market, the top vendors in 1998 were Siebel Systems, Vantive, and Clarify, who together represent 40% of the CRM tool market. Siebel became the market leader by changing its focus from client/server sales force automation applications to developing an integrated, Web-based CRM suite, with sales, marketing, and customer modules. It has generated more than 50 partnerships with industry giants, such as the recent alliance with IBM. With strategy, their revenues increased from $36 million in 1996 to $329 million in 1998 (Zerega 1999).

Because of the immense potential of the CRM market and because it fits well with their attempts to turn their product lines toward an e-business orientation, all the major ERP vendors are now looking to expand into the front-office domain. ERP vendors are doing this by acquiring CRM vendors, developing alliances with pure CRM vendors, developing their own packages, or as in the case of SAP, a combination of these. In October of 1999, Peoplesoft announced that it was acquiring one of the leading CRM vendors, Vantive. Similarly, Baan has already purchased Aurum Software and has formed an alliance with Cap Gemini to integrate its CRM applications into BaanERP (Goldbaum 1999). Of the top five ERP vendors, Oracle is the only one currently offering a front-office system. It is ahead of the ERP market in developing a suite of Web-enabled CRM applications that integrate easily with its tools for back-office enterprise systems. It has aggressively pursued alliances with hardware vendors such as HP to allow Oracle and HP salespeople to collaborate and share information over the Internet (Stroud 1999). In this way, it cosells its CRM solutions and shares customer data. Oracle also announced in March of 1999 that it would integrate its CRM suite with SAP's ERP tools (Sykes 1999). In contrast, SAP does not currently offer a CRM module for its product, R/3.

SAP is the ERP market leader with the most comprehensive and integrated package of ERP applications. Yet it is seen as being late to move its focus to Web-enabled enterprise application systems. In the fall of 1999, it unveiled its long-awaited MySAP.com and is attempting to use its large client base of active installations for leverage into the CRM market. Given its huge investments in R&D, SAP has never been inclined to purchase niche players in related software markets but has preferred to develop its own tools in-house. With respect to CRM tools, its eventual plan is to package CRM modules as a part of its new MySAP.com architecture for e-business portals (Bowen 1999). It will be browser-based, using Microsoft's Internet Explorer, and will provide seamless access to R/3's enterprise-wide applications. Although SAP has yet to deliver its own CRM modules, it is predicting that CRM-related revenues will eventually outpace revenues from sales of "pure" ERP packages (Bowen 1999).

Because of its huge growth potential, the CRM market is very dynamic, with a stream of new entrants and the expansion of current CRM vendors' tools. With respect to ERP packages, the trend is toward the eventual blending of ERP with CRM modules. This will occur as the major ERP vendors continue to turn their focus toward e-business. It is expected that this new amalgam of front-office with back-office applications will lead to a seamless new set of IS development tools called "e-business suites" (Goldbaum 1999).

4.6.3. Enterprise Tools and Electronic Commerce (EC)

As the ERP market has matured, ERP vendors have rushed to be the first to redesign their products so that they Web-enable their enterprise tools. The rapidly evolving model of ERP and e-commerce means that users anywhere in the world will be able to access their specific enterprise-wide ISs via a standard, browser-based interface. In this model, the ERP platform defines a new suite of e-business modules that are distributed to suppliers and clients using the standards of the Internet. The ERP tool can thus be used to build an e-business ''portal'' that is designed specifically for everything from small ''e-tailers'' to large multinational corporations. This portal will streamline links with customers, suppliers, employees, and business partners. It will extend the linkage between the enterprise and transorganizational classes of ISs.

One way that this model is emerging is as a turnkey supplier of e-business function support. For example, SAP's new web portal model, MySAP.com, can be used to help a new e-tailer design and build its website. Using an innovative natural language interface, a business person can describe the features he or she wants for the company website and a basic web page will be automatically generated. The website will be further linked with whatever functionality is desired from the back-office enterprise IS, via the Web-enabled suite of modules in MySAP.com. These modules might include processing customer orders, creating and maintaining a corporate catalog for customers to browse, processing bank transactions, monitoring customer satisfaction, and allowing customers to check the status of their orders. The same platform can be used to maintain the company's business-to-business applications, such as eProcurement and information sharing with business partners and clients. For a fee, MySAP.com users can ''rent'' back-office decision support software for forecasting, data mining, and inventory planning and management. These services are delivered over the Internet and users pay on a per-transaction basis. This web portal also serves as the platform for business-employee transactions, helping employees communicate better, monitor their benefit plans, plan for and receive training, and possibly provide more advanced knowledge management support.

5. TOOLS FOR ANALYSIS AND DESIGN OF IS

Managing the development and implementation of new IS is vital to the long-term viability of the organization. In this section, we present and discuss some of the tools and methodologies that have emerged over the last 40 years to help facilitate and manage the development of information systems. The systems development life cycle (SDLC) is introduced, and the tools used within each step of the life cycle are explained. It is important to realize that although professional systems developers have employed these tools and methodologies for the last 20 years with some success, the tools do not guarantee a successful outcome. Utilization of the SDLC will increase the likelihood of development success, but other forces may affect the outcome. Careful attention must also be paid to the needs of users of the system and to the business context within which the system will be implemented. This attention will increase the likelihood of system acceptance and viability.

5.1. The Systems Development Life Cycle

The SDLC was developed as a methodology to aid in the development of information systems. By defining the major activities in the process, the SDLC ensures that all the required tasks are completed, and the time and resources necessary in the different phases can be more precisely estimated. The SDLC separates the tasks that have to be performed when developing an IS into five phases:

1. Systems planning
2. Systems analysis
3. Systems design
4. Systems implementation/testing
5. Systems use and maintenance

Some have referred to this process as a waterfall because one phase naturally leads to the next, in a descending cascade. In business, all information systems become obsolete over time, either functionally or operationally. When the system fails to achieve the desired results, a change in that system is necessary. The existing system may be in the use and maintenance phase; however, it is necessary to move into the systems planning phase in order to initiate a change in the existing system.

During the systems planning phase, an investigation is conducted into the desirability and feasibility of changing the existing system. At this point, the major purpose is to understand the problem and ascertain whether it is cost effective to change it. At the outset of this phase, a systems development team is formed, made up of members of user groups, members of the information technology group, and some members of management. This team typically works together through the entire SDLC. At the end of this phase, a feasibility report is produced. This report should outline the major

business needs to be met by the new system, the system's major inputs and outputs, the scope of the actual problem, and an estimate of the time and resources necessary to solve the problem.

The tools used during this phase usually include automated tools that enable team members to model the existing system using a context diagram and an economic analysis using tools that enable the team to conduct traditional financial analysis, such as net present value and return on investment. A determination is made at the end of this phase whether to continue on with the development or terminate the project. Often the project is either too trivial or cannot be solved in a cost-effective manner to warrant continuation. In such cases, the project is terminated at the end of this phase without major expenditures. If the team decides that the project is worth pursuing, they will proceed to the system analysis phase.

In the system analysis phase, some of the planning activities are repeated in order to flush out the details. The analysts must fully understand the entire problem and begin to create a guide to solve it. This involves a much more detailed study of the existing system. The analysts will question users in much more depth to gather data on their exact requirements. The existing system is typically modeled using tools such as data flow diagrams, data dictionaries, and entity relationship diagrams. Each of these tools will be discussed in greater detail in a following section. The modeling tools allow the analyst team to gain a thorough understanding of the existing system. This understanding, when compared with the new system requirements, will generate the new system proposal. This proposal spells out the changes necessary to correct the deficiencies in the existing system. The proposal is typically presented to a management group that is responsible for funding the next step in the process, system design. At this point, management determines whether the project should continue. They will either provide funds for the project to move on to the system design phase or terminate the project. If the project is terminated at this point, only labor costs are incurred because no information technology expenditures have yet been expanded.

In the design phase, the team will determine how user requirements will be met, working from the outputs backward. A new physical model of the proposed system is created. If the analysts are able to determine precisely what outputs the users require, they can then work back through the processes needed to produce those outputs and the input data needed in the process. This provides a blueprint for the design: the formulation of the data files, the specifications for the software, and the configuration of the needed hardware. The data configuration and software and hardware requirements are determined during this phase. The rule of thumb in systems has been to work in this manner because the data and software design drive the purchase of the actual computing equipment. If the hardware were designed first, later it might either prove inadequate for the long-term requirements of the new system or overshoot those requirements so much as to be less cost effective. At this point, nothing has actually been purchased. The new physical design is summarized in a new system proposal, which is presented to management for funding. If management declines to fund the proposal, the design team disbands. If management funds the new proposal, then the project moves on to system implementation.

If the project reaches this phase, it has reached the point of no return. During the implementation phase, the new system design is used to produce a working physical system. The needed pieces of the system are either created or acquired, then installed and tested on the hardware that has been earmarked for this system. Generally, the team begins by creating the test data needed for the new system. The software specifications are then converted into computing code and tested with the test data. The users are trained in the procedures required to use the new system. The site where the system will be installed is prepared, and the new equipment is installed and tested. The entire system typically undergoes final tests before being released into the production environment.

After the system has been installed, the system enters the use and maintenance phase. In order for the system to deliver value to the organization, minor maintenance typically is necessary to correct errors, ensure system currency, enhance features, or adapt hardware. The system will be periodically tested and audited to increase the reliability of the system outputs. When the system ages to a point where it can no longer be easily modified, the SDLC will shift back to the planning phase and the life cycle will begin again.

During each phase of the SDLC, the organization should maintain detailed documentation of the system. This documentation is the accumulation of all the models, analysis and design specifications, and records during system development. Such documentation is invaluable to the next team charged with a development project because it explains all of the steps and assumptions made during the system's development. The team must keep meticulous records of all meetings, findings, and results, which together make up the system document. This document is maintained at the organization as long as the system is in production.

5.2. Systems Development Tools

This section examines the models and methodologies that are used during the different phases of the SDLC.

5.2.1. Feasibility Analysis

Information systems development projects are almost always done under tight budget and time constraints. This means that during the systems planning phase of the SDLC, a feasibility assessment of the project must be performed to ensure that the project is worth the resources invested and will generate positive returns for the organization. Typically, feasibility is assessed on several different dimensions, such as technical, operational, schedule, and economic. Technical feasibility ascertains whether the organization has the technical skills to develop the proposed system. It assesses the development group's understanding of the possible target technologies, such as hardware, software, and operating environments. During this assessment, the size of the project is considered, along with the systems complexity and the group's experience with the required technology. From these three dimensions, the proposed project's risk of failure can be estimated. All systems development projects involve some degree of failure risk; some are riskier than others. If system risk is not assessed and managed, the organization may fail to receive anticipated benefits from the technology, fail to complete the development in a timely manner, fail to achieve desired system performance levels, or fail to integrate the new system properly with the existing information system architecture. Reducing the scope of the system, acquiring the necessary development skills from outside, or unbundling some of the system components to make the development project smaller can reduce these risks.

Operational feasibility examines the manner in which the system will achieve desired objectives. The system must solve some business problem or take advantage of opportunities. The system should make an impact on value chain activities in such a way that it supports the overall mission of the organization or addresses new regulations or laws. The system should be consistent with the operational environment of the organization and should, at worst, be minimally disruptive to organizational procedures and policies.

Another dimension of feasibility, projected schedule feasibility, relates to project duration. The purpose of this assessment is to determine whether the timelines and due dates can be met and that meeting those dates will be sufficient to meet the objectives of the organization. For example, it could be that the system must be developed in time to meet a regulatory deadline or must be completed at a certain point in a business cycle, such as a holiday or a point in the year when new products are typically introduced to market.

Usually, the economic feasibility assessment is the one of overriding importance. In this case, the system must be able to generate sufficient benefits in either cost reductions or revenue enhancements to offset the cost of developing and operating the system. The benefits of the system could include reducing the occurrence of errors associated with a certain procedure; reducing the time involved in processing transactions; reducing the amount of human labor associated with a procedure; or providing a new sales opportunity. The benefits that can be directly measured in dollars are referred to as tangible benefits. The system may also have some benefits that, though not directly quantifiable, assist the organization in reaching its goals. These are referred to as intangible benefits. Only tangible benefits will be used in the final economic feasibility assessment, however. After benefits have been calculated, the tangible costs of the systems are estimated. From a development perspective, these costs include hardware costs, labor costs, and operational costs such as site renovation and employee training. The costs can be divided into two classes: one-time (or sunk) costs and those costs associated with the operation of the new system, or recurring costs. The benefits and costs are determined for a prespecified period of time, usually the depreciable life of the system. This time period could be 1 year, 5 years, or 10 years, depending on the extent of the investment and the financial guidelines used within the organization.

The tangible costs and benefits are then used to determine the viability of the project. Typically, this involves determining the net present value (NPV) of the system. Since the cost of developing the system is incurred before the systems begins to generate value for the organization over the life of the system, it is necessary to discount the future revenue streams to determine whether the project is worth undertaking. The present value of anticipated costs at a future point in time is determined by:

$$\mathrm{PV}_n = \left(\frac{Y_n}{(1+i)^n}\right)$$

where PV_n is the present value of an anticipated cash inflow or outflow Y_n (Y_n is the monetary value (\$) of the cost or benefit) in the nth year into the project's life and i is the interest rate at which future cash flows are to be discounted. The net present value (NPV) of the project is:

$$\mathrm{NPV} = -C_0 + \sum_{t=1}^{T} PV_t$$

where C_0 is the cost of developing the system and putting it into production and T is the useful life of the system.

Other financial analyses that provide useful information as one seeks to determine whether the organization should proceed with the project include return on investment (ROI) and break-even (BE) analysis. ROI is the ratio of the net returns from the project divided by the cash outlays for the project. BE analysis seeks to determine how long it will take before the early cost outlays can be recouped. If the ROI is high and the BE point is small (i.e., reached quickly), the project becomes more desirable because cash flow estimates far into the future are much more difficult to forecast accurately. Table 2 is a simple spreadsheet that was used to determine economic feasibility.

5.2.2. Process Modeling Using Data Flow Diagrams

During the analysis phase, it is critical that the development team gain a good understanding of the existing system so that they can be in a position to know how the current system produces information. This understanding must be at a very low level of detail, at the level of the processes used to produce information. This level of understanding is best obtained by developing models of the existing system. Typically, the existing system is first graphically represented using a diagramming method known as a data flow diagram (DFD). This method provides a simple way to describe the system graphically. The diagrams can be produced quickly by the development team yet can provide a rich level of detail as they are expanded on lower levels. They are also easy for novices to read, which means they can be powerful communication tools among the development team, managers, and users. Finally, they can be decomposed, that is, logically broken down, showing increasing levels of detail without losing their ability to convey meaning to users and management.

DFDs are drawn with just four symbols: data sources and sinks, processes, data flows and data stores (see Figure 5). Data sources are entities that provide data to the system (a source) or receive information from the system (a sink). These sources lie outside the boundary of the system and are not active participants in the processing that occurs within the system. A process is any activity that converts data into information. Generally, processes are named with a verb of the action in the process and are numbered at the top of the symbol. Numbers are useful for cross-referencing processes on lower-level diagrams to the activities in higher-level diagrams. Processes are interconnected with other processes by data flows. Data flows are symbols that represent data in motion. Each data flow is named with a noun that describes the data represented in the flow. A data flow must be attached to a process at some point, either as a source or as a sink. A data store is a representation of the data at rest. Examples of data stores could include electronic data files, a database table, or a physical file folder.

When the symbols are used in combination, they trace the movement of data from its origin, the source, through all of the steps that transform that data into information for the users, to its eventual destination, a sink. The feature of DFDs that make it so useful in the context of system development is that the diagrams are decomposable. Every system must be understood at a high level of detail.

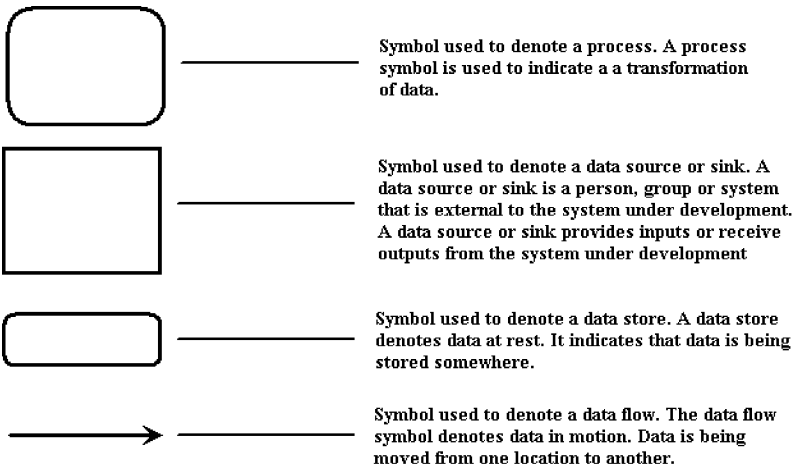

Figure 5 Data Flow Diagram Symbols.

DFDs allow the same system to be examined at many levels of detail, from the context diagram level through whatever level the development team chooses to stop at.

The lowest level of detail in a DFD is called a context diagram, also called a ''black box'' diagram, because it shows only the sources and sinks and their connection to the system through aggregate data flows. The system itself is represented by only one process. That central process will be decomposed into many subsystems in the Level 0 diagram, which shows the system's major processes, data flows, and data stores at a higher level of detail. Figure 6 shows a level 0 diagram for a simple payroll processing system. Each process is numbered, and each represents a major information-processing activity. When the diagram moves to Level 1, each subsystem from Level 0 is individually decomposed. Thus, process 1.0 on the DFD may be functionally subdivided into processes 1.1, 1.2, 1.3, and so on for as many steps as necessary. In Figure 7, we show a Level 1 diagram that decomposes the third process from the Level 0 diagram in Figure 6. As the diagrams are decomposed further, at Level 2 the steps in process 1.1 may be decomposed into subprocesses 1.1.1, 1.1.2, 1.1.3, etc. Each Level 2 DFD will expand on a single process from Level 1. These diagrams can continue to be leveled down until the steps are so simple that they cannot be decomposed any further. This set of DFDs would be referred to as primitive diagrams because no further detail can be gained by decomposing further. The power of this tool is that while it is conceptually simple, with only four symbols, it is able to convey a great degree of detail from the nesting of the decompositions. For systems analysis, this detail is invaluable for an understanding of existing system functionality and to understand the processes.

5.2.3. Structured English

The next step in process modeling, usually performed after the creation of the DFDs, is to model process logic with Structured English, a modified form of the English language used to express information system process procedures. This tool uses the numbering convention from the DFDs to designate the process under examination, then semantically describes the steps in that DFD process. Structured English is used to represent the logic of the process in a manner that is easy for a programmer to turn into computer code. In fact, similar tools were called ''pseudo-code'' to indicate that they were closely related to the design of computer programs. At that point they were used

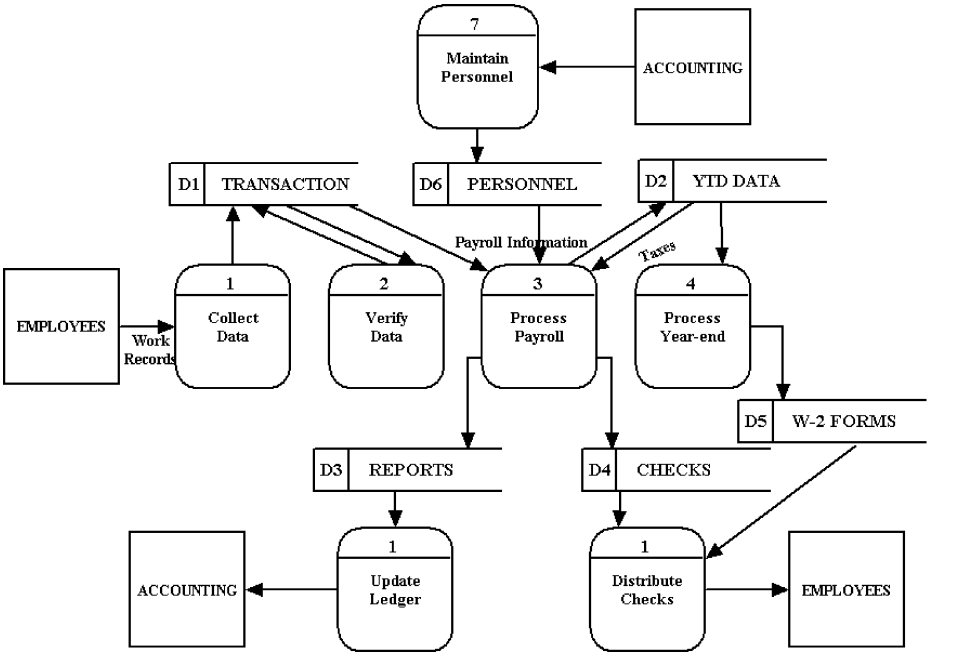

Figure 6 Data Flow Diagram for a Simple Payroll System.

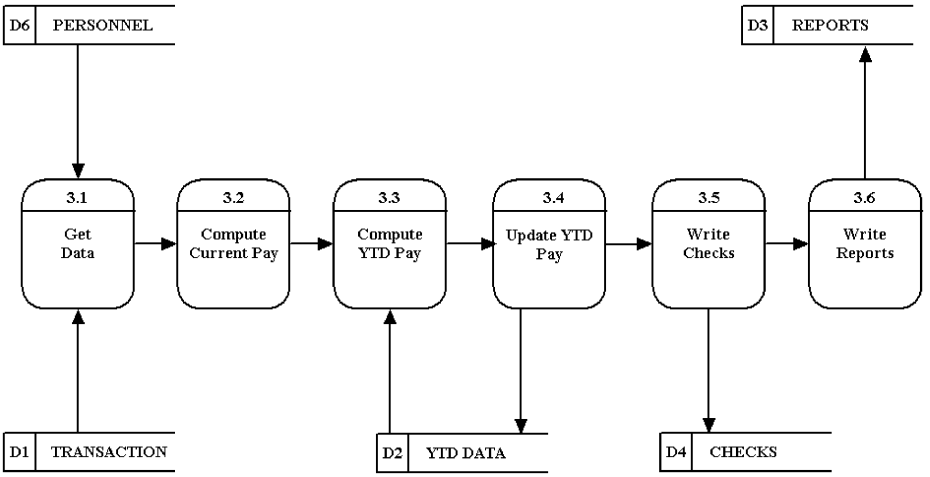

Figure 7 An Explosion of the Process Payroll Process.

to describe individual programs, not entire information systems. As a tool, Structured English representations of processes help in the implementation of the system, making it much easier to develop specifications that can be handed off to those who will develop the programs. Generally, Structured English is generic enough that it can used to develop programs in most programming languages.

The steps in developing Structured English versions of a process are fairly straightforward. First, describe the steps in the process being examined, beginning with a strong verb. The verb modifies a noun, which is generally a data structure, data element, or data flow. Any given statement should include no adjectives or adverbs. While there is no standard for Structured English, it represents basically three types of processes: sequence, conditional statements, and iterations. Sequences are lists of statements where one statement simply follows another. An example of a sequence is:

```
Process 1.1: Update Master File
DO
     OPEN Master File
     READ Record
     MATCH Key to Master File Key
     REPLACE Master record with New Master Record
     CLOSE Master File
END DO
```

The second type of Structured English process is a conditional statement. A case statement is declared, followed by a group of possible actions that will be executed after the evaluation of the case. Programmers refer to this as an ''if/then'' statement. An example of a conditional statement is:

```
Process 2.3: Order Inventory
BEGIN IF
     IF Quantity on hand is less than Reorder quantity
     THEN generate New order
     ELSE do nothing
END IF
```

The last type of Structured English process is an iteration. Iterations are special cases of the conditional statement, where steps are repeated until a stated condition is satisfied. This type of process is also sometimes referred to as a repetition. An example of an iteration is:

```
Read Order File
WHILE NOT End Of File DO
     BEGIN IF

END DO
```

Structured English has been found to be a good supplement to DFDs because, in addition to helping developers at the implementation stage, they have been found to be a useful way to communicate processing requirements with users and managers. They are also a good way to document user requirements for use in future SDLC activities.

5.2.4. ERD/Data Dictionaries

During the analysis phase of the SDLC, data are represented in the DFDs in the form of data flows and data stores. The data flows and data stores are depicted as DFD components in a processing context that will enable the system to do what is required. To produce a system, however, it is necessary to focus on the data, independent of the processes. Conceptual data modeling is used to examine the data ''at rest'' in the DFD to provide more precise knowledge about the data, such as definitions, structure, and relationships within the data. Without this knowledge, little is actually known about how the system will have to manipulate the data in the processes. Two conceptual data modeling tools are commonly used: entity relationship diagrams (ERDs), and data dictionaries (DDs). Each of these tools provides critical information to the development effort. ERDs and DDs also provide important documentation of the system.

An ERD is a graphical modeling tool that enables the team to depict the data and the relationships that exist among the data in the system under study. Entities are anything about which the organization stores data. Entities are not necessarily people; they can also be places, objects, events, or concepts. Examples of entities would be customers, regions, bills, orders, and divisions. Entity types are collections of entities that share a common property or characteristic, and entity instances are single occurrences of an entity type. For example, a CUSTOMER is an entity type, while Bill Smith is an entity instance. For each entity type, one needs to list all the attributes of the entity that one needs to store in the system. An attribute is a named property or characteristic of an entity type. For example, the attributes for a CUSTOMER could be customer number, customer name, customer address, and customer phone number. One or a combination of the attributes uniquely identifies an instance of the entity. Such an attribute is referred to as a *Candidate key,* or *identifier*. The candidate key must be isolated in the data: it is the means by which an entity instance is identified.

Associations between entity types are referred to as *relationships*. These are the links that exist between the data entities and tie together the system's data. An association usually means that an event has occurred or that some natural linkage exists between the entity types. For example, an order is associated with an invoice, or a customer is associated with accounts receivable instances. Usually the relationship is named with a meaningful verb phase that describes the relationship between the entities. The relationship can then be ''read'' from one entity to the other across the relationship. Figure 8 shows a simple ERD for a system in a university environment.

Once an ERD has been drawn and the attributes defined, the diagram is refined with the degree of the relationships between the entities. A unary relationship is a one-to-one or one-to-many relationship within the entity type—for example, a person is married to another person, or an employee manages many other employees. A binary relationship is a one-to-one, one-to-many, or many-to-many relationship between two entity types—for example, an accounts receivable instance is associated with one customer, or one order contains many items. A tenary relationship is a simultaneous relationship between three entity types—for example, a store, vendor, or part, all sharing stock-on-hand. Once the degree of the relationships have been determined, the ERD can be used to begin the process of refining the data model via normalization of the data. Normalization is necessary to increase the stability of the data so that there are fewer data updating and concurrency anomalies. The normalization process is described in detail in every database management textbook (e.g., McFadden et al., 1999).

The ERD is an excellent tool to help understand and explore the conceptual data model. It is less useful, however, for documentation purposes. To address the documentation requirements, a data dictionary (DD) is used. The DD is a repository of all data definitions for all the data in the system. A DD entry is required for each data flow and data store on every DFD and for each entity in the ERDs. Developing a DD entry typically begins with naming the data structure being described, either by flow name, file name, or entity type. The list of attributes follow, with a description of the attribute, the attribute type, and the maximum size of the attribute, in characters. The attribute type is specified (e.g., integer, text, date, or binary). In the case of a data file, the average size of the file is indicated.

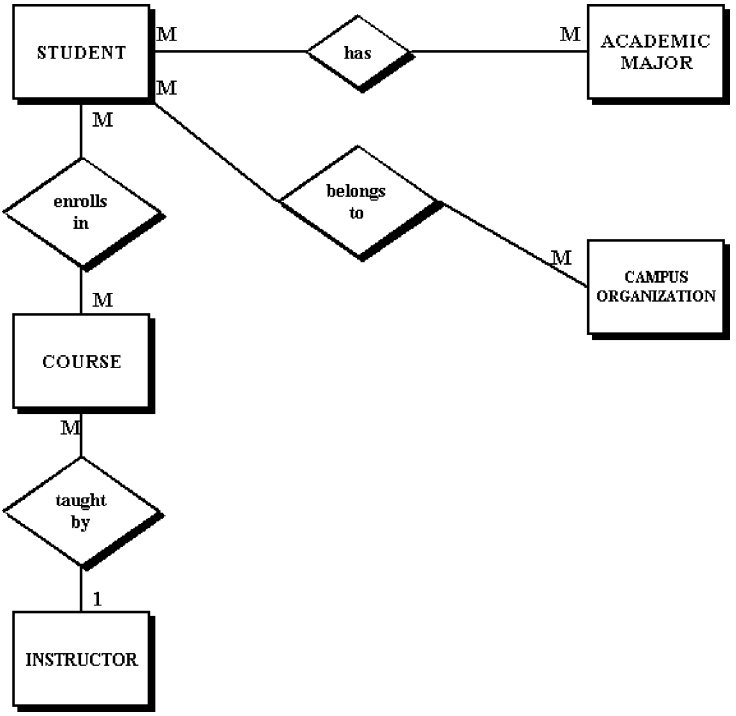

Figure 8 An Entity-Relationship Diagram.

For a data flow, the minimum, maximum, and average number of occurrences of that flow in a business day is determined and listed with the attributes. For the entity type, the entry will note the various associations that the entity type has with the other entities. An example of a DD entry is:

```
          Data Stores

Name:   Customer Mailing List

Key     Customer Number

Size    250,000

                    Name              Definition              Type        Size

Attributes:      Cust_Num       Unique customer Number     Integer        5
                 Cust_Name      Customer name              Text          25
                 Cust_Add       Customer Address           Text          30
```

5.2.5. Gantt/PERT Diagram

Gantt charts and PERT diagrams are used in the planning phase of the SDLC to schedule and allocate time to key activities in the development process. Gantt charts are two-dimensional charts that show major activities on one axis and a time line on the other. The duration of the activities listed is designated with a solid bar under the time line, next to the name for that activity. The time lines for the bars can overlap because certain activities may overlap during the development process. An

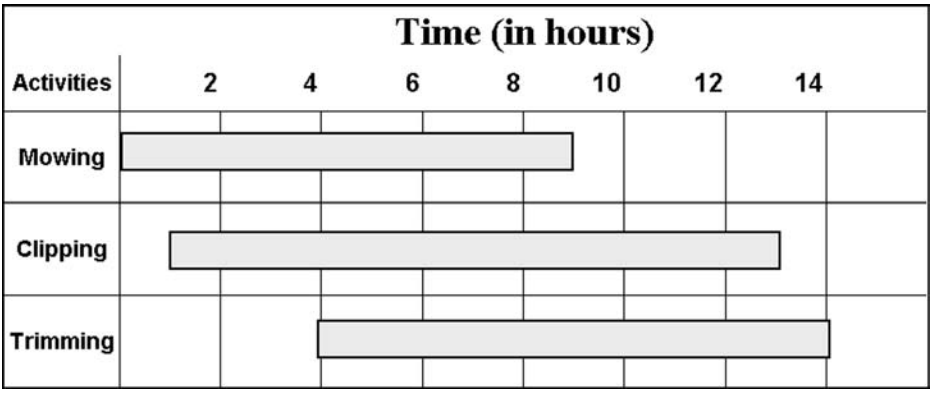

Figure 9 A Gantt Chart for a Simple Lawn-Maintenance Task.

example of this would be program code development and site preparation during system implementation. Figure 9 shows a Gantt chart for a lawn maintenance job with two workers assigned to each activity (Wu and Wu 1994).

PERT diagrams serve the same function as Gantt charts but are more complex and more detailed. They are essential tools for managing the development process. PERT is an acronym for Program Evaluation and Review Technique and was developed by the United States military during World War II to schedule the activities involved in the construction of naval vessels. Since then, PERT has found its way into production environments and structured system development because it allows one to show the causal relationships across activities, which a Gantt chart does not depict. PERT diagrams show the activities and then the relationships between the activities. They also show which activities must be completed before other activities can begin and which activities can be done in parallel. Figure 10 shows an example of a PERT diagram for the lawn maintenance job (Wu and Wu 1994).

Which planning tool is chosen depends upon the complexity of the system being developed. In the case of a systems development effort that is relatively small and simple and where the design can be completed quickly, the Gantt chart is preferable. Where the design is large, complex, and involves many activities that must be carefully coordinated, the PERT diagram is best.

5.2.6. JAD/RAD

Rapid application deployment (RAD), joint application deployment (JAD), and prototyping are approaches used in system development that bypass parts of the SDLC in an effort to speed up the

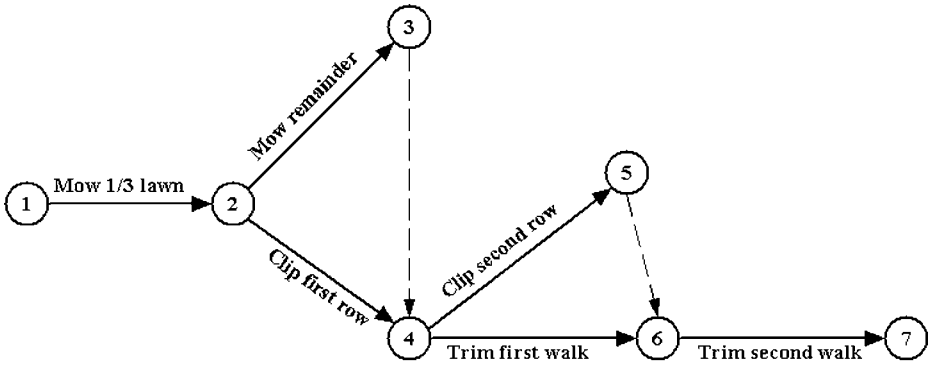

Figure 10 A PERT Diagram for a Simple Lawn-Maintenance Task.

development of the system. Traditionally, the development team will use the analysis phase of the SDLC to determine how the existing system functions and assess what the users of the new system would like to see in that system. RAD and JAD methods have emerged in an effort to remove or greatly reduce the time spent in the analysis phase of development. They are designed for development efforts that jump from planning directly to implementation, such as when software is acquired from a third party. RAD and JAD eliminate the detailed study required during the analysis phase and in doing so speed up user requirements analysis.

JAD is a structured approach whereby users, managers, and analysts work together for several days of intensive meetings to specify or review systems requirements. The coordination of these groups during these meetings determines whether the effort is successful. The groups must agree to work together to iron out any differences and have to work closely together to elicit requirements that might take months to emerge using traditional methods. RAD works by compressing the SDLC steps into four stages: planning, design, development, and cutover. Working only on the systems functions and user interface characteristics shortens planning and design. Then design and development work in an iterative fashion as the model is designed and implemented, then refined through further design and implementation until it produces the features that users require. RAD entails the use of a prototyping tool, which is a software tool that allows the rapid development of a new physical model that can be used and tested by the users. The distinction between prototyping and RAD as development approaches is that in many cases prototypes are never utilized in production environments. They are used to elicit requirements, but the actual prototype is then discarded in favor of a physical model produced with traditional SDLC methods. In RAD, the designed model will be implemented once it has reached a stage where no further refinement is necessary. That change would occur in the implementation phase.

The advantage of these approaches is in the speed with which systems can be developed. For smaller systems, or systems whose failure would not significantly affect the ability of the organization to engage in commerce, these approaches work very well. For systems that handle a significant volume of data, or where security and controls are a concern, these approaches are not advisable. The time saved using these approaches is usually gained at the expense of the attention paid to security, controls, and testing when the traditional development approach is used. Time is the usual hedge against the risk of systems failure: time in analysis and time in design. That time is sacrificed in these approaches.

5.2.7. CASE

Another way to speed systems development is to use computer aided software engineering (CASE) tools. In contrast to RAD or JAD, CASE tools are used with the traditional SDLC methodology. CASE aids the SDLC by using automation in place of manual methods. CASE tools support the activities in the SDLC by increasing productivity and improving the overall quality of the finished product. There are basically three different types of CASE tools. Upper CASE supports the planning, analysis and design phases of the SDLC. Upper CASE usually has planning and scheduling tools as well as DFD generators and data dictionary support. Lower CASE supports the latter parts of the SDLC, such as maintenance and implementation. Last come cross-life cycle CASE toolboxes, which support all the SDLC activities, from planning through maintenance.

There are many compelling reasons to use CASE tools. CASE tools can greatly shorten development times without sacrificing system quality. The tools usually enforce consistency across different phases by providing automated consistency checking between DFDs, ERDs, and the data dictionary to ensure that the attributes and data structures have been named and defined consistently across all of them. This, in turn, can increase the productivity of the SDLC team because a data store defined in a DFD can be automatically inserted as an entry in the data dictionary. This, in turn, can increase the consistency of the development effort across projects.

The disadvantages of CASE mostly revolve around cost. CASE tools tend to be very expensive, both in monetary and in resource terms. CASE tools cost a lot, and learning to use them can be very time consuming because of the number of features and the functionality that they provide. They also place great demands on the hardware in terms of processing needs and storage requirements at the server and workstation level. Essentially, all they do is automate manual processes, so the decision to use CASE hinges on the traditional tradeoff between labor costs and automation costs.

6. CONCLUSION

Over the past 35 years, tremendous strides have been made in management information systems, contributing greatly to organizations' abilities to grow, provide quality outputs, and operate efficiently. These strides have been fostered by continually improving hardware, advances in software tools for building ISs, formal methods for IS development, and progress in understanding the management of ISs. There is no sign that these trends are abating. Nor is there any sign that an organization's needs

for ISs will disappear. Thus, even though their platforms, delivery methods, interfaces, and features will change, information systems will persist as indispensable elements of tomorrow's organizations, continuing to satisfy record keeping and reporting needs.

Integration will be a keynote as we look ahead. Integration is a collaborative interplay of components. It is operative at several levels. At the tool level, we should see a trend towards integration of traditionally distinct functions (Watabe et al., 1991). The resultant tools will enable more rapid IS development and the construction of systems having features not readily achieved with conventional means. At the IS level, we should expect to see a trend toward integration across IS classes. For instance, local ISs will increasingly be built to plug into (i.e., operate on the data of) functional and enterprise ISs; the modular ERP tools are designed for cross-functional IS integration; enterprise-wide ISs will increasingly exhibit transorganizational features. Within a very few years, all major ERP tools will be Internet-based and oriented toward collaborative activity.

At the level of business computing systems, the integration trend will manifest itself in efforts to incorporate decision support functionality into conventional management information systems. IS record keeping and reporting will still be essential for operational control, regulatory compliance, and legal purposes, but their records can be further leveraged for decision support. This can already be seen in ISs equipped with ad hoc query facilities. The use of IS records to build data warehouses that are subject to online analytical processing and data mining is another example in this direction. ERP vendors will increasingly offer decision support modules that work with their tools for building enterprise ISs (Holsapple and Sena 1999). Websites that handle transactions (create/update records and produce transaction reports) will increasingly incorporate facilities to support the decisions that underpin those transactions (Holsapple and Singh 2000).

At an organizational level, the rise of transorganizational ISs has been an important factor enabling and facilitating the appearance of network organizations and virtual corporations (Ching et al. 1996). Advances in supply chain, customer relationship, electronic commerce, and collaborative computing tools will add impetus to this trend. Its business driver is the increasingly dynamic and competitive nature of the global marketplace, in which collaboration and agility are vital. Dynamic, open business models are replacing those characterized by static trading partners.

Artificial intelligence technologies have long been recognized in the DSS realm, particularly in the guise of expert systems (Bonczek et al. 1980). It is likely that tools for building ISs will increasingly employ artificial intelligence technologies. This will lead to ISs that interact with users via speech (based on speech recognition/synthesis and natural language technologies), are self-maintaining (based on automated reasoning technologies), and can modify themselves in light of their experiences (based on machine learning and automatic program-generation technologies).

Application service providers will grow in importance as developers and hosts of information systems, particularly for small and mid-sized firms. These are firms that need an IS (e.g., for human resources functions) but cannot afford the infrastructure. For a rental fee, an application service provider (ASP) operates ISs for other companies on its own computing facilities (i.e., servers). ASP customers access their ISs via the Internet or private networks. ASPs specialize in various ways, such as hosting ISs for a particular industry (e.g., health care) or a particular class of ISs (e.g., transorganizational).

Information systems have become the centerpiece of the much-heralded Information Age. However, this 50-year era is rapidly being engulfed by the emerging knowledge economy, populated by knowledge workers and knowledge-based organizations (Holsapple and Whinston 1987). Information is being subsumed within the far richer notion of knowledge. The technology-driven aspect of this knowledge economy is variously known as the digital economy or the network economy, and its fabric is being defined by a multitude of electronic commerce initiatives (Holsapple et al. 2000). To be competitive in the knowledge economy, organizations (both traditional and virtual) strive to ensure that throughout their operations the right knowledge is available to the right processors (human and computer-based) at the right times in the right presentation formats for the right cost. Along with decision support systems, information systems built with tools such as those described here have a major role to play in making this happen.

CHAPTER 4
Decision Support Systems

ANDREW P. SAGE
George Mason University

1. INTRODUCTION

In very general terms, a decision support system (DSS) is a system that supports technological and managerial decision making by assisting in the organization of knowledge about ill-structured, semi-structured, or unstructured issues. For our purposes, a structured issue is one that has a framework with elements and relations between them that are known and understood within a context brought by the experiential familiarity of a human assessing the issue or situation. The three primary components of a decision support system are generally described as:

- *A database management system* (DBMS)
- *A model-based management system* (MBMS)
- *A dialog generation and management system* (DGMS)

The emphasis in the use of a DSS is upon providing support to decision makers to increase the effectiveness of the decision making effort. This need should be a major factor in the definition of

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

requirements for and subsequent development of a DSS. A DSS is generally used to support humans in the formal steps of problem solving, or systems engineering (Sage 1992, 1995; Sage and Rouse 1999a; Sage and Armstrong 2000), that involve:

- *Formulation* of alternatives
- *Analysis* of their impacts
- *Interpretation* and selection of appropriate options for implementation

Efficiency in terms of time required to evolve the decision, while important, is usually secondary to effectiveness. DSSs are intended more for use in strategic and tactical situations than in operational situations. In operational situations, which are often well structured, an expert system or an accounting system may often be gainfully employed to assist novices or support the myriads of data elements present in these situations. Those very proficient in (experientially familiar with) operational tasks generally do not require support, except perhaps for automation of some routine and repetitive chores. In many application areas the use of a decision support system is potentially promising, including management and planning, command and control, system design, health care, industrial management, and generally any area in which management has to cope with decision situations that have an unfamiliar structure.

1.1. Taxonomies for Decision Support

Numerous disciplinary areas have contributed to the development of decision support systems. One area is computer science, which provides the hardware and software tools necessary to implement decision support system design constructs. In particular, computer science provides the database design and programming support tools that are needed in a decision support system. Management science and operations research provides the theoretical framework in decision analysis that is necessary to design useful and relevant normative approaches to choice making, especially those concerned with systems analysis and model base management. Organizational behavior and behavioral and cognitive science provide rich sources of information concerning how humans and organizations process information and make judgments in a descriptive fashion. Background information from these areas is needed for the design of effective systems for dialog generation and management systems. Systems engineering is concerned with the process and technology management issues associated with the definition, development, and deployment of large systems of hardware and software, including systems for decision support.

Many attempts have been made to classify different types of decisions. Of particular interest here is the decision type taxonomy of Anthony, which describes four types of decisions (Anthony 1965; Anthony et al. 1992):

1. *Strategic planning decisions* are decisions related to choosing highest level policies and objectives, and associated resource allocations.
2. *Management control decisions* are decisions made for the purpose of ensuring effectiveness in the acquisition and use of resources.
3. *Operational control decisions* are decisions made for the purpose of ensuring effectiveness in the performance of operations.
4. *Operational performance decisions* are the day-to-day decisions made while performing operations.

Figure 1 illustrates how these decisions are related and how they normatively influence organizational learning. Generally, low-consequence decisions are made more frequently than high-consequence decisions. Also, strategic decisions are associated with higher consequences and are likely to involve more significant risk and therefore must be made on the basis of considerably less perfect information than are most operational control decisions.

A decision support system should support a number of abilities. It should support the decision maker in the formulation or framing or assessment of the decision situation in the sense of recognizing needs, identifying appropriate objectives by which to measure successful resolution of an issue, and generating alternative courses of action that will resolve the needs and satisfy objectives. It should also provide support in enhancing the decision maker's abilities to assess the possible impacts of these alternatives on the needs to be fulfilled and the objectives to be satisfied. This analysis capability must be associated with provision of capability to enhance the ability of the decision maker to provide an interpretation of these impacts in terms of objectives. This interpretation capability will lead to evaluation of the alternatives and selection of a preferred alternative option. These three steps of formulation, analysis, and interpretation are fundamental for formal analysis of difficult issues. They are the fundamental steps of systems engineering and are discussed at some length in Sage (1991,

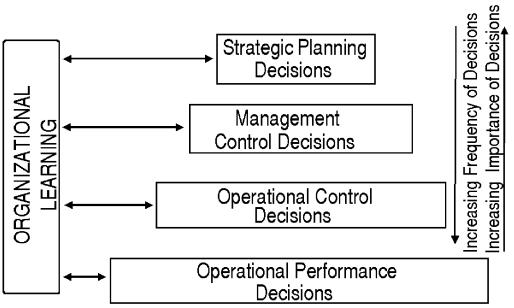

Figure 1 Organizational Information and Decision Flow.

1992, 1995), from which much of this chapter is derived. It is very important to note that the purpose of a decision support system is to support humans in the performance of primarily cognitive information processing tasks that involve decisions, judgments, and choices. Thus, the enhancement of information processing in systems and organizations (Sage 1990) is a major feature of a DSS. Even though there may be some human supervisory control of a physical system through use of these decisions (Sheridan 1992), the primary purpose of a DSS is support for cognitive activities that involve human information processing and associated judgment and choice. Associated with these three steps must be the ability to acquire, represent, and utilize information or knowledge and the ability to implement the chosen alternative course of action.

The extent to which a support system possesses the capacity to assist a person or a group to formulate, analyze, and interpret issues will depend upon whether the resulting system should be called a management information system (MIS), a predictive management information system (PMIS), or a decision support system. We can provide support to the decision maker at any of these several levels, as suggested by Figure 2. Whether we have a MIS, a PMIS, or a DSS depends upon the type of automated computer-based support that is provided to the decision maker to assist in reaching the decision. Fundamental to the notion of a decision support system is assistance provided in assessing the situation, identifying alternative courses of action and formulating the decision situation, structuring and analyzing the decision situation, and then interpreting the results of analysis of the alternatives in terms of the value system of the decision maker. In short, a decision support system provides a decision recommendation capability. A MIS or a PMIS does not, although the information provided may well support decisions.

In a classical management information system, the user inputs a request for a report concerning some question, and the MIS supplies that report. When the user is able to pose a "what if?" type question and the system is able to respond with an "if then" type of response, then we have a

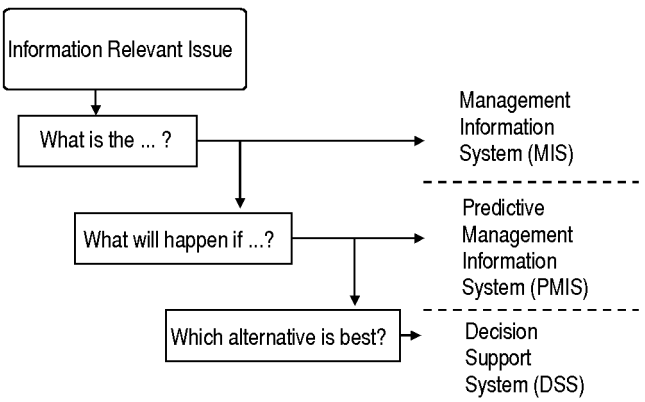

Figure 2 Conceptual Differences Between MIS, PMIS, and DSS.

predictive management information system. In each case there is some sort of formulation of the issue, and this is accompanied by some capacity for analysis. The classic MIS, which needs only to be able to respond to queries with reports, is composed of capabilities for data processing, structured data flows at an operational level, and preparation of summary reports for the system user. The predictive management system would also include an additional amount of analysis capability. This might require an intelligent database query system, or perhaps just the simple use of some sort of spreadsheet or macroeconomic model.

To obtain a decision support system, we would need to add the capability of model-based management to a MIS. But much more is needed, for example, than just the simple addition of a set of decision trees and procedures to elicit examination of decision analysis-based paradigms. We also need a system that is flexible and adaptable to changing user requirements such as to provide support for the decision styles of the decision maker as these change with task, environment, and experiential familiarity of the support system users with task and environment. We need to provide analytical support in a variety of complex situations. Most decision situations are fragmented in that there are multiple decision makers and their staffs, rather than just a single decision maker. Temporal and spatial separation elements are also involved. Further, as Mintzberg (1973) has indicated so very well, managers have many more activities than decision making to occupy themselves with, and it will be necessary for an appropriate DSS to support many of these other information-related functions as well. Thus, the principal goal of a DSS is improvement in the effectiveness of organizational knowledge users through use of information technology. This is not a simple objective to achieve as has been learned in the process of past DSS design efforts.

1.2. Frameworks for the Engineering of Decision Support Systems

An appropriate decision support system design framework will consider each of the three principal components of decision support systems—a DBMS, an MBMS, and a DGMS—and their interrelations and interactions. Figure 3 illustrates the interconnection of these three generic components and illustrates the interaction of the decision maker with the system through the DGMS. We will describe some of the other components in this figure soon.

Sprague and Carlson (1992), authors of an early, seminal book on decision support systems, have indicated that there are three technology levels at which a DSS may be considered. The first of these is the level of DSS tools themselves. This level contains the hardware and software elements that enable use of system analysis and operations research models for the model base of the DSS and the database elements that comprise the database management system. The purpose of these DSS tools is to design a *specific DSS* that is responsive to a particular task or issue. The second level is that of a decision support system generator. The third level is the specific DSS itself. The specific DSS may be designed through the use of the DSS tools only, or it may be developed through use of a generic DSS generator that may call upon elements in the generic MBMS and DBMS tool repository for use in the specific DSS.

Often the best designers of a decision support system are not the specialists primarily familiar with DSS development tools. The principal reason for this is that it is difficult for one person or small group to be very familiar with a great variety of tools as well as to be able to identify the

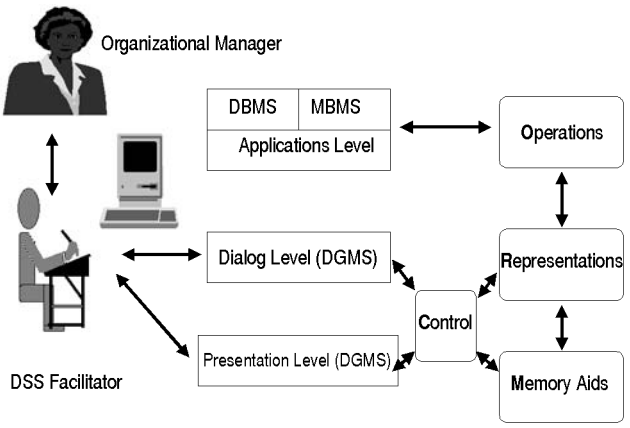

Figure 3 Generic Components in a Decision Support System, Including the ROMC Elements.

requirements needed for a specific DSS and the systems management skills needed to design a support process. This suggests that the decision support generator is a potentially very useful tool, in fact a design level, for DSS system design. The DSS generator is a set of software products, similar to a very advanced generation system development language, which enables construction of a specific DSS without the need to formally use micro-level tools from computer science and operations research and systems analysis in the initial construction of the specific DSS. These have, in effect, already been embedded in the DSS generator. A DSS generator contains an integrated set of features, such as inquiry capabilities, modeling language capabilities, financial and statistical (and perhaps other) analysis capabilities, and graphic display and report preparation capabilities. The major support provided by a DSS generator is that it allows the rapid construction of a prototype of the decision situation and allows the decision maker to experiment with this prototype and, on the basis of this, to refine the specific DSS such that it is more representative of the decision situation and more useful to the decision maker. This generally reduces, often to a considerable degree, the time required to engineer and implement a DSS for a specific application. This notion is not unlike that of software prototyping, one of the principal macro-enhancement software productivity tools (Sage and Palmer 1990) in which the process of constructing the prototype DSS through use of the DSS generator leads to a set of requirements specifications for a DSS that are then realized in efficient form using DSS tools directly.

The primary advantage of the DSS generator is that it is something that the DSS designer can use for direct interaction with the DSS user group. This eliminates, or at least minimizes, the need for DSS user interaction with the content specialists most familiar with micro-level tools of computer science, systems analysis, and operations research. Generally, a potential DSS user will seldom be able to identify or specify the requirements for a DSS initially. In such a situation, it is very advantageous to have a DSS generator that may be used by the DSS engineer, or developer, in order to obtain prototypes of the DSS. The user may then be encouraged to interact with the prototype in order to assist in identifying appropriate requirements specifications for the evolving DSS design.

The third level in this DSS design and development effort results from adding a decision support systems management capability. Often, this will take the form of the dialog generation and management subsystem referred to earlier, except perhaps at a more general level since this is a DGMS for DSS design and engineering rather than a DGMS for a specific DSS. This DSS design approach is not unlike that advocated for the systems engineering of large scale systems in general and DSS in particular.

There are many potential difficulties that affect the engineering of trustworthy systems. Among these are: inconsistent, incomplete, and otherwise imperfect system requirements specifications; system requirements that do not provide for change as user needs evolve over time, and poorly defined management structures. The major difficulties associated with the production of trustworthy systems have more to do with the organization and management of complexity than with direct technological concerns. Thus, while it is necessary to have an appropriate set of quality technological methods and tools, it is also very important that they be used within a well chosen set of lifecycle processes and set of systems management strategies that guide the execution of these processes (Sage 1995; Sage and Rouse 1999a).

Because a decision support system is intended to be used by decision makers with varying experiential familiarity and expertise with respect to a particular task and decision situation, it is especially important that a DSS design consider the variety of issue representations or frames that decision makers may use to describe issues, the operations that may be performed on these representations to enable formulation analysis and interpretation of the decision situation, the automated memory aids that support retention of the various results of operations on the representations, and the control mechanisms that assist decision makers in using these representations, operations, and memory aids. A very useful control mechanism results in the construction of heuristic procedures, perhaps in the form of a set of production rules, to enable development of efficient and effective standard operating policies to be issued as staff directives. Other control mechanisms are intended to encourage the decision maker to personally control and direct use of the DSS and also to acquire new skills and rules based on the formal reasoning-based knowledge that is called forth through use of a decision support system. This process independent approach toward development of the necessary capabilities of a specific DSS is due to Sprague and Carlson (1982) and is known as the ROMC approach (representations, operations, memory aids, and control mechanisms). Figure 3 illustrates the ROMC elements, together with the three principal components (DBMS, MBMS, and DGMS) of a DSS.

2. DATABASE MANAGEMENT SYSTEMS

As we have noted, a database management system is one of the three fundamental technological components in a decision support system. Figure 3 indicates the generic relationship among these components, or subsystems. We can consider a database management system as composed of a

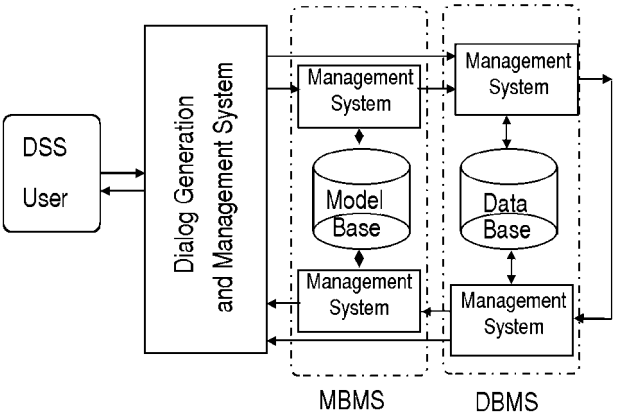

Figure 4 Expanded View of DSS Indicating Database and Management System for DBMS and Model Base and Management System for MBMS.

database (DB) and a management system (MS). This sort of expansion holds for the model base management system also. Figure 4 indicates the resulting expanded view of a DSS. The DBMS block itself can be expanded considerably, as can the other two subsystems of a DSS. Figure 5 indicates one possible expansion to indicate many of the very useful components of a database management system that we will briefly examine later in this section.

Three major objectives for a DBMS are data independence, data redundancy reduction, and data resource control, such that software to enable applications to use the DBMS and the data processed are independent. If this is not accomplished, then such simple changes to the data structure as adding four digits to the ZIP code number in an address might require rewriting many applications programs. The major advantage to data independence is that DSS developers do not need to be explicitly concerned with the details of data organization in the computer or how to access it explicitly for information processing purposes, such as query processing. Elimination or reduction of data redundancy will assist in lessening the effort required to make changes in the data in a database. It may also assist, generally greatly, in eliminating the inconsistent data problem that often results from updating data items in one part of a database but (unintentionally) not updating this same data that

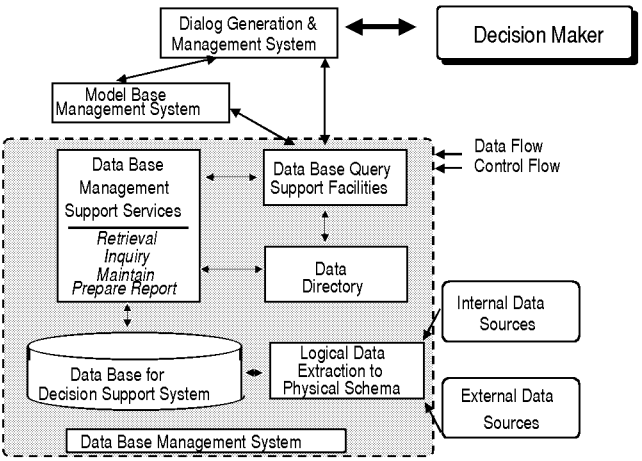

Figure 5 Generic Components in Decision Support System, with Expansion of Database Management System.

exists elsewhere in the database because of data redundancy. With many people potentially using the same database, resource control is essential. The presence of these three features in a DBMS is the major factor that differentiates it from a file management system.

The management system for a database is composed of the software that is beneficial to the creation, access, maintenance, and updating of a database. A database contains data that are of value to an individual or an organization and that an individual or an organization desires to maintain. Maintenance should be such that the data survive even when the DBMS system hardware and/or software fails. Maintenance of data is one of the important functions provided for in DBMS design.

There are many tasks that we desire to perform using a database. These five are especially important:

1. *Capturing* relevant data for use in the database
2. *Selecting* relevant data from the database
3. *Aggregating* data to form totals, averages, moments, and other items that support decision making
4. *Estimating, forecasting, and predicting* in order to obtain extrapolations of events into the future, and such other activities as
5. *Optimizing* in order to enable selection of a ''best'' alternative

We note that these database raise issues that are associated with the model base management system. In a similar way, the dialog generation and management system determines how data is viewed and is therefore also important for use of a DBMS.

2.1. DBMS Design, Selection, and Systems Integration

As with any information systems engineering-based activity, DBMS design should start with an identification of the DBMS design situation and the user requirements. From this, identification of the logical or conceptual data requirements follows specification of a logical database structure in accordance with what is known as a data definition language (DDL). After this, the physical database structure is identified. This structure must be very concerned with specific computer hardware characteristics and efficiency considerations. Given these design specifications, an operational DBMS is constructed and DBMS operation and maintenance efforts begin. The logical database design and physical database design efforts can each be disaggregated into a number of related activities. The typical database management system lifecycle will generally follow one of the systems engineering development life cycles discussed in the literature (Sage 1992, 1995; Sage and Rouse 1999a).

The three important DBMS requirements—data independence, redundancy reduction, and increased data resource control—are generally applicable both to logical data and to physical data. It is highly desirable, for example, to be able to change the structure of the physical database without affecting other portions of the DBMS. This is called physical data independence. In a similar way, logical data independence denotes the ability of software to function using a given applications-oriented perspective on the database even though changes in other parts of the logical structure have been made. The requirements specification, conceptual design, logical design, and physical design phases of the DBMS development life cycle are specifically concerned with satisfaction of these requirements.

A number of questions need to be asked and answered successfully in order to design an effective DBMS. Among these are the following (Arden 1980):

1. Are there data models that are appropriate across a variety of applications?
2. What DBMS designs that enable data models to support logical data independence?
3. What DBMS designs enable data models to support logical data independence, and what are the associated physical data transformations and manipulations?
4. What features of a data description language will enable a DBMS designer to control independently both the logical and physical properties of data?
5. What features need to be incorporated into a data description language in order to enable errors to be detected at the earliest possible time such that users will not be affected by errors that occur at a time prior to their personal use of the DBMS?
6. What are the relationships between data models and database security?
7. What are the relationships between data models and errors that may possibly be caused by concurrent use of the database by many users?
8. What are design principles that will enable a DBMS to support a number of users having diverse and changing perspectives?
9. What are the appropriate design questions such that applications programmers, technical users, and DBMS operational users are each able to function effectively and efficiently?

The bottom line question that summarizes all of these is, How does one design a data model and data description language to enable efficient and effective data acquisition, storage, and use? There are many related questions; one concerns the design of what are called standard query languages (SQLs) such that it is possible to design a specific DBMS for a given application.

It is very important that, whenever possible, a specific DBMS be selected prior to design of the rest of the DSS. There are a variety of reasons why this is quite desirable. The collection and maintenance of the data through the DSS are simplified if there is a specified single DBMS structure and architecture. The simplest situation of all occurs when all data collection (and maintenance) is accomplished prior to use of the DSS. The DBMS is not then used in an interactive manner as part of DSS operation. The set of database functions that the DSS needs to support is controlled when we have the freedom to select a single DBMS structure and architecture prior to design of the rest of the DSS. The resulting design of the DSS is therefore simplified. Further, the opportunities for data sharing among potentially distributed databases are increased when the interoperability of databases is guaranteed. Many difficulties result when this is not possible. Data in a DBMS may be classified as *internal data,* stored in an internal database, and *external data,* stored in an external database. Every individual and organization will necessarily have an internal database. While no problem may exist in ensuring DBMS structure and architecture compatibility for internal data, this may be very difficult to do for external data. If both of these kinds of data can be collected and maintained prior to use of a DSS, then there will generally be no data integration needs. Often, however, this will not be possible. Because we will often be unable to control the data structure and architecture of data obtained externally, the difficulties we cite will often be real, especially in what are commonly called real-time, interactive environments. When we have DBMSs that are different in structure and architecture, data sharing across databases is generally difficult, and it is often then necessary to maintain redundant data. This can lead to a number of difficulties in the systems integration that is undertaken to ensure compatibility across different databases.

In this chapter, as well as in much DSS and information system design in practice, we may generally assume that the DBMS is preselected prior to design of the rest of the DSS and that the same DBMS structure and architecture are used for multiple databases that may potentially be used in the DSS. This is often appropriate, for purposes of DSS design, since DBMS design technology (Rob and Coronel 1997; Kroenke 1998; Date 1999; Purba 1999; Atzeni et al. 2000) is now relatively mature in contrast to MBMS and DGMS design. This does not suggest that evolution and improvements to DBMS designs are not continuing. It is usually possible, and generally desirable, to select a DBMS, based on criteria we will soon discuss, and then design the MBMS and DGMS based on the existing DBMS. This will often, but surely not always, allow selection of commercial off-the-shelf (COTS) DBMS software. The alternate approach of designing a MBMS and DGMS first and then specifying the requirements for a DBMS based on these is possible and may in some cases be needed. Given the comparatively developed state of DBMS software development as contrasted with MBMS and DGMS software, this approach will usually be less desirable from the point of view of design economy in engineering the DSS.

2.2. Data Models and Database Architectures

We will now expand very briefly on our introductory comments concerning data model representations and associated architectures for database management systems. Some definitions are appropriate. A data model defines the types of data objects that may be manipulated or referenced within a DBMS. The concept of a logical record is a central one in all DBMS designs. Some DBMS designs are based on mathematical relations, and the associated physical database is a collection of consistent tables in which every row is a record of a given type. This is an informal description of a relational database management system, a DBMS type that is a clear outgrowth of the file management system philosophy. Other DBMS may be based on hierarchical or network structures, which resemble the appearance of the data in the user's world and may contain extensive graphical and interactive support characteristics.

There are several approaches that we might take to describing data models. Date (1983, 1999), for example, discusses a three-level representation in which the three levels of data models are:

1. An external model, which represents a data model at the level of the user's application and is the data model level closest and most familiar to users of a DBMS or DSS
2. A conceptual model, which is an aggregation model that envelopes several external models
3. An internal model, which is a technical-level model that describes how the conceptual model is actually represented in computer storage

Figure 6 is a generic diagram that indicates the mappings and data translations needed to accommodate the different levels of data models and architectures. The relations between the various levels, called mappings. These specify and describe the transformations that are needed in order to obtain one model from another. The user supplies specifications for the source and target data structures in

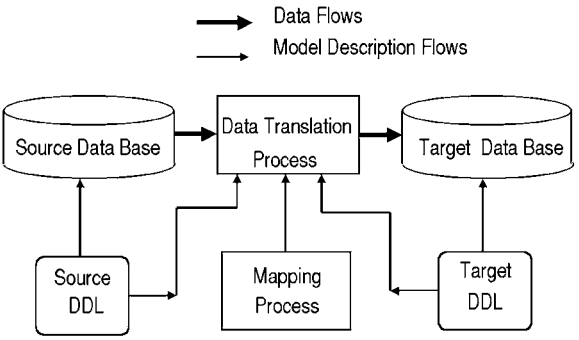

Figure 6 Data Transforms and Model Mappings.

a data description language (DDL) and also describes the mapping that is desired between source and target data. Figure 7 represents this general notion of data transformation. This could, for example, represent target data in the form of a table that is obtained from a source model composed of a set of lists.

Figure 7 is a very simple illustration of the more general problem of mapping between various schemas. Simply stated, a schema is an image used for comparison purposes. A schema can also be described as a data structure for representing generic concepts. Thus, schemas represent knowledge about concepts and are structurally organized around some theme. In terms appropriate here, the user of a database must interpret the real world that is outside of the database in terms of real-world objects, or entities and relationships between entities, and activities that exist and that involve these objects. The database user will interact with the database in order to obtain needed data for use or, alternatively, to store obtained data for possible later use. But a DBMS cannot function in terms of real objects and operations. Instead, a DBMS must use data objects, composed of data elements and relations between them, and operations on data objects. Thus, a DBMS user must perform some sort of mapping or transformation from perceived real objects and actions to those objects' and actions' representations that will be used in the physical database.

The single-level data model, which is conceptually illustrated in Figure 7, represents the nature of the data objects and operations that the user understands when receiving data from the database. In this fashion the DBMS user models the perceived real world. To model some action sequence, or the impact of an action sequence on the world, the user maps these actions to a sequence of operations that are allowed by the specific data model. It is the data manipulation language (DML) that provides the basis for the operations submitted to the DBMS as a sequence of queries or programs. The development of these schemas, which represent logical data, results in a DBMS architecture or DBMS framework, which describes the types of schemas that are allowable and the way in which these schemas are related through various mappings. We could, for example, have a two-schema framework or a three-schema framework, which appears to be the most popular representation at this time. Here

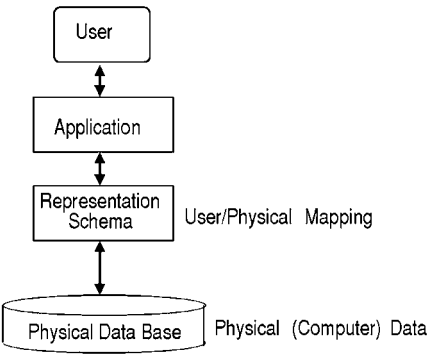

Figure 7 Single-Level Model of Data Schema.

the external schemas define the logical subset of the database that may be presented to a specific DBMS user. The conceptual schemas define conceptual models as represented in the database. The internal schema describes physical data structures in the database. These data structures provide support to the conceptual models. The mappings used establish correspondence between various objects and operations at the three levels. If consistency of the conceptual models is to be ensured, we must be able to map the internal, or physical, and external, or logical, schemas to the conceptual schemas.

Useful documentation about the database structure and architecture is provided through the various schemas, which represent explicit data declarations. These declarations represent data about data. The central repository in which these declarations are kept is called a data dictionary or data directory, and is often represented by the symbol DD. The data directory is a central repository for the definitions of the schemas and the mappings between schemas. Generally, a data dictionary can be queried in the same manner as can the database, thereby enhancing the ability of the DBMS user to pose questions about the availability and structure of data. It is often possible to query a data directory with a high-level, or fourth-generation, query language.

A data dictionary is able to tell us what the records in the data dictionary consist of. It also contains information about the logical relationships that pertain to each of the particular elements in the database. The development of a data dictionary generally begins with formation of lists of desired data items or fields that have been grouped in accordance with the entities that they are to represent. A name is assigned for each of these lists, and a brief statement of the meaning of each is provided for later use. Next, the relationships between data elements should be described and any index keys or pointers should be determined. Finally, the data dictionary is implemented within the DBMS. In many ways, a data dictionary is the central portion of a DBMS. It performs the critical role of retaining high-level information relative to the various applications of the DBMS and thereby enables specification, control, review, and management of the data of value for decision making relative to specific applications.

For very large system designs, it is necessary that the data dictionary development process be automated. A typical data dictionary for a large system may include several thousand entries. It is physically impossible to manually maintain a dictionary of this size or to retain consistent and unambiguous terms for each data element or composite of data elements. Therefore, automated tools are needed for efficient and effective development and maintenance of a data dictionary. These are provided in contemporary DBMSs.

This ability to specify database structures, through use of schemas, enables efficient and effective management of data resources. This is necessary for access control. The use of one or more subschemas generally simplifies access to databases. It may also provide for database security and integrity for authorized users of the DBMS. Since complex physical (computer) structures for data may be specified, independent of the logical structure of the situation that is perceived by DBMS users, it is thereby possible to improve the performance of an existing and operational database without altering the user interface to the database. This provides for simplicity in use of the DBMS.

The data model gives us the constructs that provide a foundation for the development and use of a database management system. It also provides the framework for such tools and techniques as user interface languages. The user of these languages is often called a database administrator (DBA). There are three types of user interface languages:

1. *Data definition languages* (DDLs) provide the basis for definition of schemas and subschemas.
2. *Data manipulation languages* (DMLs) are used to develop database applications.
3. *Data query languages* (DQLs) or simply *query languages* (QLs) are used to write queries and reports. Of course, it is possible to combine a DDL, DML, and DQL into a single database language.

In general, a data model is a paradigm for representation, storing, organizing, and otherwise managing data in a database. There are three component sets in most data models:

1. A set of data structures that define the fields and records that are allowed in the database. Examples of data structures include lists, tables, hierarchies, and networks.
2. A set of operations that define the admissible manipulations that are applied to the fields and records that comprise the data structures. Examples of operations include *retrieve, combine, subtract, add,* and *update*.
3. A set of integrity rules that define or constrain allowable or legal states or changes of state for the data structures that must be protected by the operations.

There are three generically different types of data model representations and several variants within these three representations. Each of these is applicable as an internal, external, or conceptual model. We will be primarily concerned with these three modeling representations as they affect the

external, or logical, data model. This model is the one with which the user of a specific decision support system interfaces. For use in a decision support system generator, the conceptual model is of importance because it is the model that influences the specific external model that various users of a DSS will interface with after an operational DSS is realized. This does not mean that the internal data model is unimportant. It is very important for the design of a DBMS. Through its data structures, operations, and integrity constraints, the data model controls the operation of the DBMS portion of the DSS.

The three fundamental data models for use in the external model portion of a DSS are record-based models, structurally based models, and expert system-based models. Each of these will now be briefly described.

2.2.1. Record-Based Models

We are very accustomed to using forms and reports, often prepared in a standard fashion for a particular application. Record-based models are computer implementations of these spreadsheet-like forms. Two types can be identified. The first of these, common in the early days of file processing systems (FPSs) or file management systems (FMSs), is the *individual record model*. This is little more than an electronic file drawer in which records are stored. It is useful for a great many applications. More sophisticated, however, is the relational database data model, in which mathematical relations are used to electronically ''cut and paste'' reports from a variety of files. Relational database systems have been developed to a considerable degree of sophistication, and many commercial products are available. Oracle and Informix are two leading providers.

The individual record model is surely the oldest data model representation. While the simple single-record tables characteristic of this model may appear quite appealing, the logic operations and integrity constraints that need to be associated with the data structure are often undefined and are perhaps not easily defined. Here, the data structure is simply a set of records, with each record consisting of a set of fields. When there is more than a single type of record, one field contains a value that indicates what the other fields in the record are named.

The relational model is a modification of the individual record model that limits its data structures and thereby provides a mathematical basis for operation on records. Data structures in a relational database may consist only of relations, or field sets that are related. Every relation may be considered as a table. Each row in the table is a record or tuple. Every column in each table or row is a field or attribute. Each field or attribute has a domain that defines the admissible values for that field.

Often there is only a modest difference in structure between this relational model and the individual record model. One difference is that fields in the various records of the individual record model represent relationships, whereas relationships among fields or attributes in a relational model are denoted by the name of the relation.

While the structural differences between the relational model and the individual record model are minimal, there are major differences in the way in which the integrity constraints and operations may affect the database. The operations in a relational database form a set of operations that are defined mathematically. The operations in a relational model must operate on entire relations, or tuples, rather than only on individual records. The operations in a relational database are independent of the data structures, and therefore do not depend on the specific order of the records or the fields. There is often controversy about whether or not a DBMS is truly relational. While there are very formal definitions of a relational database, a rather informal one is sufficient here. A relational database is one described by the following statements.

1. Data are presented in tabular fashion without the need for navigation links, or pointer structures, between various tables.
2. A relational algebra exists and can be used to prepare joins of logical record files automatically.
3. New fields can be added to the database without the necessity of rewriting any programs that used previous versions of the database.

If a DBMS does not satisfy these three criteria, then it is almost surely NOT a relational database.

2.2.2. Structural Models

In many instances, data are intended to be associated with a natural structural representation. A typical hierarchical structure is that of a classic organization. A more general representation than a hierarchy, or tree, is known as a *network*. It is often possible to represent a logical data model with a hierarchical data structure. In a hierarchical model, we have a number of nodes that are connected by links. All links are directed to point from ''child'' to ''parent,'' and the basic operation in a hierarchy is that of searching a tree to find items of value. When a query is posed with a hierarchical database, all branches of the hierarchy are searched and those nodes that meet the conditions posed in the query are noted and then returned to the DBMS system user in the form of a report.

Some comparisons of a hierarchical data model with a relational data model are of interest here. The structures in the hierarchical model represent the information that is contained in the fields of the relational model. In a hierarchical model, certain records must exist before other records can exist. The hierarchical model is generally required to have only one key field. In a hierarchical data model, it is necessary to repeat some data in a descendant record that need be stored only once in a relational database regardless of the number of relations. This is so because it is not possible for one record to be a descendant of more than one parent record. There are some unfortunate consequences of the mathematics involved in creating a hierarchical tree, as contrasted with relations among records. Descendants cannot be added without a root leading to them, for example. This leads to a number of undesirable characteristic properties of hierarchical models that may affect our ability to easily add, delete, and update or edit records.

A network model is quite similar to but more general than the hierarchical model. In a hierarchy, data have to be arranged such that one child has only one parent, and in many instances this is unrealistic. If we force the use of a hierarchical representation in such cases, data will have to be repeated at more than one location in the hierarchical model. This redundancy can create a number of problems. A record in a network model can participate in several relationships. This leads to two primary structural differences between hierarchical and network models. Some fields in the hierarchical model will become relationships in a network model. Further, the relationships in a network model are explicit and may be bidirectional. The navigation problem in a network data model can become severe. Because search of the database can start at several places in the network, there is added complexity in searching, as well.

While spreadsheet type relational records are very useful for many purposes, it has been observed (Kent 1979) that not all views of a situation, or human cognitive maps, can be represented by relational data models. This has led to interest in entity and object-oriented data models and to data models based on artificial intelligence techniques. The basic notion in the use of an ER model is to accomplish database design at the conceptual level, rather than at the logical and/or physical levels. ER models (Chen 1976) are relatively simple and easy to understand and use, in large part because of the easy graphical visualization of the database model structure. Also, ER modeling capability is provided by many computer aided software engineering (CASE) tools. While such limitations as lack of a very useful query language are present (Atzeni and Chen 1983), much interest in ER data models, especially at the conceptual level, exists at this time. Figure 8 illustrates the conceptual orientation of the ER modeling approach.

ER models are based on two premises: (a) information concerning entities and relationships exists as a cognitive reality, and (b) this information may be structured using entities and relationships among them as data. An entity relationship data model is a generalization of the hierarchical and network data models. It is based on well-established graph theoretic developments and is a form of structured modeling. The major advantage of the ER approach is that it provides a realistic view of the structure and form for the DBMS design and development effort. This should naturally support the subsequent development of appropriate software. In addition, the approach readily leads to the

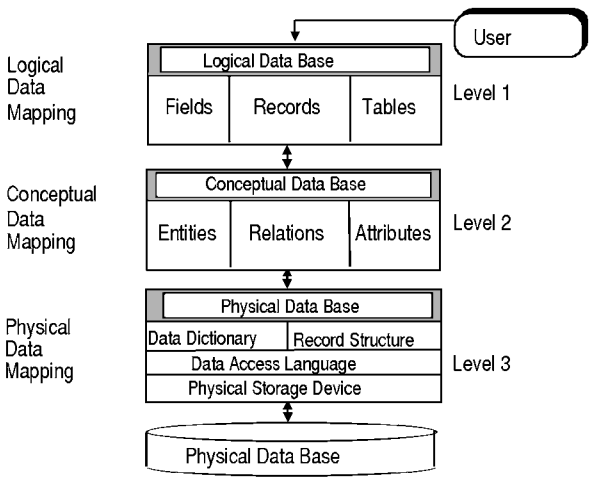

Figure 8 The Potential Role of ER Data Models at the Conceptual Data Level.

development of the data dictionary. The primary difficulties that may impede easy use of the ER method are in the need for selection of appropriate verbs for use as contextual relationships, elimination of redundancy of entities, and assurances that all of the needed ER have been determined and properly used. Often a considerable amount of time may be needed to identify an appropriate set of entities and relations and obtain an appropriate structural model in the form of an ER diagram.

2.2.3. Expert and Object-Oriented Database Models

An expert database model, as a specialized expert database system, involves the use of artificial intelligence technology. The goal in this is to provide for database functionality in more complex environments that require at least some limited form of intelligent capability. To allow this may require adaptive identification of system characteristics, or learning over time as experience with an issue and the environment into which it is embedded increases. The principal approach that has been developed to date is made up of an object-oriented database (OODB) design with any of the several knowledge representation approaches useful in expert system development. The field is relatively new compared to other database efforts and is described much more fully in Kerschberg (1987, 1989), Myloupoulos and Brodie (1989), Parsaye et al. (1989), Debenham (1998), Poe et al. (1998), and Darwen and Date (1998).

The efforts to date in the object oriented area concern what might be more appropriately named object-oriented database management systems design (OODBMS). The objective in OODBMS design is to cope with database complexity, potentially for large distributed databases, through a combination of object-oriented programming and expert systems technology. Object-oriented design approaches generally involve notions of separating internal computer representations of elements from the external realities that lead to the elements. A primary reason for using object-oriented language is that it naturally enables semantic representations of knowledge through use of 10 very useful characteristics of object-oriented approaches (Parsaye et al. 1989): information hiding, data abstraction, dynamic binding and object identity, inheritance, message handling, object oriented graphical interfaces, transaction management, reusability, partitioning or dividing or disaggregating an issue into parts, and projecting or describing a system from multiple perspectives or viewpoints. These could include, for example, social, political, legal, and technoeconomic perspectives (Sage 1992).

There are at least two approaches that we might use in modeling a complex large-scale system: (1) functional decomposition and structuring and (2) purposeful or object decomposition and structuring. Both approaches are appropriate and may potentially result in useful models. Most models of real-world phenomena tend to be purposeful. Most conventional high-level programming languages are functionally, or procedurally, oriented. To use them, we must write statements that correspond to the functions that we wish to provide in order to solve the problem that has been posed. An advantage of object decomposition and structuring is that it enables us to relate more easily the structure of a database model to the structure of the real system. This is the case if we accomplish our decomposition and structuring such that each module in the system or issue model represents an object or a class of objects in the real issue or problem space. Objects in object-oriented methodology are not unlike elements or nodes in graph theory and structural modeling. It is possible to use one or more contextual relations to relate elements together in a structural model. An object may be defined as a collection of information and those operations that can be performed upon it. We request an object to perform one of its allowable operations by instructing it with a message.

Figure 9 illustrates the major conceptual difference between using a conventional programming approach and using an object-oriented approach for construction of a DBMS. In the conventional approach, procedures are at the nexus and procedures update and otherwise manipulate data and return values. In the object-oriented approach, the collection of independent objects are at the nexus and communicate with each other through messages or procedures. Objects investigate requests and behave according to these messages. Object-oriented design often provides a clear and concise interface to the problem domain in that the only way to interact with an object is through the operations or messages to the object. These messages call for operations that may result in a change of state in the object in question. This message will affect the particular object called and only that one, as no other object is affected. This provides a high degree of modularity and increased ability to verify and validate outcomes and thus provides an increased sense of reliability in the resulting DBMS design. Object-oriented languages are, for the most part, very high-level languages used to accomplish precisely the same results as high-level languages. By focusing upon the entities of objects and the relationships between objects, they often provide a simpler way to describe precisely those elements needed in detailed design procedures.

Object-oriented DBMS design is based on appropriate linking of objects, or data items or entities, and the operations on these, such that the information and processing is concentrated on the object classes, attributes, and messages that transfer between them. The features that set object-oriented approaches from other approaches are the capability of object-oriented languages to support abstraction, information hiding, and modularity. The items used in object-oriented DBMS design are objects,

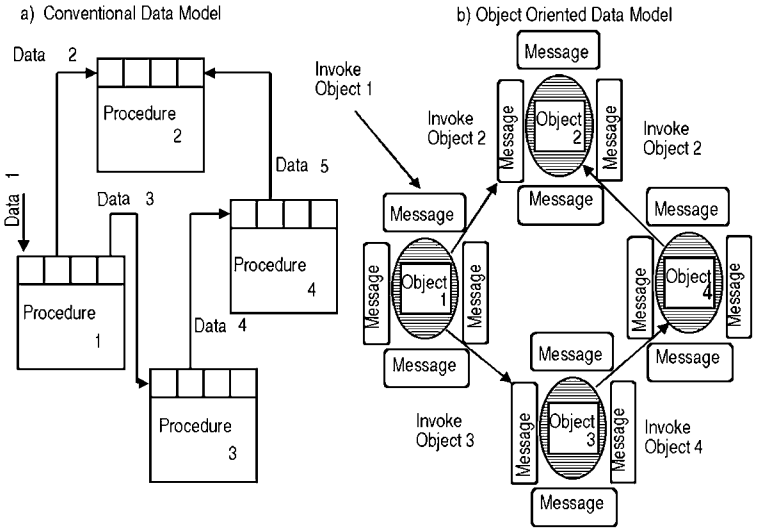

Figure 9 Conventional and Object-Oriented Data Models.

abstracts or physical entities that pertain to the domain of the system; attributes, or characteristics of objects; operations, or dynamic entities that may change with time; and messages, or requests to an object to perform an operation. Objects represent such real-world entities as machines, files, products, signals, persons, things, and places. They may be either physical entities or abstract representations. The attributes are characteristics that describe the properties ascribed to objects. Each attribute may be dynamically associated with a numerical value, and the combination of these values together with the description of the object in the problem domain presents the state of the object. Thus, the attributes are related to the object as subobjects. Attributes include such things as the name of the object, the number of specific objects in a file, or the name for the place, and the like. The basic attribute, one that may not be further decomposed, is the primitive type of object or subobject. Attributes may also be nonnumeric. Operations consist of processes and data structures that apply to the object to which it is directed. These are generally dynamic entities whose value may change over time. Each object may be subjected to a number of operations that provide information relative to control and procedural constructs that are applied to the object. Defining an object such as to have a private part and then assigning a message to address the appropriate processing operation enables us to achieve information hiding. Messages are passed between objects in order to change the state of the object, address the potentially hidden data parts of an object, or otherwise modify an object.

Coad and Yourdon (1990) identify five steps associated with implementing an object-oriented approach:

1. Identify objects, typically by examining the objects in the real world.
2. Identify structures, generally through various abstracting and partitioning approaches that result in a classification structure, an assembly structure, or a combination of these.
3. Identify subjects through examining objects and their structures to obtain this more complex abstract view of the issue. Each classification structure and each assembly structure will comprise one subject.
4. Identify attributes that impart important aspects of the objects that need to be retained for all instances of an object.
5. Identify services such that we are aware of occurrence services, creation or modification of instances of an object, calculation services, or monitoring of other processes for critical events or conditions.

Steps such as these should generally be accomplished in an iterative manner because there is no unique way to accomplish specification of a set of objects, or structural relations between objects.

A major result from using object-oriented approaches is that we obtain the sort of knowledge representation structures that are commonly found in many expert systems. Thus, object-oriented

design techniques provide a natural interface to expert system-based techniques for DBMS design. This is so because objects, in object-oriented design, are provided with the ability to store information such that learning over time can occur; process information by initiating actions in response to messages; compute and communicate by sending messages between objects; and generate new information as a result of communications and computations. Object-oriented design also lends itself to parallel processing and distributed environments. Object-oriented design and analysis is a major subject in contemporary computer and information system subject areas and in many application domains as well (Firesmith 1993; Sullo 1994; Jacobson et al. 1995; Zeigler 1997).

2.3. Distributed and Cooperative Databases

We have identified the three major objectives for a DBMS as data independence, data redundancy reduction, and data resource control. These objectives are important for a single database. When there are multiple databases potentially located in a distributed geographic fashion, and potentially many users of one or more databases, additional objectives arise, including:

1. Location independence or transparency to enable DBMS users to access applications across distributed information bases without the need to be explicitly concerned with where specific data is located
2. Advanced data models, to enable DBMS users to access potentially nonconventional forms of data such as multidimensional data, graphic data, spatial data, and imprecise data
3. Extensible data models, which will allow new data types to be added to the DBMS, perhaps in an interactive real-time manner, as required by specific applications.

An important feature of a distributed database management systems (DDBMSs) is that provisions for database management are distributed. Only then can we obtain the needed "fail-safe" reliability and "availability" even when a portion of the system breaks down. There are a number of reasons why distributed databases may be desirable. These include and are primarily related to distributed users and cost savings. Some additional costs are also involved, and these must be justified.

A distributed database management system will generally look much like replicated versions of a more conventional single-location database management system. We can thus imagine replicated versions of Figure 7. For simplicity, we show only the physical database, the database access interface mechanism, and the data dictionary for each database. Figure 10 indicates one possible conceptual

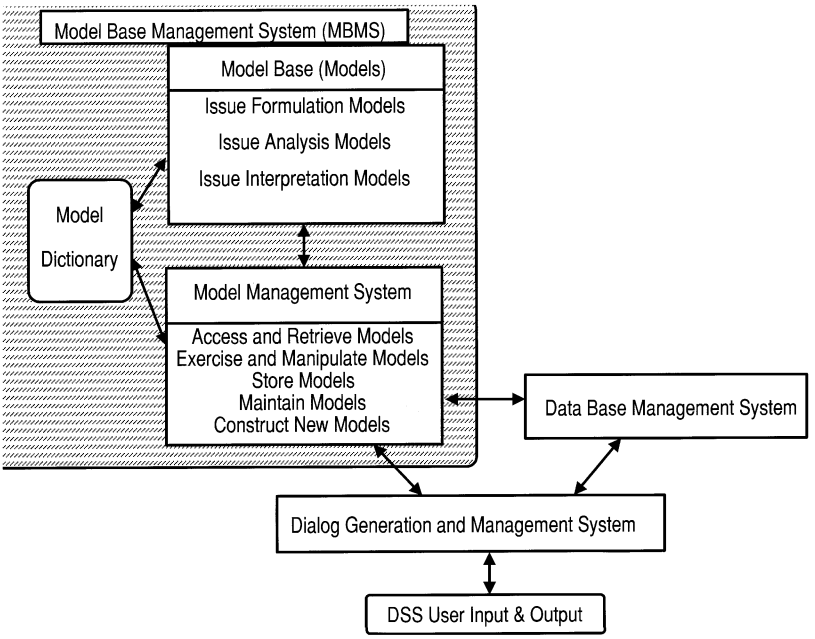

Figure 10 Prototypical Structure of Model Management System.

architecture of a distributed database in which there are two requests for data being simultaneously submitted. Through use of protocols, all requests for data are entered as if those data were stored in the database of the requesting user. The data dictionaries of the distributed system are responsible for finding the requested data elements and delivering them to the requesting user. All of these auxiliary requests are accomplished in a manner that is transparent to the requesting database user. Data transmission rate concerns must be resolved in order for this to be done satisfactorily. Potentially, however, real-time access to all of the data in the entire distributed system can be provided to any local user.

It is important to note that completion of the above steps does not transfer the requested data into the database of the requesting user, except perhaps in some temporary storage fashion. The very good reason why this is not done is that it would result in database redundancy and also increase database security difficulties.

An alternate approach to this distributing of data is to use what is often called cooperative processing or cooperative database management. This involves central database and distributed database concepts, blended to produce better results than can be had with either approach. Central to this are various approaches for the distributing and coordinating of data. We could use function, geography, or organizational level as the basis for distributing and cooperating, and possible system configurations may be based upon background communications, microcomputer-based front-end processing for host applications, and peer-to-peer cooperative processing.

The database component of a DSS provides the knowledge repository that is needed for decision support. Some sort of management system must be associated with a database in order to provide the intelligent access to data that is needed. In this section we have examined a number of existing constructs for database management systems. We now turn to the model-based portion of a DSS.

3. MODEL BASE MANAGEMENT SYSTEMS

There are four primary objectives of a DBMS:

1. To manage a large quantity of data in physical storage
2. To provide logical data structures that interact with humans and are independent of the structure used for physical data storage
3. To reduce data redundancy and maintenance needs and increase flexibility of use of the data, by provision of independence between the data and the applications programs that use it
4. To provide effective and efficient access to data by users who are not necessarily very sophisticated in the microlevel details of computer science.

Many support facilities will typically be provided with a DBMS to enable achievement of these purposes. These include data dictionaries to aid in internal housekeeping and information query, retrieval, and report generation facilities to support external use needs.

The functions of a model base management system (MBMS), a structure for which is illustrated in Figure 10, are quite analogous to those of a DBMS. The primary functions of a DBMS are separation of system users, in terms of independence of the application, from the physical aspects of database structure and processing. In a similar way, a MBMS is intended to provide independence between the specific models that are used in a DSS and the applications that use them. The purpose of a MBMS is to transform data from the DBMS into information that is useful for decision making. An auxiliary purpose might also include representation of information as data such that it can later be recalled and used.

The term *model management system* was apparently first used over 15 years ago (Will 1975). Soon thereafter, the MBMS usage was adopted in Sprague and Carlson (1982) and the purposes of an MBMS were defined to include creation, storage, access, and manipulation of models. Objectives for a MBMS include:

1. To provide for effective and efficient creation of new models for use in specific applications
2. To support maintenance of a wide range of models that support the formulation, analysis, and interpretation stages of issue resolution
3. To provide for model access and integration, within models themselves as well as with the DBMS
4. To centralize model base management in a manner analogous to and compatible with database management
5. To ensure integrity, currency, consistency, and security of models.

Just as we have physical data and logical data processing in a DBMS, so also do we have two types of processing efforts in a MBMS: model processing and decision processing (Applegate et al.

1986). A DSS user would interact directly with a decision processing MBMS, whereas the model processing MBMS would be more concerned with provision of consistency, security, currency, and other technical modeling issues. Each of these supports the notion of appropriate formal use of models that support relevant aspects of human judgment and choice.

Several ingredients are necessary for understanding MBMS concepts and methods. The first of these is a study of formal analytical methods of operations research and systems engineering that support the construction of models that are useful in issue formulation, analysis, and interpretation. Because presenting even a small fraction of the analytical methods and associated models in current use would be a mammoth undertaking, we will discuss models in a somewhat general context. Many discussions of decision relevant models can be found elsewhere in this Handbook, most notably in Chapters 83 through 102. There are also many texts in this area, as well as two recent handbooks (Sage and Rouse 1999a; Gass and Harris 2000).

3.1. Models and Modeling

In this section, we present a brief description of a number of models and methods that can be used as part of a systems engineering-based approach to problem solution or issue resolution. Systems engineering (Sage 1992, 1995; Sage and Rouse 1999a; Sage and Armstrong 2000) involves the application of a general set of guidelines and methods useful to assist clients in the resolution of issues and problems, often through the definition, development, and deployment of trustworthy systems. These may be product systems or service systems, and users may often deploy systems to support process-related efforts. Three fundamental steps may be distinguished in a formal systems-based approach that is associated with each of these three basic phases of system engineering or problem solving:

1. Problem or issue formulation
2. Problem or issue analysis
3. Interpretation of analysis results, including evaluation and selection of alternatives, and implementation of the chosen alternatives

These steps are conducted at a number of phases throughout a systems life cycle. As we indicated earlier, this life cycle begins with definition of requirements for a system through a phase where the system is developed to a final phase where deployment, or installation, and ultimate system maintenance and retrofit occur. Practically useful life cycle processes generally involve many more than three phases, although this larger number can generally be aggregated into the three basic phases of definition, development, and deployment. The actual engineering of a DSS follows these three phases of definition of user needs, development of the DSS, and deployment in an operational setting. Within each of these three phases, we exercise the basic steps of formulation, analysis, and interpretation. Figure 11 illustrates these three steps and phases and much more detail is presented in Sage (1992, 1995), Sage and Rouse (1999a), Sage and Armstrong (2000), and in references contained therein.

3.1.1. Issue, or Problem, Formulation Models

The first part of a systems effort for problem or issue resolution is typically concerned with problem or issue formulation, including identification of problem elements and characteristics. The first step in issue formulation is generally that of definition of the problem or issue to be resolved. Problem

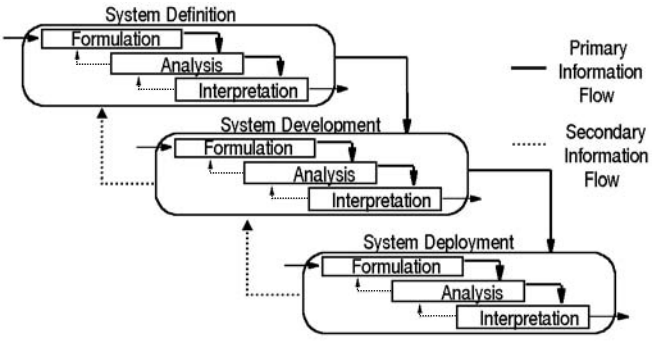

Figure 11 Basic Phases and Steps in Systems Engineering.

definition is generally an outscoping activity because it enlarges the scope of what was originally thought to be the problem. Problem or issue definition will ordinarily be a group activity involving those familiar with or impacted by the issue or the problem. It seeks to determine the needs, constraints, alterables, and social or organizational sectors affecting a particular problem and relationships among these elements.

Of particular importance are the identification and structuring of objectives for the policy or alternative that will ultimately be chosen. This is often referred to as *value system design,* a term apparently first used by Hall (1969) in one of his seminal works in systems engineering. Generation of options (Keller and Ho 1990) or alternative courses of action is a very important and often neglected portion of a problem solving effort. This option generation, or system or alternative synthesis, step of issue formulation is concerned primarily with the answers to three questions:

1. What are the alternative approaches for attaining objectives?
2. How is each alternative approach described?
3. How do we measure attainment of each alternative approach?

The answers to these three questions lead to a series of alternative activities or policies and a set of activities measures.

Several of the methods that are particularly helpful in the identification of issue formulation elements are based on principles of collective inquiry (McGrath 1984). The term *collective inquiry* refers to the fact that a group of interested and motivated people is brought together in the hope that they will stimulate each other's creativity in generating elements. We may distinguish two groups of collective inquiry methods here, depending upon whether or not the group is physically present at the same physical location.

3.1.1.1. Brainstorming, Synectics, and Nominal Group Techniques These approaches typically require a few hours of time, a group of knowledgeable people gathered in one place, and a group leader or facilitator. The nominal group technique is typically better than brainstorming in reducing the influence of dominant individuals. Both methods can be very productive: 50–150 ideas or elements may be generated in less than one hour. Synectics, based on problem analogies, might be very appropriate if there is a need for truly unconventional, innovative ideas. Considerable experience with the method is a requirement, however, particularly for the group leader. The nominal group technique is based on a sequence of idea generation, discussion, and prioritization. It can be very useful when an initial screening of a large number of ideas or elements is needed. Synectics and brainstorming are directly interactive group methods, whereas nominal group efforts are nominally interactive in that the members of the group do not directly communicate.

3.1.1.2. Questionnaires, Survey, and Delphi Techniques These three methods of collective inquiry do not require the group of participants to gather at one place and time, but they typically take more time to achieve results than the methods above. In most questionnaires and surveys a large number of participants is asked, on an individual basis, to generate ideas or opinions that are then processed to achieve an overall result. Generally no interaction is allowed among participants in this effort. Delphi usually provides for written anonymous interaction among participants in several rounds. Results of previous rounds are fed back to participants, and they are asked to comment, revise their views as desired, and so on. The results of using the Delphi technique can be very enlightening, but it usually takes several weeks or months to complete the effort.

Use of some of the many structuring methods, in addition to leading to greater clarity of the problem formulation elements, will typically lead also to identification of new elements and revision of element definitions. Most structuring methods contain an analytical component and may therefore be more properly labeled as analysis methods. The following element structuring aids are among the many modeling aids available that are particularly suitable for the issue formulation step.

There are many approaches to problem formulation (Volkema 1990). In general, these approaches assume that ''asking'' will be the predominant approach used to obtain issue formulation elements. Asking is often the simplest approach. Valuable information can often be obtained from observation of an existing and evolving system or from study of plans and other prescriptive documents. When these three approaches fail, it may be necessary to construct a ''trial'' system and determine issue formulation elements through experimentation and iteration with the trial system. These four methods (asking, study of an existing system, study of a normative systems, experimentation with a prototype system) are each very useful for information and system requirements determination (Davis 1982).

3.1.2. Models for Issue Analysis

The analysis portion of a DSS effort typically consists of two steps. First, the options or alternatives defined in issue formulation are analyzed to assess their expected impacts on needs and objectives. This is often called impact assessment or impact analysis. Second, a refinement or optimization effort

is often desirable. This is directed towards refinement or fine-tuning a potentially viable alternative through adjustment of the parameters within that alternative so as to obtain maximum performance in terms of needs satisfaction, subject to the given constraints.

Simulation and modeling methods are based on the conceptualization and use of an abstraction, or model, that hopefully behaves in a similar way as the real system. Impacts of alternative courses of action are studied through use of the model, something that often cannot easily be done through experimentation with the real system. Models are, of necessity, dependent on the value system and the purpose behind utilization of a model. We want to be able to determine the correctness of predictions based on usage of a model and thus be able to validate the model. There are three essential steps in constructing a model:

1. Determine those issue formulation elements that are most relevant to a particular problem.
2. Determine the structural relationships among these elements.
3. Determine parametric coefficients within the structure.

We should interpret the word ''model'' here as an abstract generalization of an object or system. Any set of rules and relationships that describes something is a model of that thing. The MBMS of a DSS will typically contain formal models that have been stored into the model base of the support system. Much has been published in the area of simulation realization of models, including a recent handbook (Banks 1998).

Gaming methods are basically modeling methods in which the real system is simulated by people who take on the roles of real-world actors. The approach may be very appropriate for studying situations in which the reactions of people to each others actions are of great importance, such as competition between individuals or groups for limited resources. It is also a very appropriate learning method. Conflict analysis (Fraser and Hipel 1984; Fang et al. 1993) is an interesting and appropriate game theory-based approach that may result in models that are particularly suitable for inclusion into the model base of a MBMS. A wealth of literature concerning formal approaches to mathematical games (Dutta 1999).

Trend extrapolation or time series forecasting models, or methods, are particularly useful when sufficient data about past and present developments are available, but there is little theory about underlying mechanisms causing change. The method is based on the identification of a mathematical description or structure that will be capable of reproducing the data. Then this description is used to extend the data series into the future, typically over the short to medium term. The primary concern is with input–output matching of observed input data and results of model use. Often little attention is devoted to assuring process realism, and this may create difficulties affecting model validity. While such models may be functionally valid, they may not be purposefully or structurally valid.

Continuous-time dynamic-simulation models, or methods, are generally based on postulation and qualification of a causal structure underlying change over time. A computer is used to explore long-range behavior as it follows from the postulated causal structure. The method can be very useful as a learning and qualitative forecasting device. Often it is expensive and time consuming to create realistic dynamic simulation models. Continuous-time dynamic models are quite common in the physical sciences and in much of engineering (Sage and Armstrong 2000).

Input-output analysis models are especially designed for study of equilibrium situations and requirements in economic systems in which many industries are interdependent. Many economic data formats are directly suited for the method. It is relatively simple conceptually, and can cope with many details. Input–output models are often very large.

Econometrics or macroeconomic models are primarily applied to economic description and forecasting problems. They are based on both theory and data. Emphasis is placed an specification of structural relations, based upon economic theory, and the identification of unknown parameters, using available data, in the behavioral equations. The method requires expertise in economics, statistics, and computer use. It can be quite expensive and time consuming. Macroeconomic models have been widely used for short- to medium-term economic analysis and forecasting.

Queuing theory and discrete event simulation models are often used to study, analyze, and forecast the behavior of systems in which probabilistic phenomena, such as waiting lines, are of importance. Queuing theory is a mathematical approach, while discrete-event simulation generally refers to computer simulation of queuing theory type models. The two methods are widely used in the analysis and design of systems such as toll booths, communication networks, service facilities, shipping terminals, and scheduling.

Regression analysis models and estimation theory models are very useful for the identification of mathematical relations and parameter values in these relations from sets of data or measurements. Regression and estimation methods are used frequently in conjunction with mathematical modeling, in particular with trend extrapolation and time series forecasting, and with econometrics. These methods are often also used to validate models. Often these approaches are called system identifi-

cation approaches when the goal is to identify the parameters of a system, within an assumed structure, such as to minimize a function of the error between observed data and the model response.

Mathematical programming models are used extensively in operations research systems analysis and management science practice for resource allocation under constraints, planning or scheduling, and similar applications. It is particularly useful when the best equilibrium or one-time setting has to be determined for a given policy or system. Many analysis issues can be cast as mathematical programming problems. A very significant number of mathematical programming models have been developed, including linear programming, nonlinear programming, integer programming, and dynamic programming. Many appropriate reference texts, including Hillier and Lieberman (1990, 1994), discuss this important class of modeling and analysis tools.

3.1.3. Issue Interpretation Models

The third step in a decision support systems use effort starts with evaluation and comparison of alternatives, using the information gained by analysis. Subsequently, one or more alternatives are selected and a plan for their implementation is designed. Thus, an MBMS must provide models for interpretation, including evaluation, of alternatives.

It is important to note that there is a clear and distinct difference between the refinement of individual alternatives, or optimization step of analysis, and the evaluation and interpretation of the sets of refined alternatives that result from the analysis step. In some few cases, refinement or optimization of individual alternative decision policies may not be needed in the analysis step. More than one alternative course of action or decision must be available; if there is but a single policy alternative, then there really is no decision to be taken at all. Evaluation of alternatives is always needed. It is especially important to avoid a large number of cognitive biases in evaluation and decision making. Clearly, the efforts involved in the interpretation step of evaluation and decision making interact most strongly with the efforts in the other steps of the systems process. A number of methods for evaluation and choice making are of importance. A few will be described briefly here.

Decision analysis (Raiffa 1968) is a very general approach to option evaluation and selection. It involves identification of action alternatives and possible consequences, identification of the probabilities of these consequences, identification of the valuation placed by the decision maker upon these consequences, computation of the expected value of the consequences, and aggregation or summarization of these values for all consequences of each action. In doing this we obtain an evaluation of each alternative act, and the one with the highest value is the most preferred action or option.

Multiple-attribute utility theory (Keeney and Raiffa 1976) has been designed to facilitate comparison and ranking of alternatives with many attributes or characteristics. The relevant attributes are identified and structured and a weight or relative utility is assigned by the decision maker to each basic attribute. The attribute measurements for each alternative are used to compute an overall worth or utility for each alternative. Multiple attribute utility theory allows for various types of worth structures and for the explicit recognition and incorporation of the decision maker's attitude towards risk in the utility computation.

Policy Capture (or *Social Judgment*) *Theory* (Hammond et al. 1980) has also been designed to assist decision makers in making values explicit and known. It is basically a descriptive approach toward identification of values and attribute weights. Knowing these, one can generally make decisions that are consistent with values. In policy capture, the decision maker is asked to rank order a set of alternatives. Then alternative attributes and their attribute measures or scores are determined by elicitation from the decision maker for each alternative. A mathematical procedure involving regression analysis is used to determine that relative importance, or weight, of each attribute that will lead to a ranking as specified by the decision maker. The result is fed back to the decision maker, who typically will express the view that some of his or her values, in terms of the weights associated with the attributes, are different. In an iterative learning process, preference weights and/or overall rankings are modified until the decision maker is satisfied with both the weights and the overall alternative ranking.

Many efforts have been made to translate the theoretical findings in decision analysis to practice. Klein (1998), Matheson and Matheson (1998), and Hammond et al. (1999) each provide different perspectives relative to these efforts.

3.2. Model Base Management

As we have noted, an effective model base management system (MBMS) will make the structural and algorithmic aspects of model organization and associated data processing transparent to users of the MBMS. Such tasks as specifying explicit relationships between models to indicate formats for models and which model outputs are input to other models are not placed directly on the user of a MBMS but handled directly by the system. Figure 11 presents a generic illustration of a MBMS. It shows a collection of models or model base, a model base manager, a model dictionary, and connections to the DBMS and the DGMS.

A number of capabilities should be provided by an integrated and shared MBMS of a DSS (Barbosa and Herko 1980; Liang 1985) construction, model maintenance, model storage, model manipulation, and model access (Applegate et al. 1986). These involve control, flexibility, feedback, interface, redundancy reduction, and increased consistency:

1. *Control:* The DSS user should be provided with a spectrum of control. The system should support both fully automated and manual selection of models that seem most useful to the user for an intended application. This will enable the user to proceed at the problem-solving pace that is most comfortable given the user's experiential familiarity with the task at hand. It should be possible for the user to introduce subjective information and not have to provide full information. Also, the control mechanism should be such that the DSS user can obtain a recommendation for action with this partial information at essentially any point in the problem-solving process.
2. *Flexibility:* The DSS user should be able to develop part of the solution to the task at hand using one approach and then be able to switch to another modeling approach if this appears preferable. Any change or modification in the model base will be made available to all DSS users.
3. *Feedback:* The MBMS of the DSS should provide sufficient feedback to enable the user to be aware of the state of the problem-solving process at any point in time.
4. *Interface:* The DSS user should feel comfortable with the specific model from the MBMS that is in use at any given time. The user should not have to supply inputs laboriously when he or she does not wish to do this.
5. *Redundancy reduction:* This should occur through use of shared models and associated elimination of redundant storage that would otherwise be needed.
6. *Increased consistency:* This should result from the ability of multiple decision makers to use the same model and the associated reduction of inconsistency that would have resulted from use of different data or different versions of a model.

In order to provide these capabilities, it appears that a MBMS design must allow the DSS user to:

1. Access and retrieve existing models
2. Exercise and manipulate existing models, including model instantiation, model selection, and model synthesis, and the provision of appropriate model outputs
3. Store existing models, including model representation, model abstraction, and physical and logical model storage
4. Maintain existing models as appropriate for changing conditions
5. Construct new models with reasonable effort when they are needed, usually by building new models by using existing models as building blocks

A number of auxiliary requirements must be achieved in order to provide these five capabilities. For example, there must be appropriate communication and data changes among models that have been combined. It must also be possible to locate appropriate data from the DBMS and transmit it to the models that will use it.

It must also be possible to analyze and interpret the results obtained from using a model. This can be accomplished in a number of ways. In this section, we will examine two of them: relational MBMS and expert system control of an MBMS. The objective is to provide an appropriate set of models for the model base and appropriate software to manage the models in the model base; integration of the MBMS with the DBMS; and integration of the MBMS with the DGMS. We can expand further on each of these needs. Many of the technical capabilities needed for a MBMS will be analogous to those needed for a DBMS. These include model generators that will allow rapid building of specific models, model modification tools that will enable a model to be restructured easily on the basis of changes in the task to be accomplished, update capability that will enable changes in data to be input to the model, and report generators that will enable rapid preparation of results from using the system in a form appropriate for human use.

Like a relational view of data, a relational view of models is based on a mathematical theory of relations. Thus, a model is viewed as a virtual file or virtual relation. It is a subset of the Cartesian product of the domain set that corresponds to these input and output attributes. This virtual file is created, ideally, through exercising the model with a wide spectrum of inputs. These values of inputs and the associated outputs become records in the virtual file. The input data become key attributes and the model output data become content attributes.

Model base structuring and organization is very important for appropriate relational model management. Records in the virtual file of a model base are not individually updated, however, as they

are in a relational database. When a model change is made, all of the records that comprise the virtual file are changed. Nevertheless, processing anomalies are possible in relational model management. Transitive dependencies in a relation, in the form of functional dependencies that affect only the output attributes, do occur and are eliminated by being projected into an appropriate normal form.

Another issue of considerable importance relates to the contemporary need for usable model base query languages and to needs within such languages for relational completeness. The implementation of joins is of concern in relational model base management just as it is in relational database management. A relational model join is simply the result of using the output of one model as the input to another model. Thus, joins will normally be implemented as part of the normal operation of software, and a MBMS user will often not be aware that they are occurring. However, there can be cycles, since the output from a first model may be the input to a second model, and this may become the input to the first model. Cycles such as this do not occur in relational DBMS.

Expert system applications in MBMS represent another attractive possibility. Four different potential opportunities exist. It might be possible to use expert system technology to considerable advantage in the construction of models (Hwang 1985; Murphy and Stohr 1986), including decisions with respect to whether or not to construct models in terms of the cost and benefits associated with this decision. AI and expert system technology may potentially be used to integrate models. This model integration is needed to join models. AI and expert system technology might be potentially useful in the validation of models. Also, this technology might find potential use in the interpretation of the output of models. This would especially seem to be needed for large-scale models, such as large linear programming models. While MBMS approaches based on a relational theory of models and expert systems technology are new as of this writing, they offer much potential for implementing model management notions in an effective manner. As has been noted, they offer the prospect of data as models (Dolk 1986) that may well prove much more useful than the conventional information systems perspective of "models as data."

4. DIALOG GENERATION AND MANAGEMENT SYSTEMS

In our efforts in this chapter, we envision a basic DSS structure of the form shown in Figure 12. This figure also shows many of the operational functions of the database management system (DBMS) and the model base management system (MBMS). The primary purpose of the dialog generation and management system (DGMS) is to enhance the propensity and ability of the system user to use and benefit from the DSS. There are doubtless few users of a DSS who use it because of necessity. Most uses of a DSS are optional, and the decision maker must have some motivation and desire to use a DSS or it will likely remain unused. DSS use can occur in a variety of ways. In all uses of a DGMS, it is the DGMS that the user interacts with. In an early seminal text, Bennett (1983) posed three questions to indicate this centrality:

1. What presentations is the user able to *see* at the DSS display terminal?
2. What must the user know about what is seen at the display terminal in order to use the DSS?
3. What can the DSS user *do* with the systems that will aid in accomplishing the intended purpose?

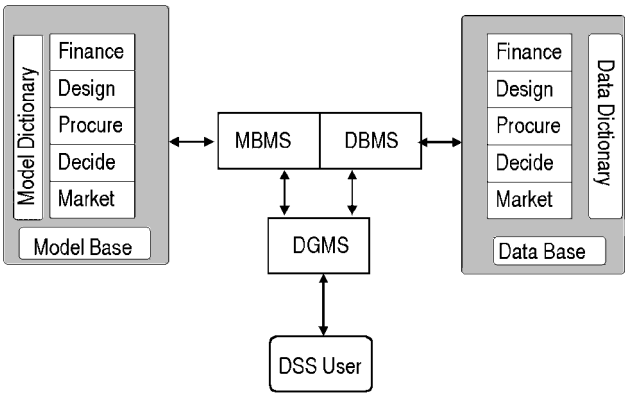

Figure 12 The DGMS as the User-Focused System in a DSS.

Bennett refers to these elements as the *presentation language,* the *knowledge base,* and the *action language*.

It is generally felt that there are three types of languages or modes of human communications: *words, mathematics,* and *graphics*. The presentation and action languages, and the knowledge base in general, many contain any or all of these three language types. The mix of these that is appropriate for any given DSS task will be a function of the task itself, the environment into which the task is embedded, and the nature of the experiential familiarity of the person performing the task with the task and with the environment. This is often called the contingency task structure. The DSS, when one is used, becomes a fourth ingredient, although it is really much more of a vehicle supporting effective use of words, mathematics, and graphics than it is a separate fourth ingredient.

Notions of DGMS design are relatively new, especially as a separately identified portion of the overall design effort. To be sure, user interface design is not at all new. However, the usual practice has been to assign the task of user interface design to the design engineers responsible for the entire system. In the past, user interfaces were not given special attention. They were merely viewed as another hardware and software component in the system. System designers were often not particularly familiar with, and perhaps not even especially interested in, the user-oriented design perspectives necessary to produce a successful interface design. As a result, many user interface designs have provided more what the designer wanted than what the user wanted and needed. Notions of dialog generation and dialog management extend far beyond interface issues, although the interface is a central concern in dialog generation and dialog management. A number of discussions of user interface issues are contained in Part IIIB of this Handbook.

Figure 14 illustrates an attribute tree for interface design based on the work of Smith and Mosier (1986). This attribute tree can be used, in conjunction with the evaluation methods of decision analysis, to evaluate the effectiveness of interface designs. There are other interface descriptions, some of which are less capable of instrumental measurement than these. On the basis of a thorough study of much of the human–computer interface and dialog design literature, Schneiderman (1987) has identified eight primary objectives, often called the ''golden rules'' for dialog design:

1. Strive for consistency of terminology, menus, prompts, commands, and help screens.
2. Enable frequent users to use shortcuts that take advantage of their experiential familiarity with the computer system.
3. Offer informative feedback for every operator action that is proportional to the significance of the action.
4. Design dialogs to yield closure such that the system user is aware that specific actions have been concluded and that planning for the next set of activities may now take place.
5. Offer simple error handling such that, to the extent possible, the user is unable to make a mistake. Even when mistakes are made, the user should not have to, for example, retype an entire command entry line. Instead, the user should be able to just edit the portion that is incorrect.
6. Permit easy reversal of action such that the user is able to interrupt and then cancel wrong commands rather than having to wait for them to be fully executed.

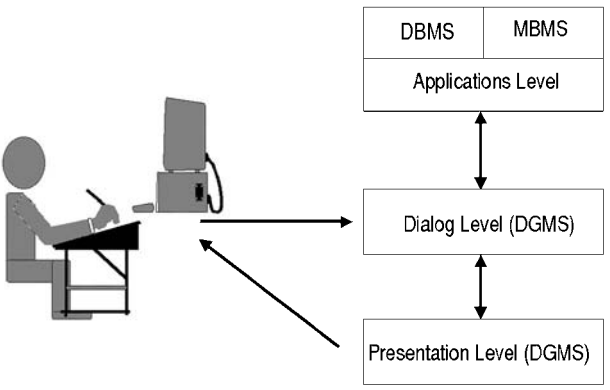

Figure 13 Dialog Generation and Management System Architecture.

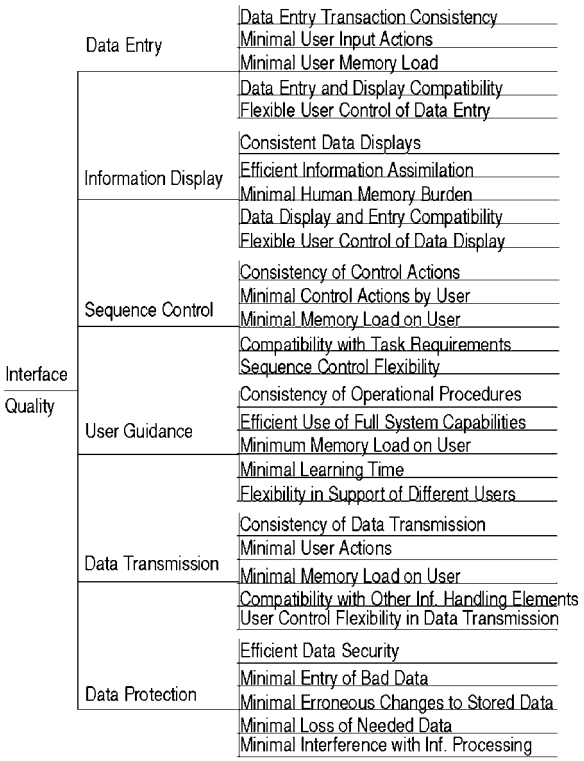

Figure 14 Attribute Tree of Smith and Mosier Elements for Interface Design Evaluation.

7. Support internal locus of control such that users are always the initiators of actions rather than the reactors to computer actions.
8. Reduce short-term memory load such that users are able to master the dialog activities that they perform in a comfortable and convenient manner.

Clearly, all of these will have specific interpretations in different DGMS environments and need to be sustained in and capable of extension for a variety of environments.

Human–computer interaction and associated interface design issues are of major contemporary importance, so it is not surprising that there have been a number of approaches to them. Some of these approaches are almost totally empirical. Some involve almost totally theoretical and formal models (Harrison and Thimbleby 1990). Others attempt approximate predictive models that are potentially useful for design purposes (Card et al. 1983). One word that has appeared often in these discussions is "consistency." This is Schneiderman's first golden rule of dialog design, and many other authors advocate it as well. A notable exception to this advocacy of consistency comes from Grudin (1989), who argues that issues associated with consistency should be placed in a very broad context. He defines three types of consistency:

1. *Internal consistency:* The physical and graphic layout of the computer system, including such characteristics as those associated with command naming and use and dialog forms, are consistent if these internal features of the interface are the same across applications.
2. *External consistency:* If an interface has unchanging use features when compared to another interface with which the user is familiar, it is said to be externally consistent.
3. *Applications consistency:* If the user interface uses metaphors or analogous representations of objects that correspond to those of the real-world application, then the interface may be said to correspond to experientially familiar features of the world and to be applications consistent.

Two of Grudin's observations relevant to interface consistency are that ease of learning can conflict with ease of use, especially as experiential familiarity with the interface grows, and that consistency can work against both ease of use and learning. On the basis of some experiments illustrating these hypotheses, he establishes the three appropriate dimensions for consistency above.

A number of characteristics are desirable for user interfaces. Roberts and Moran (1982) identify the most important attributes of text editors as functionality of the editor, learning time required, time required to perform tasks, and errors committed. To this might be added the cost of evaluation. Harrison and Hix (1989) identify usability, completeness, extensibility, escapability, integration, locality of definition, structured guidance, and direct manipulation as well in their more general study of user interfaces. They also note a number of tools useful for interface development, as does Lee (1990).

Ravden and Johnson (1989) evaluate usability of human computer interfaces. They identify nine top-level attributes: visual clarity, consistency, compatibility, informative feedback, explicitness, appropriate functionality, flexibility and control, error prevention and correction, and user guidance and support. They disaggregate each into a number of more measurable attributes. These attributes can be used as part of a standard multiple-attribute evaluation.

A goal in DGMS design is to define an abstract user interface that can be implemented on specific operating systems in different ways. The purpose of this is to allow for device independence such that, for example, switching from a command line interface to a mouse-driven pull-down-menu interface can be easily accomplished. Separating the application from the user interface should do much towards ensuring portability across operating systems and hardware platforms without modifying the MBMS and the DBMS, which together comprise the applications software portions of the DSS.

5. GROUP AND ORGANIZATIONAL DECISION SUPPORT SYSTEMS

A group decision support system (GDSS) is an information technology-based support system designed to provide decision making support to groups and/or organizations. This could refer to a group meeting at one physical location at which judgments and decisions are made that affect an organization or group. Alternatively, it could refer to a spectrum of meetings of one or more individuals, distributed in location, time, or both. GDSSs are often called *organizational decision support systems,* and other terms are often used, including *executive support systems* (ESSs), which are information technology-based systems designed to support executives and managers, and *command and control systems,* which is a term often used in the military for a decision support system. We will generally use GDSS to describe all of these.

Managers and other knowledge workers spend much time in meetings. Much research into meeting effectiveness suggests that it is low, and proposals have been made to increase this through information technology support (Johansen 1988). Specific components of this information technology-based support might include computer hardware and software, audio and video technology, and communications media. There are three fundamental ingredients in this support concept: technological support facilities, the support processes provided, and the environment in which they are embedded. Kraemer and King (1988) provide a noteworthy commentary on the need for group efforts in their overview of GDSS efforts. They suggest that group activities are economically necessary, efficient as a means of production, and reinforcing of democratic values.

There are a number of predecessors for group decision support technology. Decision rooms, or situation rooms, where managers and boards meet to select from alternative plans or courses of action, are very common. The first computer-based decision support facility for group use is attributed to Douglas C. Engelbart, the inventor of the (computer) mouse, at Stanford in the 1960s. A discussion of this and other early support facilities is contained in Johansen (1988).

Engelbart's electronic boardroom-type design is acknowledged to be the first type of information technology-based GDSS. The electronic format was, however, preceded by a number of nonelectronic formats. The Cabinet war room of Winston Churchill is perhaps the most famous of these. Maps placed on the wall and tables for military decision makers were the primary ingredients of this room. The early 1970s saw the introduction of a number of simple computer-based support aids into situation rooms. The first system that resembles the GDSS in use today is often attributed to Gerald Wagner, the Chief Executive Officer of Execucom, who implemented a planning laboratory made up of a U-shaped table around which people sat, a projection TV system for use as a public viewing screen, individual small terminals and keyboards available to participants, and a minicomputer to which the terminals and keyboards were connected. This enabled participants to vote and to conduct simple spreadsheet-like exercises. Figure 15 illustrates the essential features of this concept. Most present-day GDSS centralized facilities look much like the conceptual illustration of a support room, or situation room, shown in this Figure.

As with a single-user DSS, appropriate questions for a GDSS that have major implications for design concern the perceptions and insights that the group obtains through use of the GDSS and the

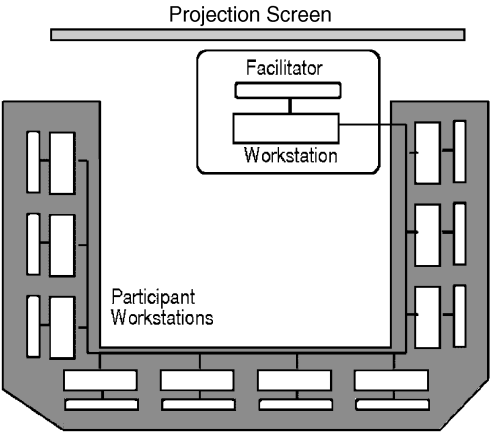

Figure 15 Early Group Decision Support System (GDSS) Situation Room.

activities that can be carried out through its use. Also, additional concerns arise regarding the public screen, interactions between the public screen and individual screens, the characteristics of individual work screens, and contingency task structural variables associated with the individuals in the group using the GDSS (Gray and Olfman 1989).

Huber (1982) has indicated both the needs for GDSS and how an appropriately designed GDSS can meet these needs. He identifies four interacting and complicating concerns:

1. Effective decision making requires not only obtaining an appropriate decision, but also ensuring that participants are happy with the process used to reach the decision and will be willing to meet and work cooperatively in the future.
2. Productivity losses occur because of dominant individuals and group pressures that lead to conformity of thought, or groupthink.
3. Miscommunications are common in group situations.
4. Insufficient time is often spent in situation assessment, problem exploration, and generation of alternative courses of action.

Huber further indicates that a GDSS can help improve the unaided decision situation, which often suffers from imperfect information processing and suboptimal decision selection.

A GDSS is made up of:

1. *Technological components,* in terms of computer hardware and software, and communication equipment
2. *Environmental components,* in terms of the people involved, their locations in time and space, and their experiential familiarity with the task at hand
3. *Process components,* or variables made up of the conventions used to support task performance and enable the other components of decision making to function appropriately.

We have already described the technological design features of DSSs. Thus, our commentary on technological design features of a GDSS will be brief. We do need to provide a perspective on groups and organizations, and we will do this in our next two sections. Then we will turn to some architectural considerations specifically relevant to GDSS.

5.1. Information Needs for Group and Organizational Decision Making

The nature of the decisions and the type of information required differ across each of these four levels identified in Figure 1. Generally, operational activities occur much more frequently than strategic planning activities. Also, there is a difference in the degree to which the knowledge required for each of these levels is structured. In 1960, Herbert Simon (Simon 1960) described decisions as structured or unstructured, depending upon whether the decision making process can be explicitly described prior to the time when it is necessary to make a decision. This taxonomy would seem to

lead directly to that in which expert skills (holistic reasoning), rules (heuristics), or formal reasoning (holistic analysis) are normatively used for judgment. Generally, operational performance decisions are much more likely than strategic planning decisions to be prestructured. This gives rise to a number of questions concerning efficiency and effectiveness tradeoffs between training and aiding (Rouse 1991) that occur at these levels.

There are a number of human abilities that a GDSS should augment.

1. It should help the decision maker to formulate, frame, or assess the decision situation. This includes identifying the salient features of the environment, recognizing needs, identifying appropriate objectives by which we are able to measure successful resolution of an issue, and generating alternative courses of action that will resolve the needs and satisfy objectives.
2. It should provide support in enhancing the abilities of the decision maker to obtain and analyze the possible impacts of the alternative courses of action.
3. It should have the capability to enhance the decision maker's ability to interpret these impacts in terms of objectives. This interpretation capability will lead to evaluation of the alternatives and selection of a preferred alternative option.

Associated with each of these three formal steps of formulation, analysis, and interpretation must be the ability to acquire, represent, and utilize information and associated knowledge and the ability to implement the chosen alternative course of action.

Many attributes will affect the quality and usefulness of the information that is obtained, or should be obtained, relative to any given decision situation. These variables are very clearly contingency task dependent. Among these attributes are the following (Keen and Scott Morton 1978).

- *Inherent and required accuracy of available information:* Operational control and performance situations will often deal with information that is relatively accurate. The information in strategic planning and management control situations is often inaccurate.
- *Inherent precision of available information:* Generally, information available for operational control and operational performance decisions is very imprecise.
- *Inherent relevancy of available information:* Operational control and performance situations will often deal with information that is fairly relevant to the task at hand because it has been prepared that way by management. The information in strategic planning and management control situations is often obtained from the external environment and may be irrelevant to the strategic tasks at hand, although it may not initially appear this way.
- *Inherent and required completeness of available information:* Operational control and performance situations will often deal with information that is relatively complete and sufficient for operational performance. The information in strategic planning and management control situations is often very incomplete and insufficient to enable great confidence in strategic planning and management control.
- *Inherent and required verifiability of available information:* Operational control and performance situations will often deal with information that is relatively verifiable to determine correctness for the intended purpose. The information in strategic planning and management control situations is often unverifiable, or relatively so, and this gives rise to a potential lack of confidence in strategic planning and management control.
- *Inherent and required consistency and coherency of available information:* Operational control and performance situations will often deal with information that is relatively consistent and coherent. The information in strategic planning and management control situations is often inconsistent and perhaps even contradictory or incoherent, especially when it comes from multiple external sources.
- *Information scope:* Generally, but not always, operational decisions are made on the basis of relatively narrow scope information related to well-defined events that are internal to the organization. Strategic decisions are generally based upon broad-scope information and a wide range of factors that often cannot be fully anticipated prior to the need for the decision.
- *Information quantifiability:* In strategic planning, information is very likely to be highly qualitative, at least initially. For operational decisions, the available information is often highly quantified.
- *Information currency:* In strategic planning, information is often rather old, and it is often difficult to obtain current information about the external environment. For operational control decisions, very current information is often needed and present.
- *Needed level of detail:* Often very detailed information is needed for operational decisions. Highly aggregated information is often desired for strategic decisions. There are many difficulties associated with information summarization that need attention.

- *Time horizon for information needed:* Operational decisions are typically based on information over a short time horizon, and the nature of the control may change very frequently. Strategic decisions are based on information and predictions based on a long time horizon.
- *Frequency of use:* Strategic decisions are made infrequently, although they are perhaps refined fairly often. Operational decisions are made quite frequently and are relatively easily changed.
- *Internal or external information source:* Operational decisions are often based upon information that is available internal to the organization, whereas strategic decisions are much more likely to be dependent upon information content that can only be obtained external to the organization.

These attributes, and others, could be used to form the basis for an evaluation of information quality in a decision support system.

Information is used in a DSS for a variety of purposes. In general, information is equivalent to, or may be used as, evidence in situations in which it is relevant. Often information is used directly as a basis for testing an hypothesis. Sometimes it is used indirectly for this purpose. There are three different conditions for describing hypotheses (Schum 1987, 1994):

1. Different alternative hypotheses or assessments are possible if evidence is imperfect in any way. A hypothesis may be imperfect if it is based on imperfect information. Imperfect information refers to information that is incomplete, inconclusive, unreliable, inconsistent, or uncertain. Any or all of these alternate hypotheses may or may not be true.
2. Hypotheses may refer to past, present, or future events.
3. Hypotheses may be sharp (specific) or diffuse (unspecified). Sharp hypotheses are usually based on specific evidence rather than earlier diffuse hypotheses. An overly sharp hypothesis may contain irrelevant detail and invite invalidation by disconfirming evidence on a single issue in the hypothesis. An overly diffuse hypothesis may be judged too vague and too uninteresting by those who must make a decision based upon the hypothesis, even though the hypothesis might have been described in a more cogent manner.

The support for any hypothesis can always be improved by either revising a portion of the hypothesis to accommodate new evidence or gathering more evidence that infers the hypothesis. Hypotheses can be potentially significant for four uses:

1. *Explanations:* An explanation usually involves a model, which can be elaborate or simple. The explanation consists of the rationale for why certain events occurred.
2. *Event predictions:* In this case the hypothesis is proposed for a possible future event. It may include the date or period when the possible event will occur.
3. *Forecasting and estimation:* This involves the generation of a hypothesis based on data that does not exist or that is inaccessible.
4. *Categorization:* Sometimes it is useful to place persons, objects, or events into certain categories based upon inconclusive evidence linking the persons, objects, or events to these categories. In this case the categories represent hypotheses about category membership.

Assessment of the validity of a given hypothesis is inductive in nature. The generation of hypotheses and determination of evidence relevant to these hypotheses involve deductive and abductive reasoning. Hypotheses may be generated on the basis of the experience and prior knowledge that leads to analogous representations and recognitional decision making, as noted by Klein (1990, 1998).

Although no theory has been widely accepted on how to quantify the value of evidence, it is important to be able to support a hypothesis in some logical manner. Usually there is a major hypothesis that is inferred by supporting hypotheses, and each of these supporting hypotheses is inferred by its supporting hypothesis, and so on. Evidence is relevant to the extent that it causes one to increase or decrease the likeliness of an existing hypothesis, or modify an existing hypothesis, or create a new hypothesis. Evidence is direct if it has a straightforward bearing on the validity of the main hypothesis. Evidence is indirect if its effect on the main hypothesis is inferred through at least one other level of supporting hypothesis.

In many cases, it is necessary to acquire, represent, use, and/or communicate knowledge that is imperfect. This is especially important in group decision situations. In describing the structure of the beliefs and the statements that people make about issues that are of importance to them, the nature of the environment that surrounds them, as well as the ways in which people reason and draw conclusions about the environment and issues that are embedded into the environment, especially when there are conflicting pieces of information and opinions concerning these, people often attempt to use one or more of the forms of logical reasoning. Many important works deal with this subject. Of particular interest here is the work of Toulmin and his colleagues (Toulmin et al. 1979), who have described an explicit model of logical reasoning that is subject to analytical inquiry and computer

implementation. The model is sufficiently general that it can be used to represent logical reasoning in a number of application areas.

Toulmin assumes that whenever we make a claim, there must be some ground on which to base our conclusion. He states that our thoughts are generally directed, in an inductive manner, from the grounds to the claim, each of which are statements that may be used to express both facts and values. As a means of explaining observed patterns of stating a claim, there must be some reason that can be identified with which to connect the grounds and the claim. This connection, called the warrant, gives the grounds–claim connection its logical validity.

We say that the grounds support the claim on the basis of the existence of a warrant that explains the connection between the grounds and the claim. It is easy to relate the structure of these basic elements with the process of inference, whether inductive or deductive, in classical logic. The warrants are the set of rules of inference, and the grounds and claim are the set of well-defined propositions or statements. It will be only the sequence and procedures, as used to formulate the three basic elements and their structure in a logical fashion, that will determine the type of inference that is used.

Sometimes, in the course of reasoning about an issue, it is not enough that the warrant will be the absolute reason to believe the claim on the basis of the grounds. For that, there is a need for further backing to support the warrant. It is this backing that provides for reliability, in terms of truth, associated with the use of a warrant. The relationship here is analogous to the way in which the grounds support the claim. An argument will be valid and will give the claim solid support only if the warrant is relied upon and is relevant to the particular case under examination. The concept of logical validity of an argument seems to imply that we can make a claim only when both the warrant and the grounds are certain. However, imprecision and uncertainty in the form of exceptions to the rules or low degree of certainty in both the grounds and the warrant do not prevent us on occasion from making a *hedge* or, in other words, a vague claim. Often we must arrive at conclusions on the basis of something less than perfect evidence, and we put those claims forward not with absolute and irrefutable truth but with some doubt or degree of speculation.

To allow for these cases, modal qualifiers and possible rebuttals may be added to this framework for logical reasoning. Modal qualifiers refer to the strength or weakness with which a claim is made. In essence, every argument has a certain modality. Its place in the structure presented so far must reflect the generality of the warrants in connecting the grounds to the claim. Possible rebuttals, on the other hand, are exceptions to the rules. Although modal qualifiers serve the purpose of weakening or strengthening the validity of a claim, there may still be conditions that invalidate either the grounds or the warrants, and this will result in deactivating the link between the claim and the grounds. These cases are represented by the possible rebuttals.

The resulting structure of logical reasoning provides a very useful framework for the study of human information processing activities. The order in which the six elements of logical reasoning have been presented serves only the purpose of illustrating their function and interdependence in the structure of an argument about a specific issue. It does not represent any normative pattern of argument formation. In fact, due to the dynamic nature of human reasoning, the concept formation and framing that result in a particular structure may occur in different ways. The six-element model of logical reasoning is shown in Figure 16.

Computer-based implementations of Figure 16 may assume a Bayesian inferential framework for processing information. Frameworks for Bayesian inference require probability values as primary inputs. Because most events of interest are unique or little is known about their relative frequencies of occurrence, the assessment of probability values usually requires human judgment. Substantial

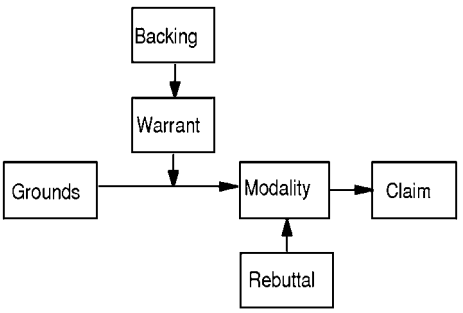

Figure 16 Representation of Toulmin Logic Structure.

psychological research has shown that people are unable to elicit probability values consistent with the rules of probabilities or to process information as they should, according to the laws of probability, in revising probability assessment when new information is obtained. For example, when people have both causal and diagnostic implications, they should weigh the causal and diagnostic impacts of the evidence. More often, however, unaided humans will reach judgments that suggest they apparently assess conditional probabilities primarily in terms of the direct causal effect of the impacts. If A is perceived to be the cause of B, for example, people will usually associate higher probabilities with $P(B|A)$ than they will with $P(A|B)$. Studies concerning the elicitation of probability values often report that individuals found it easier and showed more confidence in assessing $P(A|B)$ if B was causal to A. This strongly suggests that the choice of which form of inference to invoke depends more on the level of familiarity of the observer with the task at hand and the frame adopted to initially represent the knowledge. Again, this supports the wisdom of appropriate structuring of decision situations.

In general, grounds can be categorized by the several means in which are warranted:

- Empirical observation
- Expert judgment
- Enumerative induction (statistics)
- Experiment (hypothesis test)
- Direct fact

A decision assessment system based on this concept is described in Janssen and Sage (2000) together with application to the issues in public policy decision making associated with agricultural pest control. This system can support several user groups, who can use the support system to state arguments for or against an important policy issue and to assist in identifying and evaluating alternatives for implementation as policy decisions. The resulting decision support system assists in improving the clarity of the lines of reasoning used in specific situations; the warrants, grounds, and backings that are used to support claims and specific lines of reasoning; and the contradictions, rebuttals, and arguments surrounding each step in the reasoning process associated with evaluating a claim or counterclaim. Thus, experts and decision makers with differing views and backgrounds can better understand each other's thought processes in complex situations. The net effect is enhanced communications and understanding of the whole picture and, in many cases, consensus on decisions to be taken.

A number of human information processing capabilities and limitations interact with organizational arrangements and task requirements to strongly influence resource allocations for organizational problem solving and decision making. These needs have provided much motivation for the development of group decision support systems (GDSSs). The purpose of these GDSSs as computerized aids to planning, problem solving, and decision making include:

1. Removing a number of common communication barriers in groups and organizations
2. Providing techniques for the formulation, analysis, and interpretation of decisions
3. Systematically directing the discussion process and associated problem solving and decision making in terms of the patterns, timing, and content of the information that influences the actions that follow from decisions that have been taken

A number of variations and permutations are possible in the provision of group and organizational decision support. These are associated with specific realization or architectural format for a GDSS to support a set of GDSS performance objectives for a particular task in a particular environment.

The same maladies that affect individual decision making and problem solving behavior, as well as many others, can result from group and organizational limitations. A considerable body of knowledge, generally qualitative, exists relative to organizational structure, effectiveness, and decision making in organizations. The majority of these studies suggest that a bounded rationality or satisficing perspective, often heavily influenced by bureaucratic political considerations, will generally be the decision perspective adopted in actual decision making practice in organizations. To cope with this effectively requires the ability to deal concurrently with technological, environmental, and process concerns as they each, separately and collectively, motivate group and organizational problem solving issues.

The influencers of decision and decision process quality are particularly important in this. We should sound a note of caution regarding some possibly overly simplistic notions relative to this. Welch (1989) identifies a number of potential imperfections in organizational decision making and discusses their relationship to decision process quality. In part, these are based on an application of seven symptoms identified in Herek et al. (1987) to the Cuban Missile Crisis of 1962. These potential imperfections include:

1. Omissions in surveying alternative courses of action
2. Omissions in surveying objectives
3. Failure to examine major costs and risks of the selected course of action (COA)
4. Poor information search, resulting in imperfect information
5. Selective bias in processing available information
6. Failure to reconsider alternatives initially rejected, potentially by discounting favorable information and overweighing unfavorable information
7. Failure to work out detailed implementation, monitoring, and contingency plans

The central thrust of this study is that the relationship between the quality of the decision making process and the quality of the outcome is difficult to establish. This strongly suggests the usefulness of the contingency task structural model construct and the need for approaches that evaluate the quality of processes, as well as decisions and outcomes, and that consider the inherent embedding of outcomes and decisions within processes that lead to these.

Organizational ambiguity is a major reason why much of the observed ''bounded rationality'' behavior is so pervasive. March (1983) and March and Wessinger-Baylon (1986) show that this is very often the case, even in situations when formal rational thought or ''vigilant information processing'' (Janis and Mann 1977) might be thought to be a preferred decision style. March (1983) indicates that there are at least four kinds of opaqueness or equivocality in organizations: *ambiguity of intention, ambiguity of understanding, ambiguity of history,* and *ambiguity of human participation.* These four ambiguities relate to an organization's structure, function, and purpose, as well as to the perception of these decision making agents in an organization. They influence the information that is communicated in an organization and generally introduce one or more forms of information imperfection. The notions of organizational management and organizational information processing are indeed inseparable. In the context of human information processing, it would not be incorrect to define the central purpose of management as development of a consensual grammar to ameliorate the effects of equivocality or ambiguity. This is the perspective taken by Karl Weick (1979, 1985) in his noteworthy efforts concerning organizations.

Starbuck (1985) notes that much direct action is a form of deliberation. He indicates that action should often be introduced earlier in the process of deliberation than it usually is and that action and thought should be integrated and interspersed with one another. The basis of support for this argument is that probative actions generate information and tangible results that modify potential thoughts. Of course, any approach that involves ''act now, think later'' behavior should be applied with considerable caution.

Much of the discussion to be found in the judgment, choice, and decision literature concentrates on what may be called formal reasoning and decision selection efforts that involve the issue resolution efforts that follow as part of the problem solving efforts of issue formulation, analysis, and interpretation that we have discussed here. There are other decision making activities, or decision-associated activities, as well. Very important among these are activities that allow perception, framing, editing and interpretation of the effects of actions upon the internal and external environments of a decision situation. These might be called information selection activities. There will also exist information retention activities that allow admission, rejection, and modification of the set of selected information or knowledge such as to result in short-term learning and long-term learning. Short-term learning results from reduction of incongruities, and long-term learning results from acquisition of new information that reflects enhanced understanding of an issue. Although the basic GDSS design effort may well be concerned with the short-term effects of various problem solving, decision making, and information presentation formats, the actual knowledge that a person brings to bear on a given problem is a function of the accumulated experience that the person possesses, and thus long-term effects need to be considered, at least as a matter of secondary importance.

It was remarked above that a major purpose of a GDSS is to enhance the value of information and, through this, to enhance group and organizational decision making. Three attributes of information appear dominant in the discussion thus far relative to value for problem solving purposes and in the literature in general:

1. *Task relevance:* Information must be relevant to the task at hand. It must allow the decision maker to know what needs to be known in order to make an effective and efficient decision. This is not as trivial a statement as might initially be suspected. Relevance varies considerably across individuals, as a function of the contingency task structure, and in time as well.
2. *Representational appropriateness:* In addition to the need that information be relevant to the task at hand, the person who needs the information must receive it in a form that is appropriate for use.

3. *Equivocality reduction:* It is generally accepted that high-quality information may reduce the imperfection or equivocality that might otherwise be present. This equivocality generally takes the form of uncertainty, imprecision, inconsistency, or incompleteness. It is very important to note that it is neither necessary nor desirable to obtain decision information that is unequivocal or totally ''perfect.'' Information need only be sufficiently unequivocal or unambiguous for the task at hand. To make it better may well be a waste of resources!

Each of these top-level attributes may be decomposed into attributes at a lower level. Each is needed as fundamental metrics for valuation of information quality. We have indicated that some of the components of equivocality or imperfection are uncertainty, imprecision, inconsistency, and incompleteness. A few of the attributes of representational appropriateness include naturalness, transformability to naturalness, and concision. These attributes of information presentation system effectiveness relate strongly to overall value of information concerns and should be measured as a part of the DSS and GDSS evaluation effort even though any one of them may appear to be a secondary theme.

We can characterize information in many ways. Among attributes that we noted earlier and might use are accuracy, precision, completeness, sufficiency, understandability, relevancy, reliability, redundancy, verifiability, consistency, freedom from bias, frequency of use, age, timeliness, and uncertainty. Our concerns with information involve at least five desiderata (Sage 1987):

1. Information should be presented in very clear and very familiar ways, such as to enable rapid comprehension.
2. Information should be such as to improve the precision of understanding of the task situation.
3. Information that contains an advice or decision recommendation component should contain an explication facility that enables the user to determine how and why results and advice are obtained.
4. Information needs should be based upon identification of the information requirements for the particular situation.
5. Information presentations and all other associated management control aspects of the support process should be such that the decision maker, rather than a computerized support system, guides the process of judgment and choice.

It will generally be necessary to evaluate a GDSS to determine the extent to which these information quality relevant characteristics are present.

5.2. The Engineering of Group Decision Support Systems

There are two fundamental types of decision making in an organization: individual decisions, made by a single person, and group or organizational decisions, made by a collection of two or more people. It is, of course, possible to disaggregate this still further. An individual decision may, for example, be based on the value system of one or more people and the individual making the decision may or may not have his or her values included. In a multistage decision process, different people may make the various decisions. Some authors differentiate between group and organizational decisions (King and Star 1992), but we see no need for this here, even though it may be warranted in some contexts. There can be no doubt at all, however, that a GDSS needs to be carefully matched to an organization that may use it.

Often groups make decisions differently from the way an individual does. Groups need protocols that allow effective inputs by individuals in the group or organization, a method for mediating a discussion of issues and inputs, and algorithms for resolving disagreements and reaching a group consensus. Acquisition and elicitation of inputs and the mediation of issues are usually local to the specific group, informed of personalities, status, and contingencies of the members of the group. Members of the group are usually desirous of cooperating in reaching a consensus on conflicting issues or preferences. The support for individual vs. group decisions is different and hence DSSs and GDSSs may require different designs. Because members of a group have different personalities, motivations, and experiential familiarities with the situation at hand, a GDSS must assist in supporting a wide range of judgment and choice perspectives.

It is important to note that the group of people may be centralized at one spot or decentralized in space and/or time. Also, the decision considered by each individual in a decision making group may or may not be the *ultimate* decision. The decision being considered may be sequential over time and may involve many component decisions. Alternatively, or in addition, many members in a decision making group may be formulating and/or analyzing options and preparing a short list of these for review by a person with greater authority or responsibility over a different portion of the decision making effort.

Thus, the number of possible types of GDSS may be relatively extensive. Johansen (1988) has identified no less than 17 approaches for computer support in groups in his discussion of groupware.

1. *Face-to-face meeting facilitation services:* This is little more than office automation support in the preparation of reports, overheads, videos, and the like that will be used in a group meeting. The person making the presentation is called a ''facilitator'' or ''chauffeur.''
2. *Group decision support systems:* By this, Johansen essentially infers the GDSS structure shown in Figure 15 with the exception that there is but a single video monitor under the control of a facilitator or chauffeur.
3. *Computer-based extensions of telephony for use by work groups:* This involves use of either commercial telephone services or private branch exchanges (PBXs). These services exist now, and there are several present examples of conference calling services.
4. *Presentation support software:* This approach is not unlike that of approach 1, except that computer software is used to enable the presentation to be contained within a computer. Often those who will present it prepare the presentation material, and this may be done in an interactive manner to the group receiving the presentation.
5. *Project management software:* This is software that is receptive to presentation team input over time and that has capabilities to organize and structure the tasks associated with the group, often in the form of a Gantt chart. This is very specialized software and would be potentially useful for a team interested primarily in obtaining typical project management results in terms of PERT charts and the like.
6. *Calendar management for groups:* Often individuals in a group need to coordinate times with one another. They indicate times that are available, potentially with weights to indicate schedule adjustment flexibility in the event that it is not possible to determine an acceptable meeting time.
7. *Group authoring software:* This allows members of a group to suggest changes in a document stored in the system without changing the original. A lead person can then make document revisions. It is also possible for the group to view alternative revisions to drafts. The overall objective is to encourage, and improve the quality and efficiency of, group writing. It seems very clear that there needs to be overall structuring and format guidance, which, while possibly group determined, must be agreed upon prior to filling out the structure with report details.
8. *Computer-supported face-to-face meetings:* Here, individual members of the group work directly with a workstation and monitor, rather than having just a single computer system and monitor. A large screen video may, however, be included. This is the sort of DSS envisioned in Figure 14. Although there are a number of such systems in existence, the Colab system at Xerox Palo Alto Research Center (Stefik et al. 1987) was one of the earliest and most sophisticated. A simple sketch of a generic facility for this purpose might appear somewhat as shown in Figure 17. Generally, both public and private information are contained in these systems. The public information is shared, and the private information, or a portion of it, may be converted to public programs. The private screens normally start with a menu screen from which participants can select activities in which they engage, potentially under the direction of a facilitator.
9. *Screen sharing software:* This software enables one member of a group to selectively share screens with other group members. There are clearly advantages and pitfalls in this. The primary advantage to this approach is that information can be shared with those who have a reason to know specific information without having to bother others who do not need it. The disadvantage is just this also, and it may lead to a feeling of ganging up by one subgroup on another subgroup.
10. *Computer conferencing systems:* This is the group version of electronic mail. Basically, what we have is a collection of DSSs with some means of communication among the individuals that comprise the group. This form of communication might be regarded as a product hierarchy in which people communicate.
11. *Text filtering software:* This allows system users to search normal or semistructured text through the specification of search criteria that are used by the filtering software to select relevant portions of text. The original system to accomplish this was Electronic Mail Filter (Malone et al. 1987). A variety of alternative approaches are also being emphasized now.
12. *Computer-supported audio or video conferences:* This is simply the standard telephone or video conferencing, as augmented by each participant having access to a computer and appropriate software.
13. *Conversational structuring:* This involves identification and use of a structure for conversations that is presumably in close relationship to the task, environment, and experiential fa-

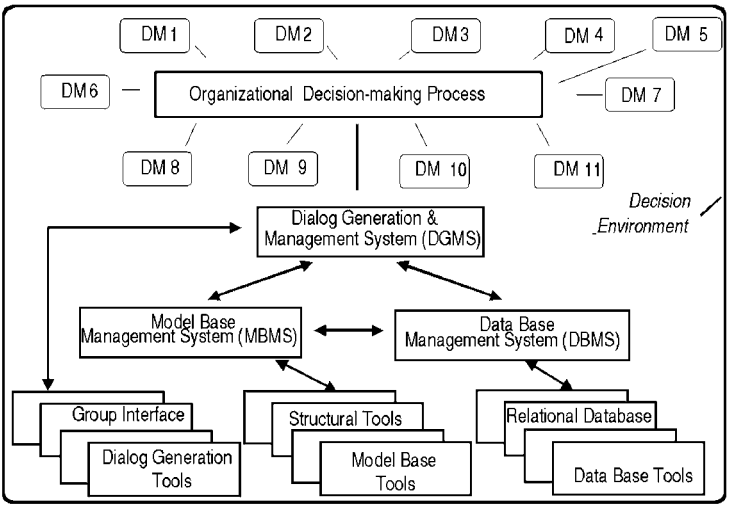

Figure 17 Level II (No Facilitator) and Level III (with Facilitator) GDSS.

miliarity of the group with the issues under consideration (Winograd and Flores 1986). For these group participants, structured conversations should often provide for enhanced efficiency and effectiveness or there may be a perception of unwarranted intrusions that may defeat the possible advantages of conversational structuring.

14. *Group memory management:* This refers to the provision of support between group meetings such that individual members of a group can search a computer memory in personally preferred ways through the use of very flexible indexing structures. The term *hypertext* (Nielson 1989) is generally given to this flexible information storage and retrieval. One potential difficulty with hypertext is the need for a good theory of how to prepare the text and associated index such that it can be indexed and used as we now use a thesaurus. An extension of hypertext to include other than textual material is known as hypermedia.
15. *Computer-supported spontaneous interaction:* The purpose of these systems is to encourage the sort of impromptu and extemporaneous interaction that often occurs at unscheduled meetings between colleagues in informal setting, such as a hallway. The need for this could occur, for example, when it is necessary for two physically separated groups to communicate relative to some detailed design issue that needs to be resolved in order to continue product development.
16. *Comprehensive work team support:* This refers to integrated and comprehensive support, such as perhaps might be achieved through use of the comprehensive DSS design philosophy described above.
17. *Nonhuman participants in team meetings:* This refers to the use of unfacilitated DSS and expert systems that automate some aspects of the process of decision making.

According to Johansen (1988), the order in which these are described above also represents the order of increasing difficulty of implementation and successful use. These scenarios of support for decision making are also characterized in terms of support for face-to-face meetings (1, 2, 4, 8); support for electronic meetings (3, 9, 10, 11, 12); and support between meetings (5, 6, 7, 13, 14, 15, 16). There is much interest in groupware as a focused subject within modern information technology developments (Shapiro et al. 1996; Chaffey 1998; Smith 1999). A number of groupware products are available, Lotus Notes arguably being the best known.

A GDSS may and doubtless will influence the process of group decision making, perhaps strongly. A GDSS has the potential for changing the information-processing characteristics of individuals in the group. This is one reason why organizational structure and authority concerns are important ingredients in GDSS designs. In one study of the use of a GDSS to facilitate group consensus (Watson et al. 1988), it was found that:

1. GDSS use tended to reduce face-to-face interpersonal communication in the decision making group.

2. GDSS use posed an intellectual challenge to the group and made accomplishment of the purpose of their decision making activity more difficult than for groups without the GDSS.
3. The groups using the GDSS became more process oriented and less specific-issue oriented than the groups not using the GDSS.

Support may be accomplished at any or all of the three levels for group decision support identified by DeSanctis and Gallupe (1987) in their definitive study of GDSS. A GDSS provides a mechanism for group interaction. It may impose any of various structured processes on individuals in the group, such as a particular voting scheme. A GDSS may impose any of several management control processes on the individuals on the group, such as that of imposing or removing the effects of a dominant personality. The design of the GDSS and the way in which it is used are the primary determinants of these.

DeSanctis and Gallupe have developed a taxonomy of GDSS. A Level I GDSS would simply be a medium for enhanced information interchange that might lead ultimately to a decision. Electronic mail, large video screen displays that can be viewed by a group, or a decision room that contains these features could represent a Level I GDSS. A Level I GDSS provides only a mechanism for group interaction. It might contain such facilities as a group scratchpad, support for meeting agenda development, and idea generation and voting software.

A Level II GDSS would provide various decision structuring and other analytic tools that could act to reduce information imperfection. A decision room that contained software that could be used for problem solution would represent a Level II GDSS. Thus, spreadsheets would primarily represent a Level II DSS. A Level II GDSS would also have to have some means of enabling group communication. Figure 17 represents a Level II GDSS. It is simply a communications medium that has been augmented with some tools for problem structuring and solution with no prescribed management control of the use of these tools.

A Level III GDSS also includes the notion of management control of the decision process. Thus, a notion of facilitation of the process is present, either through the direct intervention of a human in the process or through some rule-based specifications of the management control process that is inherent in Level III GDSS. Clearly, there is no sharp transition line between one level and the next, and it may not always be easy to identify at what level a GDSS is operating. The DSS generator, such as discussed in our preceding section, would generally appear to produce a form of Level III DSS. In fact, most of the DSSs that we have been discussing in this book are either Level II or Level III DSSs or GDSSs. The GDSS of Figure 17, for example, becomes a Level III GDSS if is supported by a facilitator.

DeSanctis and Gallupe (1987) identify four recommended approaches:

1. Decision room for small group face-to-face meetings
2. Legislative sessions for large group face-to-face meetings
3. Local area decision networks for small dispersed groups
4. Computer-mediated conferencing for large groups that are dispersed

DeSanctis and Gallupe discuss the design of facilities to enable this, as well as techniques whereby the quality of efforts such as generation of ideas and actions, choosing from among alternative courses of action, and negotiating conflicts may be enhanced. On the basis of this, they recommend six areas as very promising for additional study: GDSS design methodologies; patterns of information exchange; mediation of the effects of participation; effects of (the presence or absence of) physical proximity, interpersonal attraction, and group cohesion; effects on power and influence; and performance/satisfaction trade-offs. Each of these supports the purpose of computerized aids to planning, problem solving, and decision making: removing a number of common communication barriers; providing techniques for structuring decisions; and systematically directing group discussion and associated problem-solving and decision making in terms of the patterns, timing, and content of the information that influences these actions.

We have mentioned the need for a GDSS model base management system (MBMS). There are a great variety of MBMS tools. Some of the least understood are group tools that aid in the issue formulation effort. Because these may represent an integral part of a GDSS effort, it is of interest to describe GDSS issue formation here as one component of a MBMS.

Other relevant efforts and interest areas involving GDSS include the group processes in computer mediated communications study; the computer support for collaboration and problem solving in meetings study of Stefik et al. (1987); the organizational planning study of Applegate et al. (1987), and the knowledge management and intelligent information sharing systems study of Malone et al. (1987). Particularly interesting current issues surround the extent to which cognitive science and engineering studies that involve potential human information processing flaws can be effectively dealt with, in the sense of design of debiasing aids, in GDSS design. In a very major way, the purpose of a GDSS is to support enhanced organizational communications. This is a very important contem-

porary subject, as evidenced by recent efforts concerning virtual organizations (DeSanctis and Monge 1999; Jablin and Putnam 2000).

5.3. Distributed Group Decision Support Systems

A single-user DSS must provide single-user-single-model and single-user-multiple-model support, whereas a GDSS model base management system (MBMS) must support multiple-user-single-model and multiple-user-multiple-model support. A centralized GDSS induces three basic components:

1. A group model base management subsystem (GMBMS)
2. A group database management subsystem (GDBMS)
3. A group dialog generation and management subsystem (GDGMS)

These are precisely the components needed in a single-user DSS, except for the incorporation of group concerns. In the GDSS, all data are stored in the group database and models are stored in the group model base. The GMBMS controls all access to the individually owned and group-owned models in the model base.

A distributed GDSS allows each user to have an individual DSS and a GDSS. Each individual DSS consists of models and data for a particular user. The GDSS maintains the GMBMS and GDBMS, as well as controlling access to the GMBMS and GDBMS and coordination of the MBMSs of various individual DSSs (Liang 1988). During actual GDSS system use, the difference between the centralized and distributed GDSSs should be transparent to the users.

We generally use models to help define, understand, organize, study, and solve problems. These range from simple mental models to complex mathematical simulation models. An important mission of a GDSS is to assist in the use of formal and informal models by providing appropriate model management. An appropriate model base management system for a GDSS can provide the following four advantages (Hwang 1985):

1. *Reduction of redundancy,* since models can be shared
2. *Increased consistency,* since more than one decision maker will share the same model
3. *Increased flexibility,* since models can be upgraded and made available to all members of the group
4. *Improved control over the decision process,* by controlling the quality of the models adopted

A model base management system provides for at least the following five basic functions (Blanning and King 1993): construction of new models, storage of existing and new models, access to and retrieval of existing models, execution of existing models, and maintenance of existing models. MBMSs should also provide for model integration and selection. Model integration by using the existing model base as building blocks in the construction of new or integrated models is very useful when ad hoc or prototype models are desired. Model integration is needed in the production of operational MBMSs.

In this section, we have provided a very broad overview of group decision support systems that potentially support group and organizational decision making functions. Rather than concentrate on one or two specific systems, we have painted a picture of the many requirements that must be satisfied in order to produce an acceptable architecture and design for these systems. This provides much fertile ground for research in many GDSS-relevant cognitive systems engineering areas (Rasmussen et al. 1995; Andriole and Adelman 1995).

6. KNOWLEDGE MANAGEMENT FOR DECISION SUPPORT

There can be no doubt that contemporary developments in information technology have changed engineering and business practices in many ways. The information revolution has, for example, created entirely new ways of marketing and pricing such that we now see very changed relationships among producers, distributors, and customers. It has also led to changes in the ways in which organizations are managed and structured, and deal with their products and services. In particular, it creates a number of opportunities and challenges that affect the way in which data is converted into information and then into knowledge. It poses many opportunities for management of the environment for these transfers, such as enhancing the productivity of individuals and organizations. Decision support is much needed in these endeavors, and so is knowledge management. It is fitting that we conclude our discussions of decision support systems with a discussion of knowledge management and the emergence in the 21st century of integrated systems to enhance knowledge management and decision support.

Major growth in the power of computing and communicating and associated networking is fundamental to the emergence of these integrated systems and has changed relationships among people, organizations, and technology. These capabilities allow us to study much more complex issues than

was formerly possible. They provide a foundation for dramatic increases in learning and both individual and organizational effectiveness. This is due in large part to the networking capability that enables enhanced coordination and communications among humans in organizations. It is also due to the vastly increased potential availability of knowledge to support individuals and organizations in their efforts, including decision support efforts. However, information technologies need to be appropriately integrated within organizational frameworks if they are to be broadly useful. This poses a transdisciplinary challenge (Somerville and Rapport 2000) of unprecedented magnitude if we are to move from high-performance information technologies and high-performance decision support systems to high-performance organizations.

In years past, broadly available capabilities never seemed to match the visions proffered, especially in terms of the time frame of their availability. Consequently, despite these compelling predictions, traditional methods of information access and utilization continued their dominance. As a result of this, comments something like ''computers are appearing everywhere except in productivity statistics'' have often been made (Brynjolfsson and Yang 1996). In just the past few years, the pace has quickened quite substantially, and the need for integration of information technology issues with organizational issues has led to the creation of related fields of study that have as their objectives:

- Capturing human information and knowledge needs in the form of system requirements and specifications
- Developing and deploying systems that satisfy these requirements
- Supporting the role of cross-functional teams in work
- Overcoming behavioral and social impediments to the introduction of information technology systems in organizations
- Enhancing human communication and coordination for effective and efficient workflow through knowledge management

Because of the importance of information and knowledge to an organization, two related areas of study have arisen. The first is concerned with technologies associated with the effective and efficient acquisition, transmission, and use of information, or *information technology*. When associated with organizational use, this is sometimes called *organizational intelligence* or *organizational informatics*. The second area, known as *knowledge management*, refers to an organization's capacity to gather information, generate knowledge, and act effectively and in an innovative manner on the basis of that knowledge. This provides the capacity for success in the rapidly changing or highly competitive environments of knowledge organizations. Developing and leveraging organizational knowledge is a key competency and, as noted, it requires information technology as well as many other supporting capabilities. Information technology is necessary for enabling this, but it is not sufficient in itself. Organizational productivity is not necessarily enhanced unless attention is paid to the human side of developing and managing technological innovation (Katz 1997) to ensure that systems are designed for human interaction.

The human side of knowledge management is very important. Knowledge capital is sometimes used to describe the intellectual wealth of employees and is a real, demonstrable asset. Sage (1998) has used the term *systems ecology* to suggest managing organizational change to create a knowledge organization and enhance and support the resulting intellectual property for the production of sustainable products and services. Managing information and knowledge effectively to facilitate a smooth transition into the Information Age calls for this systems ecology, a body of methods for systems engineering and management (Sage 1995; Sage and Rouse, 1999a,b) that is based on analogous models of natural ecologies. Such a systems ecology would enable the modeling, simulation, and management of truly large systems of information and knowledge, technology, humans, organizations, and the environments that surround them.

The information revolution is driven by technology and market considerations and by market demand and pull for tools to support transaction processing, information warehousing, and knowledge formation. Market pull has been shown to exert a much stronger effect on the success of an emerging technology than technology push. Hardly any conclusion can be drawn other than that society shapes technology (Pool 1997) or, perhaps more accurately stated, that technology and the modern world shape each other in that only those technologies that are appropriate for society will ultimately survive.

The potential result of this mutual shaping of information technology and society is knowledge capital, and this creates needs for knowledge management. Current industrial and management efforts are strongly dependent on access to information. The world economy is in a process of globalization, and it is possible to detect several important changes. The contemporary and evolving world is much more service oriented, especially in the more developed nations. The service economy is much more information and knowledge dependent and much more competitive. Further, the necessary mix of job skills for high-level employment is changing. The geographic distance between manufacturers and

consumers and between buyers and sellers is often of little concern today. Consequently, organizations from diverse locations compete in efforts to provide products and services. Consumers potentially benefit as economies become more transnational.

Information technology-based systems may be used to support taking effective decisions. Ideally, this is accomplished through both critical attention to the information needs of humans in problem solving and decision making task and provision of technological aids, including computer-based systems of hardware and software and associated processes, to assist in these tasks. There is little question but that successful information systems strategies seek to meaningfully evolve the overall architecture of systems, the systems' interfaces with humans and organizations, and their relations with external environments. In short, they seek to enhance systems integration effectiveness (Sage and Lynch 1998).

Although information technology and information systems do indeed potentially support improvement of the designs of existing organizations and systems, they also enable fundamentally new ones, such as virtual corporations (DeSanctis and Monge 1999), and they also enable major expansions of organizational intelligence and knowledge. They do this not only by allowing for interactivity in working with clients to satisfy present needs, but also through proactivity in planning and plan execution. An ideal organizational knowledge strategy accounts for future technological, organizational, and human concerns to support the graceful evolution of products and services that aid clients. Today, we realize that human and organizational considerations are vital to success in using information technology to better support decisions. A major challenge is to ensure that people gain maximal benefit from these capabilities. This is why information technology must be strongly associated with information ecology, knowledge management, and other efforts that we discuss here and that will ultimately lead to an effective systems ecology (Sage 1998).

There are three keys to organizations prospering in this type of environment: speed, flexibility, and discretion (Rouse 1999). Speed means rapid movement in understanding a situation, such as a new product development or market opportunity; formulating a plan for pursuing this opportunity, such as an intended joint venture for the new product; and deploying this plan so as to proceed through to product availability in stores. Flexibility is crucial for reconfiguring and redesigning organizations, and consequently reallocating resources. Functional walls must be quite portable, and generally the few of them the better.

Discretion transforms flexibility into speed. Distributed organizations must be free to act. While they may have to play by the contemporary and evolutionary rules of the game, they need to be able to adapt rapidly when things are not working well. Resources can thus be deployed effectively and speedily and results monitored quickly. Resource investments that are not paying off in the anticipated time frame can be quickly redeployed elsewhere, thereby ensuring adaptive and emergent evolution of the organization.

A major determinant of these organizational abilities is the extent to which an organization possesses intellectual capital, or knowledge capital, such that it can create and use innovative ideas to produce productive results. The concept of intellectual capital has been defined in various ways (Brooking 1996; Edvisson and Malone 1997; Stewart 1997; Klein 1998; Roos et al. 1998). We would add communications to the formulation of Ulrick (1998), representing intellectual capital to yield:

$$\text{Intellectual capital} = \text{Competence} \times \text{Commitment} \times \text{Communications}$$

Other important terms, such as *collaboration* and *courage,* could be added to this generic equation.

Loosely structured organizations and the speed, flexibility, and discretion they engender in managing intellectual capital fundamentally affect knowledge management (Myers 1997; Ruggles 1997; Prusak 1997; Albert and Bradley 1997; Liebowitz and Wilcox, 1997). Knowledge workers are no longer captive and hence know-how is not ''owned'' by the organization. What matters most is the ability to make sense of market and technology trends, quickly decide how to take advantage of these trends, and act faster than other players. Sustaining competitive advantage requires redefining market-driven value propositions and quickly leading in providing value in appropriate new ways. Accomplishing this in an increasingly information-rich environment is a major challenge, both for organizations experiencing contemporary business environments (Allee 1997; Stacey 1996) and for those who devise and provide decision support systems for supporting these new ways. The major interactions involving knowledge work and intellectual capital and the communications-driven information and knowledge revolution suggest many and profound, complex, adaptive system-like changes in the economy of the 21st century (Hagel and Armstrong 1997; Shapiro and Varian 1999; Kelly 1998; Hagel and Singer 1999). In particular, this has led to the notion of virtual enterprises and virtual communities and markets where customers make the rules that enhance net gain and net worth.

All of this creates major challenges for the evolution of knowledge organizations and appropriate knowledge management. One of the major challenges is that of dealing in an appropriate manner with the interaction among humans, organizations, and technologies and the environment surrounding

these. Davenport and Prusak (1998) note that when organizations interact with environments, they absorb information and turn it into knowledge. Then they make decisions and take actions. They suggest five modes of knowledge generation:

1. Acquisition of knowledge that is new to the organization and perhaps represents newly created knowledge. Knowledge-centric organizations need to have appropriate knowledge available when it is needed. They may buy this knowledge, potentially through acquisition of another company, or generate it themselves. Knowledge can be leased or rented from a knowledge source, such as by hiring a consultant. Generally, knowledge leases or rentals are associated with knowledge transfer.
2. Dedicated knowledge resource groups may be established. Because time is required for the financial returns on research to be realized, the focus of many organizations on short-term profit may create pressures to reduce costs by reducing such expenditures. Matheson and Matheson (1998) describe a number of approaches that knowledge organizations use to create value through strategic research and development.
3. Knowledge fusion is an alternative approach to knowledge generation that brings together people with different perspectives to resolve an issue and determine a joint response. Nonaka and Takeuchi (1995) describe efforts of this sort. The result of knowledge fusion efforts may be creative chaos and a rethinking of old presumptions and methods of working. Significant time and effort are often required to enable group members to acquire sufficient shared knowledge, work effectively together, and avoid confrontational behavior.
4. Adaptation through providing internal resources and capabilities that can be utilized in new ways and being open to change in the established ways of doing business. Knowledge workers who can acquire new knowledge and skills easily are the most suitable to this approach. Knowledge workers with broad knowledge are often the most appropriate for adaptation assignments.
5. Knowledge networks may act as critical conduits for innovative reasoning. Informal networks can generate knowledge provided by a diversity of participants. This requires appropriate allocation of time and space for knowledge acquisition and creation.

In each of these efforts, as well as in much more general situations, it is critical to regard technology as a potential enabler of human effort, not as a substitute for it. There are, of course, major feedbacks here because the enabled human efforts create incentives and capabilities that lead to further enhanced technology evolution.

Knowledge management (Nonaka and Takeuchi 1995; Cordata and Woods 1999; Bukowitz and Williams, 1999) refers to management of the environment for knowledge creation, transfer, and sharing throughout the organization. It is vital in fulfilling contemporary needs in decision support. Appropriate knowledge management considers knowledge as the major organizational resource and growth through enhanced knowledge as a major organizational objective. While knowledge management is dependent to some extent upon the presence of information technology as an enabler, information technology alone cannot deliver knowledge management. This point is made by McDermott (1999), who also suggests that the major ingredient in knowledge management, leveraging knowledge, is dramatically more dependent upon the communities of people who own and use it than upon the knowledge itself.

Knowledge management is one of the major organizational efforts brought about by the realization that knowledge-enabled organizations are best posed to continue in a high state of competitive advantage. Such terms as *new organizational wealth* (Sveiby 1997), *intellectual capital* (Brooking 1996; Edvinsson and Malone 1997; Klein 1998; Roos et al. 1998), the *infinite resource* (Halal 1998), and *knowledge assets* (Boisot 1998) are used to describe the knowledge networking (Skyrme, 1999) and working knowledge (Davenport and Prusak 1998) in knowledge-enabled organizations (Liebowitz and Beckman 1998; Tobin 1998). Major objectives of knowledge management include supporting organizations in turning information into knowledge (Devin 1999) and, subsequent to this through a strategy formation and implementation process (Zack 1999), turning knowledge into action (Pfeffer and Sutton 2000). This latter accomplishment is vital because a knowledge advantage is brought to fruition only through an action advantage. Appropriate information technology and knowledge management tools (Ruggles 1997) are necessary but not at all sufficient to enable knowledge creating organizations or knowing organizations. The result of appropriate creation of knowledge in organizations (Prusak 1997) leads to a very important result, a knowing organization in which organizations use information to construct meaning, to create knowledge, and to use this knowledge in taking decisions. The term *fourth generation R&D* has been given to the efforts necessary for management of knowledge, technology, and innovation. A framework to enable this is described in Miller and Morris (1999).

The major increase in interest in knowledge management in recent years has been brought about by the reality that contemporary engineering and business success are progressively more linked to abilities associated with the management of data, information, and knowledge. Knowledge management is concerned with knowledge creation, knowledge acquisition, knowledge packaging, knowledge transfer, and knowledge use and reuse by humans and organizations. Knowledge management and decision support each support a common purpose: making decisions and actions taken on the basis of information and knowledge more effective. Thus, it is reasonable to suggest that an objective of knowledge management is to make appropriate knowledge available in a timely and cost-effective manner to decision makers. It seems very safe to predict that computer-based decision support systems will increasingly employ or be associated with various knowledge management techniques to enhance the representation and processing of information such that it can be best associated with contingency task structures to become the beneficial knowledge that is absolutely needed for effective decision support.

The development of intellectual capital such as to optimize organizational value is of particular importance in effective decision support. This is accomplished by using information to construct meaning and create knowledge and thereby enable appropriate decision and action. Such an organization has been called a ''knowing organization'' (Choo 1998). The major challenge in all of this is very often that of making sense of a wealth of opportunities concerning alternative schools and strategies. These include dramatic increases in available data, as well as an ever-growing set of potentially useful methods and tools—and the major need to convert data into information and thence into knowledge—and to manage knowledge successfully in the networked economy. Sage and Rouse (1999a,b) identifies 10 important challenges and paradigms: systems modeling, emergent and complex phenomena, uncertainties and control, access to and utilization of information and knowledge, information and knowledge requirements, information and knowledge support systems, inductive reasoning, learning organizations, planning and design, and measurement and evaluation. Ongoing trends in information technology and knowledge management pose substantial challenges for information systems frontiers. Addressing the 10 key challenges elaborated here requires a new, broader perspective on the nature of information access and utilization, as well as knowledge management. Satisfactorily addressing these 10 key challenges, will require that decision support systems engineering efforts move beyond structure-bound views of the world and the natural tendency to nail down requirements and constraints before proceeding. The current dynamics of information technology and knowledge management make such ''givens'' obsolete almost as quickly as they are envisioned. These appears to be the major decision support systems engineering challenges today, and in a very real sense they are challenges for all of engineering and engineering management. In large part, they provide a major motivation for this Handbook.

CHAPTER 5
Automation Technology

CHIN-YIN HUANG
Tunghai University, Taiwan

SHIMON Y. NOF
Purdue University

1. INTRODUCTION

Accompanying the evolution of human society, tools have been developed to assist humans to perform all kinds of activities in humans' daily life. Tools not only reduce the effort that men have to put into those activities, they also help men perform activities that would otherwise be impossible due to the limitations of the human body—for example, using a telescope to see objects on the moon. However, humans are not satisfied with developing tools to enhance productivity or conquer their limitations. People have always dreamed of building machines to do their work for them, allowing them more leisure time. This dream can be realized through the help of modern computer and communication technologies. Activities in the manufacturing enterprises that are automated by computer and communication technologies can be summarized into (but not limited by) the following seven categories (Huang and Nof 1999):

1. *Design:* Powerful computation speeds up activities in enterprises. For example, design activities are improved because of powerful CAD workstations.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

2. *Decisions:* Powerful computation allows many simulation trials to find a better solution in decision making. For example, an optimal material handling equipment selection can be obtained through repeated simulation runs.
3. *Sensing:* Input devices (e.g., sensors, bar code readers) can gather and communicate environmental information to computers or humans. A decision may be made by computer systems based on the input information. The decision may also trigger output devices (e.g., robot arms, monitors) to realize the decisions.
4. *Recovery:* Computer systems may apply techniques of artificial intelligence (AI) (e.g., fuzzy rules, knowledge-based logic, neural networks) to improve the quality of activities. For example, a robot system may be recovered automatically from error conditions through decisions made by AI programs.
5. *Collaboration:* Distributed designers can work together on a common design project through a computer supported collaborative work (CSCW) software system.
6. *Partners:* A computer system in an organization may automatically find cooperative partners (e.g., vendors, suppliers, and subcontractors) from the Internet to fulfill a special customer order without any increase in the organization's capacity.
7. *Logistics:* Logistics flows of products and packages are monitored and maintained by networked computers.

Although these seven categories reflect the impact of computer and communication technologies, they are driven by four automation technologies: physical automation systems, automatic control systems, artificial intelligence systems, and integration technology. Physical automation systems and automatic control systems represent two early and ongoing achievements in automation technology. Through automatic control theories, most systems can be controlled by the set points defined by users. With the support of both automatic control theories and modern digital control equipment, such as the programmable logic controller (PLC), physical automation systems that consist of processing machines (e.g., CNCs), transportation equipment (e.g., robots and AGVs), sensing equipment (e.g., bar code readers) can be synchronized and integrated.

Artificial intelligence systems and integration technology are two relatively recent technologies. Many AI techniques, such as artificial neural networks, knowledge-based systems, and genetic algorithms, have been applied to automate the complex decision making processes in design, planning, and managerial activities of enterprises. Additionally, integration techniques, such as electronic data interchange (EDI), client-server systems, and Internet-based transactions, have automated business processes even when the participants are in remote sites.

In this chapter, we will discuss the above four technologies to give readers comprehensive knowledge of automation technology. Section 2 addresses physical automation technologies that are applied in the processing, transportation, and inspection activities. Section 3 introduces classical automatic control theory. The purpose of addressing automatic control theory is to review the traditional methods and explain how a system can be automatically adjusted to the set point given by users. Section 4 addresses artificial intelligence techniques and introduces basic application approaches. Section 5 introduces integration technology, which is based mostly on today's information technology. Section 6 introduces the emerging trends of automation technologies, which include virtual machines, tool perspective environment, and autonomous agents. Section 7 makes some concluding remarks.

2. PHYSICAL AUTOMATION TECHNOLOGY

Since MIT demonstrated the first numerically controlled machine tool in 1952, information technologies have revolutionized and automated the manufacturing processes. See Chapter 12 for physical automation techniques such as robots. In general, physical automation technology can be applied in three areas: processing, transportation/storage, and inspection. Representative examples of automated equipment are:

1. *Automated processing equipment:* CNC machine tools, computer-controlled plastic-injection machines, etc.
2. *Automated transportation/storage equipment:* Industrial robots, automatic guided vehicles (AGV), an automatic storage/retrieval systems (AS/RS), etc.
3. *Automated inspection equipment:* Coordination measuring machines (CMM), machine vision systems, etc.

3. AUTOMATIC CONTROL SYSTEMS

Control is the fundamental engineering and managerial function whose major purpose is to measure, evaluate, and adjust the operation of a process, a machine, or a system under dynamic conditions so

that it achieves desired objectives within its planned specifications and subject to cost and safety considerations. A well-planned system can perform effectively without any control only as long as no variations are encountered in its own operation and its environment. In reality, however, many changes occur over time. Machine breakdown, human error, variable material properties, and faulty information are a few examples of why a system must be controlled.

When a system is more complex and there are more potential sources of dynamic variations, a more complicated control is required. Particularly in automatic systems where human operators are replaced by machines and computers, a thorough design of control responsibilities and procedures is necessary. Control activities include automatic control of individual machines, material handling, equipment, manufacturing processes, and production systems, as well as control of operations, inventory, quality, labor performance, and cost. Careful design of correct and adequate controls that continually identify and trace variations and disturbances, evaluate alternative responses, and result in timely and appropriate actions is therefore vital to the successful operation of a system.

3.1. Fundamentals of Control

Automatic control, as the term is commonly used, is "self-correcting," or feedback, control; that is, some control instrument is continuously monitoring certain output variables of a controlled process and is comparing this output with some preestablished desired value. The instrument then compares the actual and desired values of the output variable. Any resulting error obtained from this comparison is used to compute the required correction to the control setting of the equipment being controlled. As a result, the value of the output variable will be adjusted to its desired level and maintained there. This type of control is known as a servomechanism.

The design and use of a servomechanism control system requires a knowledge of every element of the control loop. For example, in Figure 1 the engineer must know the dynamic response, or complete operating characteristics, of each pictured device:

1. The indicator or sampler, which senses and measures the actual output
2. The controller, including both the error detector and the correction computer, which contain the decision making logic
3. The control value and the transmission characteristics of the connecting lines, which communicate and activate the necessary adjustment
4. The operating characteristics of the plant, which is the process or system being controlled

Dynamic response, or *operating characteristics,* refer to a mathematical expression, for example, differential equations, for the transient behavior of the process or its actions during periods of change in operating conditions. From it one can develop the transfer function of the process or prepare an experimental or empirical representation of the same effects.

Because of time lags due to the long communication line (typically pneumatic or hydraulic) from sensor to controller and other delays in the process, some time will elapse before knowledge of changes in an output process variable reaches the controller. When the controller notes a change, it must compare it with the variable value it desires, compute how much and in what direction the control valve must be repositioned, and then activate this correction in the valve opening. Some time is required, of course, to make these decisions and correct the valve position.

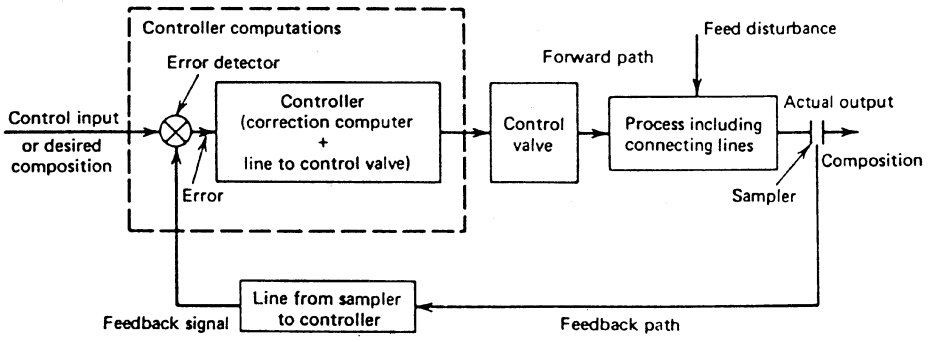

Figure 1 Block Diagram of a Typical Simple, Single Control Loop of a Process Control System. (From Williams and Nof 1992)

Some time will also elapse before the effect of the valve correction on the output variable value can reach the output itself and thus be sensed. Only then will the controller be able to know whether its first correction was too small or too large. At that time it makes a further correction, which will, after a time, cause another output change. The results of this second correction will be observed, a third correction will be made, and so on.

This series of measuring, comparing, computing, and correcting actions will go around and around through the controller and through the process in a closed chain of actions until the actual process valve is finally balanced again at the desired level by the operator. Because from time to time there are disturbances and modifications in the desired level of the output, the series of control actions never ceases. This type of control is aptly termed *feedback control.* Figure 1 shows the direction and path of this closed series of control actions. The closed-loop concept is fundamental to a full understanding of automatic control.

Although the preceding example illustrates the basic principles involved, the actual attainment of automatic control of almost any industrial process or other complicated device will usually be much more difficult because of the speed of response, multivariable interaction, nonlinearity, response limitations, or other difficulties that may be present, as well as the much higher accuracy or degree of control that is usually desired beyond that required for the simple process just mentioned.

As defined here, automatic process control always implies the use of a feedback. This means that the control instrument is continuously monitoring certain output variables of the controlled process, such as a temperature, a pressure, or a composition, and is also comparing this output with some preestablished desired value, which is considered a reference, or a set point, of the controlled variable. An error that is indicated by the comparison is used by the instrument to compute a correction to the setting of the process control valve or other final control element in order to adjust the value of the output variable to its desired level and maintain it there.

If the set point is altered, the response of the control system to bring the process to the new operating level is termed that of a servomechanism or self-correcting device. The action of holding the process at a previously established level of operation in the face of external disturbances operating on the process is termed that of a regulator.

3.2. Instrumentation of an Automatic Control System

The large number of variables of a typical industrial plant constitute a wide variety of flows, levels, temperatures, compositions, positions, and other parameters to be measured by the sensor elements of the control system. Such devices sense some physical, electrical, or other informational property of the variable under consideration and use it to develop an electrical, mechanical, or pneumatic signal representative of the magnitude of the variable in question. The signal is then acted upon by a transducer to convert it to one of the standard signal levels used in industrial plants (3–15 psi for pneumatic systems and 1–4, 4–20, or 10–50 mA or 0–5 V for electrical systems). Signals may also be digitized at this point if the control system is to be digital.

The signals that are developed by many types of sensors are continuous representations of the sensed variables and as such are called analog signals. When analog signals have been operated upon by an analog-to-digital converter, they become a series of bits, or on–off signals, and are then called digital signals. Several bits must always be considered together in order to represent properly the converted analog signal (typically, 10–12 bits).

As stated previously, the resulting sensed variable signal is compared at the controller to a desired level, or set point, for that variable. The set point is established by the plant operator or by an upper-level control system. Any error (difference) between these values is used by the controller to compute the correction to the controller output, which is transmitted to the valve or other actuator of the system's parameters.

A typical algorithm by which the controller computes its correction is as follows (Morriss 1995). Suppose a system includes components that convert inputs to output according to relationships, called gains, of three types: proportional, derivative, and integral gains. Then the controller output is

$$\text{Output} = K_P e(t) + K_I \int e(t)\, dt + K_D \frac{d(e(t))}{dt}$$

where K_P, K_D, and K_I = proportional, derivative, and integral gains, respectively, of the controller.

The error at time t, $e(t)$, is calculated as

$$e(t) = \text{set point} - \text{feedback signal}$$

3.3. Basic Control Models

3.3.1. Control Modeling

Five types of modeling methodologies have been employed to represent physical components and relationships in the study of control systems:

1. Mathematical equations, in particular, differential equations, which are the basis of classical control theory (transfer functions are a common form of these equations)
2. Mathematical equations that are used on state variables of multivariable systems and associated with modern control theory
3. Block diagrams
4. Signal flow graphs
5. Functional analysis representations (data flow diagram and entity relationships)

Mathematical models are employed when detailed relationships are necessary. To simplify the analysis of mathematical equations, we usually approximate them by linear, ordinary differential equations. For instance, a characteristic differential equation of a control loop model may have the form

$$\frac{d^2x}{dt^2} + 2\alpha\frac{dx}{dt} + \beta^2 x = f(t)$$

with initial conditions of the system given as

$$x(0) = X_0$$
$$x'(0) = V_0$$

where $x(t)$ is a time function of the controlled output variable, its first and second derivatives over time specify the temporal nature of the system, α and β are parameters of the system properties, $f(t)$ specifies the input function, and X_0 and V_0 are specified constants.

Mathematical equations such as this example are developed to describe the performance of a given system. Usually an equation or a transfer function is determined for each system component. Then a model is formulated by appropriately combining the individual components. This process is often simplified by applying Laplace and Fourier transforms. A graph representation by block diagrams (see Figure 2) is usually applied to define the connections between components.

Once a mathematical model is formulated, the control system characteristics can be analytically or empirically determined. The basic characteristics that are the object of the control system design are:

1. Response time
2. Relative stability
3. Control accuracy

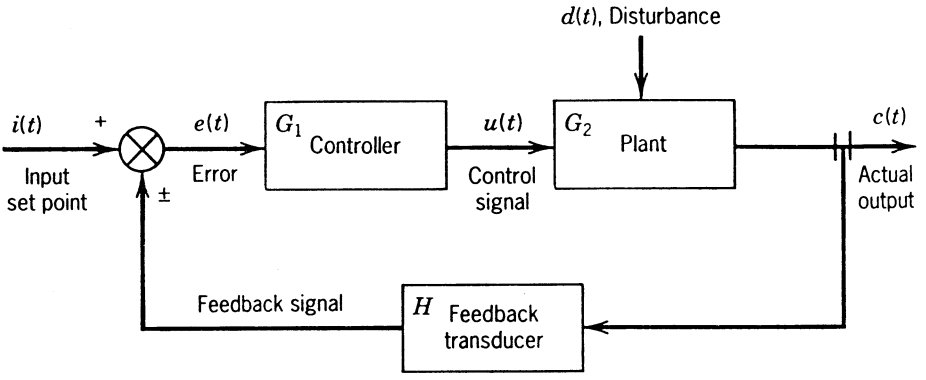

Figure 2 Block Diagram of a Feedback Loop. (From Williams and Nof 1992)

They can be expressed either as functions of frequency, called frequency domain specifications, or as functions of time, called time domain specifications. To develop the specifications the mathematical equations have to be solved. Modern computer software, such as MATLAB (e.g., Kuo 1995), has provided convenient tools for solving the equations.

3.3.2. Control Models

Unlike the open-loop control, which basically provides a transfer function for the input signals to actuators, the feedback control systems receive feedback signals from sensors then compare the signals with the set point. The controller can then control the plant to the desired set point according to the feedback signal. There are five basic feedback control models (Morriss 1995):

1. *On/off control:* In on/off control, if the $e(t)$ is smaller than 0, the controller may activate the plant; otherwise the controller stays still. Most household temperature thermostats follow this model.
2. *Proportional (PE) control:* In PE control, the output is proportional to the $e(t)$ value, i.e., $e(t) = K_P e(t)$. In PE, the plant responds as soon as the error signal is non-zero. The output will not stop exactly at the set point. When it approaches the set point, the $e(t)$ becomes smaller. Eventually, the output is too small to overcome opposing force (e.g., friction). Attempts to reduce this small $e(t)$, also called steady state error, by increasing K_P can only cause more overshoot error.
3. *Proportional-integral (PI) control:* PI control tries to solve the problem of steady state error. In PI, output $= K_P e(t) + K_I \int e(t)\, dt$. The integral of the error signal will have grown to a certain value and will continue to grow as soon as the steady state error exists. The plant can thus be drawn to close the steady state error.
4. *Proportional-derivative (PD) control:* PD control modifies the rate of response of the feedback control system in order to prevent overshoot. In PD,

$$\text{Output} = K_P e(t) + K_D \frac{d(e(t))}{dt}$$

   When the $e(t)$ gets smaller, a negative derivative results. Therefore, overshoot is prevented.
5. *Proportional-integral-derivative (PID) control:* PID control takes advantage of PE, PI, and PD controls by finding the gains (K_P, K_I, and K_D) to balance the proportional response, steady state reset ability, and rate of response control, so the plant can be well controlled.

3.4. Advanced Control Models

Based on the control models introduced in Section 3.3, researchers have developed various advanced control models for special needs. Table 1 shows the application domains and examples of the models, rather than the complicated theoretical control diagram. Interested readers can refer to Morriss (1995).

4. TECHNOLOGIES OF ARTIFICIAL INTELLIGENCE

Automation technologies have been bestowed intelligence by the invention of computers and the evolution of artificial intelligence theories. Because of the introduction of the technologies of artificial intelligence, automated systems, from the perspective of control, can intelligently plan, actuate, and control their operations in a reasonable time limit by handling/sensing much more environmental input information (see the horizontal axis in Figure 3). Meanwhile, artificial intelligence increases the decision making complexity of automation technology, but the cost of the system that is automated by the technologies of artificial intelligence is relatively low compared with the system automated by the automatic control theory (see the vertical axis in Figure 3). Figure 3 shows a roadmap of how various automation technologies influence the development of automation systems in two axes. In the following subsections, those technologies of artificial intelligence, including neural networks (NN), genetic algorithms (GA), knowledge-based systems (KBS), fuzzy control, and the hybrid of the above-mentioned technologies will be introduced in general.

4.1. Knowledge-Based Systems

The structure of a knowledge-based system (KBS) in control is presented in Figure 4. The control decisions are achieved by reasoning techniques (inference engine) rather than quantitative computation and can deal with uncertainties and unstructured situations. The knowledge base is updated by continuously acquiring the knowledge from experts, the decisions made by the operator and the feedback from the process. Nowadays, KBSs have been applied in many fields to diagnose causes of problems, such as in medical diagnosis, vehicle troubleshooting, and loan strategy planning in banks.

TABLE 1 System Characteristics and Examples of Advanced Control Models

Control Models	When to Apply (System Characteristics)	Examples
(1) Nested Control Loops	More than one characteristic of a system's output to be controlled at the same time	Robot controllers
(2) Directed Synthesis Control	Time lag between output and feedback reception is long	Satellite guidance systems
(3) Adaptive Directed Synthesis Control	Allow a direct synthesis control system to be adjusted when actual feedback is received	Modern machine tools
(4) Feedforward Control; Cascade Control	Set points are given by the sensed conditions upstream of the process.	Chemical process control
(5) Ratio Control	Use a sensor in one stream to control the processes in one or more parallel streams	Chemical process control
(6) Multiple Output Control	A single control provides the output signal to a group of parallel actuators. Then the result of the multiple actuation is fed back to the controller.	Complex hydraulic cylinders
(7) Constraint Control	More than one controller in the system. Under normal conditions, one of the controllers does the controlling, but if a preset limit is exceeded at a sensor, the second controller overrides the first and takes over control.	Chemical process control

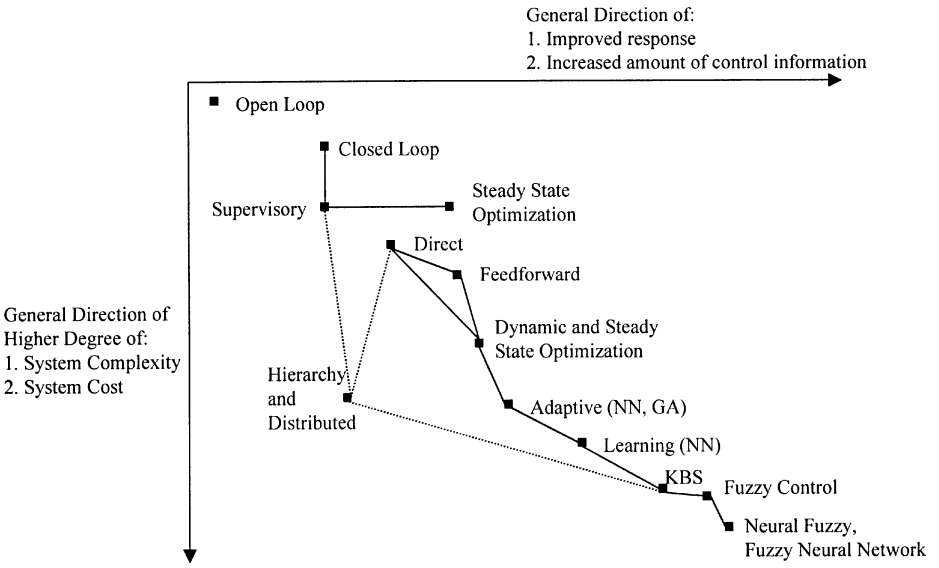

Figure 3 Roadmap of Control Models. (Revised from Williams and Nof 1992)

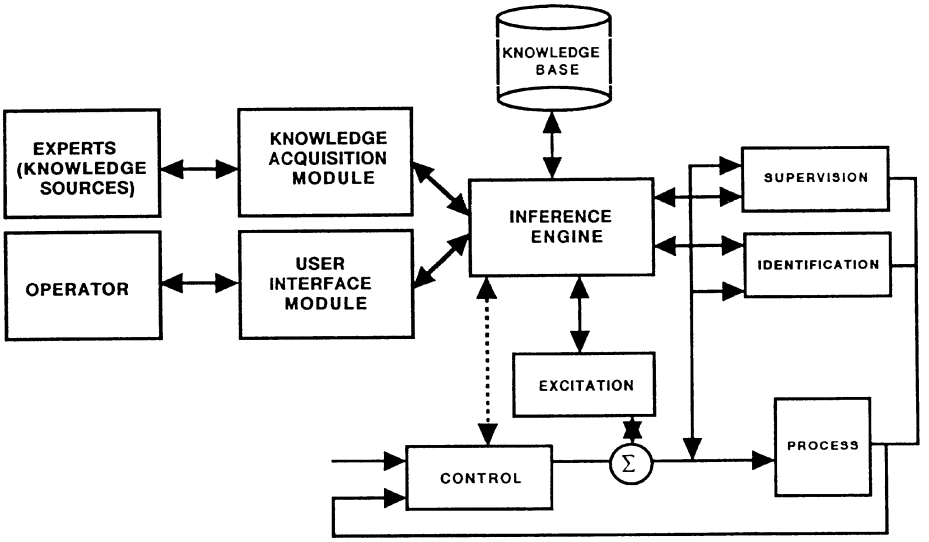

Figure 4 Block Diagram of a Knowledge-Based Control System. (From Williams and Nof 1992)

The numerous industrial engineering applications of control models in computer information systems can be classified into two types: (1) development of decision support systems, information systems that provide the information, and decisions to control operations, and (2) maintenance of internal control over the quality and security of the information itself. Because information systems are usually complex, graphic models are typically used.

Any of the control models can essentially incorporate an information system, as indicated in some of the examples given. The purpose of an information system is to provide useful, high-quality information; therefore, it can be used for sound planning of operations and preparation of realistic standards of performance. Gathering, classifying, sorting, and analyzing large amounts of data can provide timely and accurate measurement of actual performance. This can be compared to reference information and standards that are also stored in the information system in order to immediately establish discrepancies and initiate corrective actions. Thus, an information system can improve the control operation in all its major functions by measuring and collecting actual performance measures, analyzing and comparing the actual to the desired set points, and directing or actuating corrective adjustments.

An increasing number of knowledge-based decision support and control systems have been applied since the mid-1980s. Typical control functions that have been implemented are:

- Scheduling
- Diagnosis
- Alarm interpretation
- Process control
- Planning
- Monitoring

4.2. Artificial Neural Networks

The powerful reasoning and inference capabilities of artificial neural networks (ANN) in control are demonstrated in the areas of

- Adaptive control and learning
- Pattern recognition/classification
- Prediction

To apply ANN in control, the user should first answer the following questions:

1. If there are training data, ANN paradigm with supervised learning may be applied; otherwise, ANN paradigm with unsupervised learning is applied.
2. Select a suitable paradigm, number of network layers, and number of neurons in each layer.
3. Determine the initial weights and parameters for the ANN paradigm.

A widely applied inference paradigm, back propagation (BP), is useful with ANN in control. There are two stages in applying BP to control: the training stage and the control stage (Figure 5).

4.2.1. Training Stage

1. Prepare a set of training data. The training data consist of many pairs of data in the format of input–output.
2. Determine the number of layers, number of neurons in each layer, the initial weights between the neurons, and parameters.
3. Input the training data to the untrained ANN.
4. After the training, the trained ANN provides the associative memory for linking inputs and outputs.

4.2.2. Control Stage

Input new data to the trained ANN to obtain the control decision. For instance, given a currently observed set of physical parameter values, such as noise level and vibration measured on a machine tool, automatically adapt to a new calculated motor speed. The recommended adjustment is based on the previous training of the ANN-based control. When the controller continues to update its training ANN over time, we have what is called learning control.

Other application examples of neural networks in automated systems are as follows:

- Object recognition based on robot vision
- Manufacturing scheduling
- Chemical process control

The ANN could be trained while it is transforming the inputs on line to adapt itself to the environment. Detailed knowledge regarding the architectures of ANN, initial weights, and parameters can be found in Dayhoff (1990), Freeman and Skapura (1991), Fuller (1995), Lin and Lee (1996).

4.3. Fuzzy Logic

Figure 6 shows a structure of applying fuzzy logic in control. First, two types of inputs must be obtained: numerical inputs and human knowledge or rule extraction from data (i.e., fuzzy rules). Then the numerical inputs must be fuzzified into fuzzy numbers. The fuzzy rules consist of the fuzzy membership functions (knowledge model) or so-called fuzzy associative memories (FAMs). Then the

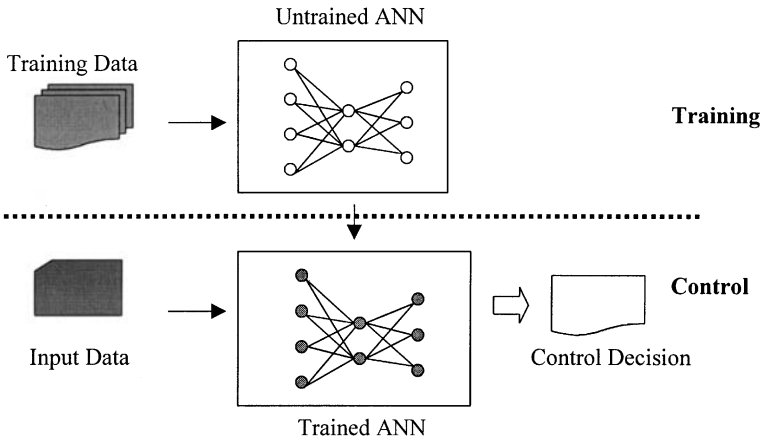

Figure 5 Structure of Applying Back-Propagation ANN in Control.

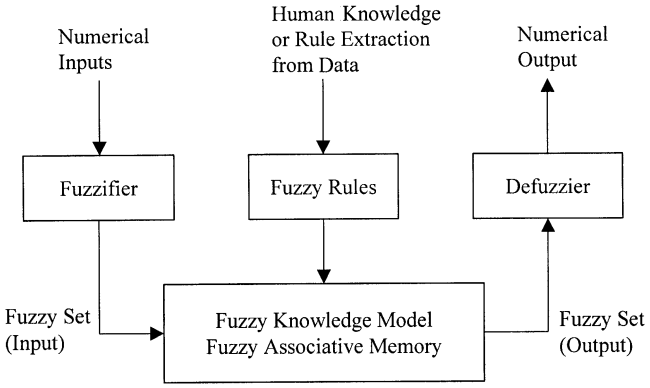

Figure 6 The Structure of Applying Fuzzy Logic in Control.

FAMs map fuzzy sets (inputs) to fuzzy sets (outputs). The output fuzzy sets should be defuzzified into numerical values to control the plant. Due to the powerful ability of fuzzy sets in describing system linguistic and qualitative behavior and imprecise and/or uncertain information, many industrial process behavior and control laws can be modeled by fuzzy logic-based approaches. Fuzzy logic has been applied in a wide range of automated systems, including:

- Chemical process control
- Autofocusing mechanism on camera and camcorder lens
- Temperature and humidity control for buildings, processes, and machines

4.4. Genetic Algorithms

Genetic algorithms (GAs), also referred to as evolutionary computation, are highly suitable for certain types of problems in the areas of optimization, product design, and monitoring of industrial systems. A GA is an automatically improving (evolution) algorithm. First the user must encode solutions of a problem into the form of chromosomes and an evaluation function that would return a measurement of the cost value of any chromosome in the context of the problem. A GA consists of the following steps:

1. Establish a base population of chromosomes.
2. Determine the fitness value of each chromosome.
3. Create new chromosomes by mating current chromosomes; apply mutation and recombination as the parent chromosomes mate.
4. Delete undesirable members of the population.
5. Insert the new chromosomes into the population to form a new population pool.

GA are useful for solving large-scale planning and control problems. Several cases indicate that GA can effectively find an acceptable solution for complex product design, production scheduling, and plant layout planning.

4.5. Hybrid Intelligent Control Models

Intelligent control may be designed in a format combining the techniques introduced above. For example, fuzzy neural networks use computed learning and the adaptive capability of neural networks to improve the computed learning's associative memory. Genetic algorithms can also be applied to find the optimal structure and parameters for neural networks and the membership functions for fuzzy logic systems. In addition, some techniques may be applicable in more than one area. For example, the techniques of knowledge acquisition in KBSs and fuzzy logic systems are similar.

5. INTEGRATION TECHNOLOGY

Recent communication technologies have enabled another revolution in automation technologies. Stand-alone automated systems are integrated via communication technologies. Integration can be identified into three categories:

1. *Networking:* Ability to communicate.
2. *Coordinating:* Ability to synchronize the processes of distributed automated systems. The coordination is realized by either a controller or an arbitrary rule (protocol).
3. *Integration:* Distributed automated systems are able to cooperate or collaborate with other automated systems to fulfill a global goal while satisfying their individual goals. The cooperation/collaboration is normally realized via a protocol that is agreed upon by distributed automated systems. However, the agreement is formed through the intelligence of the automated systems in protocol selection and adjustment.

In this section, automated technologies are introduced based on the above categories. However, truly integrated systems (technologies) are still under development and are mostly designed as agent-based systems, described in Section 6. Only technologies from the first two categories are introduced in this section.

5.1. Networking Technologies

To connect automated systems, the simplest and the most economic method is to wire the switches on the automated systems to the I/O modules of the programmable logic controller (PLC). Ladder diagrams that represent the control logic on the automated systems are popularly applied in PLCs. However, as the automated systems are remotely distributed, automated systems become more intelligent and diversified in the communication standards that they are built in, and the coordination decisions become more complex, the simple messages handled by the PLC-based network are obviously not enough for the control of the automated systems. Hence, some fundamental technologies, such as field bus (Mahalik and Moore 1997) and local area networks (LANs), and some advanced communication standards, such as LonWorks, Profibus, Manufacturing Automation Protocol (MAP), Communications Network for Manufacturing Applications (CNMA), and SEMI* Equipment Communication Standard (SECS) are developed.

In a field bus, automated devices are interconnected. Usually the amount of data transmitted in the bus is not large. In order to deliver message among equipment's timely in a field bus, the seven layers of the open system interconnection (OSI) are simplified into three layers: *physical layer, data link layer,* and *application layer.* Unlike a field bus, which usually handles the connections among devices, office activities are automated and connected by a LAN. Usually more than one file server is connected in a LAN for data storage, retrieval, and sharing among the connected personal computers. Three technological issues have to be designed/defined in a LAN topology, media, and access methods (Cohen and Apte 1997).

For the advanced communication standard, MAP and CNMA are two technologies that are well known and widely applied. Both technologies are based on the Manufacturing Message Specification (MMS) (SISCO 1995), which was developed by the ISO Industrial Automation Technical Committee Number 184. MMS provides a definition to specify automated equipment's external behaviors (Shanmugham et al. 1995). Through the specification, users can control the automated equipment with little knowledge about the internal message conversion within MMS and the equipment.

SECS is currently a popular communication standard in semiconductor industries (SEMI 1997). The standard was developed by SEMI based on two standards, SECS-I (SEMI Equipment Communications Standard Part 1 Message Transfer) and SECS-II (SEMI Equipment Communication Standard 2 Message Content). The relationship between SECS-I and SECS-II, as shown in Figure 7, shows that SECS-I transmits the message that is defined by SECS-II to RS-232. SECS-II's message

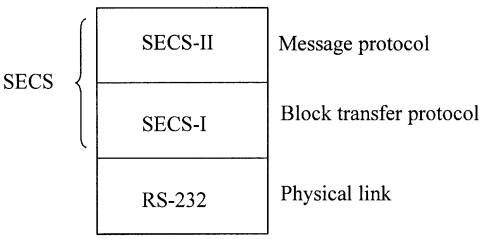

Figure 7 Basic Structure of SECS.

*SEMI stands for Semiconductor Equipment and Materials International.

is added as control information by the SECS-I so the transmission message can conform the format of RS-232 for message delivery. For SECS-II, it provides a set of interequipment communication standards under various situations. Hence, engineers only need to know and follow the SECS-II to control the connected automated equipment, rather than taking time to define the detailed message conversion.

5.2. Object Orientation and Petri Net Techniques

Object orientation and Petri net are automation techniques in modeling and analysis levels. Automated systems and their associated information and resources can be modeled by object models. The coordination and communication among the automated systems can then be unified with the message passing among the objects. However, the complex message passing that is used to coordinate behaviors of the automated systems relies on the technique of Petri net. The graphical and mathematically analyzable characteristics make Petri net a very suitable tool for synchronizing the behaviors and preventing deadlocks among automated systems. Combinations of both techniques have been developed and applied in the controllers of flexible manufacturing systems (Wang 1996; Wang and Wu 1998).

5.3. Distributed Control vs. Central Control

The rapid development of microprocessor technology has made distributed control possible and attractive. The use of reliable communication between a large number of individual controllers, each responsible for its own tasks rather than for the complete operation, improves the response of the total system. We can take PLC-based control as a typical example of central control system and LonWorks, developed by Echelon, as an example of distributed control system. In LonWorks, each automated device is controlled by a control module—LTM-10 (Figure 8). The control modules are connected on a LonTalk network that provides an ISO/OSI compatible protocol for communication.

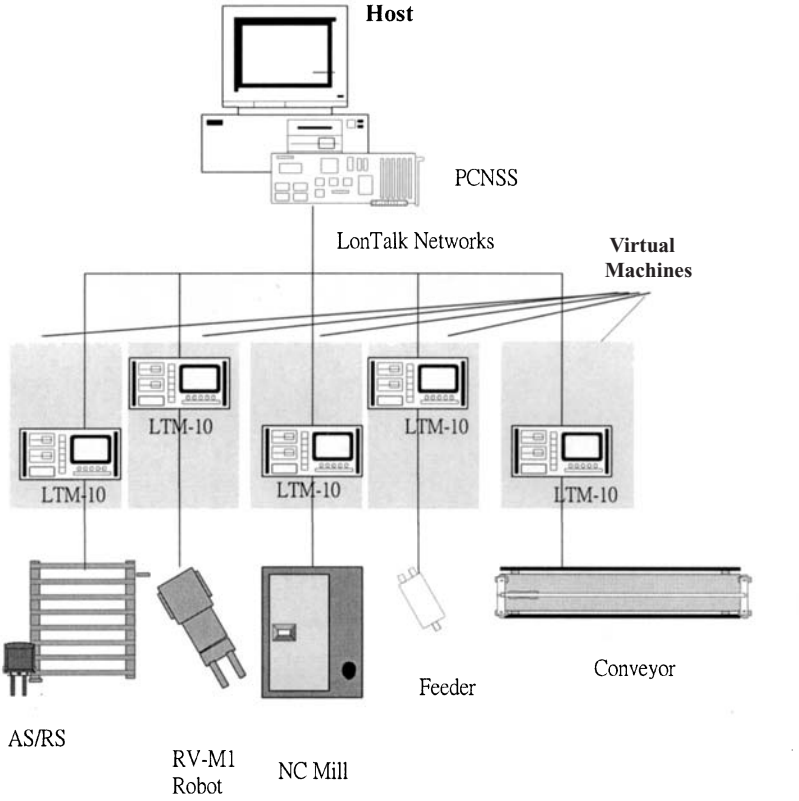

Figure 8 Applying LonWorks to Develop Virtual Machines.

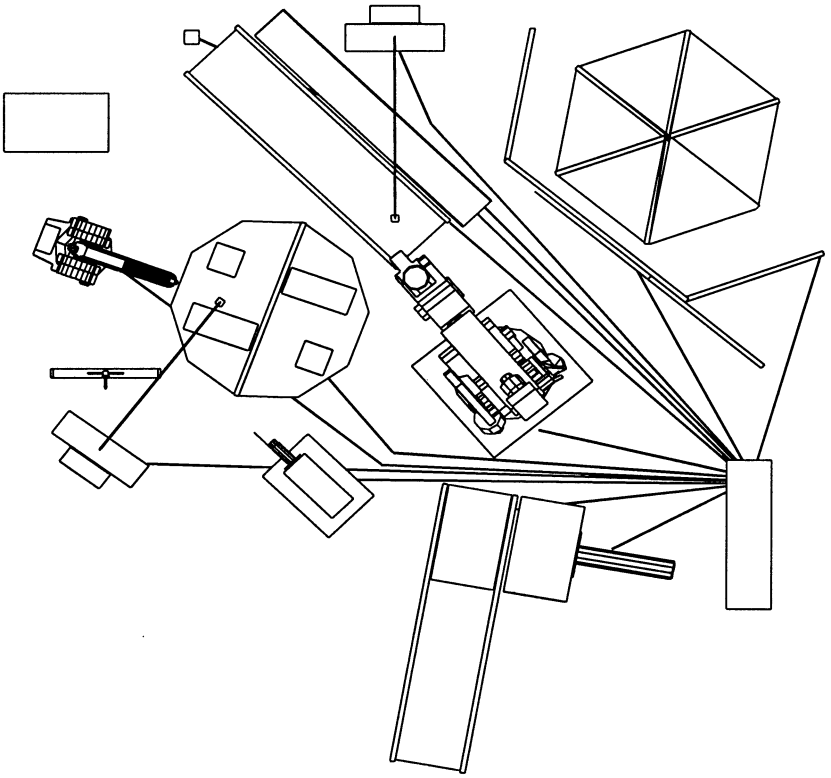

Figure 9 An Example of a Robot Emulator. (From Witzerman and Nof 1995)

Usually the control modules are loaded with Neuron C programs from a host computer that has a PCNSS network card for network management and Neuron C programming. Hence, under running mode the host computer is not necessary and the control modules can work under a purely distributed environment.

Distributed automated systems have the following advantages over centralized automated systems:

- Higher system reliability
- Better response to local demands
- Lower cost in revising the system control programs when automated equipment is added or deleted from the system

5.4. Robot Simulator/Emulator

In recent years, powerful robot simulators/emulators have been developed by several companies (Nof 1999). Examples include ROBCAD by Tecnomatix and RAPID by Adept Technologies. With these highly interactive, graphic software, one can program, model, and analyze both the robots and their integration into a production facility. Furthermore, with the geometric robot models, the emulation can also check for physical reachability and identify potential collisions. Another important feature of the robot simulators/emulators is off-line programming of robotic equipment, which allows designers to compare alternative virtual design before the program is transferred to actual robots (see Figure 9).

6. EMERGING TRENDS

Automation technology has reached a new era. An automation system is automated not only to reach the setting point but to situate itself intelligently in its complex environment. The individual automated systems are also networked to accomplish collaborative tasks. However, networking automated

systems is not an easy task. It involves the technologies from the physical levels, which handle the interface and message conversion between automation systems, to the application level, which handles mostly the social interactions between the automation systems. Three typical ongoing research directions are described next to present the trends of automation technology.

6.1. Virtual Machines

Traditionally, a hierarchy structure of the computer control system for a fully automated manufacturing system can be divided into four levels (Figure 10). The supervisory control is responsible for managing the direct digit control by sending control commands, downloading process data, monitoring the process, and handling exception events. From the perspective of message transmission, the hierarchy in Figure 10 can be classified into three standard levels, as shown in Figure 11:

1. *Production message standard:* a standard for obtaining/sending production information from /to low-level computers. The production information can be a routing, a real-time statistics, etc. Usually the information is not directly related to the equipment control.
2. *Control message standard:* a standard for controlling the equipment logically. The control message includes commands, the parameters associated with the command, and data. SECS-II is a standard that can fulfill such a need (Elnakhal and Rzehak 1993).

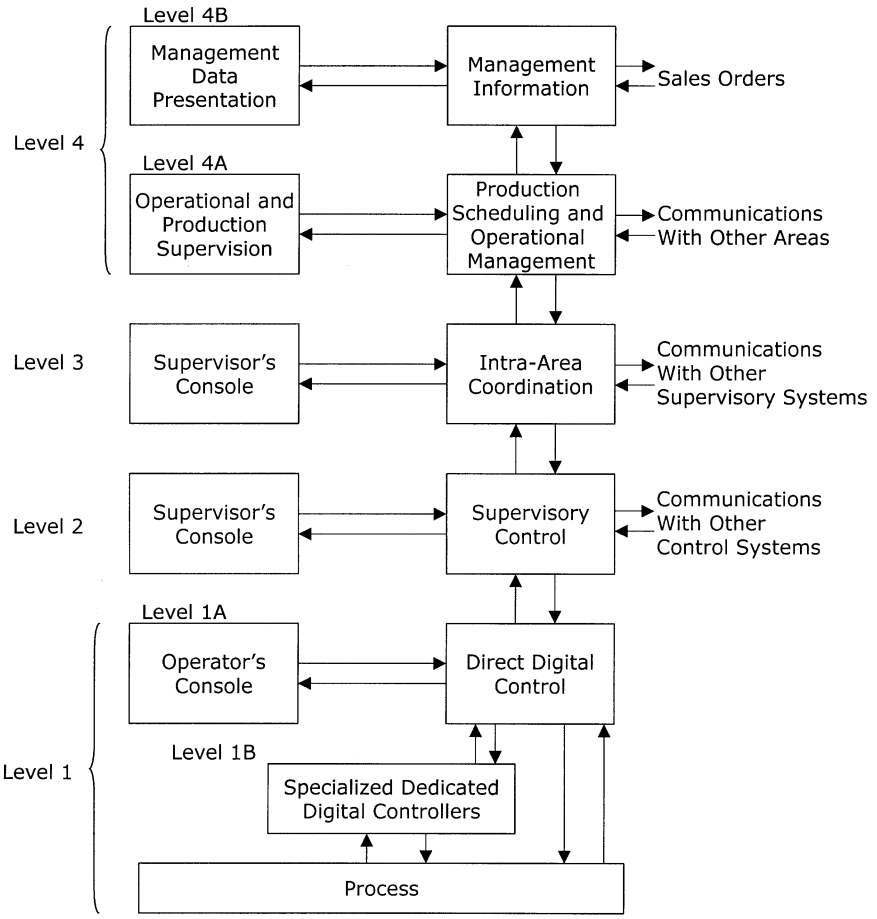

Figure 10 The Hierarchy Structure of the Computer Control System for a Fully Automated Industrial Plant. (From Williams and Nof 1992)

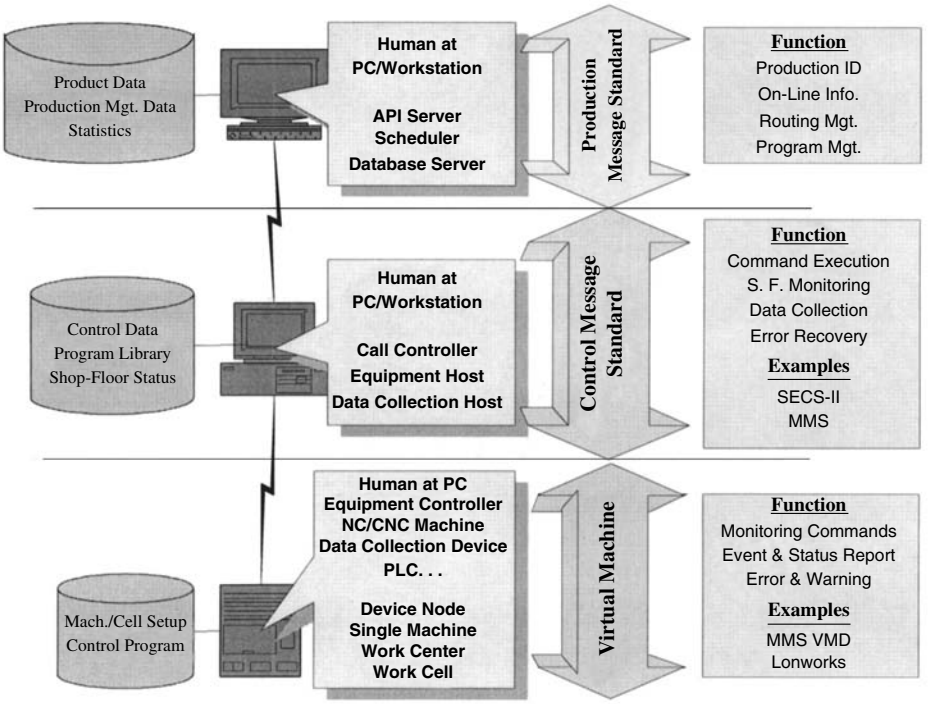

Figure 11 Three Layers of Message Transmission.

3. *Virtual machine:* a mechanism that converts the logical commands based on the control message standard, e.g., SECS-II, to commands format that can be accepted by a physical machine. Figure 12 shows that a virtual machine is laid between a host that delivers SECS-II commands and a real device that receives and executes the commands in its format. A virtual machine is therefore responsible for bridging the message format gap.

The development of virtual machines reduces the problems of incompatibility in an automated system, especially when the automated equipment follows different communication standards and protocols. It also enables the high-level controller to focus on his or her control activities, such as sequencing and scheduling, rather than detailed command incompatibility problems. Further information on virtual machines and automation can be found in Burdea and Coiffet (1999).

6.2. Tool Perspective Environment

Modern computer and communication technologies not only improve the quality, accuracy, and timeliness of design and decisions but also provide tools for automating the design and decision making processes. Under such a tool perspective, human experts focus on developing tools, then users can apply the tools to model and resolve their automation problems (see the right-side diagram in Figure 13). In contrast with traditional approaches, difficulties occur only during the tool development. For traditional approaches, ''experts'' are the bottlenecks in design projects. They must understand not only the problems but also the applications and limitations in practice. In practice, the costs of looking for and working with the experts are the main expense. For tool perspective, the cost of training the users becomes the major expense. However, frequent environment changes usually result in the design of a flexible system to respond to repeated needs to modify and evaluate the existing system. Modification and evaluation needs can be fulfilled by rapidly applying computerized tools, which provide relatively high flexibility in design. Some researchers have noted the importance of modeling manufacturing systems with the tool perspective. A sample survey is presented in Table 2. The three modeling concerns ((1) conflicts among designers, (2) constraints in physical environment, (3) the information flows in manufacturing systems) are part of the criteria in the survey table. It is found

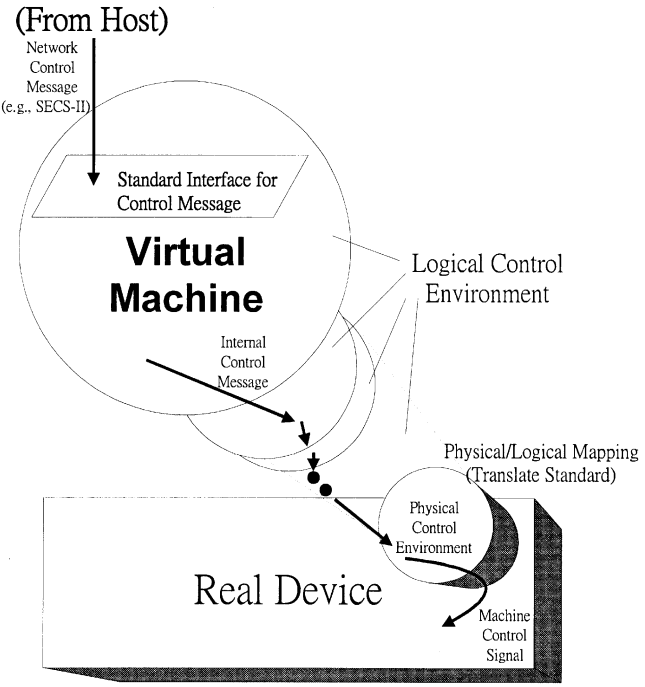

Figure 12 Role of Virtual Machine in Automation Applications.

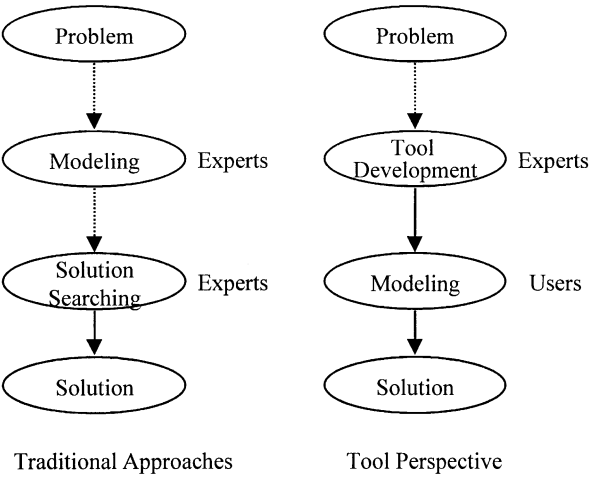

Figure 13 A Comparison of Traditional Approaches and Tool Perspective. (From Huang and Nof 1998)

TABLE 2 A Sample Survey of Models of Material Handling and Robotics with the Tool Perspective

No.	Modeling Approach/Tool, Reference	Methodologies Applied	Measured Criteria or Goal of the Model	Three Modeling Concerns Addressed?
1.	Nadoli and Rangaswami (1993)	Expert system, simulator	Waiting time, congestion level, etc.	No
2.	Chadha et al. (1994)	IDEF0, Data flow diagram, extended entity relationship	Develop an integrated information system	(3) only
3.	Prakash and Chen (1995)	SIMAN IV simulator	Speed of AGV and dispatching rules	No
4.	Sly (1995)	AutoCAD with FactoryFLOW	Minimum distance of material flows	No
5.	*FDL* (Witzerman and Nof 1995, 1996); FDL/CR (Lara et al. 2000)	ROBCAD and simulator	Integrated tool for distributed engineers; computer support for conflict resolution	(1), (2), and (3)
6.	*CFS* (Furtado and Nof 1995)	Data/control flow diagram, Petri net	Integrated tool to incorporate material flows, information flows, and control signals	(1) and (3) only

Adapted from Huang and Nof (1998).

that the concerns are not addressed by the first four models. The approach of the first four models still follows the traditional approaches, except for the second model. In the following paragraphs, two automated, integrated tools for manufacturing system design are introduced to present the above concept: facility description language (FDL) and the other is concurrent flexible specification (CFS).

6.2.1. Facility Description Language (FDL)

FDL provides an integrated modeling tool for distributed engineers working on various aspects of manufacturing system design (Witzerman and Nof 1995, 1996; Lara et al. 2000). FDL is implemented in a 3D emulation environment, ROBCAD (Tecnomatix 1989), which provides a dynamic and physically visible (comparing with ''iconically visible'' in simulation animation) CAD environment. Therefore, all the materials, operations of robots and material handling facilities, and machines are shown by their true physical relationships.

In the framework of FDL, the manufacturing systems are modeled by computer information and graphics. Various information teams are included in the model that are not seen in traditional models (Witzerman and Nof 1995):

1. Organizational relationship among facility components
2. Specification of working locations for robots
3. Flow of parts and materials through the facility
4. Location of personnel and equipment aisles
5. Control relationships between devices
6. Designation of sensors and their targets

These information items are supported by the modeling functions of FDL (Table 3). An example of modeling an aisle by an FDL function is:

TABLE 3 FDL Modeling Functions

Function Class	Function
FDL Definition Input Functions	Aisle, Capabiity, Control, Define (aisle, path, perimeter), Device, Facility, Part, Process, ProcessPart, Sensor, Transfer, Workpoint
FDL Manipulation Input Functions	Attach, Delete, Detach, Display (top, lower, bottom, name), Moveback, ShiftBy, ShiftTo
FDL Utility Input Functions	Comment, Print, Save
FDL Evaluation Function	Reconcile Database, Evaluate Aisles, Evaluate Device Reach, Display Material Flow Paths, Evaluate Fields of View

Aisle	*Redefine aspects pertaining to an aisle.*	
	syntax	***aisle*** *action path parent size*
	action	char (A, C, D) add, change, delete record (mandatory)
	path	char[16] path name (ROBCAD name)
	parent	char[16] parent name from device table
	size	char ''HUMAN'', ''AGV'', ''SMALL_FL'', or ''LARGE_FL''

The model in FDL then becomes a list of syntax. The list of syntax triggers the ROBCAD program to construct a 3D emulation model (see the model inside the window of Figure 14). Figure 14 is an example of FDL in a ROBCAD system. The upper left window is used to input the information of the system, including the geometric information of facilities, material flow information, and material flow control information. The lower left window is used to show the output information (e.g., a collision occurring to the robot during the material handling). In addition, FDL provides a reconciliation function (see the right function menu in Figure 14). Therefore, all the control and physical conflicts on the manufacturing systems can be resolved according to the built in algorithm. The reconciliation function may change the positions of robots or machines to avoid the collision or unreachability of material handling. Recently, FDL/CR has been developed to provide knowledge-based computer support for conflict resolution among distributed designers.

Because FDL provides such direct syntax specifications, the designers can use the syntax to model and develop their subsystems. When the designers are in different locations, their subsystems can submit input to the host ROBCAD system to construct the entire system, then use the reconciliation function to adjust the subsystems if conflicts occur. Therefore, the cooperation of designers in different locations for different subsystems can be achieved in FDL. In the FDL working environment, two types of information are exchanged among the designers: (1) the design based on FDL syntax and (2) the operations of the facilities described by a task description language (TDL). TDL represents the control functions of the facilities. Thus, not only the models of the material flow but also the control information are presented and shared among the designers.

6.2.2. Concurrent Flexible Specifications (CFS)

By specification, engineers describe the way that a system should be constructed. Concurrent, flexible specifications for manufacturing systems, in other words, are provided by several engineers to model manufacturing systems with flexibility to design changes. In a manufacturing system, there is a physical flow of raw materials, parts, and subassemblies, together with an information and control flow consisting of status (system state) and control signals. The control and status signals govern the behavior of the physical flows. In order to simultaneously achieve optimal capacity loading with maintained or increased flexibility, an exact definition of material and information flow becomes necessary. This approach is followed by CFS modeling (Furtado and Nof 1995). The specification should represent not only the logical structures of different functions but also their logical connections, such as the structures of material and information flow in a manufacturing cell (Csurgai et al. 1986).

Another important requirement of specification is the ability to define precisely the real-time behavior of the system. In a real-time system, many of the inputs to the system are signals that indicate the occurrence of events. These inputs do not pass data to the system to be processed. Generally they occur in streams over time and their purpose is to trigger some process in the system

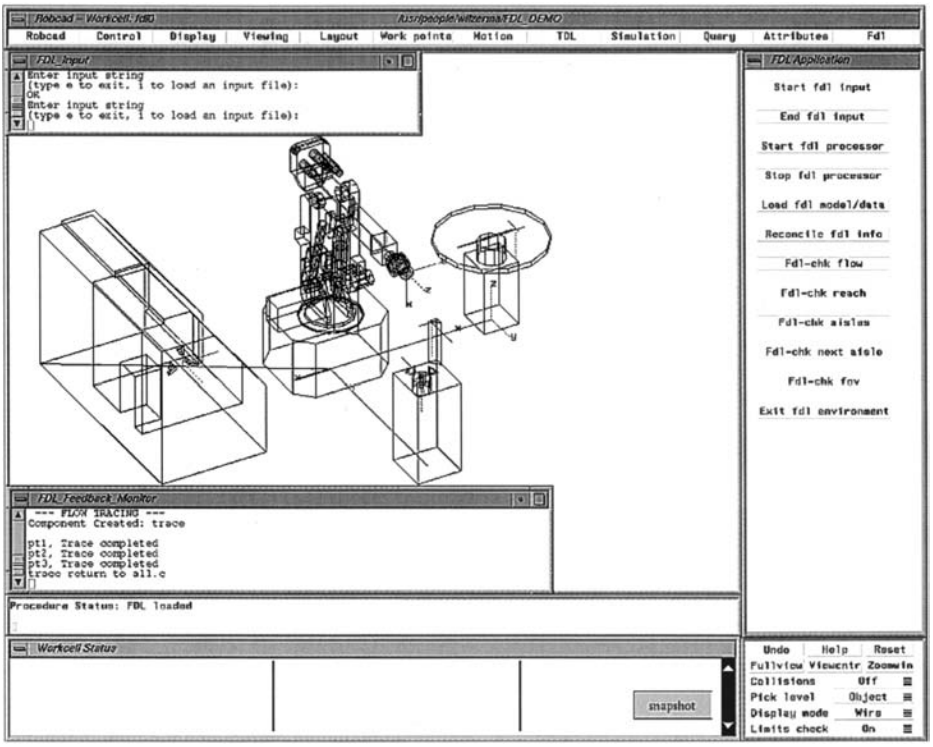

Figure 14 An Example of Facility Description Language in ROBCAD System.

repeatedly. Furthermore, many systems are made up of subsystems, any of which may be active or nonactive at a particular time during system operation. For this reason, the treatment of timing is an essential element of the specification.

To integrate the above requirements, tools that can incorporate material flows, information flows, and control signals are required. Therefore, different representations of specifications through different tools should not be independent or mutually exclusive but should support each other by forming a concurrent, comprehensive specification of the system. For manufacturing systems, the specification of *functional* and *real-time logic* is important because these attributes describe what and how the system is executing. This information is necessary to determine how the processes are to be implemented with physical equipment. By utilizing two complementary representations, both these aspects of system behavior can be specified concurrently.

Data/control flow diagrams (DFD/CFDs), which are enhanced with real-time extensions when used in conjunction with Petri nets, provide a suitable framework for concurrent specification of functional and real-time state logic. The main reason for this is the ability to maintain identical structural decompositions in both representations at all levels of detail in the specification. This model is accomplished by maintaining identical partitioning of processes in both specifications.

With DFD/CFDs, partitioning is accomplished by hierarchical decomposition of bubbles that represent processes or tasks. An identical hierarchical partitioning can be created with Petri nets by representing processes with subnets at higher levels and then showing the detailed, internal net at lower levels of detail. The DFD/CFDs provide a process definition model of the system, while the Petri nets provide a process analysis model for the study of real-time state behavior. Even though object-oriented modeling is becoming a more popular technique of system design, data/control flow diagrams are still an acceptable technique in our case study. Researchers have proved the possibility of transforming data flow diagrams to object models (Alabiso 1988).

Both these techniques are realized by two software packages: Teamwork and P-NUT. Teamwork is a computer aided software engineering (CASE) tool family that automates standard structured methodologies using interactive computer graphics and multiuser workstation power. P-NUT is a set of tools developed by the Distributed Systems Project in the Information and Computer Science

Department of the University of California at Irvine (Razouk 1987) to assist engineers in applying various Petri net-based analysis methods.

6.3. Agent-Based Control Systems

Early agents were defined for distributed artificial intelligence, which includes two main areas: distributed problem solving (DPS) and multi-agent systems (MASs). DPS focuses on centrally designed systems solving global problems and applying build-in cooperation strategies. In contrast, MAS deals with heterogeneous agents whose goal is to plan their utility-maximizing coexistence. Examples of DPS are mobile robots exploring uncertain terrain, and task scheduling in manufacturing facilities. Both can be operated with centralized programs, but in relatively more distributed environments they are usually more effective with autonomous programs, or agents. Examples of MAS are collaborative product design and group behavior of several mobile robots.

Recent research has explored the concept of autonomous agents in control. An agent is a computing system that can autonomously react and reflex to the impacts from the environment in accordance with its given goal(s). An agent reacts to the environment by executing some preloaded program. Meanwhile, there is an autonomous adjustment mechanism to provide a threshold. When the environmental impacts are higher than the threshold, the agent reflexes; otherwise it is intact. An agent may seek collaboration through communicating with other agents. The communication among agents is regulated by protocols, structure of dialogue, to enhance the effectiveness and efficiency of communication.

An important difference between autonomous agents and other techniques is that an autonomous agent evaluates the rules that it will perform. It may even automatically change its goal to keep itself alive in a harsh environment. Autonomous agents have been applied in many control systems, including air traffic control, manufacturing process control, and patient monitoring.

Usually an agent functions not alone, but as a member of a group of agents or an agent network. The interaction and communication among agents can be explained by the analogy of organizational communication. An organization is an identifiable social pursuing multiple objectives through the coordinated activities and relations among members and objects. Such a social system is open ended and depends for its effectiveness and survival on other individuals and subsystems in the society of all related organizations and individuals. (It is actually similar for both human societies and agent societies.) Following this analogy, three characteristics of an organization and of an agent network can be observed (Weick 1990):

1. Entities and organization
2. Goals and coordinated activities
3. Adaptability and survivability of the organization

Five motivations have been observed for organizational and agent network communication (Jablin 1990):

1. Generate and obtain information
2. Process and integrate information
3. Share information needed for the coordination of interdependent organizational tasks
4. Disseminate decisions
5. Reinforce a group's perspective or consensus

These five motivations can serve as a checklist for developing protocols. One of the most influential factors affecting interpersonal or interagent communication patterns among group members is the characteristic of the task on which they are working. As task certainty increases, the group coordinates itself more through formal rules and plans than through individualized communication modes. Therefore, the interacting behaviors and information exchanges among agents have to follow interaction and communication protocols.

Although different agent applications will require different agent design, five general areas have to be addressed:

1. Goal identification and task assignment
2. Distribution of knowledge
3. Organization of the agents
4. Coordination mechanism and protocols
5. Learning and adaptive schemes

Research into intelligent, collaborative agents is extremely active and in its preliminary stages (Nof 1999; Huang and Nof 2000). While the best-known applications have been in Internet search and remote mobile robot navigation, emerging examples combine agents through computer networks with remote monitoring for security, diagnostics, maintenance and repair, and remote manipulation of robotic equipment. Emerging agent applications will soon revolutionize computer and communication usefulness. Interaction and communication with and among intelligent tools, home appliances, entertainment systems, and highly reliable, safe mobile service robots will change the nature of manufacturing, services, health care, food delivery, transportation, and virtually all equipment-related activities.

7. CONCLUSION

This chapter discusses automation technology in various levels:

1. *Single process:* automatic control theory and technology
2. *Single machine:* artificial intelligence and knowledge-based technology
3. *Distributed machines and distributed systems:* integration theory and technology

Additionally, the trends in future automation technology are classified into another three levels:

1. *Machine integration:* virtual machines
2. *Human–machine integration:* tool-oriented technologies
3. *Machine autonomy:* agent-based technologies

In our postulation, how to automate machines in terms of operations will soon be a routine problem because of the technological maturity of actuators, sensors, and controllers. The application of automation technology will then focus on the issues of intelligence, integration, and autonomy. Another emerging trend involves the incorporation of micro-electromechanical systems (MEMSs) as sensors and controllers of automation and the microscale. However, education and training of workers who interact with intelligent and autonomous machines may be another important research issue in the future.

Acknowledgments

The authors would like to thank Professor Ted J. Williams of Purdue University and Professor Li-Chih Wang, Director of the Automation Laboratory, Tunghai University, Taiwan, for their valuable contributions to this chapter.

Edited by Gavriel Salvendy

1. INTRODUCTION

Computer networks serve today as crucial components of the background infrastructure for virtually all kinds of human activities. This is the case with Industrial Engineering and any related activities.

The importance of these computer networks stems from their role in communication and information exchange between humans (as actors in any kind of activities) and/or organizations of these human actors.

In contrast to the situation several decades ago, a number of key attributes of the working environment today serve as basic new supportive elements of working conditions. Some of the most important such elements are:

- Computer technology has moved to the desktop, making possible direct access to advanced techniques of high-speed information processing and high-volume information storage from individual workstations.
- Interconnection of computers has been developing at an exponentially increasing rate, and today high-speed global connectivity is a reality, providing fast and reliable accessibility of high-volume distant information at any connected site worldwide.
- Global addressing schemes, structured information content, and multimedia information handling have become an efficiently functioning framework for computer-to-computer (and thus human-to-human) communication and information exchange, as well as for storing and delivering large amounts of highly sophisticated information at millions of sites, accessible by any other authorized sites anywhere within the global network of networks, the Internet.

Computer networks and services themselves, as well as related applications, are briefly investigated in this chapter. The topic is very broad and there are thousands of sources in books and other literature providing detailed information about all the aspects of computer networking introduced here. This chapter therefore provides a condensed overview of selected key subtopics. However, emphasis is given to every important element of what the network infrastructure looks like, what the main characteristics of the services and applications are, and how the information content is being built and exploited. Some basic principles and methods of computer networking are repeatedly explained, using different approaches, in order to make these important issues clear from different aspects.

This chapter starts with an introductory description of the role of computer networking in information transfer. Then, after a short historical overview, the networking infrastructure is investigated in some detail, including the basic technical elements of how networking operates in practice. Later sections deal with services and applications based on networked computer systems. Separate subsections are devoted to the World Wide Web, which is probably the most important tool at the start of the third millennium for communication, information access, and collaboration. Some questions of content generation and provision are then investigated, after which aspects of future development in computer networking are briefly dealt with. Other subsections deal with a few practical issues, including some related to industrial engineering.

The following major issues are dealt with in the following references at the end of the chapter:

- *Networking in general:* Derfler and Freed (1998); Hallberg (1999); Keshav (1997); Kosiur (1998); Lynch and Rose (1993); Marcus (1999); Taylor (1999)
- *Internet in general:* Minoli and Schmidt (1999); Quercia (1997); Smythe (1995); Young (1999)
- *History of networking:* Salus (1995)
- *Intranets:* Ambegaonkar (1999); Bernard (1997); Hills (1996); Minoli (1996)
- *Extranets:* Baker (1997); Bort and Felix (1997)
- *World Wide Web:* Stout (1999)

- *Multimedia:* Agnew and Kellerman (1996); Buford (1994); Wesel (1998)
- *Virtual reality:* Singhal and Zyda (1999)
- *Quality of service:* Croll and Packman (1999)
- *Security:* Cheswick and Bellovin (1994); Goncalves (1999); Smith (1997)
- *Applications:* Angell and Heslop (1995); Hannam (1997); Kalakota and Whinston (1997); McMahon and Browne (1998); Treese and Stewart (1998)
- *Practical issues:* Derfler (1998); Dowd (1996); Guengerich et al. (1996); Murhammer et al. (1999); Ptak et al. (1998); Schulman and Smith (1997); Ward (1999)
- *Future trends:* Conner-Sax and Krol (1999); Foster and Kesselman (1998); Huitema (1998); Mambretti and Schmidt (1999)

2. THE ROLE OF COMPUTER NETWORKING

Computer networks (see Figure 1) are frequently considered as analogous to the nervous system in the human body. Indeed, like the nerves, which connect the more or less autonomous components in the body, the links of a computer network provide connections between the otherwise stand-alone units in a computer system. And just like the nerves, the links of the network primarily serve as communication channels between the computers. This is also the basis of the global network of networks, the Internet.

The main task in both cases is information transfer. Connected and thus communicating elements of the system can solve their tasks more efficiently. Therefore, system performance is not just the sum of the performance of the components but much more, thanks to the effect of the information exchange between the components.

Computer networks consist of computers (the basic components of the system under consideration), connecting links between the computers, and such additional things as devices making the information transfer as fast, intelligent, reliable, and cheap as possible.

- Speed depends on the capacity of the transmission lines and the processing speed of the additional devices, such as modems, multiplexing tools, switches, and routers. (A short description of these devices is given in Section 4, together with more details about transmission line capacity.)
- Intelligence of the network depends on processing capabilities as well as stored knowledge of these active devices of the network. (It is worth mentioning that network intelligence is different from the intelligence of the interconnected computers.)
- Reliability stems from, first of all, the decreased risk of losing, misinterpreting, or omitting necessary information, as well as from the well preprocessed character of the information available within the system.

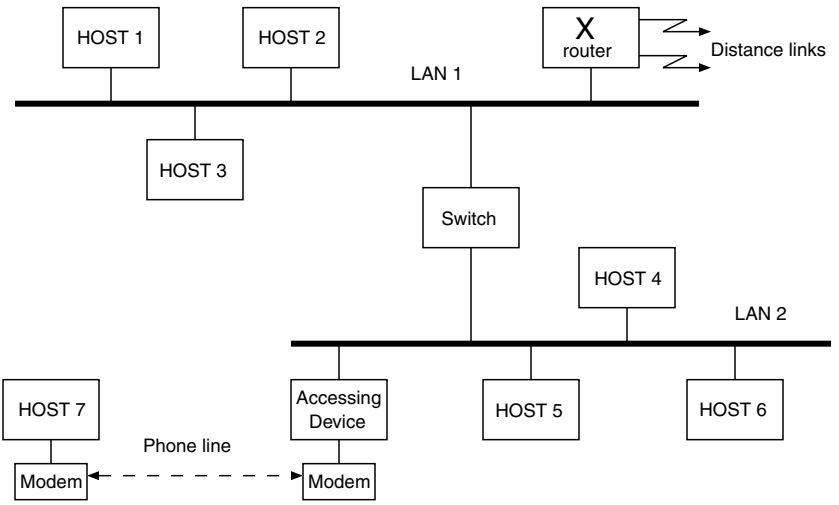

Figure 1 Networks and Network Components.

- Cost is associated with a number of things. The most important direct costs are purchase costs, installation costs, and operational costs. Indirect costs cover a wide range, from those stemming from faulty system operation to those associated with loss of business opportunity. In the planning of the system, the cost/performance ratio must always be taken into consideration.

It is important not to forget that adequate system operation requires adequate operation of all components.

Obviously, adequate operation of each component in a system requires intensive interaction among them. However, direct information transfer between these components makes the interaction much faster and more reliable than traditional means of interaction. This means highly elevated adequacy in the behavior of each component and thus of the system itself.

Another important capability of a system consisting of connected and communicating components is that the intelligence of the individual components is also connected and thus each component can rely not only on its own intelligence but also on the knowledge and problem solving capability of the other components in the system. This means that the connections between the computers in the network result in a qualitatively new level of complexity in the system and its components. The network connections allow each system component to:

- Provide information to its partners
- Access the information available from the other system components
- Communicate while operating (thus, to continuously test, correct, and adapt its own operation)
- Utilize highly sophisticated distant collaboration among the system components
- Exploit the availability of handling virtual environments*

These features are described briefly below. As will be shown below, these basic features pave the way for:

- The systematic construction of network infrastructures
- The continuous evolution of network services
- The rapid proliferation of network-based applications
- The exponentially increasing amount of information content accumulated in the network of interconnected computers

2.1. Information Access

Information access is one of the key elements of what networking provides for the users of a computer connected to other computers. The adequate operation of a computer in a system of interconnected computers naturally depends on the availability of the information determining what, when, and how to perform with it. Traditionally, the necessary information was collected through ''manual'' methods: through conversation and through traditional information carriers: first paper, and then, in the computer era, magnetic storage devices.

These traditional methods were very inefficient, slow, and unreliable. The picture has now totally changed through computer networking. By the use of the data communication links connecting computers and the additional devices making possible the transfer of information, all the information preprocessed at the partner sites can be easily, efficiently, immediately, and reliably downloaded from the partner computers to the local machine.

The model above works well until individual links are supposed to serve only the neighbor computers in accessing information at each other's sites. But this was the case only at the very beginning of the evolution of networking. Nowadays, millions of computers can potentially access information stored in all of the other ones. Establishing individual links between particular pairs of these computers would be technically and economically impossible.

The solution to the problem is a hierarchical model (see Figure 2). Very high-speed backbones (core network segments) interconnect major nodes located at different geographical regions, and somewhat lower-speed access lines transfer the information from/to these nodes to/from those servers within the region, which then take care of forwarding/collecting the information traffic in their local

*Handling virtual environments means that the individual components don't communicate continuously with the outside world but systematically use a mirrored synthetic picture about their embedding. This is done by utilizing the information accumulated by their neighbors and thus constructing and using a virtual reality model about the outside world. Of course, direct access to this outside world may provide additional information by which such a virtual reality model can be completed so that the result is a so-called augmented reality model.

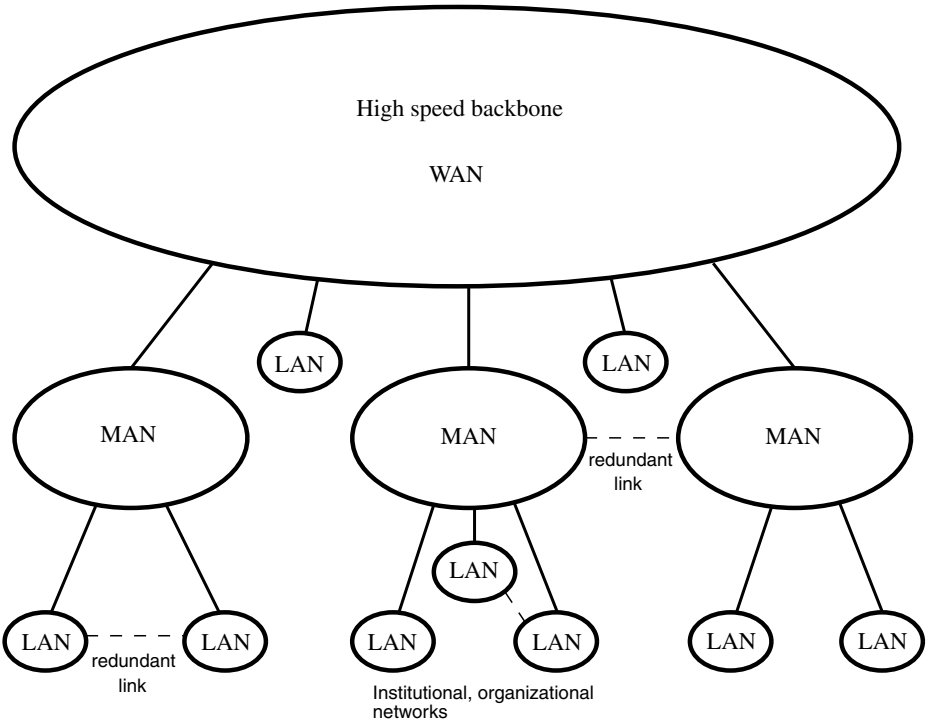

Figure 2 Hierarchical Network Model.

area. Local area networks (LANs) arise from this way of solving the information traffic problem. The hierarchy can be further fragmented, and thus metropolitan area networks (MANs) and wide area networks (WANs) enter the picture. Although this model basically supposes tree-like network configurations (topologies), for sake of reliability and routing efficiency, cross-connections (redundant routes) are also established within this infrastructure.

If a network user wishes to access information at a networked computer somewhere else, his or her request is sent through the chain of special networking devices (routers and switches; see Section 4) and links. Normally this message will be sliced into packets and the individually transferred packets will join possibly thousands of packets from other messages during their way until the relevant packets, well separated, arrive at their destination, recombine, and initiate downloading of the requested information from that distant site to the local machine. The requested information will then arrive to the initiator by a similar process. If there is no extraordinary delay anywhere in the routes, the full process may take just a few seconds or less. This is the most important strength of accessing information through the network.

Note that the described method of packet-based transmission is a special application of time division multiplexing (TDM). The TDM technique utilizes a single physical transmission medium (cable, radiated wave, etc.) for transmitting multiple data streams coming from different sources. In this application of TDM, all the data streams are sliced into packets of specified length of time, and these packets, together with additional information about their destination, are inserted into time frames of the assembled new, higher-bit rate data stream. This new data stream is transmitted through a well-defined segment of the network. At the borders of such network segments, the packets may be extracted from the assembled data stream and a new combination of packets can be assembled by a similar way. By this technique, packets from a source node may even arrive to their destination node through different chains of network segments. More details about the technique will be given in Sections 6.2 and 6.3.

The next subsection describes the basic prerequisites at the site providing the information. First a basic property of the data communication links will be introduced here.

The capability of transmitting/processing high-volume traffic by the connecting lines in the network depends on their speed/bandwidth/capacity. Note that these three characteristic properties are

equivalent in the sense that high bandwidth means high speed and high speed means high capacity. Although all three measures might be characterized by well-defined units, the only practically applied unit for them is the one belonging to the speed of the information transfer, bits per second (bps). However, because of the practical speed values, multiples of that elementary unit are used, namely Kbps, Mbps, Gbps, and more recently, Tbps (kilobits, megabits, gigabits, and terabits per second, respectively, which means thousands, millions, billions and thousand billions of bits per second).

2.2. Information Provision

Access to information is not possible if the information is not available. To make information accessible to other network users, information must be provided. Provision of information by a user (individual or corporate or public) is one of the key contributors to the exponential development of networking and worldwide network usage. How the information is provided, whether by passive methods (by accessible databases or, the most common way today, the World Wide Web on the Internet) or by active distribution (by direct e-mail distribution or by using newsgroups for regular or irregular delivery), is a secondary question, at least if ease of accessing is not the crucial aspect.

If the information provided is freely accessible by any user on the network, the information is public. If accessibility is restricted, the information is private. Private information is accessible either to a closed group of users or by virtually any user if that user fulfils the requirements posed by the owner of the information. Most frequently, these requirements are only payment for the access. An obvious exception is government security information.

All information provided for access has a certain value, which is, in principle, determined by the users' interest in accessing it. The higher the value, the more important is protection of the related information. Providers of valuable information should take care of protecting that information, partly to save ownership but also in order to keep the information undistorted. Faulty, outdated, misleading, irrelevant information not only lacks value but may also cause problems to those accessing it in the belief that they are getting access to reliable content.

Thus, information provision is important. If the provider makes mistakes, whether consciously or unconsciously, trust will be lost. Providing valuable (relevant, reliable, and tested) information and taking care of continuous updating of the provided information is critical if the provider wants to maintain the trustworthiness of his information.

The global network (the millions of sites connected by the network) offers an enormous amount of information. The problem nowadays is not simply to find information about any topic but rather to find the best (most relevant and most reliable) sources of the required information. Users interested in accessing proper information should either turn to reliable and trusted sources (providers) or take the information they collect through the Internet and test it themselves.

That is why today the provision of valuable information is separated from ownership. Information brokerage plays an increasingly important role in where to access adequate information. Users looking for information about any topic should access either those sources they know and trust or the sites of brokers who take over the task of testing the relevance and reliability of the related kinds of information. Information brokerage is therefore an important new kind of network-based service.

However, thoroughly testing the validity, correctness, and relevance of the information is difficult or even impossible, especially because the amount of the stored and accessible information increases extremely fast. The final answer to the question of how to control the content (i.e., the information available worldwide) is still not known. One of the possibilities (classifying, rating, and filtering) is dealt with in more detail in a later section.

Besides the difficulty of searching for adequate information, there is a further important aspect associated with the increasing interest worldwide in accessing information. It relates to the volume of information traffic generated by the enormous number of attempts to download large amounts of information.

Traffic volume can be decreased drastically by using the caching technique (see Figure 3). In the case of frequently accessed information sources, an enormous amount of traffic can be eliminated by storing the frequently requested information in dedicated servers that are much closer to the user than the original information provider. The user asking for these kinds of information doesn't even know if the requested information arrives at the requesting site from such a cache server or from the primary source of the information. Hierarchical cache server systems help to avoid traffic congestion on network links carrying intensive traffic.

2.3. Electronic Communication

Providing and accessing information, although extremely important, is just one element of information traffic through the network. Electronic communication in general, as far as the basic function of the network operation is concerned, involves a lot more.

The basic function of computer networks is to make it possible to overcome distance, timing, and capability problems.

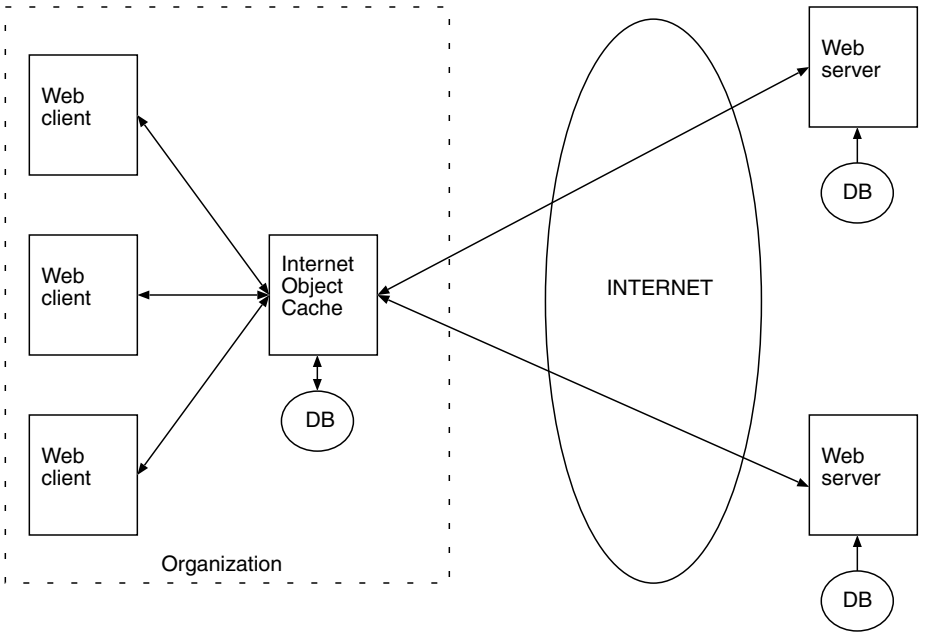

Figure 3 Caching.

- Distance is handled by the extremely fast delivery of any messages or other kinds of transmitted information at any connected site all over the world. This means that users of the network (again individual, corporate, or public) can do their jobs or perform their activities so that distances virtually disappear. Users or even groups of users can talk to each other just as if they were in direct, traditional contact. This makes, for example, remote collaboration a reality by allowing the formation of virtual teams.
- Timing relates to the proper usage of the information transmitted. In the most common case, information arrives at its destination in accordance with the best efforts method of transmission provided by basic Internet operation. This means that information is carried to the target site as soon as possible but without any guarantee of immediate delivery. In most cases this is not a problem because delays are usually only on the order of seconds or minutes. Longer delays usually occur for reasons other than simple transmission characteristics. On the other hand, e-mail messages are most often read by the addressees from their mail servers much later than their arrival. Although obviously this should not be considered the basis of network design, the fact that the recipient doesn't need to be at his or her machine when the message arrives is important in overriding timing problems. However, some information can be urgently needed, or real-time delivery may even be necessary, as when there are concurrent and interacting processes at distant sites. In these cases elevated-quality services should be provided. Highest quality of service (QoS) here means a guarantee of undisturbed real-time communication.
- Capability requirements arise from limited processing speed, memory, or software availability at sites having to solve complex problems. Networked communication helps to overcome these kinds of problems by allowing distributed processing as well as quasisimultaneous access to distributed databases or knowledge bases. Distributed processing is a typical application where intensive (high-volume) real-time (high-speed) traffic is assumed, requiring high-speed connection through all the routes involved in the communication.

The latter case already leads us to one of the more recent and most promising applications of the network. Although in some special areas, including highly intensive scientific computations, distributed processing has been used for some time, more revolutionary applications are taking place in networked remote collaboration. This new role of computer networking is briefly reviewed in the following section.

2.4. Networked Collaboration

Computer networks open new ways of increasing efficiency, elevating convenience, and improving cost and performance of collaboration. The basis of this overall improvement is provided by the properties of computer networks mentioned above, their ability to help overcome distance, timing, and capability problems. The workplace can thus be dislocated or even mobile, the number of collaborators can be theoretically infinite, the cooperating individuals or groups can be involved in joint activities and in shifted time periods (thus even geographical time zone problems can be virtually eliminated), and the collaborating partners can input their information without having to move high-volume materials (books and other documents) to a common workplace. These are all important issues in utilizing the opportunities that networks provide for collaborating when communities are geographically dispersed.

However, the key attribute of networked collaboration is not simply the possibility of avoiding having to collect all the collaborating partners at a well-defined venue and time for a fixed time period. The fact that the network interconnects computers, rather than human users, is much more useful. The reason is that networked computers are not just nodes in a network but also intelligent devices. They not only help exchange information between the collaborating individuals or groups, but also provide some important additional features.

- The information processing capability of the computers at the network nodes of the collaborating parties may also solve complex problems.
- The intelligence of each computer connected and participating in the joint activities is shareable among the collaborating partners.
- The intelligence in these distant computers can be joined to solve otherwise unsolvable problems by utilizing an enormously elevated computing power.

However, appropriate conditions for efficient and successful collaboration assume transmission of complex information. This information involves not only the data belonging to the joint task but also the multimedia information stemming from the networked character of the collaboration. This may be a simple exchange of messages, such as e-mail conversation among the participants, but may also be a true videoconference connection between the cooperating sites. Thus, in many cases networked collaboration requires extremely high bandwidths. Real-time multimedia transmission, as the basis of these applications, supposes multi-Mbps connectivity throughout. Depending on the quality demands, the acceptable transmission speed varies between one or two Mbps and hundreds of megabits per second. The latter speeds have become a reality with the advent of gigabit networking.

If the above conditions are all met, networked collaboration provides multiple benefits:

- Traditional integration of human contributions
- Improvement in work conditions
- Integration of the processing power of a great many machines
- High-quality collaboration attributes through high-speed multimedia transmission

The highest level of networked collaboration is attained by integrated environments allowing truly integrated activities. This concept will be dealt with later in the chapter. The role of the World Wide Web in this integration process, the way of building and using intranets for, among others, networked collaboration, and the role of the different security aspects will also be outlined later.

2.5. Virtual Environments

Network-based collaboration, by using highly complex tools (computers and peripherals) and high-speed networking, allows the participating members of the collaborating team to feel and behave just as if they were physically together, even though the collaboration is taking place at several distant sites. The more the attributes of the environment at one site of the collaboration are communicated to the other sites, the more this feeling and behavior can be supported. The environment itself cannot be transported, but its attributes help to reconstruct a virtual copy of the very environment at a different site. This reconstruction is called a virtual environment.

This process is extremely demanding as far as information processing at the related sites and information transfer between distant sites are concerned. Although the available processing power and transmission speed increase exponentially with time, the environment around us is so complex that full copying remains impossible. Thus, virtual environments are only approximated in practice.

Approximation is also dictated by some related practical reasons:

- Practical feasibility (even if a certain level of copying the target environment is theoretically possible, it would require the implementation of prohibitively complex practical solutions)
- Cost effectiveness (although the practical solution is feasible, the cost is so high that the application doesn't allow the very level of emulation)
- Intended approximation (although a certain level of true copying would be possible and cost effective, the application requires a model of the virtual copy rather than the true original because of experimental applications, trials regarding modifying the environment, etc.)
- Inaccessible environments (the environment to be copied is inaccessible either because of being outside the connected sites or because of transient lack of some prerequisites)

In such cases, virtual environments are substituted for by virtual reality models. These models provide virtual reality by mimicking the supposed environment but not copying it. However, in some applications a mix of virtual copies and virtual models is needed. In *augmented reality,* transmitted information about the attributes of the considered real environment is used together with model parameters about a model environment to build up a virtual construct for the supposed environment.

Virtual constructs are essential tools in a number of applications utilizing the concept of telepresence and/or teleimmersion by users of networked computers. Teleinstruction, telemedicine, and different types of teleworking are examples of how the development of networked communication and collaboration leads to an increasing number of applications using virtual and augmented reality.

3. A SHORT HISTORY OF COMPUTER NETWORKING

Computer networking started in the United States in the late 1960s. Through the rapid development of computing and telecommunications, in 1969 the ARPANet program was launched.

The first voice transmission over cables (1876) and by radio waves (1896), the first radio transfer of video images (1936), the first electronic computer (1944), and the first transistor (1948) preceded this milestone of technical history, but the first microprocessor (1971) and the first IBM personal computer (1981), as well as the first digital radio transmission of voice (1988) and image (1991), came later.

The ARPANet program started with the aim of connecting just a few sites, but the first networking experiments immediately proved that ''Internetting'' was a feasible idea. The program led to the development of the TCP/IP protocol suite (see Section 6), having served as the basis of Internet technology for more than 30 years. These developments resulted in a proliferation in activity, and the number of Internet hosts (networked computers serving several users by Internet services) rapidly increased. As a result of the annual doubling of host numbers, as of the end of the 1990s, dozens of millions of hosts served a worldwide community of an estimated more than 200 million users.

The Internet was established early in the 1980s as a solid infrastructure of networking, mainly in the United States but also with connected subnetworks in Europe and the Asia Pacific region. The organizational, coordinating, and mainly informal controlling frameworks of the Internet were also established by that time. A conscious standardization process also started. These activities resulted in a solid background for an efficiently operating global system of interconnected computers.

Perhaps the most important property of the TCP/IP protocol suite is that it makes possible the interconnection and interworking of subnetworks. The introduction and wide application of the concept of such subnetworks played a fundamental role in the rapid and successful proliferation of the Internet technology. The value of integrating diverse subnetworks into one cohesive Internet is what makes the Internet such a great network tool.

After more than 10 years of exclusively special (defense, and later scientific) applications of the emerging network, commercial use began to evolve. Parallel activities related to leading-edge academic and research applications and everyday commodity usage appeared. This parallelism was more or less maintained during more recent periods, as well, serving as a basis of a fast and continuous development of the technology. A breakthrough occurred when, in the mid-1980s, the commercial availability of system components and services was established. Since then the supply of devices and services has evolved continuously, enabling any potential individual, corporate, or public user simply to buy or hire what it needed for starting network-based activities.

While the leading edge in the early 1980s was still just 56 Kbps (leased line), later in the decade the 1.5 Mbps (T1) transmission speed was achieved in connecting the emerging subnetworks.

Late in the 1980s the basics of electronic mail service were also in use. This was probably the most important step in the application of networking to drive innovation prior to the introduction of the World Wide Web technology.

Early in the 1990s the backbone speed reached the 45 Mbps level, while the development and spread of a wide range of commercial information services determined the directions of further evolution in computer networking.

The 1990s brought at least three new developments.

1. The development of a new-generation Internet was initiated in order to overcome the weaknesses of the traditional Internet technology in handling the exponential growth of the user community, the fast change in quality, reliability, and security requirements, and the increased complexity of the transmitted information. (Strictly speaking, security is outside of the Internet itself. The need for security became a hot topic with the advent of readily accessible information via the Internet. The present TCP/IP protocol suite does not provide security itself.)
2. The speed of transmission (or the speed of the network) and the coverage of the global infrastructure (including worldwide proliferation as well as dense regional network population) reached new records. This development is still far from saturation. As of the turn of the century, the dozens of millions of Internet hosts had, not homogeneously but steadily, spread out through all continents of the world. At the same time, the high-level backbones operated, at least in the more developed areas, at Gbps speed, and the continents were connected by thousands of optical fibers capable of keeping an extremely high volume of traffic.
3. World Wide Web technology has become a standard all over the world, and by the end of the 1990s an enormous amount of information provision and information access had taken place through the Web.

Through these revolutionary advancements, networking has begun to play an important role worldwide in reforming a great many human activities. Parallel to the developments in speed, quality, reliability, manageability, and cost/performance, many international organizations, national governments, and civil initiatives have launched joint projects with the aim of establishing a new and unavoidable worldwide ''Information Society.'' New forms of cooperation among governments, industry, telecom, and network service providers, as well as civil organizations, have emerged, and further development is inevitable.

4. THE NETWORKING INFRASTRUCTURE

As mentioned in Section 2.1, the background of the information transfer is provided by the networking infrastructure. As mentioned, the solution of the problem of how to handle millions of transfers of data simultaneously over the global network in very short time frames is based on a hierarchical model. The infrastructure consists of links and nodes whose role depends on their status in the hierarchy. At the highest level are the largest information exchange centers, which are connected with very high-speed lines. The very high-speed networks of these large exchange nodes and the high-capacity links connecting them are called backbones. The main nodes of the backbones communicate among each other and also collect and distribute the relevant traffic from and to the regional nodes around them. The lines connecting the large exchange nodes to the regional nodes also work at very high speeds and are therefore able to transmit very high-volume traffic.

Lower in the hierarchy, around the regional nodes, somewhat lower-speed access lines transfer the information from and to the area servers (connected to routers and/or switches, i.e., special machines taking care of the direction of the transmitted information packets in the network) within the region. These active devices serve either LANs, MANs, or WANs, depending on the topology and the further hierarchical structure of the network around these area servers. Their task is to collect/distribute the information traffic in their area.

The hierarchical structure might mean a simple (but of course highly segmented and in this respect very complex) tree-like topology. However, as already mentioned, for the purpose of reliability and routing efficiency, cross-connections (redundant routes) are also established within the infrastructure. Obviously, the difficulty of handling the traffic is in relation with the complexity of the network structure, but this is the price for satisfactory global network operation.

The key elements, besides the communication links themselves, in this technique of information transfer through the network are the routers and switches, which take care of directing the information packets through the nodes in this hierarchy so that they finally arrive at their destination.

The speed of the information transfer depends on the bandwidth of the links and the processing speed of the routers and switches in the infrastructure. Taking into account the requirements stemming from the characteristics of the transmitted information and the traffic volume, that is, from the estimated average and peak number of requested transmission transactions, allows the speed of the different sections of the infrastructure to be determined. Some basic figures are as follows:

- Simple alphanumeric messages require a speed that is not too high at the last mile sections, that is, at the lines closest to the transmitters/receivers of the information. Several Kbps is considered satisfactory in such cases of message delivery without special requirements regarding the delivery time.

- Real-time transmission of similarly simple alphanumeric information requires either similar speed, as above, or, in case of higher volume of these kinds of data, a certain multiple of that speed.
- Real-time transmission of sampled, digitized, coded, and possibly compressed information, stemming from high-fidelity voice, high-resolution still video, or high-quality real video signals do require much higher speed. The last-mile speed in these cases ranges from dozens of Kbps to several and even hundreds of Mbps (HDTV). This information is quite often cached by the receiver to overcome short interruptions in the network's delivery of the information at high speed, providing the receiver a smooth uninterrupted flow of information.

This means that although until recently the last-mile line speeds were in the range of several dozens of Kbps, the area access lines were in the range of several Mbps, and the top-level backbones were approaching the Gbps speed, lately, during the 1990s, these figures have increased to Mbps, several hundreds of Mbps, and several Gbps level, respectively. The near future will be characterized by multi-Gbps speed at the backbone and area access level, and the goal is to reach several hundreds of Mbps even at the last-mile sections. Of course, the development of the infrastructure means coexistence of these leading-edge figures with the more established lower-speed solutions. And obviously, in the longer term, the figures may increase further.

As far as the organization of the operation of the infrastructure, the physical and the network infrastructure should be distinguished. Providing physical infrastructure means little more than making available the copper cables or fibers and the basic active devices of the transmission network, while operating the network infrastructure also means managing of the data traffic. Both organizational levels of the infrastructure are equally important, and the complexity of the related tasks has, in an increasing number of cases, resulted in the jobs being shared between large companies specializing in providing either the physical or the network infrastructure.

The first step from physical connectivity to network operation is made with the introduction of network protocols. These protocols are special complex software systems establishing and controlling appropriate network operation. The most important and best-known such protocol is the Internet Protocol.

The elementary services are built up on top of the infrastructure outlined above. Thus, the next group of companies working for the benefit of the end users is the Internet service providers (ISPs), which take care of providing network access points.

Although network services are discussed separately in Section 7, it should be mentioned here that one of the basic tasks of these services is to take care of the global addressing system. Unique addressing is perhaps the most important element in the operation of the global network. Network addresses are associated with all nodes in the global network so that the destination of the transmitted information can always be specified. Without such a unique, explicit, and unambiguous addressing system, it would not be possible even to reach a target site through the network. That is why addressing (as well as naming, i.e., associating unique symbolic alphanumeric names with the numeric addresses) is a crucial component of network operation. The task is solved again by a hierarchy of services performed by the domain name service (DNS) providers. This issue is dealt with in more detail later. Note that it is possible, as a common practice, to proxy the end-node computer through an access point to share the use of a unique address on the Internet. The internal subnetwork address may in fact be used by some other similarly isolated node in a distinctly separate subnetwork (separate intranet).

Everything briefly described above relates to the global public network. However, with the more sophisticated, serious, and sometimes extremely sensitive usage of the network, the need to establish closed subsets of the networked computers has emerged. Although virtual private networks (subnetworks that are based on public services but that keep traffic separated by the use of special hardware and software solutions) solve the task by simply separating the general traffic and the traffic within a closed community, some requirements, especially those related to security, can only be met by more strictly separating the related traffic. The need for this kind of separation has led to the establishment of intranets (special network segments devoted to a dedicated user community, most often a company) and extranets (bunches of geographically distant but organizationally and/or cooperatively connected intranets, using the public network to connect the intranets but exploiting special techniques for keeping the required security guarantees). Although building exclusively private networks, even wide area ones, is possible, these are gradually disappearing, and relying on public services is becoming common practice even for large organizations.

5. INTERNET, INTRANETS, EXTRANETS

The Internet is the world's largest computer network. It is made up of thousands of independently operated (not necessarily local) networks collaborating with each other. This is why it is sometimes

called the network of networks. Today it extends to most of the countries in the world and connects dozens of millions of computers, allowing their users to exchange e-mails and data, use online services, communicate, listen to or watch broadcast programs, and so on, in a very fast and cost-effective way. Millions of people are using the Internet today in their daily work and life. It has become part of the basic infrastructure of modern human life.

As was already mentioned above, the predecessor of the Internet was ARPANet, the first wide area packet switched data network. The ARPANET was created within a scientific research project initiated by the U.S. Department of Defense in the late 1960s. Several universities and research institutes participated in the project, including the University of Utah, the University of California at Los Angeles, the University of California at Santa Barbara, and the Stanford Research Institute. The goal of the project was to develop a new kind of network technology that would make it possible to build reliable, effective LANs and WANs by using different kinds of communication channels and connecting different kinds of computers. By 1974, the basics of the new technology had been developed and the research groups led by Vint Cerf and Bob Kahn had published a description of the first version of the TCP/IP (Transmission Control Protocol and Internet Protocol) suite.

The experimental TCP/IP-based ARPANet, which in its early years carried both research and military traffic, was later split into the Internet, for academic purposes, and the MILNet, for military purposes. The Internet grew continuously and exponentially, extending step by step all over the world. Early in the 1990s, the Internet Society (see www.isoc.org) was established, and it has served since then as the driving force in the evolution of the Internet, especially in the technological development and standardization processes.

The invention of the World Wide Web in 1990 has given new impetus to the process of evolution and prompted the commercialization of the Internet. Today the Internet is a general-purpose public network open to anyone who wishes to be connected.

Intranets are usually TCP/IP-based private networks. They may in fact gateway through a TCP/IP node, but this is not common. They operate separately from the worldwide Internet, providing only restricted and controlled accessibility. Although an intranet uses the same technology as the Internet, with the same kinds of services and applications, it principally serves only those users belonging to the organization that owns and operates it. An intranet and its internal services are closed to the rest of the world. Often this separation is accomplished by using network addresses reserved for such purposes, the so-called ten net addresses. These addresses are not routed in the Internet, and a gateway must proxy them with a normal address to the Internet.

Connecting intranets at different geographical locations via the public Internet, results in extranets. If an organization is operating at different locations and wants to interconnect its TCP/IP-based LANs (intranets), it can use the inexpensive public Internet to establish secure channels between these intranets rather than build very expensive, large-scale, wide area private networks. This way, corporate-wide extranets can be formed, allowing internal users to access any part of this closed network as if it were a local area network.

6. TECHNICAL BACKGROUND

To understand the possibilities of the TCP/IP-based networks fully, it is important to know how they work and what kinds of technical solutions lie behind their services.

6.1. Architecture of the Internet

As mentioned in the previous section, the Internet can be described as a network of local area networks (see Figure 4). Therefore, perhaps the most important component of the Internet is LANs. LANs connect computers or, in other words, hosts, and are connected to other LANs by gateways and communication lines. Thus, the four basic logical components of the Internet (or of intranets) are:

1. Hosts
2. Local area networks
3. Gateways
4. Communications lines

The main role of gateways is to provide connections between the communication lines and the local area networks and to route the data packets toward their destinations. This is why they are often called routers. Gateways also play an important role in security by protecting the local area network against external attacks and other illegal or unauthorized access. Quite often, a security zone, referred to as the DMZ, is set up where network traffic is passed through a gateway into a firewall (see Section 15.2). The firewall then provides application-level security to network traffic before sending the information through an internal router to pass to end systems in the intranet.

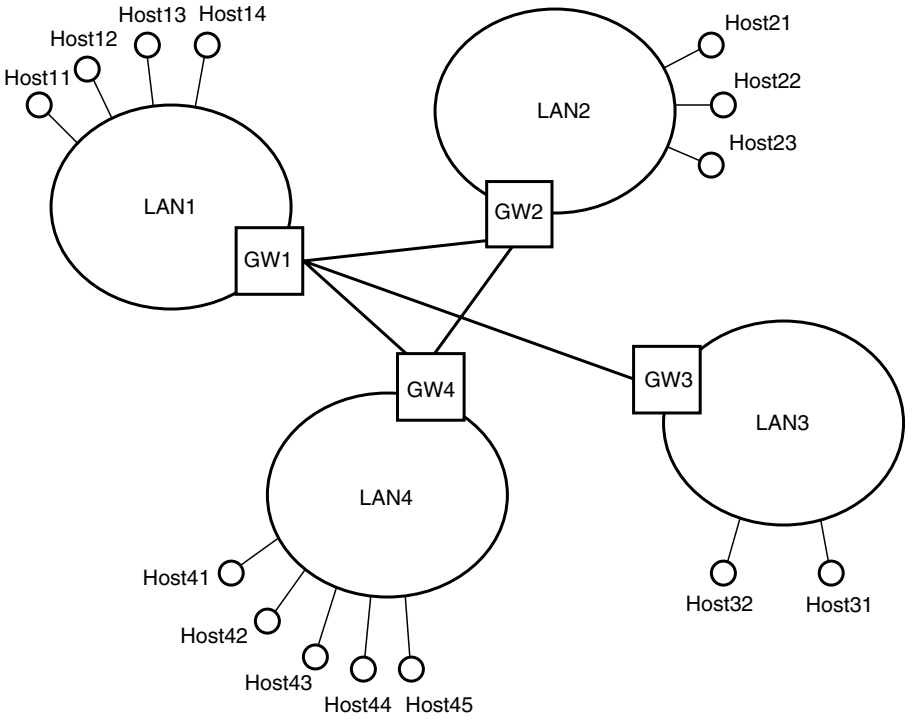

Figure 4 Internet Architecture.

In most cases, communication lines establish steady, 24-hour connection between their endpoints. In order to increase reliability, and sometimes also for traffic load balancing reasons, alternative routes can be built between the local area networks. If any of the lines is broken, the gateways can automatically adapt to the new, changing topology. Thus, the packets are continuously delivered by the alternative routes. Adaptive routing is possible at gateways, particularly for supporting 24×7 operation. It commonly occurs in the backbone of the Internet.

6.2. Packet Switching

Packet switching is one of the key attributes of the TCP/IP technology. The data stream belonging to a specific communication session is split into small data pieces, called packets. The packets are delivered independently at the target host. The separated packets of the same communication session may follow different routes to their destination. In contrast to line-switching communication technologies, in packet switched networks there is no need to set up connections between the communicating units before the start of the requested data transmission. Each packet contains all of the necessary information to route it to its destination. This means that packets are complete from a network perspective.

A good example of line-switched technology is the traditional public phone service. In contrast to packet switching, line switching assumes a preliminary connection setup procedure being performed before a conversation starts. After the connection is set up, an individual communication channel (called a circuit) is provided for the data transmission of that communication session. When the data transmission is over, the connection should be closed.

6.3. Most Important Protocols

A network protocol is a set of rules that determines the way of communication on the network. All the attached hosts must obey these rules. Otherwise they won't be able to communicate with the other hosts or might even disturb the communication of the others. For proper high-level communication, many protocols are needed.

The system of protocols has a layered structure. High-level protocols are placed in the upper layers and low-level protocols in the lower layers. Each protocol layer has a well-defined standard

interface by which it can communicate with the other layers, up and down. TCP/IP itself is a protocol group consisting of several protocols on four different layers (see Figure 5). TCP and IP are the two most important protocols of this protocol group.

IP is placed in the internetworking layer. It controls the host-to-host communication on the network. The main attributes of IP are that it is connectionless, unreliable, robust, and fast. The most astounding of these is the second attribute, unreliability. This means that packets may be lost, damaged, and/or multiplied and may also arrive in mixed order. IP doesn't guarantee anything about the safe transmission of the packets, but it is robust and fast. Because of its unreliability, IP cannot satisfy the needs of those applications requiring high reliability and guaranteed QoS.

Built upon the services of the unreliable IP, the transport layer protocol, TCP, provides reliable communication for the applications. Reliability is guaranteed by positive acknowledgement and automatic retransmission. TCP performs process-to-process communication. It also checks the integrity of the content. TCP is connection oriented, although the TCP connections are virtual, which means that there is no real circuit setup, only a virtual one. A TCP connection is a reliable, stream-oriented, full-duplex, bidirectional communication channel with built-in flow control and synchronization mechanisms.

There are also routing and discovery protocols that play an important role in affecting network reliability, availability, accessibility, and cost of service.

6.4. Client–Server Mechanism

Any communication on a TCP/IP network is performed under the client–server scheme (see Figure 6). When two hosts are communicating with each other, one of them is the client and the other is the server. The same host can be both client and server, even at the same time, for different communication sessions, depending on the role it plays in a particular communication session. The client sends requests to the server and the server replies to these requests. Such servers include file servers, WWW servers, DNS servers, telnet servers, and database servers. Clients include ftp (file transfer) programs, navigator programs (web browsers), and telnet programs (for remote access). Note that the term *server* does not imply special hardware requirements (e.g. high speed, or large capacity, or continuous operation).

The typical mode of operation is as follows: The server is up and waits for requests. The client sends a message to the server. The requests arrive at particular ports, depending on the type of the expected service. Ports simply address information that is acted upon by the serving computer. Clients provide port information so that server responses return to the correct application. Well-known ports are assigned to well-known services. Communication is always initiated by the client with its first message.

Because multiple requests may arrive at the server at the same time from different clients, the server should be prepared to serve multiple communication sessions. Typically, one communication

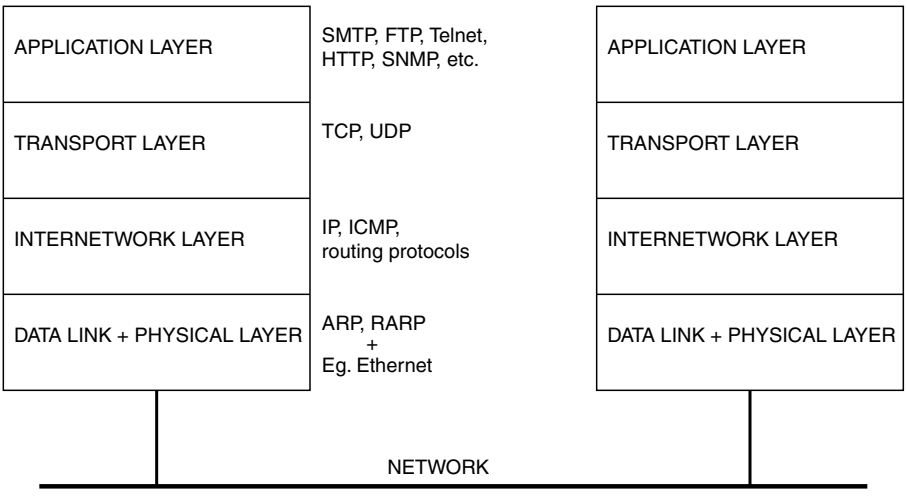

Figure 5 The Layered TCP/IP Protocol Stack.

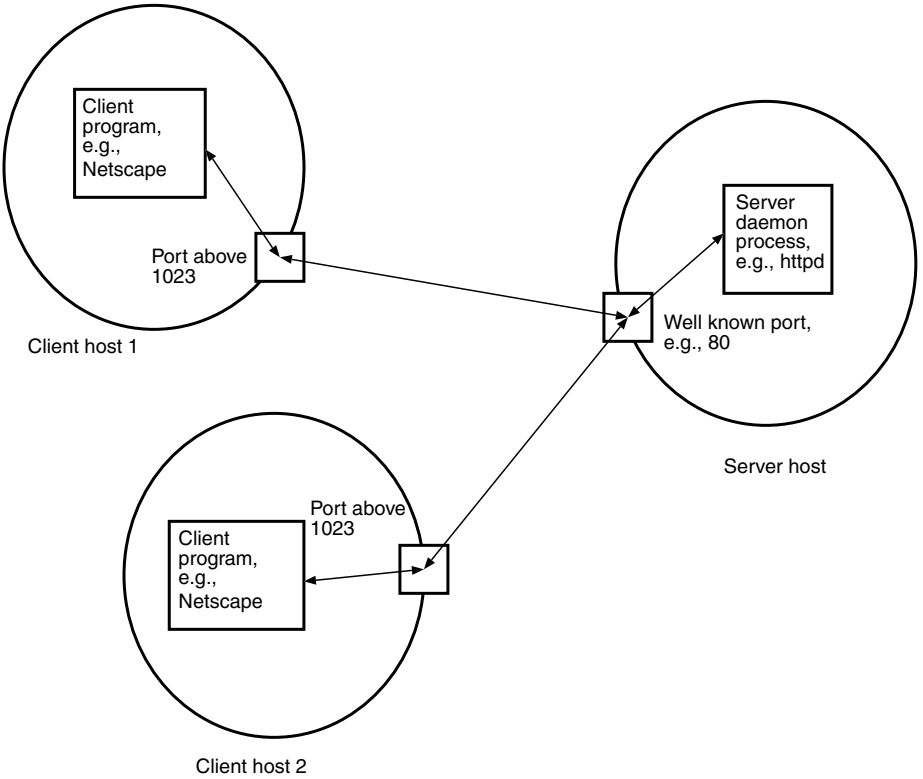

Figure 6 Client/Server Scheme.

session is served by one process or task. Therefore, servers are most often implemented on multitasking operating systems. There is no such requirement at the client side, where only one process at a time may be acting as a client program.

One of the main features in the new concept of computing grids is the substitution of the widely used client–server mechanism by realizations of a more general distributed metacomputing principle in future computer networking applications (see Section 12.3).

6.5. Addressing and Naming

In order to be unambiguously identifiable, every host in a TCP/IP network must have at least one unique address, its IP address. IP addresses play an essential role in routing traffic in the network. The IP address contains information about the location of the host in the network: the associated number (address) of the particular LAN and the associated number (address) of the host in the LAN.

Currently, addresses in the version 4 Internet protocol are 32 bits long (IPv4 addresses) and are classified into five groups: A, B, C, D, and E classes. Class A has been created for very large networks. Class A networks are rare. They may contain up to 2^{24} hosts. Class B numbers (addresses) are given to medium-sized networks (up to 65,534 hosts), while class C network numbers are assigned to small (up to 254 hosts) LANs.

The 32-bit-long IP addressing allows about 4 billion different combinations. This means that in principle, about 4 billion hosts can be attached to the worldwide Internet, by using IPv4 addressing. However, intranets, because they are not connected to the Internet or connected through firewalls, may use IP addresses being used by other networks too.

Because the number of Internet hosts at the start of the third millennium is still less than 100 million, it seems that the available IPv4 address range is wide enough to satisfy all the needs. However, due to the present address classification scheme and other reasons, there are very serious limitations in some address classes (especially in class B). The low efficiency of the applied address

distribution scheme has led to difficult problems. Because of the high number of medium-sized networks, there are more claims for class B network numbers than the available free numbers in this class.

Although many different suggestions have been made to solve this situation, the final solution will be brought simply by implementing the new version of the Internet protocol, IPv6, intended to be introduced early in the 2000s. It will use 128-bit-long IP addresses. This space will be large enough to satisfy any future address claims even if the growth rate of the Internet remains exponential.

There are three different addressing modes in the current IPv4 protocol:

- Unicast (one to one)
- Multicast (one to many)
- Broadcast (one to all)

The most important is unicast. Here, each host (gateway, etc.) must have at least one class A, class B, or class C address, depending on the network it is connected to. These classes provide unicast addresses.

Class D is used for multicasting. Multicast applications, such as radio broadcasting or video conferencing, assign additional D class addresses to the participating hosts.

Class E addresses have been reserved for future use.

Class A, B, and C addresses consist of three pieces of information: the class prefix, the network number, and the host number. The network number, embedded into the IP address, is the basic information for routing decisions. If the host number part of the address contains only nonzero bits (1s), the address is a broadcast address to that specific network. If all the bits in the host number part are zeroes (0s), the address refers to the network itself.

In order to make them easier to manage, IP addresses are usually described by the four bytes they contain, all specified in decimal notation, and separated by single dots. Examples of IP addresses are:

- Class A: 16.1.0.250
- Class B: 154.66.240.5
- Class C: 192.84.225.2

The human interface with the network would be very inconvenient and unfriendly if users had to use IP addresses when referring to computers they would like access. IP addresses are long numbers, making them inconvenient and difficult to remember and describe, and there is always a considerable risk of misspelling them. They don't even express the type, name, location, and so on of the related computer or the organization operating that computer. It is much more convenient and reliable to associate descriptive names with the computers, the organizations operating the computers, and/or the related LANs. The naming system of the TCP/IP networks is called the domain name system (DNS). In this system there are host names and domains.

Domains are multilevel and hierarchical (see Figure 7). They mirror the organizational/administrative hierarchy of the global network.

At present, top-level domains (TLDs) fall into two categories:

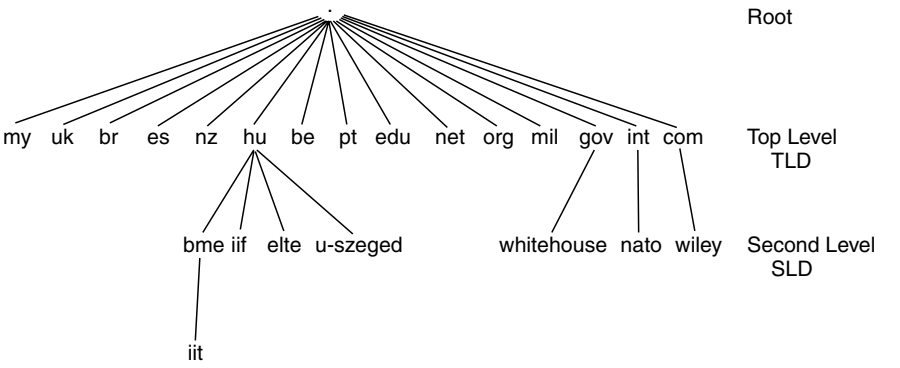

Figure 7 DNS Hierarchy.

1. Geographical (two-letter country codes by ISO)
2. Organizational (three-letter abbreviations reflecting the types of the organizations: edu, gov, mil, net, int, org, com)

Second-level domains (SLDs) usually express the name or the category of the organization, in a particular country. Lower-level subdomains reflect the hierarchy within the organization itself.

The tags of the domain names are separated by dots. The first tag in a domain name is the hostname. The tags are ordered from most specific to least specific addressing.

The domain name service is provided by a network of connected, independently operated domain name servers. A domain name server is a database containing information (IP address, name, etc.) about hosts, domains, and networks under the authority of the server. This is called the domain zone.

Domain name servers can communicate with each other by passing information retrieved from their databases. If a host wishes to resolve a name, it sends a query to the nearest domain name server, which will provide the answer by using its local database, called a cache. However, if necessary, it forwards the query to other servers. The Internet domain name service system is the largest distributed database in the world.

7. OVERVIEW OF NETWORKING SERVICES

Thirty years ago, at the beginning of the evolution of computer networking, the principal goal was to create a communication system that would provide some or all of the following functional services:

- Exchanging (electronic) messages between computers (or their users)—today the popular name of this service is e-mail
- Transferring files between computers
- Providing remote access to computers
- Sharing resources between computers

E-mail is perhaps the most popular and most widely used service provided by wide area computer networks. E-mail provides easy-to-use, fast, cheap, and reliable offline communication for the users of the network. It allows not only one-to-one communication but one-to-many. Thus, mailing lists can be created as comfortable and effective communication platforms for a group of users interested in the same topics.

Of course, file transfer is essential. Computer files may contain different kinds of digitized information, not only texts and programs but formatted documents, graphics, images, sounds, movies, and so on. File transfer allows this information to be moved between hosts.

With the remote access service, one can use a distant computer just as if one were sitting next to the machine. Although not all operating systems allow remote access, most of the multiuser operating systems (UNIX, Linux, etc.) do.

Sharing resources makes it possible for other machines to use the resources (such as disk space, file system, peripheral devices, or even the CPU) of a computer. Well-known examples of resource sharing are the file and printer servers in computer networks.

Besides the above-listed basic functions, computer networks today can provide numerous other services. Operating distributed databases (the best example is the World Wide Web), controlling devices, data acquisition, online communication (oral and written), teleconferencing, radio and video broadcasting, online transaction management, and e-commerce are among the various possibilities.

8. OVERVIEW OF NETWORK-BASED APPLICATIONS

As mentioned at the beginning of this chapter, computer networking has gradually entered all possible fields of applications. Providing an exhaustive overview of the many applications would be practically impossible, so only a brief overview will be given here of what is (and what still will be) available. Classification itself is subjective in this case, so the aspects mentioned below provide only an approach to systematic handling of the wide spectrum of network-based applications.

First, applications can be categorized by what kind of community is interested in them. The two main groups are:

- Public applications, available for any individual or group/organization of individuals
- Private applications, available only to a certain subset of individuals or groups/organizations

Although the realizations of the applications within the two distinct groups are not different in principle from each other, there are at least two basic differences in the background attributes. On one hand, the infrastructure behind an application closely reflects the width of its user community

(wide area public network, in contrast to intranet/extranet-type solutions using private or virtual private networks). On the other hand, security issues are definitely different: on top of the general security and privacy requirements, special security and authorization aspects require special firewall techniques in the case of private applications.

Second, applications can be distinguished by how they are utilized. The three main classes are:

- Personal applications (individual and family use)
- Administrative applications (use by governments, municipalities, etc., in many cases with overall, or at least partly authorized, citizen access)
- Industrial applications (practically any other use, from agriculture to manufacturing to commercial services)

The major differences among these three classes are the required levels of availability, geographical distribution, and ease of access. As far as networking is concerned, the classes differ in the required quality of service level/grade.

Third, there is a well-structured hierarchy of the networked applications based on their complexity. This hierarchy more or less follows the hierarchy of those single-computer applications that are enhanced by the introduction of network-based (distributed, dislocated) operation:

- Low-level applications in this hierarchy include distributed word processing, database handling, document generation, computer numerical control, etc.
- Medium-complexity applications include network-integrated editing and publishing, networked logistics and inventory control, CAD (computer aided design), CAM (computer aided manufacturing), etc.
- High-complexity applications include integrated operations management systems, such as integrated management and control of a publishing/printing company, integrated engineering/management of a CAD-CAM-CAT system, etc.

Note that high-complexity applications include lower-complexity applications, while low-complexity applications can be integrated to build up higher-level applications in the hierarchy. Computer networking plays an important role not only in turning from single-computer applications to network-based/distributed applications but also in the integration/separation process of moving up and down in the hierarchy.

Finally, network-based applications can be classified by the availability of the related application tools (hardware and software). The possible classes (custom, semicustom, and off-the-shelf solutions) will be considered later in Section 13.

9. THE WORLD WIDE WEB

Next to e-mail, the World Wide Web is perhaps the most popular application of the Internet. It is a worldwide connected system of databases containing structured, hypertext, multimedia information that can be retrieved from any computer connected to the Internet.

9.1. History

The idea and basic concept of the World Wide Web was invented in Switzerland. In the late 1980s, two engineers, Tim Berners-Lee from the United Kingdom and Robert Cailliau from Belgium, working at CERN (the European Laboratory of Particle Physics) in Geneva, decided to develop a new communication system for Internet-based international collaboration for physicists. The idea became a reality in 1990, when the first version of HTTP (the Hypertext Transfer Protocol), HTML (the Hypertext Markup Language), and URL (the Universal Resource Locator) addressing scheme were introduced and implemented.

For the first three years of its life, the growth of the World Wide Web was quite slow. Only a few dozen web servers were set up, and the Web was used only for what it was originally invented for: scientific communication.

The growth rate of the Web began to accelerate significantly in the second half of 1993 after the introduction of the first portable, graphical web browser, X Mosaic. This was the first browser facilitating the new Internet application, the Web, to spread rapidly and penetrate all over the world. The Web has become a general-purpose technology, today serving not only scientific but all kinds of communication and information presentation needs.

The commercialization of the Internet also started with the birth of the World Wide Web. Companies not previously interested in using the Internet suddenly discovered the new possibilities and became the most active driving force in the development of networking. The first version of Netscape, another important web browser, was released in October 1994. The World Wide Web (W3) Consor-

tium, formed in 1994, drives and leads the technological development and standardization processes of Web technology.

9.2. Main Features and Architecture

As mentioned above, the World Wide Web is a hypertext-based database system of multimedia content. It can be used for building either local or global information systems. It is interactive, which means that the information flow can be bidirectional (from the database to the user and from the user to the database). It integrates all the other traditional information system technologies, such as ftp, gopher (a predecessor of the WWW in organizing and displaying files on dedicated servers), and news.

The content of a Web database can be static or dynamic. Static information changes rarely (or perhaps never), while dynamic content can be generated directly preceding (or even parallel to) actual downloading.

The Web content is made available by web servers, and the information is retrieved through the use of web browsers. The more or less structured information is stored in web pages. These pages may refer to multimedia objects and other web pages, stored either locally or on other Web servers. Thus, the network of the Internet web servers forms a coherent, global information system. Nevertheless, because the different segments of this global system have been created and are operated and maintained independently, there is no unified structure and layout. This fact may result in considerable difficulties in navigating the Web.

The Universal Resource Locator is a general addressing scheme that allows unambiguous reference to any public object (or service), of any type, available on the Internet. It was originally invented for the Word Wide Web, but today URL addressing is used in many other Internet applications. Examples of different URLs include:

- http://www.bme.hu/index.html
- ftp://ftp.funet.fi/
- mailto:maray@fsz.bme.hu

9.3. HTTP and HTML

Hypertext Transfer Protocol (HTTP) is the application-level network protocol for transferring Web content between servers and clients. (Hypertext is a special database system of multimedia objects linked to each other.) HTTP uses the services of the TCP transport protocol. It transfers independently the objects (text, graphics, images, etc.), that build up a page. Together with each object, a special header is also passed. The header contains information about the type of the object, its size, its last modification time, and so on. HTTP also supports the use of proxy and cache servers. HTTP proxies are implemented in firewalls to pass HTTP traffic between the protected network and the Internet. Object caches are used to save bandwidth on overloaded lines and to speed up the retrieval process.

Hypertext Markup Language (HTML) is a document description language that was designed to create formatted, structured documents using hypertext technique (where links are associated to content pieces of the document so that these links can be easily applied as references to other related documents).

As originally conceived, HTML focused on the structure of the document. Later it was improved to provide more formatting features. In spite of this evolution, HTML is still quite simple. An HTML text contains tags that serve as instructions for structuring, formatting, linking, and so on. Input forms and questionnaires can also be coded in HTML. A simple example of an HTML text is as follows:

```
<HTML>
<HEAD>
<TITLE>Example</TITLE>
</HEAD>
<BODY>
<CENTER>
<H1>Example</H1>
</CENTER>
This is just a short <B>HTML</B> example, containing almost nothing.
<P>
<HR>
</BODY>
</HTML>
```

Details about the syntax can be found in the titles related to multimedia and the World Wide Web in the References. The above example will be displayed by the browser like this:

Example

This is just a short **HTML** example, containing almost nothing.

9.4. Multimedia Elements

The World Wide Web is sometimes called a multimedia information system because Web databases may contain also multimedia objects. It is obvious that in a well-designed and formatted document page graphic information and images can be used in addition to text. Web technology allows the inclusion of sound and moving pictures as well. Web pages may also contain embedded programs (e.g., Javascript, a language for designing interactive WWW sites) and thus can have some built-in intelligence.

10. THE ROLE OF THE WORLD WIDE WEB IN COMMUNICATION, INTEGRATION, AND COLLABORATION

The following subsections provide an insight into the role of the World Wide Web in information access, communication, exchanging information, collaboration, and integration.

10.1. The World Wide Web as a Means for Universal Information Access

In the past few years the World Wide Web has become an essential tool of common application in many areas of human life. Today it is a universal, global, and widely used information system that makes it possible for every user of the Internet to access a vast amount of information from every segment of human activity, including science, business, education, and entertainment.

The World Wide Web is universal because it can easily be adapted to almost any kind of information publishing needs. It can substitute for traditional paper-based publications like books, newspapers, newsletters, magazines, catalogs, and leaflets. But it is much more. It can be dynamic, multimedia based, and interactive.

The World Wide Web is global because using the transport provided by the Internet, it can be used worldwide. It allows any kind of information to flow freely to any destination, regardless of physical distance.

The available human interfaces (editors, browsers, etc.) of the Web are friendly and easy to use, making it open for everyone. The Web technology supports different national languages and character sets and thus helps to eliminate language barriers.

10.2. The World Wide Web as a Tool for Communicating and Exchanging Information

The basic role of the Web is to allow users to share (exchange) information. Accessing a particular set of web pages can be free to anybody or restricted only to a group of users.

However, the Web is also a technology for communication. There are Web-based applications for online and offline communication between users, for teleconferencing, for telephoning (Voice over IP [VoIP]), for using collective whiteboards, and so on.

Because the Web integrates almost all other Internet applications (including e-mail), it is an excellent tool for personal and group communication.

10.3. Collaboration and Integration Supported by the World Wide Web

An increasing amount of Web-based applications are available in the market for supporting collaborative and collective work (see the titles related to the World Wide Web and applications in the References). This evolution is based on the fact that the Web technology (including formats and protocols) is standardized, widespread, inexpensive, and platform independent.

Any network user can have access to the Web, regardless of the type of machine he or she works with or the way that machine is connected to the network. Thus, distributing information among collaborating partners is made easier by using the Web.

The Web can also be used for cooperative preparation of documents and/or software by collaborating network users, even if they are far away from each other. That is why Web technology is becoming increasingly popular in intranets and extranets as well. Companies and organizations can thus increase the efficiency of collective work within their staff by using Web-based tools.

Web technology can also be integrated in many different applications or products where there is a need for or a function of sharing or distributing information and/or communicating between different parties and users.

11. CONTENT GENERATION AND CONTENT PROVISION

Generation, provision, distant accessibility, and remote processing of information content can be considered the ultimate goal in introducing computer networks into an organization.

As many systems of information content can be postulated as there are organizations and applications within these organizations. Successful integration of the applications within an organization

requires the integration of these separate sets of information content as well. Moreover, the organizations' outside relations can be made most effective if the information content within the organization is correlated to the relevant information content accessible in communicating with partner organizations.

As far as the structure of the correlated individual systems of information content is concerned, widely accepted distributed database techniques, and especially the worldwide-disseminated World Wide Web technology, provide a solid background. However, the structure and the above-mentioned techniques and technologies provide only the common framework for communicating and cooperating with regard to the related systems of information content. Determining what information and knowledge should be involved and how to build up the entire content is the real art in utilizing computer networks. There are no general recipes for this part of the task of introducing and integrating computer and network technologies into the activities of an organization.

The generation and accessibility (provision) of information content are briefly investigated in the following subsections. Also provided is a short overview of the classification of the information content, along with a subsection on some aspects of content rating and filtering.

11.1. Electronic I/O, Processing, Storage, and Retrieval of Multimedia Information

Generation and provision of information content involves a set of different steps that generally take place one after the other, but sometimes with some overlapping and possibly also some iterative refinement. In principle, these steps are independent of the type of the information. However, in practice, multimedia information requires the most demanding methods of handling because of its complexity. (''Multimedia'' means that the information is a mix of data, text, graphics, audio, still video, and full video components.)

Obviously, before starting with the steps, some elementary questions should answered: what information is be to put into the stored content, how, and when is this information to be involved? These questions can be answered more or less independently of the computer network.

If the answers to these questions above are known, the next phase is to start with that part of the task related to the network itself. The basic chain of steps consists of the following elements:

1. Inputting the information electronically into the content-providing server
2. Processing the input in order to build up the content by using well-prepared data
3. Storing the appropriate information in the appropriate form
4. Providing ''anytime accessibility'' of the information

The first step is more or less straightforward using the available input devices (keyboard, scanner, microphone, camera, etc.)

The next steps (processing and storing) are a bit more complicated. However, this kind of processing should be built into the software belonging to the application system. This kind of software is independent of the information itself and normally is related exclusively to the computer network system being under consideration.

More important is how to find the necessary information when it is needed, whether the information is internal or external to the organization.

The task is relatively simple with internal information: the users within an organization know the system or at least have direct access to those who can supply the key to solving any problems in accessing it.

However, the task of looking for external information will not be possible without the most recent general tools. These tools include different kinds of distributed database handling techniques. More important, they include a number of efficient and convenient World Wide Web browsers, search engines, directories, general sites, portals, topical news servers, and custom information services. With these new ways of accessing the required information and a good infrastructure as a basis, there is virtually no search task that cannot be solved quickly and efficiently, provided that the requested information is recognizable.

11.2. Classification of Electronically Accessible Information Content

The more application areas there are (see Section 8 above), the more content classes can be identified. Thus, we can distinguish between:

- Public and private contents (depending on who can access them)
- Personal, administrative, and industrial contents (depending on where they were generated and who accesses them)
- Contents of varying complexity (depending on volume of information, structure of storage and accessibility, kind of information, distribution of storage, etc.)
- Contents of varying commercial availability (off-the-shelf, semi-custom, or custom generated).

These classifications determine the requirements for the contents that are under consideration. The main aspects of these requirements are:

- Availability (where and how the content can be reached)
- Accessibility (what authorization is needed for accessing the content)
- Reliability (what levels of reliability, validity, and completeness are required)
- Adequacy (what level of matching the content to the required information is expected)
- Updating (what the importance is of providing the most recent related information)
- Ease of use (what level of difficulty in accessing and using the information is allowed)
- Rating (what user groups are advised to, discouraged from, prevented from accessing the content)

Some of these aspects are closely related to the networking background (availability, accessibility), while others are more connected to the applications themselves. However, because accessing is always going on when the network is used, users may associate their possibly disappointing experiences with the network itself. Thus, reliability, adequacy, updating, ease of use, and rating (content qualification) are considered special aspects in generating and providing network accessible contents, especially because the vast majority of these contents are available nowadays by using the same techniques, from the same source, the World Wide Web. Therefore, special tools are available (and more are under development) for supporting the care taken of these special aspects.

Networking techniques can't help too much with content reliability. Here the source (provider or broker) is the most important factor in how the user may rely on the accessed content. The case is similar with adequacy and updating, but here specific issues are brought in by the browsers, search techniques/engines, general sites, portal servers (those responsible for supporting the search for adequate information), and cache servers (mirroring Web content by taking care of, for example, correct updating).

Some specific questions related to rating and filtering are dealt with in the next subsection.

11.3. Rating and Filtering in Content Generation, Provision, and Access

Although the amount of worldwide-accessible information content is increasing exponentially, the sophistication, coverage, and efficiency of the tools and services mentioned in the previous two subsections are increasing as well. However, one problem remains: the user can never exactly know the relevance, reliability, or validity of the accessed information. This problem is well known, and many efforts are being made to find ways to select, filter, and, if possible, rate the different available sources and sites (information providers) as well as the information itself. An additional issue should be mentioned: some information content may be hurtful or damaging (to minorities, for example) or corrupting, especially to children not well prepared to interpret and deal with such content when they accidentally (or consciously) access it.

There is no good, easily applicable method available today or anticipated in the near future for solving the problem. The only option at the moment is to use flags as elementary information for establishing a certain level of rating and filtering. This way, special labels can be associated with content segments so that testing the associated labels before accessing the target content can provide information about the content, itself. These flags can provide important facts about the topics, the value, the depth, the age, and so on, of the related content and about the target visitors of the site or target audience of the content.

The flags can be associated with the content by the content provider, the content broker, the service provider, or even the visitors to the related sites. However, because appropriate flags can be determined only if the content is known, the most feasible way is to rely on the content provider. The problem is that if the provider consciously and intentionally wishes to hide the truth about the content or even to mislead the potential visitors/readers, there is practically no way of preventing such behavior. This is a real problem in the case of the above-mentioned hurtful, damaging, or corrupting contents, but also with any other contents as well, as far as their characteristics (validity, value, adequacy, age, etc.) are concerned.

If flags are present, filtering is not a difficult task. It can be performed either ''manually'' (by a human decision whether to access or not access) or even by an automated process, inhibiting the access if necessary or advisable.

However, the above procedure assumes standardized techniques and standard labeling principles/rules, as well as fair usage. There is still a lot of work to do before these conditions will generally be met (including codification).

More has to be done with respect to future intelligent machine techniques that could automatically solve the tasks of labeling and filtering. Solving this problem is extremely complex but also extremely

important and urgent because of the exponentially increasing amount of content accessible through the Internet.

12. TRENDS AND PERSPECTIVES

Computer networking is a continuously developing technology. With the rapid evolution of the theory and techniques behind them, the worldwide infrastructure, the globally available services, the widening spectrum of applications, the exponentially growing amount of accessible content, and the ability and readiness of hundreds of millions of users are all going through an intensive developmental process. With the progression of the networks (sometimes simply called the Internet), together with the similarly rapid evolution of the related computing, communications, control, and media technologies and their applications, we have reached the first phase of a new historical period, the Information Society. The evolving technologies and applications penetrate every segment of our life, resulting in a major change in how people and organizations, from small communities to global corporations, live their lives and manage their activities and operations.

Behind the outlined process is the development of computer networking in the last 30 years. Global connectivity of cooperating partners, unbounded access to tremendous amounts of information, as well as virtually infinite possibilities of integrating worldwide distributed tools, knowledge, resources, and even human capabilities and talents are becoming a reality as we go rapidly down a road that we have only just started to pave. Although the future of networking is impossible to see today, some important facts can already be recognized.

The most important attributes of the evolution in computer networking are openness, flexibility, and interoperability:

- Openness, in allowing any new technologies, new solutions, new elements in the global, regional, and local networks to be integrated into the existing and continuously developing system of infrastructure, services, and applications
- Flexibility, in being ready to accept any new idea or invention, even if unforeseen, that takes global advancement a step ahead
- Interoperability, in allowing the involvement of any appropriate tool or device so that it can work together with the existing system previously in operation

These attributes stem from:

- The more conscious care taken of the hierarchical and/or distributed architecture in networking technology
- The cautious standardization processes going on worldwide
- The carefulness in taking into consideration the requirements for interfacing between evolving new tools and devices

As a result, the progression in networking continues unbroken and the proliferation of network usage unsaturated, even at the start of the third millennium. Some trends in this development process are briefly outlined in the following subsections.

12.1. Network Infrastructure

Major elements of the trends in the development of the network infrastructure can be summarized, without aiming at an exhaustive listing, as follows:

- Transmission speeds are increasing rapidly. The trend is characterized by the introduction of more fiberoptic cables; the application of wavelength division multiplexing and multiple wavelengths in the transmission technique (utilizing the fact that a single fiber can guide several different frequency waves in parallel and sharing these waves among the information coming from different sources and being transmitted to different destinations); the integration of both guided and radiated waves in data communication by combining terrestrial and satellite technologies in radio transmission; the introduction of new techniques for mobile communication; the application of a more structured hierarchy in the infrastructure; and more care being taken of ''last-mile'' connectivity (to the access speeds at the final sections of the connections, close to the individual PCs or workstations), so that multiple-Mbps cable modems and digital subscriber lines, or cable TV lines, direct satellite connections, or wireless local loops, are applied close to the user terminals.
- Active devices of the infrastructure, together with the end user hardware and software tools and devices, are improving continually, allowing more intelligence in the network.

- The number, capability, and knowhow of the public network and telecom operators is increasing, so market-oriented competition is continuously evolving. The result is lower prices, which allows positive feedback on the wider dissemination of worldwide network usage.
- Governments and international organizations are supporting intensive development programs to help and even motivate fast development. Tools applied include financial support of leading-edge research and technological development, introduction of special rules and regulations about duties and taxes related to information technologies, and, last but not least, accelerating codification on Internet-related issues.

As a result of these elements, the network infrastructure is developing rapidly, allowing similarly fast development in the service sector.

12.2. Services

The trends in the evolution of networking services, available mostly through Internet service providers (ISPs) and covering domain registration and e-mail and Web access provision, as well as further service types related to providing connectivity and accessibility, can be characterized by continuing differentiation.

Although the kinds of services don't widen considerably, the number of users needing the basic services is growing extremely fast, and the needs themselves are becoming more fragmented. This is because the use of the network itself is becoming differentiated, covering more different types of applications (see Section 12.3) characterized by different levels of bandwidth and quality demand.

Quality of service (QoS) is the crucial issue in many cases. From special (e.g., transmission-intensive critical scientific) applications to real-time high-quality multimedia videoconferencing to bandwidth-demanding entertainment applications and to less demanding e-mail traffic, the different quality-level requirements of the service result in multiple grades of QoS, from best-efforts IP to guaranteed transmission capacity services.

Different technologies, from asynchronous transfer mode (ATM) managed bandwidth services (MBS) to new developments in Internet Protocol (IP) level quality management, support the different needs with respect to QoS grades. Lower quality demand may result in extremely low prices of service.

An important trend is that access to dark fiber (optical cables as physical infrastructure elements rather than leased bandwidths or managed connectivity services) and/or just separate wavelengths (specific segments of the physical fiber capacity) is becoming available and increasingly popular among well-prepared users, besides the traditional, mainly leased-line, telecom services. While this new element in the service market assumes higher levels of technological knowhow from the user, the cost aspects may make this possibility much more attractive in some cases than buying the more widespread traditional services. This also means an important new kind of fragmentation in the market, based on buying fiber or wavelength access and selling managed transmission capacity.

Another trend is also evolving with respect to services, namely in the field of providing and accessing content on the Web. It is foreseeable that content provision services such as hierarchical intelligent caching/mirroring, as well as content-accessing services such as operating general and topical portals or general and topical sites, will proliferate rapidly in the future, together with the above-mentioned trend toward separation of content provision and content brokerage.

These trends in networking services will result in a more attractive background for the increasing amount of new applications.

12.3. Applications

An overview of the development trends in network infrastructure and networking services is not difficult to provide. In contrast, summarizing similar development trends in the far less homogeneous applications is almost impossible because of their very wide spectrum. However, some general trends can be recognized here.

First, the areas of applications do widen. Just to mention some key potential trends:

- The most intensive development is foreseeable in the commercial and business applications (e-commerce, e-business).
- Industrial applications (including the production and service industries) are also emerging rapidly; one of the main issues is teleworking, with its economic as well as social effects (*teleworking* means that an increasing number of companies are allowing or requesting part of their staff to work for them either at home or through teamwork, with team members communicating through the network and thus performing their joint activities at diverse, distant sites).

- Applications in the entertainment sector (including home entertainment) are also becoming more common, but here the trends in the prices of the service industry have a strong influence.
- Applications in governmental administration and the field of wide access to publicly available administrative information seem to be progressing more slowly at the start of the new millennium. The reasons are probably partly financial, partly political (lack of market drive and competition results in lack of elevated intensity in the development of the networking applications too).
- Applications related to science and art will also evolve rapidly, but the speed will be less impressive than in the commercial area, although internal interest and motivation complement specific market drive elements here.
- Some special factors are playing an important role in the fields of telemedicine and teleteaching (teleinstruction). Here, the healthy mix of market-driven competitive environments, governmental commitment, and wide public interest will probably result in an extremely fast evolution.

Second, some general features of the applications are showing general trends as well, independently of the application fields themselves. Two of these trends are:

- Multimedia transmission is gradually entering practically all applications, together with exploitation of the above-mentioned techniques of telepresence and teleimmersion (these techniques are characterized by combining distant access with virtual reality and augmented reality concepts; see Section 2).
- The concept of grids will probably move into a wide range of application areas. In contrast to the well-known client–server scheme, this concept exploits the potential of integrating distributed intelligence (processing capability), distributed knowledge (stored information), and distributed resources (computing power) so that a special set of tools (called middleware) supports the negotiation about and utilization of the intelligence, knowledge, and resource elements by goal-oriented integration of them within a grid. (A grid is a specific infrastructure consisting of a mutually accessible and cooperative set of the joined hosting sites, together with the distributed intelligence, knowledge, and resources and the middleware tools.)

The development trends in the field of the applications obviously deeply influence the trends in the area of content generation and content provision.

12.4. Information Content

Forecasting in the area of content generation and content provision is even more difficult than in the field of network applications. Only some basic issues can be mentioned here.

The first important trend is the emergence of a new branch of industry, the content industry. No longer are content generation and content provision secondary to building the infrastructure, providing services, and/or introducing or keeping applications. The related complex tasks (at least in the case of professional activities of a high standard) require large investments and call for adequate return on these investments. Well-organized joint efforts of highly educated and talented staff are required in such demanding activities.

The second trend is directly linked to the amount of work and money to be invested in content generation. Contents will gain more and more value in accordance with such investments. Moreover, while accessing the infrastructure and hiring services will probably become less expensive in the future, the price for accessing valuable information will probably grow considerably. The price for accessing any information (content) will soon be cost based, depending on the size of the investment and the potential number of paying users.

The third trend is also due to the increasing complexity of the tasks related to content generation and content provision. Task complexities have initiated the separation of the activities related to generating contents from those related to organizing services for content provision to the public. This means that special expertise can be achieved more easily in both of these types of demanding activities.

The fourth trend is related to storing the information. Future contents will be distributed: because transmission will get cheaper and cheaper, merging distant slices of information content will be made much cheaper by maintaining the current distance and accessing the required remote sites as needed instead of transporting these slices into a central site and integrating them on-site. However, in order to exploit this possibility, a certain level of distributed intelligence is also required, as well as inexpensive access to the connectivity services. This trend is closely related to those regarding portals and grids discussed in the previous subsection.

XML is an emerging protocol of note. Applied for exchange of structured information, it is increasingly used in e-commerce applications.

13. NETWORKING IN PRACTICE

The following subsections go into some detail about the practical issues of networking. A brief overview is provided of the suggested way of starting activities devoted to advance analysis of the environment, planning the applications and their prerequisites, designing the network itself, and implementing the appropriate hardware and software. Classification of networking solutions and implementation of network technology are investigated separately. As in the other parts of this chapter, the reader should look for a more detailed discussion in the specialized literature, some of which is listed in the References.

13.1. Methodology

Designing a good network is a complex task. It is essential that the planning and implementation phase be preceded by a thorough survey in which the following questions, at least, have to be answered:

- What is the principal goal of building the network?
- What is the appropriate type and category of the network?
- Is there a need for integration with existing networks?
- What kinds of computers and other hardware equipment are to be connected?
- What kinds of applications are to be implemented over the network?
- What kind of protocols should be supported?
- How much traffic should be carried by the network? What is the required bandwidth and throughput of the network? What is the highest expected peak load of the network?
- What is the maximum acceptable delay (latency) on the network?
- What level of reliability should be guaranteed?
- What level of security has to be reached?
- What kinds of enhancements and improvements are expected in the future? What level of scalability is desirable?
- What kinds of physical constraints (distance, trace, etc.) should be taken into consideration?

The actual process of implementation depends on the answers to these questions. The result (the adequacy and quality of the network) will greatly depend on how consistently the rules have been followed about building networks.

Designing the most appropriate topology is one of the key issues. Many other things depend on the actual topology. If the topology is not designed carefully, the network may be far from having optimum adequacy, quality, and cost/performance.

Choosing the right physical solutions and low-level protocols is also very important. Low-level protocols (TCP/IP, etc.) have a strong impact on the functionality of the network. Building a multiprotocol network is advisable only if there is an explicit need for such a selection; this may increase the costs and make the management and maintenance tasks difficult and complicated.

13.2. Classification

Classification of networks by type may help significantly in selecting the solution for a specific application. Obviously, different types of networks are designed to serve different types of application needs.

Networks can be classified by a number of attributes. Important classification factors include:

- Purpose (general, industrial, process control, etc.)
- Size (local area network, metropolitan area network, wide area network)
- Technology (ethernet, fast ethernet, token ring, fiber digital data interface [FDDI], asynchronous transfer mode [ATM], etc.)
- Applied low-level protocols (TCP/IP, IPX/SPX, Decnet, AppleTalk, etc.)
- Speed (low, medium, high, ultrahigh)
- Mode of operation (open, private, intranet, extranet, etc.)

Often more than one kind of technology and/or protocol has to be used in the same network. Especially if the size of the network is large, different segments can be built up by using different

technologies and/or protocols. Fortunately, modern network equipment allows the use of different technologies and protocols at the same time within the same network. This equipment takes care of the necessary translations when routing the information traffic.

13.3. Implementation Issues

Like the design process, implementation is a complex task that can involve difficult problems. The design team should understand the available technological solutions well in order to select the most appropriate ones for each part of the system.

As an example, ethernet technology is a widespread, efficiently functioning solution in most cases, but because it does not guarantee appropriate response times, it cannot be used in certain real-time environments. Ethernet is a reliable, effective, inexpensive, and very good technology, but the applied CSMA/CD algorithm is not real time. In practice, the process to be controlled by the network may be much slower than the ethernet technology. Therefore, especially if oversized network capacity is implemented, there will be no problem in such cases. But theoretically it is not the best choice. Of course, the choice and the means of implementation are also a financial question, and all the important factors should be taken into consideration in looking for a good compromise.

Decisions about what and how to implement have a serious impact on the reliability and security of the network, too. For building a high-reliability, high-availability network, redundant components must be used. Communication lines and passive and active network components all have to be multiplied in a well-designed way to get a partly or fully fault-tolerant system. Of course, this may result in significant extra costs. Similarly, if extra-high levels of security must be guaranteed, a number of additional hardware and software components may be needed. Again, a good compromise can be found by taking into account all the reliability and security aspects and cost considerations.

14. NETWORKING IN THE PRODUCTION AND SERVICE INDUSTRIES

The application of computer networks in the production and service industries should be fitted to the required complexity and coverage.

As far as complexity of network usage, two main aspects should be taken into consideration:

1. What kind of infrastructure is built within the organization (including internal structure and technology as well as connectivity towards the outside world)? The spectrum goes from connecting a few workplaces (PCs) to each other, and possibly to the Internet, by the simplest LAN techniques and telephone modems, respectively, to using the most complex high-speed intranet and/or extranet applications with high-end workstations, or even large computer centers, together with broadband connections to the global Internet.
2. What kinds of services are applied? In this respect, the simplest solutions make possible only the simple exchange of messages between workplaces, while the other end is characterized by the exchange of the most complex multimedia information by using World Wide Web techniques, accessing large databases, applying distributed information processing, utilizing virtual environments, exploiting network-based long-distance collaboration, and so on.

Coverage of network usage also involves two important aspects:

1. What kinds of applications within the organization are introduced? The low end is simple word processing with possible electronic document handling. The other extreme is characterized by a complex system of network-based planning, computer-based distributed decision making, network-based integrated management, computer aided design, manufacturing, and testing, distributed financing by the use of computer networking, computerized human resource management, networked advertising, promotion, marketing, retailing, online sales transactions, public relations, and so on.
2. What amount and complexity of information content are generated, processed, and stored by the networked system of the organization? Here the levels are very much company specific, but it can be said that companies in both the production and the service industries can start with applications using elementary sets of information and may get ahead until virtually the entire information and knowledge base about the full spectrum of activities within the company (and also about the related outside world) are appropriately stored and processed by a well-established system of networked services and applications.

The basic principle here is that introducing computers and computer networks amplifies the strengths as well as the weaknesses of the organization. Well-organized companies can gain a lot from computerized and networked applications. However, those with considerable organizational

problems mustn't look for a miracle: they will rapidly realize that these tools increase rather than decrease the problems of operating the related production or service activities.

The full process (from the first elementary steps until completing the implementation of the network-based system) is a combination of two basic components:

1. Introducing and integrating network technology (infrastructure and services) inside the company
2. Introducing and integrating networked applications into the activities within the company (together with continuously building up the information content).

If careful introduction and integration of the new technologies and methods is performed in a systematic manner and by appropriately restructuring and re-forming all the related activities within the company, the results will be higher efficiency, better performance, and lower costs, provided that good management exploits the opportunities that are made available.

Moreover, properly introduced and appropriately applied computer techniques and network technologies will not only help in getting ahead with enhancing efficiency and performance as well as cost cutting, but also result in elevated competitiveness. This way, survival against the increasing worldwide competition is supported, too.

15. SOME PRACTICAL ASPECTS OF INTRODUCING AND USING COMPUTER NETWORKS IN INDUSTRIAL ENGINEERING

As mentioned above, applying up-to-date computer networks in the production and service industries requires two basic steps:

1. Integrating network technology (Internet connectivity and accessibility) in the related organization or company
2. Integrating networking services and network-based applications (Internet technology) in the operations and activities of the organization or company.

The most important practical issues with regard to these steps are briefly investigated in the following subsections but some preliminary comments should be made.

First, there are, in principle, two distinct possibilities, based on the top-down and the bottom-up approach, respectively:

- In the case of fast top-down introduction of network technology, an advance analysis (feasibility study) should be performed, in order to avoid the potential risks associated with lack of careful preparation for taking a giant step ahead with networking in the company.
- In the case of applying the bottom-up approach, the speed of ''getting networked'' company-wide is much lower, but getting ahead step-by-step makes it possible to correct any mistakes and adapt to all the recognized internal circumstances so that the risks are minimized.

In any case, the top-down approach usually requires outside guidance from a professional company that specializes in introducing and integrating network technology in the organization and activities of industrial companies. This is normally not required with the bottom-up approach, although preliminary analysis and outside advice may help a lot there, too.

Another issue is coverage and depth in introducing networked information technology. The basic questions are where to stop with the bottom-up approach and what goals to define with the top-down approach. Coverage here means organizational (what departments to involve) and geographic (which sites to connect to the corporate network) coverage, while depth relates to the level at which network technology is introduced (which tasks to involve and what level of completion to achieve by network integration).

A further issue is to determine whether buying an off-the-shelf solution, buying a semicustom solution and adapting it to the local circumstances, or starting in-house development of a full custom solution is preferable. For small enterprises, the first alternative will be optimum; for high-end corporations, in many cases, the third. Although today the second alternative is the most common way of integrating network technology in a company, each organization should be considered separately, requiring its own specific handling.

15.1. Internet Connectivity

The introduction of Internet technology in industrial engineering starts with a preliminary definition of the company's business requirements and objectives. From these, the potential network applications can be derived. The planning and implementation phases can be started.

The first steps in the process of establishing Internet connectivity at an industrial company are to define the specifications and launch the necessary procedures:

- Consulting with experts about possibilities and goals
- Identifying what Internet applications will be introduced
- Defining human resource needs and deciding on staff issues related to networking
- Contracting an advisor/consultant to support activities related to company networking
- Estimating what bandwidth the selected applications will require
- Determining what equipment (hardware and software devices and tools) will be necessary
- Deciding about security issues and the extra equipment required
- Selecting the most appropriate Internet service provider (which may be the company itself)
- Deciding about the domain name(s) to be applied by the company
- Negotiating with the ISP about services to be bought (provided that the company is not its own ISP)
- Starting purchasing the necessary equipment

Naturally, the above steps do not follow each other in linear order. An iterative–interactive process is to be assumed, in which earlier decisions may sometimes be changed because of later recognition of specific problems, barriers, or difficulties.

The next steps should be devoted to preparations inside the company (or company sites). This means not just planning and building the in-house infrastructure (cabling, server room, etc.), but also deciding about the internal server structure (domain name server, mail server, web server, etc.). Another issue is starting the purchasing of the components (HW and SW) of the internal infrastructure and services that will be needed for covering the target applications. A further task is to prepare the tools and devices for the applications themselves.

Ideally, the full process may only take several weeks, but it may last several months (e.g., in the case of a complex infrastructure covering several sites, each bringing its own complex networking tasks into the picture).

Behind some of the above decisions and steps are several opportunities and choices (bandwidth of connectivity, level of security, server structure, equipment brands, etc.). Some also involve selecting among different technology variants. These alternatives require careful analysis before decisions are made.

It is not surprising that the Internet connection is to be upgraded later. This is normally not a problem at all and can be performed relatively simply, even if the upgrade also means a technological change.

15.2. LANs, Intranets, WANs, and Extranets

Establishing Internet connectivity is just the first step in the process. It makes communication with the outside world possible, but it doesn't yet solve the task of establishing internal connections within the enterprise.

In the case of a small enterprise and a single company site, the only additional task in establishing connectivity is to implement interconnections between the PCs and workstations used by the company staff. This is done by building the LAN (local area network) of the organization so that the resources (servers as well as PCs and workstations) are connected to the in-house infrastructure, in most cases an ethernet network, of the company. The required speed of the internal network depends on the traffic estimates. New ethernet solutions allow even gigabit per second transmission.

Once the internal LAN is established, the next question is how the users within the LAN will communicate with their partners outside the corporate LAN. Here is where the company intranet enters the picture.

The intranet is a network utilizing the TCP/IP protocols that are the basis of the Internet but belonging exclusively to the company and accessible only to the company staff. This means that outside partners can access the machines within the intranet only if they have appropriate authorization to do so. The intranet is in most cases connected to the global Internet through a firewall, so that although the websites within the intranet look and behave just like other websites outside the intranet, the firewall in front of the Intranet prevents unauthorized access.

In companies with separate, distant sites, all these sites may have their own LANs, firewalls, and intranets. In most cases these are connected to each other through the public MAN (high-speed metropolitan area network of a town or city), or sometimes through the regional WAN (extra-high-speed wide area network of a large region), although private network connections can also be applied in case of specific security or traffic requirements.

However, intranets connected through public MANs or WANs may also be interconnected so that, in spite of the geographically scattered locations of the related company sites, they behave as a single

intranet. A common solution is to establish extranets so that the separate LANs are connected by a virtual private network over the public MAN or WAN and authorized access is controlled by a set of firewalls taking care of intranet-like traffic between the authorized users (company staff and authorized outside partners). Thus, extranets may also be considered as distributed Intranets accessible not only to company employees, but partially accessible to authorized users outside the organization or company.

LANs, intranets, and extranets provide a means for organizations or companies to utilize best the possibilities stemming from integrating the Internet in their operations and activities without losing security.

Although LANs, intranets and extranets are quite scalable, it is good to think ahead when planning the infrastructure and services of the company so that extension and upgrading do not occur more frequently than really necessary. The network address schema is impacted by the infrastructure, so changing network numbering can be costly.

15.3. World Wide Web Communication, Integration, and Collaboration

Once the LANs are in place, with their servers, PCs, and workstations, and the intranet/extranet infrastructure is working well, by taking care of secure interconnectivity towards the outside world, and by utilizing appropriate routing and firewall equipment, the details of the applications come into the picture. Here the best solutions can be built up by exploiting the possibilities that modern World Wide Web systems provide.

The Web is the global system of specialized Internet servers (computers delivering web pages to machines asking for them). The Web is also a tool integrating:

- Worldwide addressing (and thus accessibility)
- Hypertext technique (allowing navigation through a multitude of otherwise separate websites by following the links associated to web page content pieces)
- Multimedia capabilities (covering a wide spectrum of formats used by the Web contents, from structured text to graphics and from audio to still and real video)

Interacting with the Web content by initiating content-oriented actions, including also customizing them, is thus supported, too.

The Web is an ideal tool not only for worldwide information access, but also for communication, integration, and collaboration inside an enterprise and among enterprises (eXtensible Markup Language [XML]). The key is the combination of Web technology with the intranet/extranet environment. Practically, this means operating several web servers within the enterprise so that some of them serve only internal purposes and thus do not allow outside access, while others support communication outside the enterprise boundaries. While the latter normally differ from any other web servers only in their special property of being able to take over public content from the internally accessible web servers, the structure, linking, and content of the former are constructed so that they directly serve internal communication, integration, and collaboration.

This type of communication differs from general e-mail usage only in providing a common interface and a well-organized archive of what has been communicated through the system. This makes it possible to build the archive of the company continuously by automatically storing all relevant and recorded documents for easy, fast, and secure retrieval. The management of the organization or company can thus be considerably improved.

More important is that such a (Web-based) store of all relevant documents also take care of integrating all the activities resulting in or stemming from those documents. If a document starts its life in the system, any access to it, modification of it, attachment to it—in general, any event related to it—is uniquely recorded by the system. Thus, a reliable and efficient way of integrating the activities within the company, as well as between the company and its partners, can be achieved. Typical examples are e-commerce and e-business.

Communication and integration within an enterprise by the use of computer networks also mean high-quality support for overall collaboration, independent of where, when, and how the collaborating staff members take part in the joint activities. The only prerequisite is that they all take into consideration the rules of how to access the company websites. (Nevertheless, efficiently functioning systems are aware of these rules, too.) Different departments, from design to manufacturing, from sales to marketing, and from service provision to overall logistics, can collaborate in this way so that the company can maintain reliable and efficient operation.

However, as mentioned above, disorder in the operations of a company is amplified when World Wide Web communication, integration, and collaboration are introduced. Thus, in order to achieve a really reliable and efficient system of operations, careful introduction and well-regulated usage of the network-based tools are a must.

All this would be impossible without computer networking. And this is how industrial engineering can benefit fully from the computer network infrastructure and services within an industrial organization or company.

16. SUMMARY

Computer networking in industrial engineering is an invaluable tool for establishing and maintaining reliable and efficient operation and thus competitiveness. By utilizing the possibilities provided by the Internet and the World Wide Web, industrial enterprises can achieve results that earlier were impossible even to imagine.

However, the present level of networking technology is just the starting phase of an intensive global evolution. The development will not be stopping, or even slowing down, in the foreseeable future. New methods and tools will continue to penetrate into all kinds of human activities, from private entertainment to business life, from government to administrations to industrial engineering.

Getting involved in the mainstream of exploiting the opportunities, by getting connected to the network and introducing the new services and applications based on the Net, means being prepared for the coming developments in computer networking. However, missing these chances means not only losing present potential benefits, but also lacking the ability to join the future network-based innovation processes.

In 1999, the worldwide Internet Society announced its slogan: ''The Internet is for everyone.'' Why not for those of us in the industrial engineering community?

1. INTRODUCTION

Unlike applications based on electronic data interchange (EDI) and other previous uses of computer networks, the Internet has brought integration and versatility to existing computer and network technologies to the extent that firms and consumers are said to be in a virtual economic arena. A variety of commercial and economic activities fall within the realm of electronic commerce as long as they are carried out in the electronic marketplace. In this chapter, we present an overview of business and industrial applications of the Internet technologies.

Specific advantages of the Internet over previous closed, proprietary networks are numerous. First, the investment cost necessary to establish an Internet presence is relatively small compared to earlier

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

private value-added networks, which limited EDI applications to large corporations. Lower costs in turn allow small firms and individuals to be connected to the global network. Open TCP/IP protocols of the Internet also ensure that communicating parties can exchange messages and products across different computing platforms and geographic regional boundaries.

In physical markets, geographical distance and political boundaries hinder the free movement of goods and people. Similarly, closed proprietary networks separate virtual markets artificially by establishing barriers to interoperability. This is equivalent to having a railway system with different track widths so that several sets of identical rail cars must be maintained and passengers must be transferred at all exchange points.

Neither computing nor networking is new to businesses and engineers. Large-scale private networks have been an essential ingredient in electronic data interchange, online banking, and automatic teller machines. Business investments in information technology over the past decades have enabled firms to reengineer manufacturing, inventorying, and accounting processes. Nevertheless, the strength of the Internet lies in its nature as an open network. Economically speaking, the open Internet allows easy entry and exit into a market because of lower costs and greater market reach. A store located on a small tropical island can effectively reach global partners and consumers, collaborating and competing with multinational corporations without investing in international branches and sales presence.

While computers and networking technologies have advanced steadily over the past decades, they have lacked the characteristics of a true infrastructure. An infrastructure needs to be open and interoperable so as to allow various private enterprises with differing products and goals to collaborate and transact business in a seamless environment. As an infrastructure, the Internet provides open connectivity and uniformity as the first technological medium of its kind that supports a persistent development of universal applications and practices.

2. ELECTRONIC COMMERCE FRAMEWORKS

An apparent rationale for implementing electronic commerce is to reduce transaction costs related to manufacturing, distribution, retailing, and customer service. Many such uses involve automating existing processes through the use of computers and networks. But more importantly, new technologies now enable economic agents to move from simple automation to process innovation and reengineering. The complex web of suppliers, distributors, and customers doing business on the World Wide Web is allowing businesses to transform traditional markets and hierarchies into a new form called a network organization. Unlike hierarchies and centralized markets common in the physical economy, this structure based on networks allows a high degree of flexibility and responsiveness, which have become two pillars of the digital economy (see Section 2.3).

The Internet-based economy is multilayered. It can be divided into several layers that help us in grasping the nature of the new economy. Barua et al. (1999) have identified four layers of the Internet economy in their measurement of the Internet economy indicators. The first two, Internet infrastructure and Internet applications layers, together represent the IP or Internet communications network infrastructure. These layers provide the basic technological foundation for Internet, intranet, and extranet applications. The intermediary/market maker layer facilitates the meeting and interaction of buyers and sellers over the Internet. Through this layer, investments in the infrastructure and applications layers are transformed into business transactions. The Internet commerce layer involves the sales of products and services to consumers or businesses. According to their measurements, the Internet economy generated an estimated $301 billion in U.S. revenues and created 1.2 million jobs in 1998. Estimates of revenues and jobs contributions by each layer are presented in Table 1.

TABLE 1 Internet Revenues and Jobs in 1998, U.S.

	Estimated Internet Revenues (millions of dollars)	Attributed Internet Jobs
Internet infrastructure layer	114,982.8	372,462
Applications layer	56,277.6	230,629
Intermediary/market maker layer	58,240.0	252,473
Internet commerce layer	101,893.2	481,990
Total	301,393.6	1,203,799

2.1. Economics of the Digital Economy

The digital revolution is often viewed as the second industrial revolution. But why does the Internet have such a great effect on business activities and the economy? How is the Internet-driven economy different from the previous industrial economy? Despite its obvious usefulness, a comparison to the industrial revolution is misleading—the digital revolution operates on quite different premises. In many respects, the digital revolution is undoing what we achieved in the previous age of industrial production. For example, the primary commodity of the digital age—information and other knowledge-based goods—behaves quite differently than industrial goods.

Industrial goods and production technologies that can churn out millions of an item with the least unit cost have been the hallmark of the modern economy. From ordinary household goods such as silverware and dishes to mass-produced industrial goods like automobiles and consumer appliances, increasing availability and decreasing price of these goods have brought an unimaginable level of mass consumption to the general public. Nevertheless, mass-produced industrial goods, typified by millions of identical Ford Model Ts, are standardized in an effort to minimize costs and as a result are unwieldy in fitting individual needs.

The characteristics of the industrial economy are summarized in Table 2. Business processes of an industrial firm are optimized for a supply-driven commerce, while the digital economy is geared toward customer demand. The economics of industrial goods has promoted least-cost solutions and a pervasive focus on costs that has become the limiting factor in both product choices offered to customers and manufacturing options open to producers. Values are created not from maximizing user satisfaction but from minimizing costs, not from flexibility in production but from production efficiency, which often disregards what the customers want and need. Value creation in the Industrial Age flows in a linear, rigid, inflexible, and predetermined stage of preproduction research, manufacturing, marketing, and sales. The need to minimize costs is so overwhelming that firms apply the same cost economics to nonmanufacturing stages of their business, such as distribution, inventory management, and retailing.

Partly because of the economic efficiency achieved during the industrial revolution, manufacturing now rarely accounts for more than half of a firm's total operating costs. Product research, marketing and advertising, sales, customer support, and other nonproduction activities have become major aspects of a business organization. This trend towards a nonmanufacturing profile of a firm is reflected in today's focus on business strategies revolving around quality management, information technology, customer focus, brand loyalty, and customization.

The Internet economy departs from the cost-minimization economics of the industrial age, but this transformation is not automatic simply because one is dealing with digital goods. For example, typical information goods such as news and databases are subject to the same economics as industrial goods as long as they are traded as manufactured goods. Cost minimization is still a necessary concern in the newspaper business. Limitations of the industrial age will translate into the Internet economy even when newspapers and magazines are put on the Web if these online products are nothing more than digitized versions of their physical counterparts. Many content producers and knowledge vendors may be selling digital goods but be far from participating in the digital economy if their products still conform to the cost-minimization economics of the industrial age.

2.2. Product and Service Customization

Knowledge is a critical part of economic activities in both industrial and digital economies, but they differ significantly in the way knowledge is utilized. While the main focus in generating and applying knowledge during the industrial age was on maximizing efficient production through lower costs, the use of knowledge in the digital economy focuses on providing customers with more choices. Instead of standardizing products, the digital revolution drives firms to focus on maximizing customer satisfaction by customizing products and meeting consumption needs.

To offer more choices and satisfaction to customers, business processes must be flexible and responsive. Web-based supply chain management, trading through online auctions, targeted marketing

TABLE 2 Industrial Economy vs. Digital Economy

Industrial Economy	Digital Economy
Supply-driven	Demand-driven
Cost minimization	Value maximization
Standardization	Customization
Linear value chain	Nonlinear value Web
Price competition	Service competition

and sales, and interactive customer service create values not simply by reducing costs but by allowing firms to be responsive to customers' needs.

2.3. Flexible and Responsive Organization

Just as new products have been born from the technologies of the Internet, so has a new organizational form. The nonlinear technology of the Web makes it possible to have an organization that represents the highest level of flexibility. In this new form, defining or classifying virtual firms and markets based on traditional organizational structures such as a hierarchy or an M-form can be very difficult. Indeed, a very flexible organization may exist only as a network organization that defies any structural formula.

In physical markets, a firm is organized into a functional hierarchy from the top-level executive to divisions and managers on down the hierarchy. It may structure its divisions following various product groups that rarely intersect in the market. The markets are organized under the natural order of products and producers from materials, intermediate goods, consumption goods, distributors, and retailers. Firms operating in traditional physical markets organize their business activities in a linear fashion. After the planning and product selection stage, the materials and labor are collected and coordinated for manufacturing. The manufactured products are then handled by the distribution and marketing divisions, followed by sales and customer service activities. These functions flow in a chain of inputs and outputs, with relatively minor feedback between stages. The value embedded in the materials is increased in each step of the manufacturing and marketing processes by the added labor, materials, and other inputs. In a linear market process such as this, the concept of the value chain can be used to highlight the links between business processes.

On the other hand, a networked economy is a mixture of firms that is not restricted by internal hierarchies and markets and does not favor controlled coordination like an assembly line. Businesses operating in this virtual marketplace lack incentives to maintain long-term relationships—based on corporate ownership or contracts—with a few suppliers or partners. Increasingly, internal functions are outsourced to any number of firms and individuals in a globally dispersed market.

Rather than adhering to the traditional linear flow, the new digital economy will reward those that are flexible enough to use inputs from their partners regardless of where they are in the linear process of manufacturing. In fact, the linear value chain has become a ''value web'' where each and every economic entity is connected to everyone else and where they may often function in a parallel or overlapping fashion. Electronic commerce then becomes an essential business tool to survive and compete in the new economy.

3. ENTERPRISE AND B2B ELECTRONIC COMMERCE

Sharing information within business and between businesses is nothing new. Electronic data interchange (EDI) has allowed firms to send and receive purchase orders, invoices, and order confirmations through private value-added networks. Today's EDI now allows distributors to respond to orders on the same day they are received. Still, only large retailers and manufacturers are equipped to handle EDI-enabled processes. It is also common for consumers to wait four to six weeks before a mail order item arrives at their door. Special order items—items not in stock—at Barnes & Noble bookstores, for example, require three to four weeks of delay. In contrast, an order placed on a website at Land's End (a clothing retailer) or an online computer store arrives within a day or two.

The business use of the Internet and electronic commerce enables online firms to reap the benefits of EDI at lower cost. The ultimate fast-response distribution system is instantaneous online delivery, a goal that a few e-businesses in select industries have already achieved. By their very nature, on-demand Internet audio and video services have no delay in reaching customers. In these examples, the efficiency stems from highly automated and integrated distribution mechanisms rather than from the elimination of distribution channels as in more traditional industries.

3.1. Web-Based Procurement

A traditional business's first encounter with e-commerce may well be as a supplier to one of the increasingly common Internet Web stores. Supply chain management is in fact a key, if not a critical, factor in the success of an Internet retailer. The number of products offered in a Web store depends not on available shelf space but on the retailer's ability to manage a complex sets of procurement, inventory, and sales functions. Amazon.com and eToys (http://www.etoys.com), for example, offer 10 times as many products as a typical neighborhood bookstore or toy shop would stock. The key application that enables these EC enterprises is an integrated supply chain.

Supply chain management refers to the business process that encompasses interfirm coordination for order generation, order taking and fulfillment, and distribution of products, services, and information. Suppliers, distributors, manufacturers, and retailers are closely linked in a supply chain as independent but integrated entities to fulfill transactional needs.

In physical markets, concerns about existing investments in warehouses and distribution systems often outweigh the desire and cost to implement fast response delivery. Some retailers still rely 100% on warehouses and distribution centers to replenish its inventory. Other retailers such as Tower Records have moved away from warehousing solutions to drop shipping, which entails shipping directly from manufacturers to retail stores. Drop shipping, just-in-time delivery, and other quick-response replenishment management systems address buyers' concerns about delays in receiving the right inventory at the right time. Many quick-response systems take this a step further and empower suppliers to make shipments on their own initiative by sharing information about sales and market demand.

Applications for a supply chain did not appear with the Internet or intranets. The supply chain concept evolved during previous decades to address manufacturers' needs to improve production and distribution where managing parts and inventories is essential in optimizing costs and minimizing production cycles. EDI on the Internet and business intranets, used by large corporations such as General Electric Information Services and 3M, are aimed at achieving efficient supply management at the lower costs afforded by the Internet. Intermediaries such as FastParts (http://www.fastparts.com) further facilitate corporate purchasing on the Internet (see Section 7.2 below for a detailed discussion of B2B auctions). Traditional retailers such as Dillard's and Wal-Mart have implemented centralized databases and EDI-based supply and distribution systems. The Internet and EC now allow small to medium-sized retailers to implement technologies in their procurement system through a low-cost, open, and responsive network.

An efficient procurement system and software, once installed, can enable firms to cross market boundaries. In a highly scalable networked environment, the size of a retailer depends only on the number of customers it attracts, rather than on capital or the number of outlets it acquires. The infrastructure set up for one product can also be expanded for other products. Amazon.com, for example, uses its integrated back office system to handle not only books but CDs, videos, and gifts. Store designs, product database and search algorithms, recommendation systems, software for shopping baskets and payments systems, security, and server implementation for book retailing have simply been reused for other products. An efficient online retailer and its IT infrastructure can be scaled for any number of products with minimum constraints added.

3.2. Contract Manufacturing

In the digital economy, the trend toward outsourcing various business functions is growing rapidly because it offers a less costly alternative to in-house manufacturing, marketing, customer service, delivery, inventorying, warehousing, and other business processes. This would be consistent with the observation that firms in the physical economy also delegate production activities to external organizations if they find it less costly than to internalize them. As long as the cost of internal production (or service provision) is higher than the cost of contracting and monitoring, firms will prefer to outsource.

Regardless of the logic of this, it appears that the type of cost savings plays a critical role in the outsourcing decision. A study by Lewis and Sappington (1991) argues that when a firm's decision to buy vs. internally produce inputs involves improvements in production technology, more in-house production and less outsourcing is preferred. Their result does not depend on whether the subcontractor's production technology was idiosyncratic (only useful to produce the buyer's inputs) or transferable (the supplier could use its production technology and facility to service other potential buyers). In the case of transferable technology, the supplier would be expected to invest more in production technology, and thus offer lower costs, which may favor more outsourcing. Nevertheless, the buyer still preferred to implement more efficient technology himself internally.

In cases where buyer's production technology is substantially inferior and monitoring costs are significantly lower, we would expect contract manufacturing to be favored. Whether this is the case or not is mostly an empirical question. However, when determining whether to outsource, one must consider not only production cost savings but also savings and other benefits in product development, marketing, and distribution. By delegating manufacturing, a firm may better utilize its resources in nonproduction functions. Because production logistics are taken care of, it may be able to consider more diverse product specifications. In fact, many Internet-based firms are focusing on customer assets and marketing value of their reputation among consumers while delegating manufacturing and distribution to third parties such as Solectron (http://www.solectron.com), who offers global manufacturing networks and integrated supply chains (see Figure 1). The prevalence of outsourcing and subcontracting goes hand in hand with the use of information technology that facilitates horizontal coordination and relationships with suppliers (Aoki 1986).

Manufacturers with a well-recognized brand name and their own manufacturing operations have used manufacturer-pushed logistics management, where manufacturers dictate terms of distribution. On the other hand, manufacturers who are concerned with product development, market competition, and other strategic issues rely on contract manufacturers for efficient bulk manufacturing and dis-

Figure 1 Global Manufacturing Networks of Contract Manufacturer Solectron. Reproduced with permission.

tributors for the ancillary tasks of moving their products to retailers. They often interact only with a few large distributors, who are expected to push assigned products down to the retail channel. Their partners are more flexible manufacturers and distributors, who have developed closer ties to end customers. For example, channel marketers in the computer industry consist of original equipment manufacturers (OEMs) who provide basic components to distributors, who build computers after orders are received. New players are now taking advantage of information technology to cut costs while delegating most functions to third parties.

Dell Computers and Gateway began a new distribution model based on direct marketing. They now rely on contract manufacturers to distribute their products. Orders received by Dell are forwarded to a third party who assembles and ships the final products directly to consumers. This built-to-order manufacturing model attains distribution objectives by outsourcing manufacturing as well as distribution functions to those who can optimize their specialized functions. Distributors, in addition to delivering products, face the task of integrating purchasing, manufacturing, and supply chain management.

For traditional in-house manufacturers and retailers, integrated distributors offer technological solutions to delegate order fulfillment and shipping tasks to outside contractors. For example, Federal Express (http://www.fedex.com) offers Internet-based logistics solutions to online retailers. FedEx introduced FedEx Ship, which evolved from its EDI-based FedEx PowerShip, in 1995. FedEx Ship is free PC software that customers can download and use to generate shipping orders. In 1996, FedEx launched its Internet version on its website, where customers can fill out pickup and shipping requests, print labels and track delivery status. As an integrated logistics operator, FedEx also offers a turnkey solution to online retailers by hosting retailer's websites or linking their servers to retailer's sites in order to manage warehouses and invoices coming from retailer's websites, then pack and ship products directly to consumers. Retailers are increasingly delegating all warehousing and shipping functions to a third party such as FedEx, while distributors expand their services into all aspects of order fulfillment.

3.3. Logistics Applications

Being ready for the digital economy means more than simply allowing customers to order via the Internet. To process orders from online customers requires seamless, integrated operation from man-

ufacturing to delivery, readiness to handle continuous feedback from and interaction with customers, and the capability of meeting the demand and offer choices by modifying product offerings and services. Clearly, being integrated goes beyond being on the Internet and offering an online shopping basket. Manufacturing, supply chain management, corporate finance and personnel management, customer service, and customer asset management processes will all be significantly different in networked than in nonnetworked firms.

Logistics management, or distribution management, aims at optimizing the movement of goods from the sources of supply to final retail locations. In the traditional distribution process, this often involves a network of warehouses to store and distribute inventoried products at many levels of the selling chain. Manufacturers maintain an in-house inventory, which is shipped out to a distributor who stores its inventory in warehouses until new outbound orders are fulfilled. At each stage the inventory is logged on separate database systems and reprocessed by new orders, adding chances for error and delayed actions. Compaq, for example, which uses an older distribution model, has to allow almost three months for its products to reach retailers, while Dell, a direct-marketing firm, fulfill the order in two to three weeks.

Wholesalers and retailers often suffer from inefficient logistics management. Distributors may have as much as 70% of their assets in inventory that is not moving fast, while retailers receive replenishments and new products long after sales opportunities have disappeared. Optimizing distribution cycles and lowering incurred costs are a common concern for manufacturers, distributors, and retailers.

A conventional logistics management model built around warehouses and distribution centers is an efficient solution when products have similar demand structure and must be moved in the same manner. In this case, distribution centers minimize overall transportation costs by consolidating freight and taking advantage of the scale economy. This practice closely mirrors the hub-and-spoke model of airline transportation. By consolidating passenger traffic around a few regional hubs, airlines can employ larger airplanes on major legs and save on the number of flights and associated costs. Nevertheless, passengers often find that they must endure extra flying time and distance because flights between small but adjacent cities have been eliminated. While the hub-and-spoke system provides many advantages, it is too inflexible to respond to individual flying patterns and preferences.

Similarly, warehousing and distribution centers fail to function when products must move speedily through the pipeline. When market prices change as rapidly as computer components, Compaq's computers, which sit in distribution centers for several months, lose their value by the time they reach consumers. Dell's more responsive pricing is made possible by its fast-moving distribution channel.

More responsive distribution management cannot be achieved by simply removing several layers of warehouses and distribution centers. Rather, distributors in the United States are being integrated into the whole value chain of order taking, supply chain, and retailing. In the traditional logistics management model, distributors remained a disjointed intermediary between manufacturers and retailers. In an integrated logistics model that depends heavily on information technology and Web-based information sharing, distributors are fully integrated, having access to manufacturing and sales data and their partners' decision making process.

4. ELECTRONIC COMMERCE AND RETAILING

The most prominent electronic commerce application is the use of the Internet for consumer retailing that will change a firm's relationship with its customers. With the growth of online retail activities, the Internet challenges not only the survival of established retail outlets but also the very mode of transactions, which in physical markets occur through face-to-face seller–buyer interactions. Online retailers such as Amazon.com, Dell, and Garden.com (http://www.garden.com) cater to customer demands and increase revenues rapidly without opening a single retail outlet. Online shops offer consumers convenience and price advantages, critical decision factors in many retail industries.

Other observers remain skeptical about consumers abandoning their daily trips to stores and shopping malls in favor of online shopping. Physical inspections of goods, personal interactions with sales representatives, the sheer act of going to a mall with friends, and other characteristics of shopping in the physical world may limit the growth of electronic retailing. However, regardless of the future extent of electronic retailing, Internet technologies have shown that they can not only make shopping more convenient but also reorganize the retail industry to meet new demands and new desires of customers.

4.1. Web Storefronts

The Internet is the most efficient information exchange medium and interactivity tool ever to impact the retail industry. The distinguishing factors of online retailing reside in offering customers useful product information and responsive customer service in all phases of their shopping experience. Applications addressing these functions tend to be maximized by new entrants in the market. For

example, Amazon.com, having no physical retail outlets to worry about, has designed a store improving the range of product and product information to match customer needs and offering fast and efficient shopping service. In contrast, players in existing retail markets are concerned with protecting their existing channels. Most retailers open their Web stores either to keep up with competitors (28%) or to explore a new distribution channel (31%) (*Chain Store Age* 1998). About 40% of retailers use their Web stores in an effort to extend their business into the virtual market.

The exceptional growth of online retailing in the United States can be traced back to several favorable characteristics. First, U.S. consumers have long and favorable previous experience with catalog shopping. Second, credit cards and checks are widely used as a preferred payment method, making it easy to migrate into the online environment. More importantly, commercial infrastructure and environment of the U.S. markets are transparent in terms of taxation, regulation, and consumer protection rules. Consumers also have access to efficient delivery networks of Federal Express and United Parcel Service in order to receive purchased products on time and in good condition. These auxiliary market factors have been essential in the initial acceptance of Web-based commerce.

4.2. E-Retailing of Physical Products

Online retailing often refers to a subcategory of business that sells "physical" products such as computers (Dell online store), automobiles (Auto-by-tel), clothing (Lands' End online), sports equipment (Golfweb), and flowers and garden tools (Garden.com). Currently, books and music CDs fall into this category, although retailers are becoming increasingly aware of their digital characteristics.

Electronic commerce in physical goods is an extension of catalog selling where the Internet functions as an alternative marketing channel. In this regard, online shops compete directly with physical retail outlets, leaving manufacturers to juggle between established and newly emerging distribution channels.

4.3. E-Retailing of Digital Products

Retailers of digital products have a distinct advantage over other sectors in that they deliver their goods via the Internet. Sellers of news (e.g., *The New York Times* [http://www.nytimes.com]), magazines (*BusinessWeek* [http://www.businessweek.com]), textbooks (SmartEcon [http://www.smartecon.com]), information, databases, and software can provide products online with no need for distribution and delivery by physical means. This sector also includes such search services as Yahoo, Excite, and other portals, although these firms currently rely on advertising revenues rather than pricing their digital products.

A number of online retailers are selling physical products that are essentially digital products but currently packaged in physical format. For example, Amazon.com sells printed books, which are in essence digital information products. Likewise, audio CDs and videos sold by Amazon.com and CDNow (http://www.cdnow.com) are digital products. Because digital products can be transferred via the network and are highly customizable, online retailing of these products will bring about fundamental changes that cannot be duplicated in physical markets.

For example, instead of being an alternative distribution channel for books and CDs, online stores can offer sampling through excerpts and RealAudio files. Books and CDs are beginning to be customized and sold to customers in individualized configurations (see Figure 2), downloadable to customer's digital book readers or recordable CDs. Digitized goods can often be delivered in real time on demand. These functions add value by providing consumers more choices and satisfaction. The primary retail function is no longer getting products to customers at the lowest cost but satisfying demand while maximizing revenues by charging what customers are willing to pay.

4.4. E-Retailing of Services

A growing subcategory of electronic retailing deals with intangible services such as online gaming, consulting, remote education, and legal services and such personal services as travel scheduling, investment, tax, and accounting. Online service providers are similar to digital product sellers because their service is delivered via the Internet. Nevertheless, transactions consist of communications and interactions between sellers and buyers, often without an exchange of any final product other than a receipt or confirmation of the transaction.

A much anticipated aspect of online service delivery involves remote services, such as telemedicine, remote education, or teleconsulting. The future of remote services is critically dependent on the maturity of technologies such as 3D and virtual reality software, video conferencing on broader bandwidth, and speech and handwriting recognition. Advances in these technologies are necessary to replicate an environment where physical contact and interaction are essential for providing personal services.

Despite a low representation of remote services on today's Internet, several types of service retailing are currently practiced. For example, 2 of the top 10 online retailing activities—travel and financial services—sell services rather than products. Airline tickets are digital products that simply

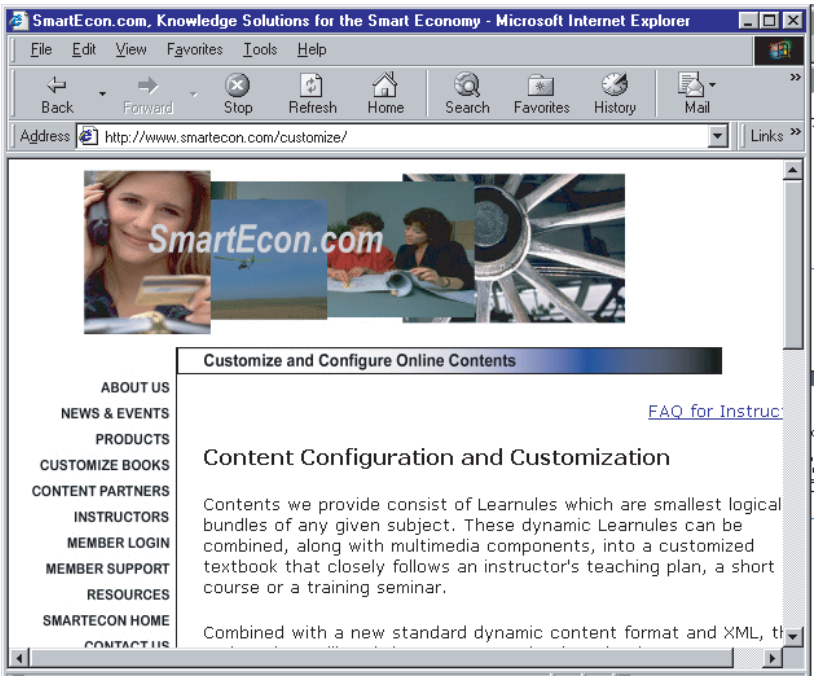

Figure 2 Online Textbooks Are Customized at SmartEcon.com. Reproduced with permission.

represent future uses of airline services. An airline ticket, therefore, signifies a service to schedule one's trips. Likewise, products in online stock markets and financial services are entitlements to company assets and notational currencies. Online service providers in these markets include those in investment, banking, and payment services.

5. PRICING IN THE INTERNET ECONOMY

In this section, we review some issues in pricing and payment in the Internet economy. In the physical market, prices are fixed for a certain period of time and displayed to potential customers. Such fixed and posted prices are commonly observed for mass-produced industrial goods such as books, music CDs, products sold through catalogs, and other consumer goods—products that are standardized and sold in mass quantity. Posted prices, in turn, allow both sellers and buyers to compare prices and often lead to highly competitive and uniform prices.

In the Internet economy, the menu cost of changing prices is relatively low, allowing sellers to change prices according to fluctuating demand conditions. Per-transaction costs of clearing payments also decline significantly with the use of online payment systems (see Choi et al. [1997, chap. 10] for an overview of online payment systems). In addition, sellers have access to an increasing amount of customer information as Web logs and network service databases are mined and analyzed to yield detailed information about buyers. Such developments raise serious questions about the use of identifiable customer information and how such information is used in setting prices.

5.1. Security and Privacy in Transaction

Complete and absolute anonymity is very rare in commercial transactions because the very nature of trade often requires some form of identification to verify payments or any legally required qualifications. The only transactions that come close to being completely anonymous are cash-based. Even with these, repeat business will convey some information about the buyer to the seller, not to speak of serial numbers of bills, fingerprints, security cameras, and so on. In many cases, anonymity means customer privacy is guaranteed by the seller. Technically, a Web vendor may assign a random number to each customer without linking the information gathered around that number to a physically identifiable consumer. If customer information is fully disclosed for personalization, the vendor may guarantee not to use it for any other purposes or sell it to outsiders. Whether we are concerned with

anonymity or privacy, the gist of the matter is the degree to which customer information is conveyed to the seller.

5.1.1. Types of Anonymity

In general, anonymity is an extreme form of privacy in that no information is transferred. But even anonymity comes in a few varieties.

- *Complete anonymity:* With complete anonymity, sellers do not know anything about customers except that a transaction has occurred. Products are not personalized, and payments are made in cash or in an untraceable form of payment. The market operates as if sellers have no means to identify customers or learn about them in any way.
- *Incomplete anonymity:* Some anonymous customers can be traced to an identifiable person. When identities are traceable, customers have incomplete anonymity. For reasons of security and criminal justice, digital files and communications have digital fingerprints that enable authorities to trace them back to their originators, albeit with difficulty. One rationale for such a compromise is that the nature of digital products and their reproducibility threaten the very viability of intellectual property on the Internet unless unauthorized copies can be identified and traced to the culprits. Microsoft has for unknown reasons surreptitiously incorporated such measures in any document created by its Word program. Some computer manufacturers have also proposed implanting serial numbers in microprocessors so as to endow each computer with its own digital identity. This sort of information does not relate directly to any identifiable persons, although they may be traceable through usage and ownership data.
- *Pseudonymity:* A pseudonym is an alias that represents a person or persons without revealing their identity. Pseudonymity operates exactly the same way as anonymity: it can be untraceable and complete or traceable and incomplete. Pseudonymity has particular significance in the electronic marketplace because a pseudonym may have the persistency to become an online persona. In some cases, an online person known only for his or her pseudonym has become a legendary figure with a complete personality profile, knowledge base, and other personal characteristics recognized by everyone within an online community. Persistent pseudonyms are also useful in providing promotional services and discounts such as frequent flyer miles and membership discounts without disclosing identity.

Privacy is concerned with an unauthorized transfer (or collection) of customer information as well as unauthorized uses of that information. Anonymity prevents such abuses by removing identity and is therefore the most effective and extreme example of privacy. Privacy can be maintained while identifiable information is being transferred to the seller, which presents no problem in and of itself. Concerns arise when that information is used without the consent of its owner (the consumer) to affect him or her negatively (e.g., junk e-mails, unwanted advertisements, and marketing messages). What a seller can and cannot do with collected information is often decided by business convention but could ultimately be determined by law.

5.1.2. Tools for Privacy

In a marketplace, whenever a consumer need or concern arises, the market attempts to address it. Here, too, the market has created technologies that address consumers' concerns about lack of privacy. The most effective way to preserve privacy is to remove information that identifies a person by physical or electronic address, telephone number, name, website, or server address. Several models are available on the Internet.

- *Anonymity services:* Anonymity systems have devised a number of ways to strip a user's identity from an online connection. In one system, an anonymous remailer receives an encrypted message from a user. The message shows only the address to which the message should be forwarded. The remailer sends the message without knowing its content or originator. This process may continue a few times until the last remailer in the chain delivers the message to the intended destination—a person, bulletin board, or newsgroup.
- *Proxy server:* A proxy server acts as an intermediary. For example, Anonymizer.com operates a server that receives a user's request for a web page and fetches it using its own site as the originator. Websites providing the content will not be able to identify original users who requested their content.
- *Relying on numbers:* Expanding on this proxy model, a group of consumers may act as a shared computer requesting a web page. Crowds, developed by AT&T Laboratories, relies on the concept that individuals cannot be distinguished in a large crowd. Here, individual requests are randomly forwarded through a shared proxy server, which masks all identifiable information

about the users. It is interesting to note that the system tries to maintain privacy by relying on crowds when the word ''privacy'' suggests being apart from a crowd.

- *Pseudonyms:* Lucent's Personalized Web Assistant and Zero Knowledge Systems' Freedom rely on pseudonyms. This approach has the advantage of providing persistent online personas or identities. Persistent personas, on the other hand, can be targeted for advertisements based on historical data, just like any real person.

These and other currently available anonymity services are effective in most cases. But whether they are secure for all occasions will depend on the business's technical and operational integrity. For example, the anonymous remailer system requires that at least one of the remailers in the chain discard the sender and destination information. If all remailers cooperate, any message can be traced back to its originator. In addition, software bugs and other unanticipated contingencies may compromise the integrity of any anonymity service. Because technologies create anonymity, they can also be broken by other technologies.

Commercial transactions conducted by anonymous or pseudonymous users still have the advantage of allowing sellers to observe and collect much more refined demand data than in physical markets. For conventional market research, identifiable information is not necessary as long as it results in better demand estimation and forecast. Even without knowing who their customers are or at what address they reside, sellers can obtain enough useful data about purchasing behaviors, product preferences, price sensitivity, and other demand characteristics.

In other cases, identifiable information may be necessary for users to receive the benefits from using online technologies. Customization and online payment and delivery clearly require users' personal information. To some extent, these activities may be handled through online pseudoidentities. However, when a reasonable level of privacy is assured, customers may be willing to reveal their identity just as they do by giving out credit card information over the phone.

Current industry-led measures to protect online privacy are aimed at reducing consumers' unwillingness to come online and mitigate any effort to seek legal solutions. Essentially, these measures require the sellers to disclose clearly to consumers what type of data they collect and what they do with it. Secondly, they also encourage sellers to offer consumers a means to specify what they are willing to agree to. In a sense, sellers and consumers negotiate the terms of information collection and uses. Some websites display logos indicating that they follow these guidelines. P3P (Platform for Privacy Preferences) by the World Wide Web Consortium (W3C; http://www.w3.org) and TRUSTe from CommerceNet (http://www.commercenet.org) are the two main industry-wide efforts toward privacy in this regard.

As the trend toward privacy disclosure indicates, consumers seem to be concerned about selling personal information to third parties. Unsolicited, unrelated junk e-mails from unknown sellers are soundly rejected. They are, however, less upset about receiving advertisements, in the form of product news, from the sellers they visit. This is largely because consumers recognize the need for information in ordinary commerce and the benefit from customization. Privacy is largely an issue of avoiding unwanted marketing messages, as collecting and selling information about consumers has long been standard practice in many industries.

5.2. Real-Time Pricing

Prices change almost instantly in auctions, but posted prices may also change, albeit at a slower pace. Any price that clears the market is determined by demand and supply conditions, which fluctuate. For example, when there is an excess demand (supply), price goes up (down) until buyers and sellers agree to make a transaction. Posted prices may be fixed during a given period, but unless a seller possesses perfect information about consumer valuations, he must rely on his information about costs and the market signal received from previous sales to decide prices. To increase sales, prices must be lowered; when there is a shortage, prices can be raised. Through this trial-and-error process, prices converge on a market clearing level until changes in demand or supply conditions necessitate further price changes.

In this vein, posted price selling is a long-term version of real-time pricing. If we consider sales trends as bids made by market participants, there is little qualitative difference between posted-price selling and auctions in terms of price movements, or how market clearing prices are attained. Nevertheless, fundamental differences exist in terms of the number of market participants, the speed at which prices are determined, or in the transactional aspects of a trade, such as menu costs.

The Web is ideal for personalized product and service delivery that employs flexible, real-time changes in pricing. Vending machines and toll collectors operating on a network may charge different prices based on outdoor temperatures or the availability of parking spaces. A soda may be sold at different prices depending on location or time of day. User-identified smart cards, which also provide relevant consumer characteristics, may be required for payment so that prices can be further differentiated in real time based on their identity.

5.3. Digital Product Pricing

Pricing strategies in the digital economy undergo significant transformation from conventional cost-based pricing. Because pricing strategies are an integral part of the overall production process, it would be folly to assume that existing economic modeling and reasoning can simply be reinterpreted and applied to the digital economy. For instance, digital products are assumed to have zero or nearly zero marginal costs relative to their high initial costs needed to produce the first copy. This implies that competitive (based on the marginal cost) prices will be zero and that all types of knowledge-based products will have to be given away for free. But no firm can survive by giving out its products for free.

For example, a firm invests $1000 to produce a digital picture of the Statue of Liberty. Suppose that it costs additional $1 (marginal cost) to make a copy of the file on a floppy disk. Because of the overwhelming proportion of the fixed cost, the average cost continues to decline as we increase the level of production (see Figure 3). Its average cost will converge toward $1, its marginal cost. If the variable cost is zero, its average cost, along with its market price, will also be zero.

This ever-declining average cost poses serious problems in devising profitable pricing strategies. A leading concern is how to recover fixed cost. For example, suppose that Microsoft spends $10 million dollars for one of its software upgrades. If it finds only 10 takers, Microsoft will lose money unless it sells it at $1 million each. At $100, its break-even sales must be no less than 100,000. Microsoft, with significant market power, will find little difficulty in exceeding this sales figure. On the other hand, many digital product producers face the possibility of not recovering their initial investment in the marketplace.

For digital products or any other products whose cost curves are declining continuously, the average cost or the marginal cost has little meaning in determining market prices. No firm will be able to operate without charging customers for their products and services. Traditional price theory, which relies heavily on finding average or marginal cost, is nearly useless in the digital economy.

As a result, we must consider two possibilities. The first is that the cost structure of a digital product may be as U-shaped as that of any other physical product. In this case, the pricing dilemma is solved. For example, the variable cost of a digital product may also increase as a firm increases its production. At the very least, the marginal cost of a digital product, for example, consists of a per-copy copyright payment. In addition, as Microsoft tries to increase its sales, it may face rapidly increasing costs associated with increased production, marketing and advertising, distribution, and customer service. In this case, traditional price theory may be sufficient to guide e-business firms for pricing.

Secondly, the possibility of extreme product customization implies that each digital product has unique features that have different cost schedules. In this case, the relevant cost schedule cannot be

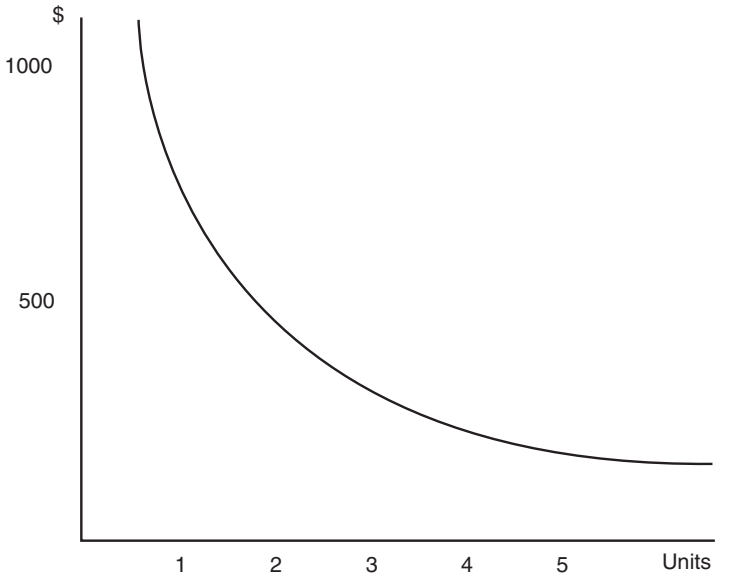

Figure 3 Decreasing Average Cost of a Digital Product Firm.

tabulated on the basis of the number of units reproduced. The marginal cost to consider is not that of reproduction, but that of production quality of a unique, personalized copy. Conventional price theory based on competitive sellers and buyers would be inadequate to deal with customized products, whether digital or physical, because of the heterogeneity of products. In such a market, cost factors have little meaning because the seller has some market power and the buyer has limited capability to substitute vendors. Instead, demand-side factors such as consumers' willingness to pay and relative positions in bargaining and negotiation determine the level of price.

6. INTERMEDIARIES AND MARKETS

The term *digital economy* makes it clear that digital technologies are more than tools that offer an alternative to conventional catalog, TV, and mall shopping activities. Digital technologies provide incentives to reorganize firms, reconfigure products and marketing strategies, and explore novel ways to make transactions. In this section, we review new forms of market mechanisms that are based on networked markets.

6.1. Types of Intermediation

Economic activities revolve around markets where sellers, buyers, and other agents must meet and interact. Therefore, the structure of the electronic marketplace plays an important role in achieving ultimate economic efficiency. How the marketplace is organized is a question that deals with the problem of matching sellers with buyers in the most efficient manner, providing complete and reliable product and vendor information and facilitating transactions at the lowest possible cost.

The three models—portals, cybermediaries, and auction markets—represent different solutions to tackling these problems:

- *Portals:* In portals, the objective is to maximize the number of visitors and to present content in a controlled environment, as in physical malls. Internet portals generate revenues from advertising or from payments by firms whose hypertext links are strategically placed on the portal's web page. Corporate portals, an extended form of intranet, do not produce advertising revenues but offer employees and customers an organized focal point for their business with the firm.
- *Cybermediaries:* Cybermediaries focus on managing traffic and providing accounting and payment services in the increasingly complex Web environment. Their revenues depend on actual sales, although the number of visitors remains an important variable. Many of them provide tertiary functions that sellers and buyers do not always carry out, such as quality guarantees, marketing, recommendation, negotiation, and other services.
- *Electronic auctions:* Electronic auction markets are organized for face-to-face transactions between sellers and buyers. The market maker, although it is a form of intermediary service, plays a limited role in negotiation and transaction between agents. Conceptually, electronic markets are a throwback to medieval markets where most buyers and sellers knew about each other's character and their goods and services. This familiarity is provided by the market maker through information, quality assessment, or guarantee. In this market, negotiations for terms of sales become the most important aspect of trade.

We find that the reason why more intermediaries are needed in electronic commerce is that the complex web of suppliers and customers—and real-time interactions with them—poses a serious challenge to fulfilling transactional requirements. Business relationships in physical markets are often hierarchical, organized along the value chain, and dominated by static arrangements in long-term contracts. Retailers typically rely on distributors and manufacturers, who in turn prefer to maintain steady and reliable relationships with suppliers. In the networked economy, however, the number of potential business partners virtually equals that of all firms and consumers. More importantly, their relationships, with no hierarchical structure, change dynamically. A simple business process such as a payment settlement between a seller and a buyer often involves several agents. For these reasons, matching sellers with buyers requires more than an advertiser-supported portal and a hypertext link. To support interactive purchases on the Internet, the electronic marketplace requires more innovative mechanisms, which we review below.

6.2. Managing Distributed Commerce

The simple act of buying an online news article may involve numerous agents who provide search information, local and out-of-state newspaper publishers who have contractual obligations, reporters and columnists (who actually produce contents), payment service providers, banks, copyright clearing houses and so on. If Yahoo or Microsoft owned most Internet firms (publishers, payment services, search sites, etc.), a customer could possibly buy (or sell) products on the company's website and necessary transactions and payments could be handled by one firm. A retailer in a physical market

provides a similar service. In a grocery store, the customer collects all necessary items and makes one payment to the owner.

To enable such a convenient buying experience, a Web store must carry all items that customers need. Otherwise a list of items in a shopping basket may come from a number of different vendors, the customer having collected the items after visiting the vendors' individual websites. Options left to stores and buyers are to:

- Process multiple transactions separately
- Choose one seller, who then arranges payment clearance among the many sellers
- Use an intermediary

In a distributed commerce model, multiple customers deal with multiple sellers. An efficient market will allow a buyer to pay for these products in one lump sum. Such an arrangement is natural if a website happens to carry all those items. Otherwise, this distributed commerce requires an equally flexible and manageable mechanism to provide buyers the convenience of paying once, settling amounts due among various vendors. The intermediary Clickshare relies on a framework for distributed user management.

For example, the Clickshare (http://www.clickshare.com) model (see Figure 4) gives certain control to member sites that operate independently while Clickshare, as the behind-the-scenes agent, takes care of accounting and billing. Going beyond payment settlement, an intermediary or ''cybermediary'' not only provides member firms with accounting and billing functions but also undertakes joint marketing and advertising campaigns and exercises some control over product selection and positioning. In this regard, a cybermediary resembles a retailer or a giant discount store. It differs from an online shopping mall, which offers location and links but little else. Unlike a portal, which is inclined to own component services, this intermediation model allows members to maintain and operate independent businesses—thus it is a distributed commerce—while at the same time trying to solve management issues by utilizing an intermediary.

Amazon.com is a well-known intermediary for publishing firms. As Amazon.com expands its product offerings, it has become an intermediary or a distributor/retailer for other products and services as well. A vertical portal such as Amazon.com or a corporate portal such as Dell is well positioned to expand horizontally and become a cybermediary dealing with their own as well as others' businesses.

It must be pointed out that Yahoo, a portal, may expand in the same way. However, portals focus on either owning a share of other businesses or arranging advertising fees for the referrals. In contrast, a cybermediary's main function is to manage commercial transactions of individuals in the distributed environment in addition to providing users with a convenient shopping location.

6.3. Association and Alliance

Conventional web portals such as Yahoo and Excite try to maximize advertising revenues by increasing the number of visitors to their sites and enticing them to stay longer to view advertisements. But advertisements as a form of marketing pose the age-old question, do the viewers really buy advertised

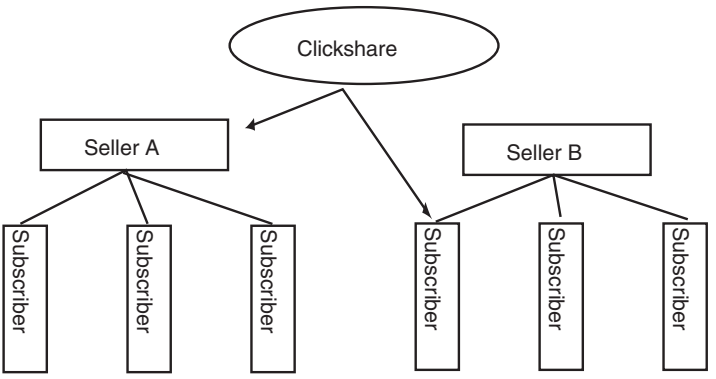

Figure 4 An Intermediary Mediates Cross-market Transactions.

products? To ensure that the message presented on visitors' web pages is producing an effect, some advertisers require click-through responses from viewers. Instead of relying on passive imprints, click-through advertisements are paid only if the viewer clicks on the ad and connects to the advertiser's website. Like hypertext links referring customers to other sites, these click-through ads are aimed at managing visitor traffic. In this way, portals become a customer referral service.

The possibility to refer and manage traffic on the Web is fully realized at Web ventures specifically designed to generate revenues from referrals. For example, Amazon.com has over 100,000 associates on the World Wide Web, who maintain their own websites where visitors may click on hypertext links that directly transport them to the Amazon.com site. Associates—that is, intermediaries—in return receive referral fees based on actual purchase by those referred by their sites. Through the Associates Program, Amazon.com has effectively opened more than 100,000 retail outlets in a couple of years. Referral fees paid to associates have replaced advertising expenses and the costs to open and manage retail stores.

Referral fees can be shared by consumers as well. SmartFrog,* for example, functions as a referrer to various online shops such as Amazon.com and eToys. After becoming a member, a Smart Frog customer visits vendor sites and, when he or she is ready to buy, goes to Smart Frog's website and clicks on the listed vendors, who pay 10% of the purchase price to Smart Frog. Out of this 10%, Smart Frog currently rebates half to its customers and keeps the remaining half.

In this way, Smart Frog, not the vendors, pays for the advertising and marketing efforts needed to generate visitors. In this cybermediated economy, the costs to advertise and attract customers are paid to entrepreneurs and consumers instead of marketing firms and the media who carry advertisements. The intermediary's profit and the benefit for consumers—in the form of lowered prices—both originate from the transaction costs previously marked for advertising and marketing. This new business opportunity and enterprise model is enabled by the distinctive nature of the networked economy.

7. ONLINE TRADING MARKETS AND AUCTIONS

Virtually all types of products are being sold through online auctions such as Onsale.com or eBay (see Figure 5). Firms and governments can implement sophisticated bidding and auction procedures for buying supplies and selling their products. Consumers can search and negotiate for best prices through auctions. By eliminating physical distance and simply increasing the number of products and trading partners available to individual bidders, online auctions offer opportunities unrealized in physical markets. Such a market arrangement, however, may produce price levels—and thus competitiveness and profit levels—that may be fundamentally different from physical markets. In this section, we present an overview of various types of auctions being implemented on the Internet and evaluate their effects on price levels, market competition, and overall economic gains and losses.

7.1. Types of Auctions

Auctions may be for a single object or a package of nonidentical items. Alternatively, auctions may be for multiple units where many units of a homogeneous, standardized good are to be sold, such as gold bullion in the auctions conducted by the International Monetary Fund and the U.S. Treasury in the 1970s and the weekly auctioning of securities by the Treasury.

Auctions discussed in this section are single auctions where either an item is offered for sale and the market consists of multiple buyers making bids to buy or an item is wanted and the market consists of multiple sellers making offers to sell. In either case, one side of the market consists of a single buyer or seller. Most online auctions are currently single auctions. On the other hand, multiple buyers and sellers may be making bids and offers simultaneously in a double auction. An example of a double auction is a stock trading pit. Because market clearing level of price may differ substantially between double and single auctions, we discuss double auctions in Section 7.5 below.

Auctions may also be classified according to the different institutional rules governing the exchange. These rules are important because they can affect bidding incentives and thus the type of items offered and the efficiency of an exchange. There are four primary types of auctions:

1. *English auction*. An English auction, also known as an ascending bid auction, customarily begins with the auctioneer soliciting a first bid from the crowd of would-be buyers or announcing the seller's reservation price. Any bid, once recognized by the auctioneer, becomes the standing bid, which cannot be withdrawn. Any new bid is admissible if and only if it is higher than the standing bid. The auction ends when the auctioneer is unable to call forth a

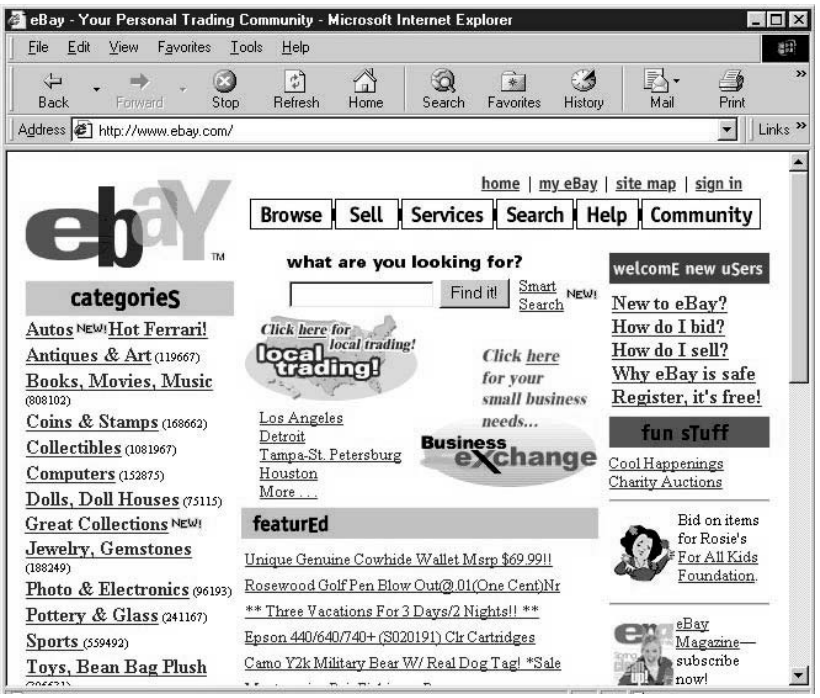

Figure 5 eBay Online Auction Site. Reproduced with permission of eBay Inc. Copyright © eBay Inc. All rights reserved.

new higher bid, and the item is ''knocked down'' to the last bidder at a price equal to that amount bid. Examples include livestock auctions in the United States and wool auctions in Australia.

2. *Dutch auction*. Under this procedure, also known as a descending bid auction, the auctioneer begins at some price level thought to be somewhat higher than any buyer is willing to pay, and the price is decreased in decrements until the first buyer accepts by shouting ''Mine!'' The item is then awarded to that buyer at the price accepted. A Dutch auction is popular for produce and cut flowers in Holland, fish auctions, and tobacco. Price markdowns in department stores or consignment stores also resemble Dutch auctions.
3. *First price auction*. This is the common form of ''sealed'' or written bid auction, in which the highest bidder is awarded the item at a price equal to the amount bid. This procedure is thus called a sealed-bid first price auction. It is commonly used to sell off multiple units, such as short-term U.S. Treasury securities.
4. *Second price auction*. This is a sealed bid auction in which the highest bidder is awarded the item at a price equal to the bid of the second highest bidder. The procedure is not common, although it is used in stamp auctions. The multiple-unit extension of this second price sealed bid auction is called a competitive or uniform price auction. If five identical items are sold through a competitive price auction, for example, the five highest bidders will each win an item but all will pay the fifth-highest price.

The distinguishing feature of an auction market is the presence of bids and offers and the competitive means by which the final price is reached. A wide variety of online markets will qualify as an auction using this definition. Less than two years after eBay appeared on the Internet, revenues from online auctions have reached billions of dollars in the United States, projected to grow into tens of billions in a few years. Major online auctions are in consumer products such as computers, airline tickets, and collectibles, but a growing segment of the market covers business markets where excess supplies and inventories are being auctioned off.

7.2. B2B Trading Markets

Online auctions for business are an extension of supply chain applications of the Internet, by which firms seek parts and supplies from a large pool of potential business partners. The real-time interaction in these auctions differs significantly from contract-based supply relationships, which may be stable but often inefficient in terms of costs. A more flexible and responsive supply chain relationship is required as the manufacturing process itself becomes more flexible to meet changing demands in real time. Especially for digital products, the business relationship between suppliers and producers may be defined by the requirement for immediate delivery of needed components.

Currently, business-to-business auctions are mainly those that sell excess or surplus inventories. For example, FastParts (http://www.fastparts.com) and FairMarket (http://www.fairmarket.com) offer online auctions for surplus industrial goods, mainly desired by corporate purchasing departments. A significant impediment to widespread B2B auctions is the fact that online auctions allow only a single item to be exchanged at a time. However, corporate purchasing managers typically deal with thousands of items. This will require them to make and monitor bids in thousands of web pages simultaneously, each handling one item. A more efficient auction will allow them to place a bid on a combination of items. Unlike auctions organized around a single item or multiple units of a single item, the new market mechanism poses serious challenge in guaranteeing market clearance because it must be able to match these combinatorial bids and offers, unbundling and rebundling them (see Section 7.5.2).

7.3. Auctions in Consumer Markets

Auctions selling consumer goods are mainly found in used merchandise and collectibles markets. Both in Onsale.com and eBay, all types of consumer goods are offered by individuals for sale. Ordinarily these items would have been sold through classified advertisements in local newspapers or in various ''for sale'' newsgroups. Online innovations stem from the size of the potential audience and the real-time and interactive bidding process.

While online markets have an inherently larger reach than physical markets in terms of the number of participants the success of eBay and onsale.com is largely due to their allowing potential buyers and sellers an easy way to interact in real time. eBay, for example, is simply an automated classified ad. The list of products offered as well as those who buy and sell at eBay site resembles those found in the classified ad market. Want and for-sale ads are largely controlled by newspapers who generate as much as 30% of their total revenues from individual advertisers. Aware of the increasing threat posed by Internet-based classified ads, several newspapers experimented with online classified advertising based on their print versions. Nevertheless, large-scale initiatives by newspapers have all but failed. Surprisingly, eBay has succeeded in the same product category.

While online classified ads offered by newspapers are nothing more than online versions of their print ads, eBay offers features that consumers find convenient. Classified ads provide buyers only with contact information for purchasing a product. The buyers must make telephone calls and negotiate with the sellers. On eBay's website, all these necessary processes are automated and made convenient. Sometimes the formula of successful online business is simply to maximize the interactivity and real-time capabilities of the online medium itself.

Besides successful online versions of classified ads, another type of online auction deals with perishable goods, which need to be sold quickly. Excess airline tickets and surplus manufacturing products comprise the second type of products sold in online auction markets. For these products, the electronic marketplace offers the necessary global market reach and responsiveness.

Despite the growing interest in online auctions, the majority of consumer goods, except those discussed above, are not suitable for auctions. For these items, conventional selling such as posted price retailing will be more than adequate. Nevertheless, the flexibility offered by online trading may offer innovative market processes. For example, instead of searching for products and vendors by visiting sellers' websites, a buyer may solicit offers from all potential sellers. This is a reverse auction, discussed below. Such a buying mechanism is so innovative that it has the potential to be used for almost all types of consumer goods.

7.4. Reverse Auctions

A reverse auction is where a buyer solicits offers from sellers by specifying terms of trade that include product specification, price, delivery schedule and so on. Once interested sellers are notified and assembled, they may compete by lowering their offers until one is accepted by the buyer. Alternatively, offers may be accepted as sealed bids until one is chosen. In this regard, a reverse auction is more akin to a buyer auction, commonly found in business procurement and government contracting.

But an online implementation of a reverse auction—e.g., Priceline.com—deals with more mundane varieties of consumer goods and services. At Priceline.com website (http://www.priceline.com),

consumers can specify the maximum price they are willing to pay for airline tickets, hotel rooms, automobiles and home mortgage (see Figure 6). Then Priceline.com acts as a reverse auction market as it searches and finds a seller who has the good that matches the buyer's requirements and is willing to provide the good or service at the specified terms.

Like classified ads, the reverse auction mechanism is commonly found in physical markets. For example, it is used to determine suppliers and contractors in large-scale projects. In some seller's markets where products are perishable, sellers compete to unload their products before they become spoiled or unserviceable. Not surprisingly, Priceline.com's main source of revenues is the airline industry, where unsold seats are perishable products that cannot be saved and resold at a later date.

As in the case of building contractors and bidders, the advantage of reverse auction hinges on the limited time span of certain products and services and the existence of competition among sellers. However, it is seldom used for manufactured consumption goods. An obvious logistical problem is that there are many more buyers than sellers. This will render reverse auctions almost impossible to handle. On the other hand, online markets may offer an opportunity for reverse auctions to be used more frequently, even for most consumer goods. In a sense, reverse auctions are a form of customer-pulled marketing and an ideal selling mechanism for the digital age.

Consumer-initiated, or pulled, searches may produce some potential vendors who have matching products for sale, but contacts have to be made separately from the search result. Online reverse auctions combine search process with direct contact and negotiation with the sellers. The prospect of using a reverse auction as an online business model depends on its ability to enable consumers to specify various aspects of the good or service they intend to purchase because individual preferences may not be matched by existing products and services. In such cases, interested sellers may engage in ex post manufacturing to satisfy customer requirements. Online searches, reverse auctions, and ex post manufacturing represent the continuing innovation of the digital economy to satisfy personalized needs.

7.5. Emerging Market Mechanisms

Auctions are typically used when sellers are uncertain about market demand but want to maximize selling prices. Conversely, buyers use auctions to obtain lowest prices for contracts and supplies. If this is the case, why would sellers use online auctions when they can obtain higher prices through posed-price selling? Revenues are maximized, because since traditional auctions usually involve one seller with multiple buyers or one buyer with multiple sellers. In each of these cases, the individual who sells an object or awards a contract is always better off as the number of bidders increases

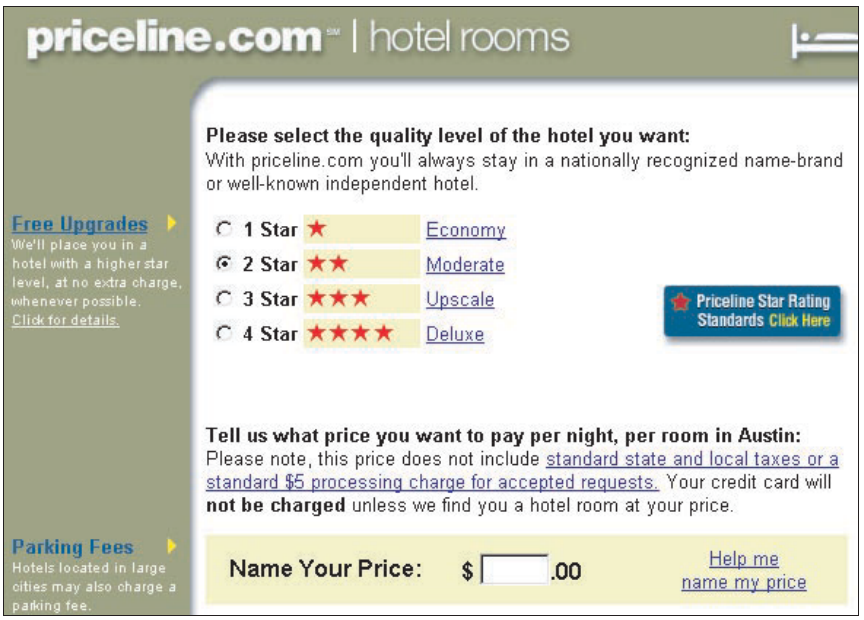

Figure 6 Customers Name Their Prices at Priceline.com. Reproduced with permission.

(Wang 1993; Bulow and Klemperer 1996). However, if the auction consists of many sellers and buyers simultaneously, the result changes dramatically. Such an auction is called a double auction market.

7.5.1. Double Auction

In a typical auction, a single seller receives bids from multiple buyers or one buyer collects offers from multiple sellers. In a double auction, both multiple sellers and buyers submit bids and offers simultaneously, similar to trading in security markets. Multiple units of different products may be auctioned off at the same time.

A double auction closely resembles supply-and-demand interactions in physical markets. Because of this simple fact, a double auction results in a very different price level from single auctions, described above. In a single auction, the selling price may be far above the competitive level due to competition among the buyers. With many sellers and buyers, however, double auction markets tend to generate competitive outcomes. A double auction is simply an interactive form of market where both buyers and sellers are competitive.

Ideally, any effort to promote competitiveness should include expanding double auctions and similar market mechanisms in the digital economy because they offer an opportunity to raise economic efficiencies unsurpassed by any physical market organizations. For auctioneers, however, single auctions generate substantially more revenues than double auctions. Where will the incentives be for them to participate in such a competitive market? Both sellers and buyers will prefer single auctions. On the other hand, a variant type of double auction may present a unique opportunity in the digital marketplace. For example, when buyers are looking for a bundle of products and services, a double auction with many sellers and buyers is necessary to clear the market.

7.5.2. Bundle Trading

Bundle trading is an essential market mechanism when products are customized and buyer's needs must be satisfied by many sellers. Customized and personalized products often consist of a collection of complementary goods and services. For example, a combination of airline tickets, hotel rooms, a rental car, meals, and amusement park admission tickets can be bundled as a packaged leisure product. Some products that are vertically related, such as a computer operating system and a web browser, may be provided by different vendors, requiring buyers to deal with multiple sellers.

While a purchase that involves multiple sellers may be carried out through a series of transactions or auctions, bundle trading offers a simplified and efficient solution. In addition, products and services are increasingly bundled and integrated rather than being sold as separate units. As a result, a different kind of problem arises, namely how to facilitate markets that allow convenient buying and selling of a wide range of products and services in one basket or transaction.

A technological solution to bundle trading is to provide an auction that allows buyers and sellers to trade any number of goods in any combination. For example, stock trading markets such as NYSE or Nasdaq are double auctions that clear individual assets one by one. On the other hand, investors usually hold their assets in a portfolio that consists of diverse assets, consistent with their investment objectives on the overall returns and values. Nevertheless, physical markets are unable to carry out unbundling and rebundling of assets offered and demanded in the market.

The networked environment on the Internet offers a possibility of allowing such portfolio-based transactions. In essence, the desired auction mechanism must unbundle and rebundle offers and bids presented by both sellers and buyers. A prototype of such a mechanism is a portfolio trading algorithm developed for the investment community (Fan et al. 1999; Srinivasan et al. 1999). Its basic setup, however, can extend into procurement process in manufacturing as well as bundle trading in physical products and personal services.

Alternatively, third-party intermediaries may provide an agent-based solution to trading bundles. Like a travel agent, an intermediary can assemble a package of products and services to match a customer's need. Because of the increasing trend toward integrated products, intermediaries or agent-based service providers will play a greater role in the Internet economy.

8. OUTLOOK AND CHALLENGES

New technologies and applications are continually developed and applied to business processes on the Internet. The basic infrastructure of the digital economy clearly consists of computers and networking technologies. However, underlying component technologies and applications are evolving rapidly, allowing us to make only a haphazard guess as to which will turn out to be most critical or most widely accepted in the marketplace.

But not all technologies are created equal: those that aid commerce in a smart way will become critical in meeting the increasing demand for more flexibility and responsiveness in a networked commercial environment. The drive toward interoperable and distributed computing extends the very advantage of the Internet and World Wide Web technologies. Broadband networking, smart cards,

and mobile network applications bring convenience and manageability in the network-centered environment. New technologies and computing models such as XML and multitier distributed computing help firms to implement more efficient management solutions. These technologies, when combined, improve and reinvent existing business processes so as to meet flexibility and responsiveness demanded by customers.

Nevertheless, regulatory as well as technical variables may become an important factor that hinders future growth of the Internet economy. Despite a high level of efficiency enabled by technologies, free markets are sometimes unable to produce efficient results when:

- Lack of information and uncertainty about products and vendors results in market failures.
- Goods and services have characteristics of public goods that private economies do not produce sufficiently.
- An industry is dominated by a monopoly or a few oligopolistic firms where outputs are reduced and prices are higher than competitive markets.
- Market players do not enjoy a transparent and universal commercial environment.

In such cases, a third party such as a government needs to intervene to provide information, promote goods production, and regulate and provide legal and commercial infrastructure. Even in the free-spirited Internet, governments play many essential roles as policy-making bodies. Business and regulatory policies as well as taxation influence firm organization and behaviors, competition, and profit levels, which ultimately determine the level of consumer welfare. (For more in-depth discussion on policies toward electronic commerce, see Choi et al. [1997] and Choi and Whinston [2000]).

Should governments regulate online markets? Various types of inefficient markets can be made efficient through regulation. A primary example is regulation of monopolies, lowering prices and increasing outputs. Health and safety regulations protect consumers. At the same time, however, regulators may be ''captured'' by those who are being regulated and protect firms' interests against consumer welfare and market efficiency. Regulation of online commerce may have similarly controversial results. It may protect consumers' interests and ensure efficiency. On the other hand, it may hinder the growth of online business. Regardless of its final effects, there is a growing list of online business activities that receive increasing attention from government agencies that want to regulate them.

In addition to still-evolving government policies toward e-commerce, technological factors continue to pose challenges to those doing business on the Internet. Recent episodes of distributed denial of service (DDoS) attacks on major e-commerce sites, where web servers are flooded with bogus service requests to the degree that normal customers become unable to connect, show how vulnerable Internet-based commerce can be. Despite heavy interest and large investments in security measures and technologies, DDoS attackers take advantage of the open infrastructure that lies at the bottom of the Internet telecommunications networking and are able to interrupt its normal performance through various types of requests, often using a host of third-party servers who become unwitting partners of the attack.

Technologies alone are unable to provide a sure firewall to prevent such attacks as long as the basic TCP/IP network of the Internet cannot distinguish the type of traffic that runs through or there exist some insecure servers on the network who become free riders on such attacks (Geng and Whinston 2000). Increasingly, economic analysis and tools are becoming an essential ingredient in solving technological problems.

Despite policy and technical barriers, the number of business applications based on the Internet is growing rapidly into teleconferencing, logistics support, online services in banking and medicine, customer service through chat lines, online publishing, distance learning, and broadband/mobile content delivery. In essence, the Internet has become the information infrastructure necessary to carry out various types of business operations, market processes, and transactional requirements in the fully digital economy. Any effort to reengineer business and industrial processes in the 21st century will necessarily involve the use of the Internet and its associated applications. Understanding the economic aspects of the Internet will become the final challenge in promoting and selecting a winning combination of technologies and business models.

1. INTRODUCTION

The rapidly growing globalization of industrial processes is defining the economic structure worldwide. The innovative power of a company is the deciding factor for success in gaining market acceptance. Strengthening innovation, however, relies on the ability to structure the design phase technically so that innovative products are generated with consideration of certain success factors such as time, expense, quality, and environment. Furthermore, these products should not only be competitive but also be able to maintain a leading position on the world market. The opportunity to increase innovation lies in deciding on novel approaches for generating products based on future-oriented, computer-integrated technologies that enable advances in technology and expertise. In the end, this is what guarantees market leadership.

In recent years, progress in product development has been made principally through the increasing use of information technology and the benefits inherent in the use of these systems. In order to fulfill the various requirements on the product development process in respect to time, costs, and quality, a large number of different approaches have been developed focusing on the optimization of many aspects of the entire development process.

This chapter provides an overview of the computer integrated technologies supporting product development processes and of the current situation of knowledge management. Section 2 discusses the design techniques affected by computer-aided technologies and the corresponding tools. Section 3 gives a general introduction of concepts of computer integrated technologies and describes basic technologies and organizational approaches. Section 4 explains possible architectures for software tools that support product development processes. Section 5 gives a wide overview of the application and development of knowledge management.

2. DESIGN TECHNIQUES, TOOLS, AND COMPONENTS

2.1. Computer-Aided Design

2.1.1. 2D Design

Like traditional design, 2D geometrical processing takes place through the creation of object contours in several 2D views. The views are then further detailed to show sections, dimensions, and other important drawing information. As opposed to 3D CAD systems, 2D CAD design occurs through conventional methods using several views. A complete and discrepancy-free geometrical description, comparable to that provided by 3D CAD systems, is not possible. Therefore, the virtual product can only be displayed to a limited extent. Two-dimensional pictures still have necessary applications within 3D CAD systems for hand-sketched items and the creation of drawing derivations.

Despite their principal limitation compared to 3D CAD systems, 2D systems are widely used. A 3D object representation is not always necessary, for example, when only conventional production drawings are required and no further computer aided processing is necessary. In addition, a decisive factor for their widespread use is ease of handling and availability using relatively inexpensive PCs.

The main areas of 2D design are the single-component design with primitives geometry, sheet metal, and electrical CAD design for printed circuit boards.

Depending on the internal data structure of the computer, classical drawing-oriented and parametrical design-oriented 2D CAD systems can be differentiated. This distinction has an essential influence on the fundamental processing principles and methodical procedures followed during the design phase. The drawing-oriented systems are then implemented efficiently in the detailing phases while new-generation parametrical systems support the development in early concept phases. With efficient equation algorithms running in the background, extensive calculations and parametrical dependencies for simulation purposes can be applied.

The essential goal in using design-oriented, 2D CAD systems is creation of manufacturing plans and documentation. From the exact idea of the topology and dimensions of the technical entity to the input of the geometry and ending with the detailing of the technical drawing and preparation of the parts list, this computer-supported process corresponds to a large degree with conventional strategies.

The technical drawings are created with the aid of geometrical elements available within the system. The following geometrical elements can be used: points, straight lines, parallel lines, tangents, circles, arcs, fillets, ellipses, and elliptical arcs such as splines. Furthermore, equidistant lines may be created. Editing commands such as *paste, delete, join, extend, trim,* and orientation operations

such as translation and rotation, exist for element manipulation purposes. Further design clarification and simplification is provided by the help functions of scaling, duplicating, locating, and mirroring on symmetrical axes. Detail work may be simplified with the use of zoom functions, and snap points aid in dimensioning and positioning of geometrical elements. The technical drawings are then completed with the use of hatching, dimensioning, and labeling.

The following strategies are recommended for the completion of drawings using 2D CAD systems:

- Do default settings for drawing parameters such as scale ratios, line characteristics and hatching, font, and measurement standards.
- Call up and blend in predefined frames with text and form fields.
- Use construction lines for added support.
- Create contour and surface in different views.
- Apply eventual cutouts and hatching
- Set measurements, tolerances, etc.
- Transfer generated objects to predefined printing or storage mediums.

An example of a complex assembly drawing is presented in Figure 1.

With the use of layers, drawing information of all types may be distributed over any desired number of named and editable layers. The layers simplify the drawing process because momentarily irrelevant information can be easily blended out. Additional text in different languages or measurement systems or norms can also be called up and implemented.

Grouping techniques allow for the summarizing of geometrical elements through various selection processes and in turn ease further working processes.

The majority of systems provide function libraries for the simplification of drawing preparation and the efficient use of results. The following areas may be simplified with the use of function libraries:

- Creation and manipulation of geometrical elements
- Geometrical calculations
- Access to saved elements using search criterion
- Creation of groups and layers
- Utilization of drawing elements such as dimensioning, hatching, and text
- Use of standard dialogs for value, point, or font input

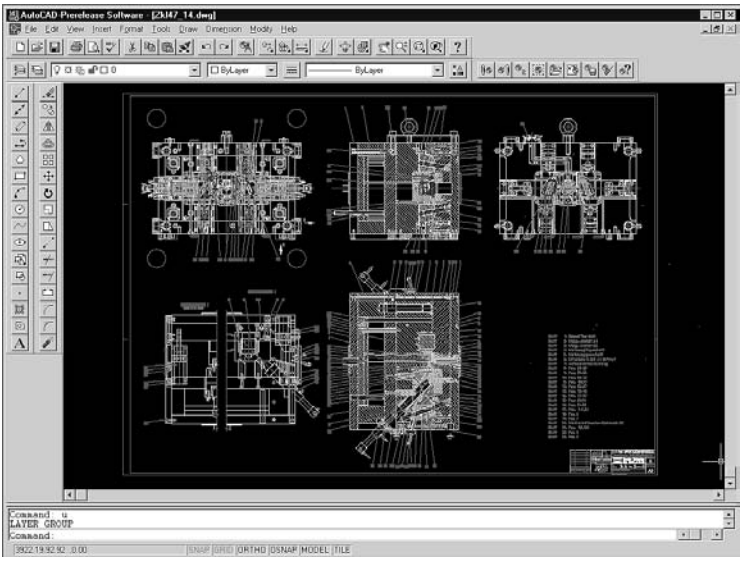

Figure 1 An Example of a 2D Drawing. (AutoCAD System. Reproduced with permission of Autodesk®)

Geometry macros are internal computer representations of dimension and form-variable component geometries of any complexity. The macros are easily called up from a database and copied by the user. The user may then easily insert the copied macro into the current object representations. The advantages of the geometry macros are seen especially when working with standard and repeat parts.

A spatial representation is desirable for a variety of tasks where primarily 2D representations are utilized. Therefore, in many systems an existing function is available for isometric figures that provide an impression of the object's spatial arrangement without the need for a 3D model. This approach is sufficient for the preparation of spare parts catalogs, operating manuals, and other similar tasks. Prismatic bodies and simplified symmetric bodies may also be processed. For the use of this function it is necessary to present the body in front and side views as well as plan and rear views where required. After the generation of the isometric view, the body must be completed by blending out hidden lines. This happens interactively because the system actually does not have any information available to do this automatically. So-called 2½ systems generate surface-oriented models from 2D planes through translation or rotation of surface copies. The main application for these models lies in NC programming and documentation activities.

To reduce redundant working steps of geometrical modifications, the dimensioning of the part must be finished before the computer-supported work phases. This approach, which underlies many CAD systems today, is connected to the software's technical structure. In geometry-oriented dimensioning, the measurement alone is not inferred but rather the totality of geometrical design of the entity. The supporting role played by the system for interactive functioning is limited to automatic or semiautomatic dimension generation. The dimensional values are derived from the geometry specified by the designer. The designer is forced to delete and redo the geometry partially or completely when he or she wishes to make changes. This creates a substantial redundancy in the work cycle for the project.

The principal procedures of dimension-oriented modeling in parametric 2D CAD systems often correspond to conventional 2D systems. For the generation of geometrical contours, the previously mentioned functions, such as lines, circles, tangents, trimming, move, and halving, are used. The essential difference is the possibility for free concentration on the constructive aspects of the design. In parametrical systems, on the other hand, the measurements are not fixed but rather are displayed as variable parameters. Associative relationships are built between the geometry and measurements, creating a system of equations. Should the geometry require modification, the parameters may be varied simply by writing over the old dimensions directly on the drawing. This in turn changes the geometrical form of the object to the newly desired values. The user can directly influence the object using a mouse, for example, by clicking on a point and dragging it to another location, where the system then calculates the new measurement. The changes cause a verification of the geometrical relationships as well as the consistency of the existing dimension in the system.

Another advantageous element of the parametrical system is the ability to define the above-mentioned constraints, such as parallel, tangential, horizontal, vertical, and symmetrical constraints. Constraints are geometrical relationships fixed by formula. They specify the geometrical shape of the object and the relevant system of equations necessary for geometry description. Thus, a tangent remains a tangent even when the respective arc's dimension or position is changed. With the constraints, further relationships can be established, such as that two views of an object may be linked to one another so that changes in one view occur the related view. This makes the realization of form variations fairly simple.

Modern CAD systems include effective sketching mechanisms for the support of the conceptual phase. For the concept design, a mouse- or pen-controlled sketching mechanism allows the user to portray hand-drawn geometries relatively quickly on the computer. Features aiding orientation, such as snap-point grids, and simplifying performing the alignment and correction of straight, curved, orthogonal, parallel, and tangential elements within predetermined tolerances. This relieves the user of time-consuming and mistake-prone calculations of coordinates, angles, or points of intersection for the input of geometrical elements. When specifying shape, the parametrical system characteristics come into play, serving to keep the design intent. The design intent containing the relative positioning is embodied by constraints that define position and measurement relationships. Component variations are easily realizable through changes of parameter values and partially with the integration of calculating table programs in which table variations may be implemented.

The existing equation system may be used for the simulation of kinematic relations. Using a predetermined, iterative variation of a particular parameter and the calculation of the dependent parameter, such as height, simple kinematic analysis of a geometrical model is possible. This simplifies packaging analysis, for example.

2.1.2. 3D Design

2.1.2.1. Surface Modeling The geometrical form of a physical object can be internally represented completely and clearly using 3D CAD systems, is contrast to 2D CAD systems. Therefore,

the user has the ability to view and present reality-like, complex entities. Thus, 3D CAD systems provide the basis for the representation of virtual products. Through 3D modeling and uniform internal computer representation, a broader application range results so that the complete product creation process can be digitally supported. This starts with the design phase and goes through the detailing, calculation, and drawing preparation phases and on to the production. Because of the complete and discrepancy-free internal computer representation, details such as sectional drawings may be derived automatically. Also, further operations such as finite element analysis and NC programs are better supported. The creation of physical prototypes can be avoided by using improved simulation characteristics. This in turn reduces the prototype creation phase.

Due to the required complete description of the geometry, a greater design expenditure results. Because of the greater expenditure, special requirements for user-friendliness of component geometry generation of components and their links to assemblies and entire products are necessary.

3D CAD systems are classified according to their internal computer representations as follows (Grätz 1989):

- Edge-oriented models (wire frames)
- Surface-oriented models
- Volume-oriented models

The functionality and modeling strategy applied depend on the various internal computer representations.

Edge-oriented models are the simplest form of 3D models. Objects are described using end points and the connections made between these points. As in 2D CAD systems, various basic elements, such as points, straight lines, circles and circular elements, ellipses, and free forming, are available to the user and may be defined as desired. Transformation, rotation, mirroring, and scaling possibilities resemble those of 2D processing and are related to the 3D space.

Neither surfaces nor volumes are recognizable in wire frame models. Therefore, it is not possible to make a distinction between the inside and outside of the object, and section cuts of the object cannot be made. Furthermore, quantifiable links from simple geometrical objects to complex components are not realizable. This is a substantial disadvantage during the practical design work. An arbitrary perspective is possible, but in general a clear view is not provided. Among other things, the blending out of hidden lines is required for a graphical representation. Because of the lack of information describing the object's surfaces, this cannot take place automatically but must be carried out expensively and interactively. Models of medium complexity are already difficult to prepare in this manner. The modeling and drawing preparation are inadequately supported. Another problem is the consistency of the geometry created. The requirements for the application of a 3D model are indeed given, but because of the low information content the model does not guarantee a mistake-free wire frame presentation (Grätz 1989).

Surface-oriented systems are able to generate objects, known as free-form surfaces, whose surfaces are made up of numerous curved and analytically indescribable surfaces. One feature visible in an internal computer representation of free-form surfaces is their interpolated or approximated nature. Therefore, various processes have been developed, such as the Bézier approximation, Coon's surfaces, the NURBS representations, and the B-spline interpolation (see Section 4.1).

As with all other models, the computer internal representation of an object implies characteristic methods and techniques used in generating free-form surfaces. In general, basis points and boundary conditions are required for the surface description. Free-form surfaces, such as the one portrayed in Figure 2, can be generated using a variety of techniques. A few examples for the generation of free-form surfaces will be described later.

In addition to the simple color-shaded representations, photorealistic model representations may be used for the review and examination of designs. The models are portrayed and used in a reality-like environment and are supported by key hardware components. This allows for the consideration of various environmental conditions such as type and position of the light source, the observer's position and perspective, weather conditions, and surface characteristics such as texture and reflectivity. Also, animation of the object during design is possible for the review of movement characteristics. Through these visualization methods it is possible to assess a product's design before prototype production begins and aid the preparation of sales brochures and other documents.

A characteristic feature and major disadvantage of surface models is the fact that the surfaces are not automatically correlated to form a body. This has important consequences for the designer. It results in a distinct modeling technique for the user that offers only limited functionality with regard to realization of the design tasks. For example, from the outset it is not defined whether a surface should face the inside or the outside of the object. Therefore, the designer must be careful to ensure a closed and complete model during design phases. Intersections are not recognizable by the system

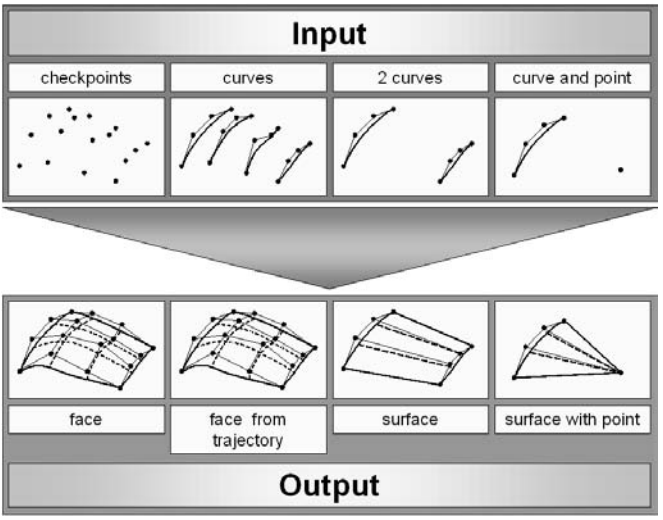

Figure 2 Modeling Processes for Free-Form Surfaces.

because of missing information describing the solid during cutting operations. The intersections are represented only by contour lines that are interactively hatched.

Surface models are applied when it is necessary to generate a portrait of free-formed objects. Such models are used in the automobile, shipbuilding, and consumer goods industries, for example. The surface formations of the model, which are distinguished into functional and esthetic surfaces, can be used as ground-level data for various applications employed later on. This includes later applications such as the generation of NC data from multiaxis processing. Another area of application is in FEM analysis, where the surface structure is segmented into a finite element structure that is subsequent to extensive mechanical or thermal examinations. With surface models, movement simulations and collision analyses can be carried out. For example, mechanical components dependent on each other can be reviewed in extreme kinematic situations for geometrical overlapping and failure detection.

2.1.2.2. Solid Modeling A very important class of 3D modelers is generated by the volume systems. The appropriate internal computer representation is broken down into either boundary representation models (B-reps) or Constructive Solid Models (CSGs). The representation depends on the basic volume modeling principles and the deciding differences between the 3D CAD system classes.

Volume modelers, also known as solid modelers, can present geometrical objects in a clear, consistent, concise manner. This provides an important advantage over previously presented modeling techniques. Because each valid operation quasi-implicitly leads to a valid model, the creativity of the user is supported and the costly verification of geometric consistency is avoided.

The main goal of volume modeling is the provision of fundamental data for virtual products. This data includes not only the geometry but also all information gathered throughout the development process, which is then collected and stored in the form of an integrated product model. The information allows for a broad application base and is available for later product-related processes. This includes the preparation of drawings, which consumes a large portion of the product development time. The generation of various views takes place directly, using the volume model, whereby the formation of sections and the blending out of hidden lines occurs semiautomatically.

Normally, volume models are created using a combination of techniques. The strengths of the 3D volume modeling systems lie in the fact that they include not only the complete spectrum of well-known modeling techniques for 2D and 3D wire frames and 3D surface modeling but also the new, volume-oriented modeling techniques. These techniques contribute significantly to the reduction of costly input efforts for geometrically complex objects.

The volume model can be built up by linking basic solid bodies. Therefore, another way of thinking is required in order to describe a body. The body must be segmented into basic bodies or provided by the system as basic elements (Spur and Krause 1984). Each volume system comes with a number of predefined simple geometrical objects that are automatically generated. The objects are generated by a few descriptive system parameters. Spheres, cubes, cones, truncated cones, cylinders, rings, and tetrahedrons are examples of the basic objects included in the system.

Many complex components can be formed from a combination of positioning and dimensioning of the basic elements.

Complex components are created in a step-by-step manner using the following connecting operations:

- Additive connection (unification)
- Substractive connection (differential)
- Section connection (average)
- Complementing

These connections are known as Boolean or set-theoretical operations. For object generation using Boolean operations, the user positions two solids in space that touch or intersect one another. After the appropriate functions are called up (unification, average, complementing, or differential), all further steps are carried out by the system automatically and then present the geometrical object.

The sequence of the operations when the set-theoretical operations are applied is of decisive importance. Some CAD systems work with terms used for manufacturing techniques in order to provide the designer with intuitive meanings. This allows for the simple modeling of drilling, milling, pockets, or rounding and chamfering. This results because each process can be represented by a geometrical object and further defined as a tool. The tool is then defined in Boolean form and the operation to perform the removal of material from the workpiece is carried out. To correct the resulting geometry, it is necessary that the system back up the complete product creation history. This is required to make a step by step pattern that can be followed to return the set-theoretical operations to their previous forms.

Set-theoretical operations provide an implementation advantage where complex model definitions must be created with relatively few input commands. These definitions are, if even realizable, extremely costly and time consuming by conventional methods. The disadvantage is that a relatively high conceptual capability is required of the user.

Solid models with a number of free-form surfaces are realized using surface-oriented modeling techniques that correspond to the surface model presented. With one of these techniques, *sweeping,* one attains a 3D body through an intermediate step when creating a 2D contour. The 2D contour is expanded to three dimensions along a set curve. The desired contours are generated with known 2D CAD system functions and are called up as bases for sweep operations.

In rotational sweeping, objects are generated through the rotation of surfaces, as well as closed or open, but restricted, contour lines around a predefined axis. The axis may not cut the surface or contour. A prismatic body originates from the expansion of a closed contour line. Shells or full bodies can be generated with sweep operations. With sweep-generated shells, movement analysis and assembly inspection can occur. The analysis takes place by the bodies' movement along a curve in space.

The modeling strategy implemented depends heavily on the actual task and the basic functionality offered by the CAD system. This means that the strategy implemented cannot be arbitrarily specified, as most CAD systems have a variety of alternative approaches within the system. For the user, it is important that a CAD system offer as many modeling methods as possible. Modeling, such as surface and solid modeling, is important, and the ability to combine and implement these methods in geometrical models is advantageous to the user. Because of the numerous modeling possibilities offered, the CAD system should have as few restrictions as possible in order to allow the user to develop a broad modeling strategy. Figure 3 shows a surface-oriented model of a bumper that was created using a simple sweep operation of a spline along a control curve. Using a variable design history, the air vent may be positioned anywhere on the bumper's surface without time-consuming design changes during modeling. The cylindrical solid model that cuts and blends into the surface of the bumper demonstrates that no difference exists between a solid and surface model representation. Both models may be hybridized within components. A CAD system supporting hybridized modeling creates a major advantage because the designer realizes a greater freedom of design.

2.1.3. Parametrical Design

Another development in CAD technology is parametrical modeling (Frei 1993). The function of parametrical systems displays basic procedure differences when compared to conventional CAD systems. The principal modeling differences were explained in the section on parametrical 2D CAD systems.

In parametrical model descriptions, the model can be varied in other areas through the selection and characterization of additional constraints.

Boundary conditions can be set at the beginning of the design phase without fixing the final form of the component. Therefore, generation of the geometry takes place through exact numerical input and sketching. The designer can enter the initial designs, such as contour, using a 2D or 3D sketcher. In this manner, geometrical characteristics, such as parallel or perpendicular properties, that lie within

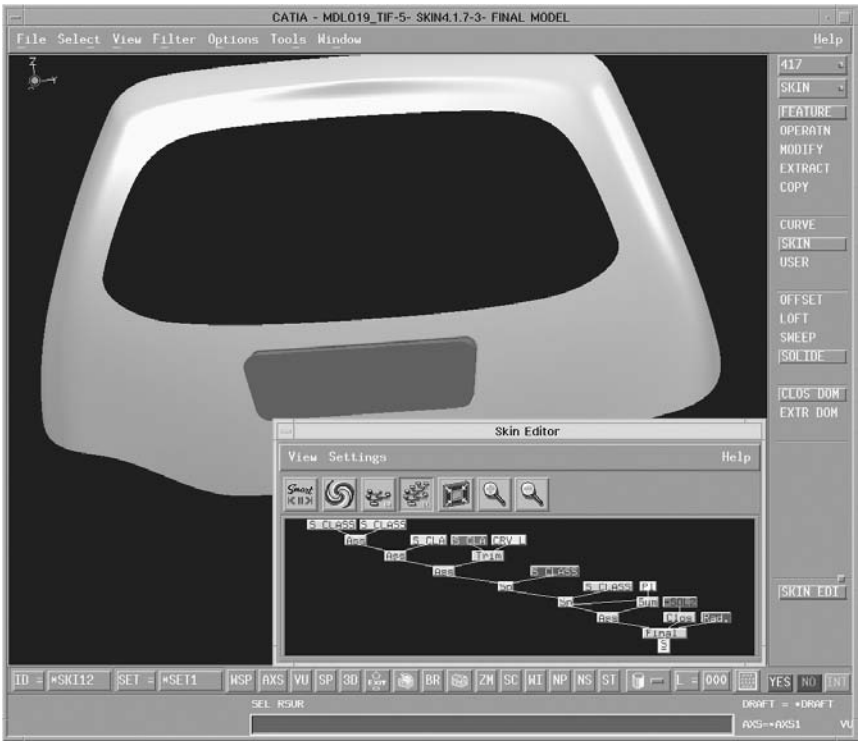

Figure 3 Hybrid Surface and Solid Model. (CATIA System, Dassault Systèmes)

set tolerances are automatically and correctly recognized. The characteristics may also be set through predetermined constraints. Subsequently, the user can develop the initial dimensions using operations that essentially resemble those of conventional measurement determination. Through associativity, the adaptation of the model presented takes places automatically.

Beginning with the first contour sketches, the designer attains the desired solid object through further modeling using operations such as sweeping. The design history is of great importance at this point of the development process. The history can subsequently be modified, influencing the geometry of the model. Because of the associative relationship between the dimensioning and the solid model, the geometry of a component is easily varied in every design phase. Based on the parametrical method implemented, the designer can define conditions for parallel, tangential, or perpendicularity characteristics. Also, complex parametrical dependencies from the system can be solved simultaneously using nonlinear equations.

Because of the parametrical relationships created in the background of the process, the user is in a position to modify the dimensions and topology of the geometry later in the project. Costly reworking of the model due to changes of the boundary conditions is avoided.

Complete process chains may be built up associatively. Downstream activities, including drawing creation and detailing, make up a large percentage of the design time. Here the generation of various views directly from the existing solid model may take place because the formation of sections and the blending out of hidden lines occurs automatically. The main advantage of this approach over previous CAD systems is due to the above-mentioned preservation of the bidirectional relationship between the solid model and the drawing derived from the model. This associative connection allows the designer to take geometrical modifications directly from a drawing, even if the designer has progressed substantiality into the detailing phase. Conversely, changes to the solid model are automatically reflected in the drawing.

The effect and the functionality of the parametric concepts do not end with the completion of the geometry. Rather, they are encompassed in all areas of product development. Solid modeling, calculations, drawing preparation, NC programming, simulation, and documentation are connected together in an associative chain so that modifications made in one area automatically take place in the other areas.

For the designer, it is important that both parametric and nonparametric geometry can be combined and implemented during the development of a component. Therefore, complex components must not be completely described parametrically. The designer decides in which areas it is advantageous to present the geometry parametrically.

2.1.4. Feature Technology

Most features in commercial CAD systems are built upon a parametrical modeler. The ability to define one's own standard design elements also exists. These elements can be tailored to the designer's way of thinking and style of expression. The elements are then stored in a library and easily selected for implementation in the design environment. Additional attributes such as quantity, size, and geometrical status can be predetermined to create logical relationships. These constraints are then considered and maintained with every change made to an element. An example of a design feature is a rounding fillet. The fillet is selected from the features library and its parameters modified to suit the required design constraints.

The library, containing standard elements, can be tailored to the user's requirements for production and form elements. This ensures consistency between product development and the ability to manufacture the product. Therefore, only standard elements that match those of available production capabilities are made available. Feature definition, in the sense of concurrent engineering, is an activity in which all aspects of product creation in design, production, and further product life phases are considered.

In most of today's commercially available CAD systems, the term *feature* is used mainly in terms of form. Simple parametric and positional geometries are made available to the user. Usually features are used for complicated changes to basic design elements such as holes, recesses, and notches. Thus, features are seen as elements that simplify the modeling process, not as elements that increase information content. With the aid of feature modeling systems, user-defined or company-specific features can be stored in their respective libraries. With features, product design capabilities should be expanded from a pure geometric modeling standpoint to a complete product modeling standpoint. The designer can implement fully described product parts in his or her product model. Through the implementation of production features, the ability to manufacture the product is implicitly considered. A shorter development process with higher quality is then achieved.

By providing generated data for subsequent applications, features represent an integration potential.

2.1.5. Assembly Technology

Complex products are made up of numerous components and assemblies. The frequently required design-in-context belongs to the area of assembly modeling. Thereby, individual parts that are relevant to the design of the component are displayed on the screen. For instance, with the support of EDM functionality, the parts can be selected from a product structure tree and subsequently displayed. The part to be designed is then created in the context already defined. If the assembly is then worked on by various coworkers, the methods for shared design are employed. For example, changes to a component can be passed on to coworkers working on related and adjacent pieces through system-supported information exchange.

An example of a complex assembly in which shared design processes are carried out is the engine in Figure 4. The goal is to be able to build and then computer analyze complex products. The assembly modeling will be supported by extensive analysis and representation methods such as interference checks as well as exploded views and section views.

Besides simple geometrical positioning of the component, assembly modeling in the future will require more freedom of modeling independent of the various components. Exploiting the association between components permits changes to be made in an assembly even late in the design phase, where normally, because of cost and time, these modifications must be left out. Because the amount of data input for assemblies and the processing time required to view an assembly on the screen are often problematic, many systems allow a simplified representation of components in an assembly, where suppression of displaying details is possible. But often the characteristics of simplified representation are to be defined by the user. It is also possible for the CAD system to determine the precision with which the component is displayed, depending on the model section considered. Zooming in on the desired location then provides a representation of the details.

A representation of the assembly structure is helpful for the modeling of the assembly. Besides the improved overview, changes to the assembly can be carried out within the structure tree and parts lists are also easily prepared.

The combination of assemblies as a digital mock-up enables control over the entire structure during the design process. Thereby, interference checks and other assembly inspections are carried out using features that make up the so-called packaging analyses of the software. For the check of collision, voxel-based representations are suitable as well. Importing and portraying assemblies from other CAD systems is also advantageous. This is possible with the creation of adequate interfaces.

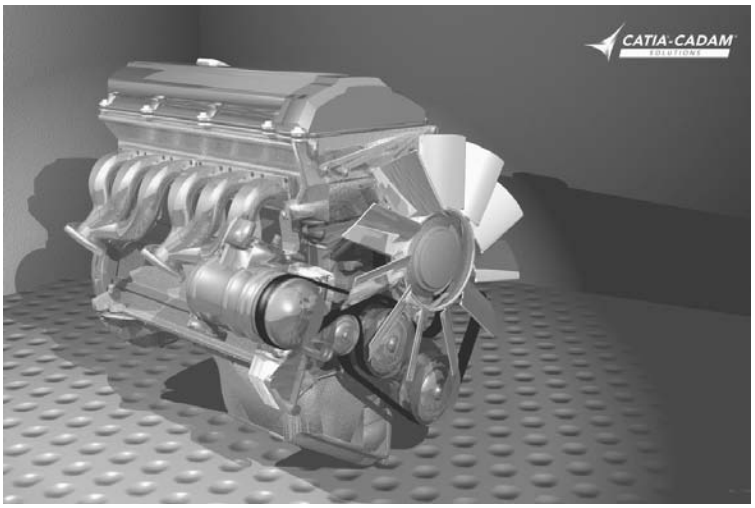

Figure 4 An Engine as a Complex Assembly. (CATIA System, Dassault Systèmes)

An important functionality in assembly modeling is the definition of geometric and functional tolerances that are supported by the respective CAD module (Figure 5). Thereby, the geometrical and functional tolerance definitions are carried out based on assembly specifications and international standards. Special analysis functions are utilized for the control of complex assemblies and products.

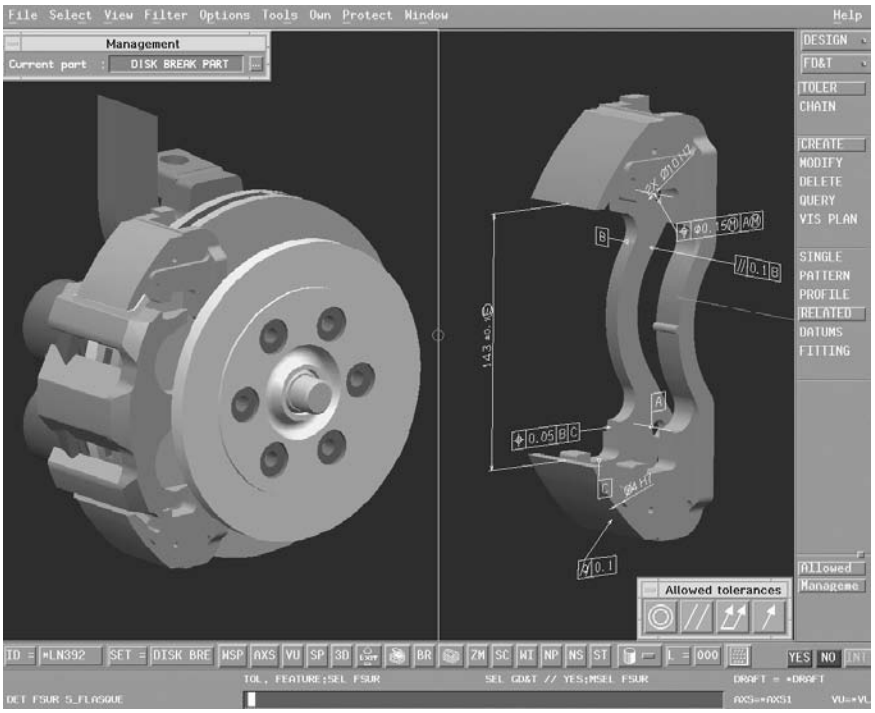

Figure 5 Definition of Tolerances in an Assembly. (CATIA System, Dassault Systèmes)

For example, the fly-through function allows the user to navigate in real time through complex assemblies. This enables visual inspections, which among other things, help in the recognition of component interference.

The design of complex assemblies requires sharing of the design processes through teamwork. This shared group work is supported by software that enables conferences over the Internet/intranet in which text, audio, and video information may be exchanged.

2.1.6. Further Technologies

Further applications in the process chain of product development can be carried out based on the 3D models created in early phases. For example, most commercial CAD systems are composed of modules and are implemented for the realization of a geometric model and other development-oriented solutions. Because the CAD systems are compatible with one another, an unhindered exchange of data is possible right from the beginning of the design through production stages. The systems must meet the requirements for continuity and openness, which are indispensable for the development of complex products. Continuity means that the product data are entered only once. They are saved in a central location and are available for use in carrying out other tasks without extensive conversion being required between the various forms of data. Openness means that, besides the ability to process data on various hardware platforms, it is possible to connect with other program systems within the same company and to external sites such as suppliers and other service providers. Further differentiation results from homogeneous and heterogeneous system environments. Using a common database for the application modules, for example in STEP format, means that conversion or interface problems between the individual applications are avoided. External application programs and data exchange between the purchaser and the supplier are simplified by the use of data exchange formats such as IGES, SET, and VDAFS. A uniform user interface improves the usability and comfort of the user.

The application modules can be related to the various tasks within the development process. In the various phases of the virtual product development, different modules come into play depending on the task involved. The following principal tasks are presented:

- *Drawing preparation:* Drawings can be derived from the solid model and displayed in various views and measurements (Figure 6). This includes the representation of details as well as component arrangements. For higher work efficiency, it should be possible to switch between the 2D drawing mode and the 3D modeling mode at any time without suffering from conversion time and problems. A further simplification of the work results if the drawing and measurement routines provide and support the drawings in standardized formats, for example.
- *Parts list generator:* The preparation of a parts list is important for product development, procurement, and manufacturing. This list is automatically generated from the CAD component layout drawing. The parts list can then be exchanged through interfaces with PPS systems.
- *Analysis and simulation applications:* Analysis and simulation components enable the characteristics of a product to be attained and optimized earlier in the development phase. The costly and time-consuming prototype production and product development are thereby reduced to a minimum.

The strength characteristics can be calculated with finite element methods (FEMs). Besides stress–strain analyses, thermodynamic and fluid dynamic tests can be carried out. Preprocessors enable automated net generation based on the initial geometric model. Most CAD systems have interfaces for common FEM programs (e.g., NASTRAN, ANSYS) or have their own equation solver for FEM tests. Based on the substantial data resulting from an FEM test, it is necessary for postprocessing of results. The results are then portrayed in deformation plots, color-coded presentations of the stress–strain process, or animations of the deformation.

Material constants, such as density, can be defined for the components of the solid model. Then other characteristics, such as volume, mass, coordinates of the center of gravity, and moment of inertia can be determined. These data are essential for a dynamic simulation of the product. For kinematic and dynamic simulations, inelastic solid elements with corresponding dynamic characteristics are derived from the solid model (Figure 7). Various inelastic solid elements can be coupled together from a library. The complete system is built up of other elements such as a spring and damper and then undergoes a loading of external forces. The calculation of the system dynamics is usually carried out using a commercial dynamics package. A postprocessor prepares a presentation of the results for display on a screen. An animation of the system can then be viewed.

- *Piping:* Piping can be laid within the 3D design using conduit application modules, as shown in Figure 8. Design parameters such as length, angle, and radius can be controlled. Intersections or overlapping of the conduit with adjacent assemblies can also be determined and repaired. The design process is supported through the use of libraries containing standard piping and accessories. The parts lists are automatically derived from the piping design.

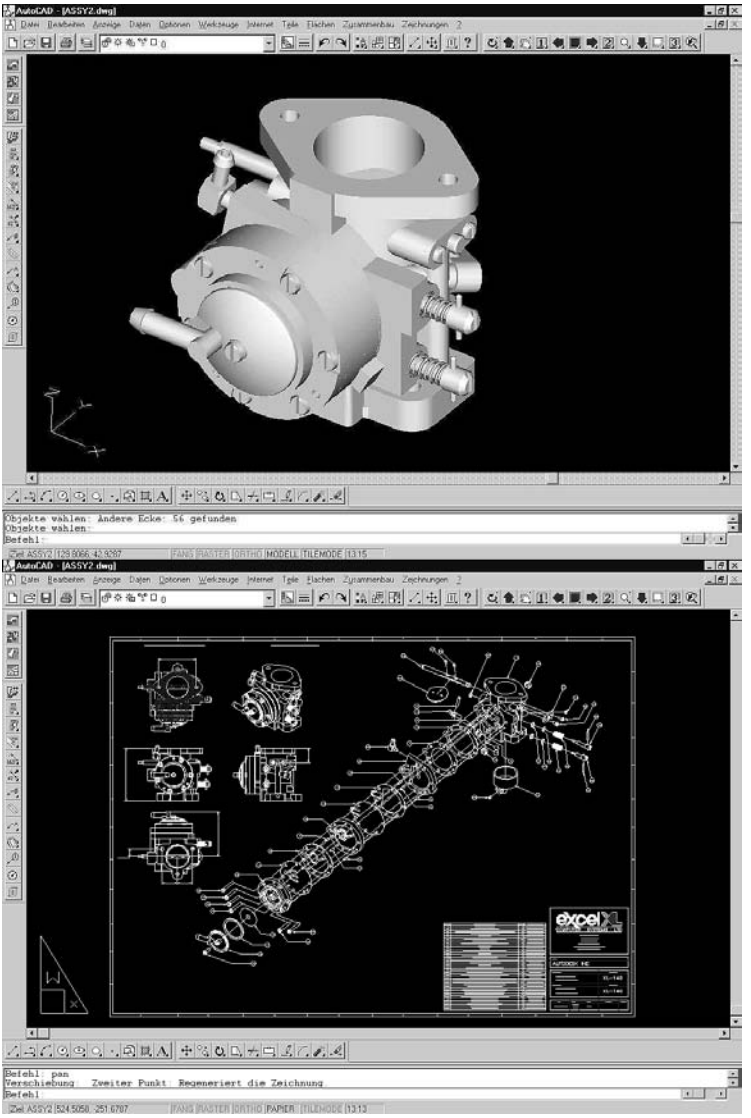

Figure 6 3D Model and the Drawing Derived from the Model. (AutoCAD System. Reproduced with permission of Autodesk®)

- *Weld design:* Weld design can also be supported by using appropriate application modules (Figure 9). Together, designers and production engineers can determine the required joining techniques and conditions for the assemblies. Thereby, the weld type and other weld parameters such as weld spacing and electrodes are chosen for the material characteristics of the components to be joined. Process information such as weld length and cost and time requirements can be derived from the weld model.
- *Integration of ECAD design:* The design of printed circuit boards and cable layouts are typical application examples of 2D designs that are related to the surrounding 3D components. With the design of printed circuit boards, layout information, such as board size and usable and unusable area, can be exchanged and efficiently stored between and within the MCAD and ECAD systems. For the design of cable layouts (Figure 10), methods similar to those used for conduit design are implemented. This simplifies the placement of electrical conductors within assemblies.

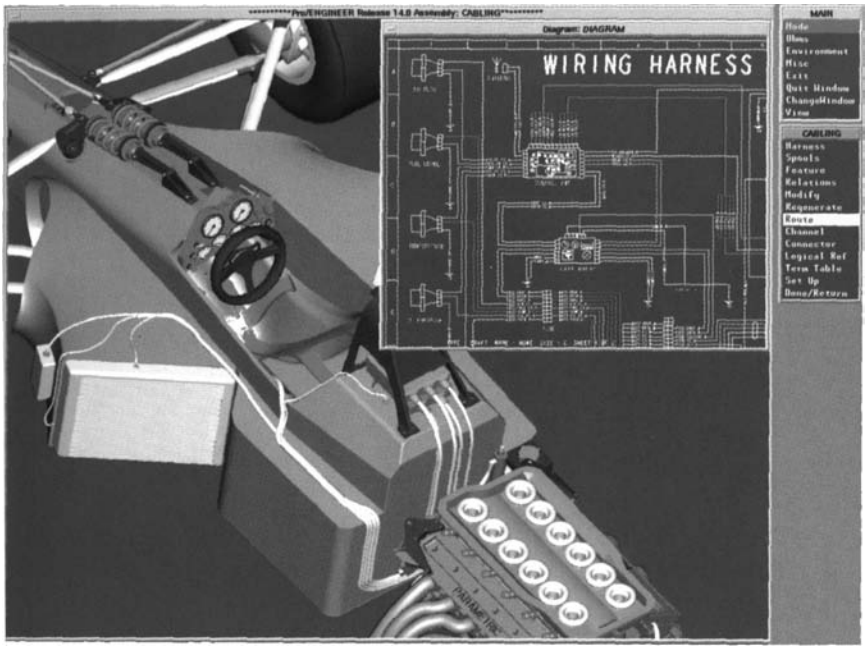

Figure 10 2D Design of a Wiring Harness. (Pro/DIAGRAM System, PTC) and Parametric Cable Layout in the 3D Assembly. (Pro/CABLING, PTC) Reprinted by permission of PTC.

- *Integration of process planning:* Product data can be taken directly from production planning. The machine tool design and planning can take place parallel to the design of the product. NC programs and control data can be derived from the finished 3D description of the geometry, although the model requires supplemental information for mountings and other devices. The tool paths are determined under consideration of the additional technical information of the different processes, such as drilling, milling, turning, eroding, and cutting. The generation of NC data in diverse formats, such as example COMPACT II, CLDATA, and APT, is carried out using a postprocessor. The NC programs derived from an optimized design can be checked by simulation.

  In addition to the three- and five-axis milling machines used for conventional production tasks, rapid prototyping processes are applied for quick design verification. For example, the process of stereo lithography can be applied. Rapid prototyping reduces the period of development and allows for the quick generation of physical prototypes for product review and evaluation purposes. A variety of materials, from plastics to metals, are used in rapid prototyping, enabling the prototypes to be presented in the most frequently used materials so that material characteristics can be easily reviewed (Gebhardt and Pflug 1995). The control data for the laser stereo lithography are generated from the geometry data.

  When molds for injection molding are made, die geometry is taken into consideration because of the possibility of material shrinkage. Rheological calculations are carried out using preprocessors (e.g., Moldflow, Cadmould 3D). The set-up of the tools takes place using catalogs provided by the machine manufacturer. Subsequently, NC data are generated for the part shape and machining plates.

  With complete product models, simulation and robot programming can take place for the various manufacturing processes. The programming and simulation take place offline. The programs generated are then sent on to the robots for execution of the process.

Only through comprehensive integration of the complete virtual product development process, with the many different working steps, can the existing potential for development time, costs, and overall productivity be optimized (VDI-EKV 1992, Krause 1992).

2.2. CAD Interfaces

2.2.1. General Explanations

Despite the lack of a clear definition for the term *interface,* its use has become quite frequent. In general, an interface can be defined as a link forming a common boundary between integrating systems. It is a system of conditions, rules, and agreements that defines the terms of information exchange between communicating systems or system components (Anderl 1993).

CAD interfaces interconnect internal CAD system components and provide a link to other software and hardware components. They connect internal CAD system components such as geometrical modeling, object representation, and realization of calculation operations to a CAD database and standardized CAD files.

CAD interfaces can be classed as device interfaces (hardware interfaces) and software interfaces (Grabowski and Anderl 1990) or, alternatively, as internal and external interfaces. Internal interfaces provide links within the application environment, enabling the exchange of information between other system programs or ensuring undisturbed communication with the user. External interfaces require a common or uniform representation of the information to be exchanged. They transmit product data, by means of graphical peripheries, to the user. The standardization of external interfaces is of special importance for the transmission of product data. Because of the exchange of data between various CAD systems, uniform data formats are required.

In Figure 11, CAD components and interfaces are displayed.

From an application in use, access to the product data and methods of a CAD system is provided through application interfaces. In the course of using a CAD system through a standardized interface, the integration of such an external application interface becomes increasingly important. Standardized application interfaces allow access to the methods employed by the various CAD systems.

Product data represent all data such as geometry, topology, technological information and organizational data to define the product. This data is generated during the design process, enhanced by the application and then internally mapped.

2.2.2. Standardization of CAD Interfaces

The primary objectives for the standardization of interfaces are:

- The unification of interfaces
- The prevention of dependencies between system producer and user
- The prevention of repeated working of redundant data

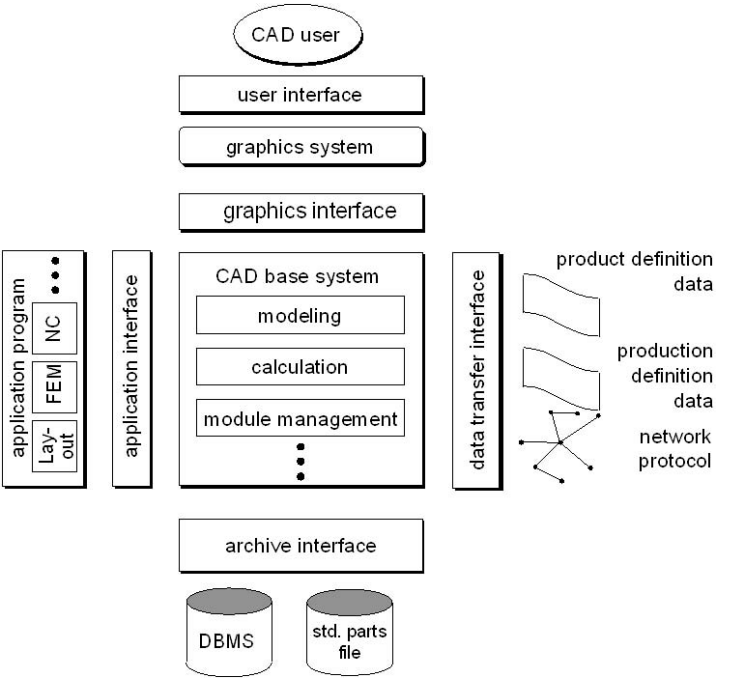

Figure 11 CAD Components and Interfaces.

The standardization of interfaces leads to the following advantages (Stanek 1989):

- The possibility of an appropriate combination of system components
- Selection between various systems
- Exchange of individual components
- Expandability to include new components
- Coupling of various systems and applications
- Greater freedom in the combining of hard and software products

2.2.2.1. Interfaces for Product Data Exchange The description of product data over the entire product life cycle can be effectively improved through the use of computer-supported systems. For this reason, uniform, system-neutral data models for the exchange and archiving of product data are desired. These enable the exchange of data within CAD systems and other computer-aided applications.

The internal computer models must be converted into one another through so-called pre- and postprocessor conversion programs. To minimize the costs of implementing such processors, a standardized conversion model is applied. The conversion models standardized to date are still of limited use because they can only display extracts of an integrated product model. Interfaces such as

- initial graphics exchange specification (IGES)
- standard d'echange et de transfert (SET)
- Verband der Automobilindustrie-FlächenSchnittstelle (VDA-FS)

have been designed and to some extent nationally standardized for geometry data exchange, mainly in the area of mechanical design (Anderl 1989).

IGES is recognized as the first standardized format for product-defined data to be applied industrially (Anderl 1993; Grabowski and Anderl 1990; Rainer 1992). The main focus is the transfer of design data. IGES is for the mapping of:

- 2D line models
- 3D wire models
- 3D dimensional surface models
- 3D solid models
- Presentation models for technical drawings

Considering the further demands on CAD/CAM systems, the integration of additional data in IGES format has been realized. Examples are the data for FEM, factory planning, and electronic/electrical applications.

The interface standard VDA-FS was developed by the German Automotive Industry Association for the transfer of CAD free-form surface data. VDA-FS is standardized and described in Standard DIN 66301 and has proven efficient for use in many areas, but its efficiency has been demonstrated principally in the German automotive industry (Grabowski and Glatz 1986; Nowacki 1987; Scheder 1991).

The STEP product model (Standard for the Exchange of Product Model Data) offers the only standardized possibility for efficiently forming the product data exchange and system integration in the CAx world (Wagner and Bahe 1994).

With the development of ISO 10303 (Product Data Representation and Exchange), also called STEP, the objective is to standardize a worldwide accepted reference model for the transfer, storage and archiving, and processing of all data needed for the entire product life cycle (Anderl 1993; Düring and Dupont 1993; Krause et al. 1994; McKay et al. 1994).

STEP can be seen as a toolbox for describing application-oriented product information models using basic elements, so-called integrated resources, while considering previously defined rules and standardized methods (Holland and Machner 1995).

ISO 10303 can be subdivided into:

- Generic and application-oriented information models
- Application protocols
- Methods for specification and implementation
- Concepts for examination and testing

Independent application specifications are referred to as generic models. An overview of the series is as follows (Figure 12):

- Series 0: fundamentals, principles
- Series 10: description or specification methods
- Series 20: implementation methods
- Series 30: test methods and criterion
- Series 40: application-independent base models
- Series 100: application-dependent base models
- Series 200: application protocols
- Series 300: abstract test methods
- Series 500: application-specific, interpreted design

The core of consists of information models in which the representational form of the product data is defined. Information models can be broken down into three categories: generic resources, application-related resources, and application protocols. Similar to a toolbox system, the generic resource models define application-independent base elements that may be used in application-specific resources or directly in application protocols. An example is geometrical information, which is required in most application models. Application-related resources are especially tailored to the demands of specific branches but also serve for the definition of application protocols. Application protocols form implementable parts for STEP. They define a section of the information structure that is needed to support a specified application.

The description methods used for defining the information structure, validation, and test methods as well as implementation methods are standardized. The object-oriented modeling language EXPRESS as well as its graphical form EXPRESS-G are implemented for the presentation of the information structures (Scholz-Reiter 1991). Validation and test methods define the specifications with which the STEP processors are examined. The following elements are included in partial models of the generic resources:

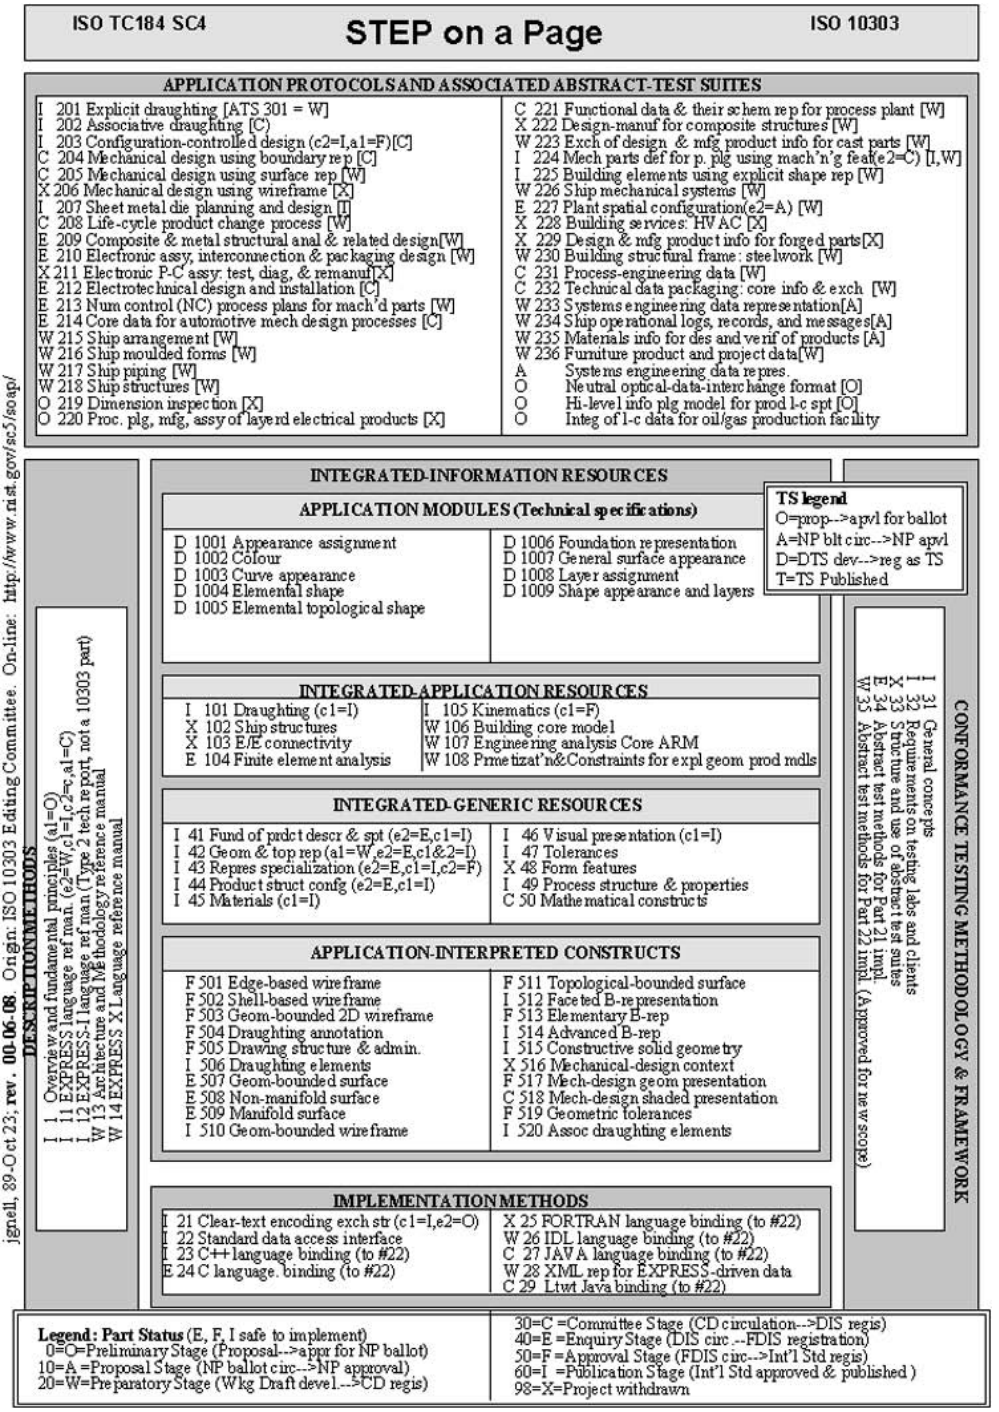

Figure 12 Overview of the ISO 10303 Structure.

- Base model
- Geometric and topological model
- Tolerance model
- Material model
- Product structure model
- Representation model and
- Process model

The significance of STEP goes much further than the exchange and archiving of product models. The innovative character of STEP development sets new standards for CAD systems. The functional requirements for new systems stem from partial models such as tolerance, form/feature, or PSCM models. In certain circumstances, STEP may be considered a reference model for the internal computer representation of CAD systems.

2.3. Engineering Data Management

Engineering data management (EDM, also an abbreviation for electronic document management or enterprise data management) is data modeling of a complete enterprise. In other words, the data modeling goes beyond the intrinsic product data. A common synonym for EDM is ''product data management'' (PDM), in which emphasis is put on the handling of product-related engineering data. *Engineering data management* was coined as a broader term. All definitions combined provide the perception that EDM is the management and support of all information within an enterprise at any point in time (Ploenzke 1997).

For the support of data modeling within a company, software systems, so-called EDM systems, exist. With these systems, various tasks are carried out depending on the product, company, and level of integration, such as the management of (Kiesewetter 1997):

- Drawing data
- CAD model data
- Parts lists
- Standard libraries
- Project data
- NC data
- Software
- Manufacturing plans
- Tools and equipment production facilities

In addition, EDM systems serve for classification and object parameter management. Generally, EDM systems provide a set of specific functions for the modeling of product and process data. Because of their specific origins, the various EDM systems focus on a variety of main functions and strengths, but all provide a basic functionality for document management as well as functions for the support of change, version, and release management. The complete functionality of an EDM system as a central information system for the product development process is made up of a broad spectrum of functions. These functions can be broken down into application-related and system-overlapping functions (Ploenzke 1997).

- *Application-related functions:* The main priority for an EDM system is the management of all product data and documentation. Application-related functions provide task-specific support of the data management. Classical data management functions such as additions, modifications, and deletions are extended to integrate additional capabilities. For example, in the case of drawing management, automatic extraction of metadata from the CAD drawing header is implemented in the EDM database or used for classification of the components.
- *System-overlapping functions:* Data and document management requires an application-neutral infrastructure that provides functions for an organized handling of the management processes. These overlapping system and application functions support the data and document management through functions created for variant and version management and ensuring the editing status of the document. Also, these functions support the provision of central services such as user management, privacy, and data protection.

Support provided by the use of an EDM system is aimed at the integration of the information flow and processes into the business processes. Integration and transparency are the essential aspects

for the EDM system to process every demand and provide the right information at the right time. The storage, management, and provision of all product-related data create the basis for:

- The integration of application systems for technical and commercial processes as well as for office systems in a common database
- The task-oriented supply of all operations with actual and consistent data and documentation
- The control and optimization of business processes

Metadata are required for the administration of product data and documentation, enabling the identification and localization of product data. Metadata represent the information about the creator, the data of generation, the release status, and the repository. The link between all relevant data is made by the workflow object, which is a document structure in which documents of various formats are filled out along a process chain. This structure is equivalent to part of the product structure and, after release, is integrated into the product structure. In general, this is the last step of a workflow.

The modeling and control of a process chain are the task of the workflow management, whereas access control is the task of document management. The users concerned in the workflow are managed by groups, roles and rights. The systems applied are integrated in the EDM system. Linking a special document with the editing system is the responsibility of the document management program.

2.4. Architecture and Components

The reference architecture, from Ploenzke (1997) (Figure 13) describes the individual components of an EDM system from a functional point of view and illustrates the connections between the respective system components.

The core of the reference architecture is the engineering data. The application-oriented and system-overlapping functions are applied to the core data. The engineering data are found within the model data and broken down into product-defined data and metadata. Model data, such as drawing data, parts lists, text files, raster data from document, and data in other formats, are not interpreted by the EDM system but are still managed by the EDM System. Metadata is interpreted by the EDM system and contains information regarding the management and organization of the product data and documents.

The application-oriented functions support the management of the model data. Although the model data may be made up of various kinds of data, the management of these data, with the help of application oriented functions, must be able to summarize the data logically in maps and folders. Also, relationships between the documents and product data can then be determined. Important application-oriented functions are (Ploenzke 1997):

- General data management
- Drawing data management

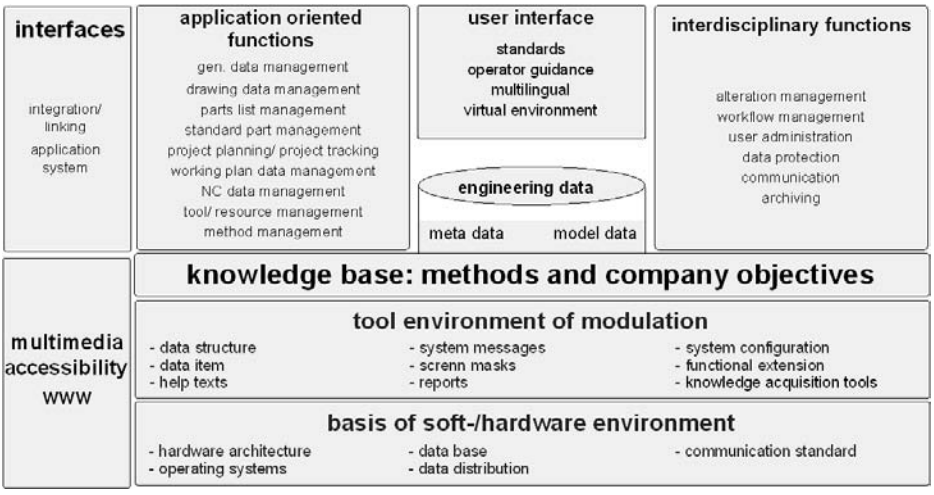

Figure 13 Reference Architecture of an EDM System. (From Ploenzke 1994. Reprinted by permission of CSC Ploenzke.)

- Classification
- Parts list management
- Standard parts management
- Project planning and management
- Production plan management
- NC data management
- Machine tool and equipment management
- Method management

System-overlapping functions support the business processes over numerous steps, such as change and workflow management. Furthermore, central system services such as user management and data security are provided. Important system-overlapping functions are (Ploenzke 1997):

- Change management
- Workflow management
- User administration
- Data security
- Data protection
- Communication
- Archiving

Besides the core components of the reference architecture, the following system components belong to the system environment (Ploenzke 1997):

- User interface
- Machine environment
- Interfaces
- Basic software and hardware environment

The user interface forms the direct interface to the user and thus must provide the look and functions desired by the user. The application environment provides methods for customizing the interface. This allows the adaptation of the EDM system to company-specific conditions and for maintenance of the system. Programming interfaces known as application procedural interfaces (APIs) enable the launching and integration of application modules for the functional extension of an EDM system. The basic software and hardware environment forms the respective operation platform of an EDM system. With the status of the technology today, client–server-based EDM systems come into operation with connecting databases. These provide the various users with the necessary client programs, increasing the economical utilization of today's workstations (Krause et al. 1996).

EDM can also be termed an enabling technology. The reference architecture is an integration platform for systems, functions, and data. Company-specific conditions and a dynamic control process, however, cause the transformation of each EDM system installation into an almost nontransferable case. Nevertheless, the EDM reference architecture forms the basis of system integration for CAD integration, PPS coupling, or archiving, regardless of the company-specific focus.

The necessity for integration and transparency of the data leads to the broad scope of functionality enabled by an EDM system. The primary functions are combined in numerous modules. The level of performance of the individual modules varies from system to system and is determined by the company philosophy and strengths of the supplier (Figure 14).

Many functions that serve for the basic control of data in the EDM already stem from other systems such as CAD or PPS systems. These functions are combined in the EDM system and make feasible the creation and management of an information pool. This supports company-wide availability and enables faster information searches (Figure 15). The information pool, known as the vault, is a protected storage area that enables the availability of all documents and ensures that no unauthorized access occurs. Access to documents held in other systems is possible through logins to the various systems. After logging off, the document is available only in a read-only form. Therefore, logging off copies the document to local memory. Logging in and opening a changed document is associated with the saving of a new version of the document. All customary EDM systems on the market are able to manage a centralized or decentralized vault.

2.5. Calculation Methods

2.5.1. General Explanation

Increasing demands for product performance necessitates a secure component configuration. The factor of safety is determined by calculations performed on the system. The following goals should be achieved:

- Assurance against failure
- Testing of product functionality
- Assessment of external effects
- High strength-to-weight ratio
- Optimal material utilization
- Achievement of an economical production process

The most important computer-supported calculation processes are:

- Finite element methods (FEM)
- Boundary element methods (BEM)
- Finite different methods (FDM)

These methods can be applied for problems in which differential equations describe any continua. The methods have different approaches for performing calculations. FEM assumes a variational formulation, BEM a formulation by means of integrals, and FDM uses differential equations. Due to the mathematical formulation, it is irrelevant whether the computational problem comes from mechanics, acoustics, or fluid mechanics. In all three methods, the discretization of the structure is common and is required in order to derive the mathematical formulations for the desired tasks.

The processes commercially available have integrated interfaces that enable them to work with geometries already developed in CAD systems. To prepare the geometry model, various support mechanisms for the particular calculation systems are offered.

Beyond FEM, BEM, and FDM, there are other calculation systems that are based on problem-specific model creation. These systems, however, are usually applied only in conjunction with an associated model. Two examples are the calculation of suspensions and the determination and layout of weld contacts.

The general sequence of a calculation is equivalent to that of an information handling process. Input in the form of the geometry, material, and forces is transformed using mathematical and physical rules to calculated results. In the majority of cases, the object geometry and material properties are simplified. Also, the stress–strain or loading characteristics are often idealized, which eases the calculation task and reduces time. In many cases assumptions and simplifications are made because otherwise the calculation of the problem might be too extensive or impossible.

2.5.2. Finite Element Methods

FEM is the most commonly used calculation process today. Their implementation spectrum covers many different areas. For example, they are applied in:

- Statics in civil engineering
- Crash research in the automotive industry
- Electromagnetic field research for generator design
- Material strength and life cycle determination in mechanical engineering
- Bone deformation in biomechanics

FEM has found its place in the field of structural mechanics. It is used for calculations in:

- Stress and deformation
- Natural shape and eigenfrequency
- Stability problems

Because complex structures, in respect to their mechanical or thermal behavior, are no longer solvable analytically, the structure must be broken down into smaller elements. The FEM process enables the breakdown of a larger structure into elements, thus enabling the description of component behavior. Therefore, very complex entities are solvable. Calculation problems from real-world appli-

cations are usually quite complex. For example, in crash testing it is necessary to reproduce or simulate the complete vehicle structure even when it consists of many different components and materials (Figure 16).

The finite elements are described geometrically using a series of nodes and edges, which in turn form a mesh. The formation of the mesh is calculable. The complete behavior of a structure can then be described through the composition of the finite elements.

An FEM computation can be divided into the following steps:

- Breakdown of the structure into finite elements
- Formulation of the physical and mathematical description of the elements
- Composition of a physical and mathematical description for the entire system
- Computation of the description according to requirements
- Interpretation of the computational results

The FEM programs commercially available today process these steps in essentially three program phases:

1. *Preprocessing:* Preparation of the operations, mesh generation
2. *Solving:* Actual finite element computation
3. *Postprocessing:* Interpretation and presentation of the results

Preprocessing entails mainly geometric and physical description operations. The determination of the differential equations is implemented in the FEM system, whereby the task of the user is limited to selecting a suitable element type.

In the following sections, the three phases of an FEM computation will be presented from a user's point of view.

2.5.2.1. FEM Preprocessing The objective of the preprocessing is the automation of the meshing operation. The following data are generated in this process:

- Nodes
- Element types
- Material properties
- Boundary conditions
- Loads

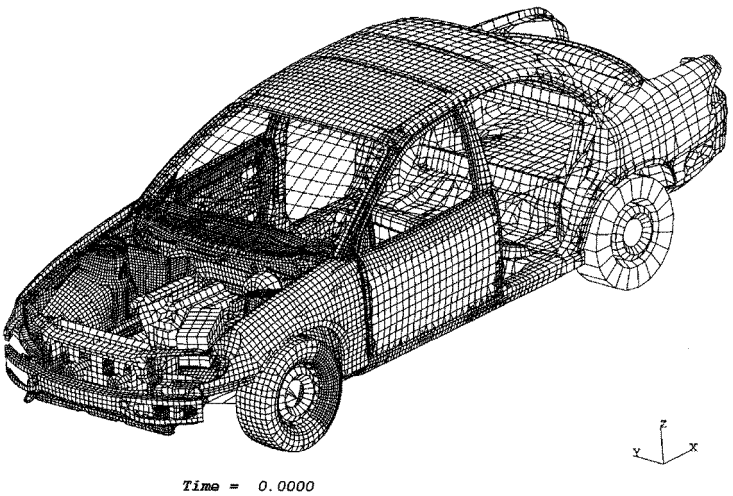

Figure 16 Opel Omega B Crash Model, 76,000 elements. (From Kohlhoff et al. 1994. Reprinted by permission of VDI Verlag GmbH.)

The data sets may be generated in various ways. For the generation of the mesh, there are basically two possibilities:

- Manual, interactive modeling of the FEM mesh with a preprocessor
- Modeling of the structure in a CAD system with a subsequent automated or semiautomated mesh generation

The generation of the mesh should be oriented towards the expected or desired calculation results. This is meaningful in order to simplify the geometry and consider a finer meshed area sooner in the FEM process. In return, the user must have some experience with FEM systems in order to work efficiently with the technology available today. Therefore, completely automatic meshing for any complex structure is not yet possible (Weck and Heckmann 1993).

Besides interactive meshing, commercially available mesh generators exist. The requirements of an FE mesh generator also depend on the application environment. The following requirements for automatic mesh generators, for both 2D and 3D models, should be met (Boender 1992):

- The user of an FE mesh generator should have adequate control over the mesh density for the various parts of the component. This control is necessary because the user, from experience, should know which areas of the part require a higher mesh density.
- The user must specify the boundary conditions. For example, it must be possible to determine the location of forces and fixed points on a model.
- The mesh generator should require a minimum of user input.
- The mesh generator must be able to process objects that are made up of various materials.
- The generation of the mesh must occur in a minimal amount of time.

The mesh created from the FE mesh generator must meet the following requirements:

- The mesh must be topologically and geometrically correct. The elements may not overlap one another.
- The quality of the mesh should be as high as possible. The mesh can be compared to analytical or experimental examinations.
- Corners and outside edges of the model should be mapped exactly using suitable node positioning.
- The elements should not cut any surfaces or edges. Further, no unmeshed areas should exist. At the end of the mesh refinement, the mesh should match the geometrical model as closely as possible. A slight simplification of the geometry can lead to large errors (Szabo 1994).
- The level of refinement should be greater in the areas where the gradient of the function to be calculated is high. This is determined with an automatic error estimation during the analysis and provides a new point for further refinement.

Various processes have been developed for automatic mesh generation. The motivation to automate the mesh generation process results from the fact that manual generation is very time consuming and quite prone to mistakes. Many processes based on 2D mesh generation, however, are increasingly being suggested for 3D processes.

The most frequently used finite element forms for 2D are three- and four-sided elements and for 3D are tetrahedrons and hexahedrons. For automatic mesh generation, triangles and tetrahedrons are suitable element shapes, whereas hexahedrons provide better results in the analysis phase (Knothe and Wessels 1992).

2.5.2.2. FEM Solution Process In the solution process, equation systems are solved that are dependent on the type of examination being carried out. As a result, various algorithms must be provided that allow for efficient solution of the problem. The main requirements for such algorithms are high speed and high accuracy.

Linear statistical examinations require only the solution of a system of linear equations. Dynamically nonlinear problems, on the other hand, require the application of highly developed integration methods, most of which are based on further developments of the Runge–Kutta method.

To reduce the computing time, matrices are often converted. This permits a more effective handling of the calculations. The objective is to arrange the coefficients with a resulting diagonal matrix. An example of an FEM calculation sequence is shown in Figure 17.

2.5.2.3. FEM Postprocessing Because the calculation results of an FEM computation only deliver nodes and their displacement and elements with the stresses or eigenforms in numerical rep-

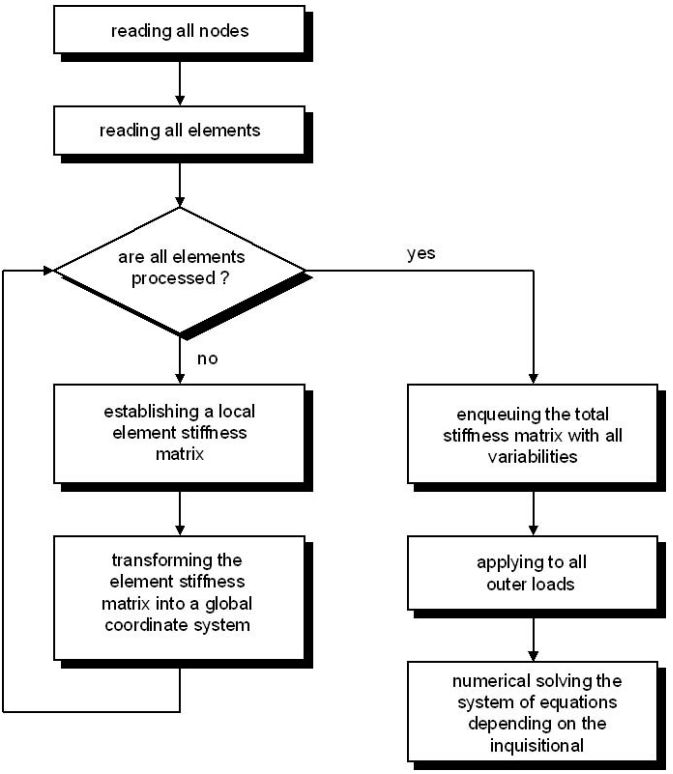

Figure 17 Sequence of a Finite Element Calculation.

resentation, postprocessors are required in order to present the results in a graphical form (Figure 18).

The postprocessing manages the following tasks:

- Visualization of the calculated results
- Plausibility control of the calculation

The performance and capability of postprocessors are constantly increasing and offer substantial presentation possibilities for:

- Stress areas and main stresses
- Vector fields for forces, deformation and stress characteristics
- Presentation of deformations
- Natural forms
- Temporary deformation analysis
- Temperature fields and temperature differences
- Velocities

It is possible to generate representations along any curve of the FEM model or, for example, to present all forces on a node. Stress fields of a component can be shown on the surface or within the component. The component can thus be reviewed in various views.

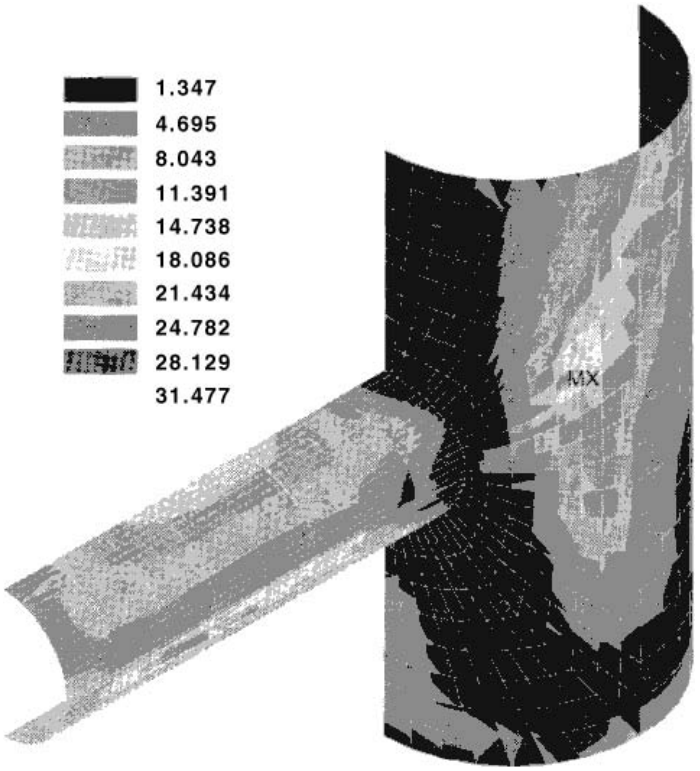

Figure 18 FEM Postprocessing Resulting from a Standard Pipe Formation. (From CAD-FEM 1995)

3. CONCEPTS

3.1. Process Chains

A process chain is a set of rules or steps carried out in a specific order in order to carry out the completion of a defined process. Processes can be executed either in sequence or in parallel. A typical example of a product development process chain is portrayed in Figure 19.

A process chain is characterized as:

- A process, divided into subtasks, in which contributions to the creation of virtual products take place
- A series of systems in which computer support for product-related subtasks is guaranteed
- A series of systems for organized support of the complete proces
- Mechanisms for the adequate exchange of data between systems

Computer support of process chains is related, on one hand, to the processing and management of product data and, on the other hand, to the organization of the supported process and the handling of associated data.

The processing and management of product data entail all tasks that concern the generation, storage, transfer, and function-related editing and provision of data (Reinwald 1995).

General classification of process chains suggests a determination of the depth of integration of the product data handling. Classification can be divided into:

- Coupled/linked process chains
- Integrated process chains
- Process chains with common data management

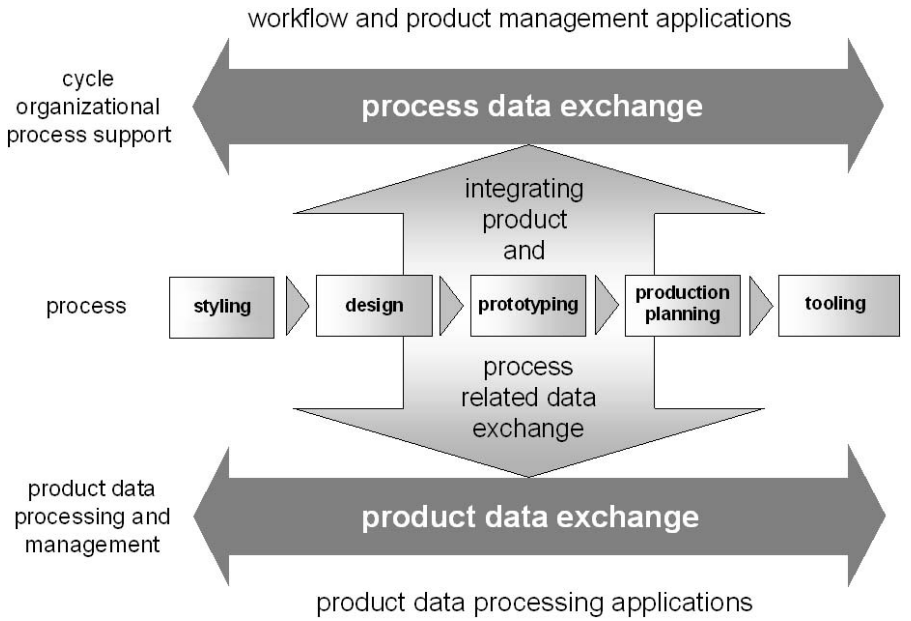

Figure 19 Layout of a Computer-Supported Process Chain.

The exchange of data within a coupled process chain takes place directly between the supporting systems. Thereby, information transferred between two respective systems is aided with the help of system-specific interfaces. This realization of information transfer quickly reaches useful limits as the complexity of the process chains increases. This is because the fact that the necessary links grow disproportionately and the information from the various systems is not always transferable (Anderl 1993).

Characteristic of integrated process chains is a common database in the form of an integrated product model that contains a uniform information structure. The information structure must be able to present in a model all relevant product data in the process chain and to portray the model with the use of a homogenous mechanism. A corresponding basis for the realization of such information models is offered by the Standard for the Exchange of Product Model Data (ISO 10303—STEP) (ISO 1994).

Basic to a process chain with common product data management based on an EDM system is the compromise between coupled and integrated process chains. With the use of common data management systems, organizational deficiencies are avoided. Thus, the EDM system offers the possibility of arranging system-specific data in comprehensive product structures. The relationship between documents such as CAD models and the respective working drawing can be represented with corresponding references. A classification system for parts and assemblies aids in locating the required product information (Jablonski 1995).

On the other hand, with joint product data management, conversion problems for system-specific data occur in process chains based on an EDM system. These problems exist in a similar form in coupled process chains. This makes it impossible to combine individual documents into an integrated data model. References within various systems, related to objects within a document rather than the document itself, cannot be made.

Besides requiring support for the processing of partial tasks and the necessary data transfer, process chains also require organized, sequential support. This includes planning tasks as well as process control and monitoring. Process planning, scheduling, and resource planning are fundamental planning requirements.

The subject of process planning involves segmenting the complete process into individual activities and defining the sequence structure by determining the order of correlation.

In the use of process plans, the following points are differentiated:

- One-time, detailed process planning (all processes are executed similarly)
- Case-by-case planning of individual processes

- One-time, rough planning of a generic process, followed by deeper detailing and specification of individual processes.

The first basic approach is typical for the majority of commercial work flow management systems. Because these systems are intended for routine tasks, their application is unproblematic only when they concern the support of completely determinable processes. Product development processes are characterized by the fact that their achievements are not precisely predictable in advance. For that reason they are treated as nondeterministic processes.

The second approach requires an independent sequence for each process path. This corresponds to the generation of a network plan using methods such as CPM (critical path method), MPM (metra potential method), and PERT (program evaluation and review technique). These techniques, as part of the project management, are employable for activities such as proper scheduling (Burghardt 1988).

The third approach involves the strategic use of rough supplementary outlines of generic processes with those of detailed, individual processes. A requirement for successful implementation of the strategy is the ability of the supporting system to map process structures hierarchically.

For scheduling, a closed sequence plan is assumed to exist. The activities and correlations must be determined beforehand. Therefore, the minimum task of the scheduling part of the process is the calculation and determination of time limits, critical paths, and buffer times. The CPM, MPM, and PERT methods are implemented for this purpose, and the incorporation of these operations leads to the calculation of complete process and buffer times using both forward and backward calculations.

The duration of a procedure depends significantly on the use of resources required for fulfilment of the process. In this respect, interaction exists between the scheduling and capacity planning (Burghardt 1988).

Capacity planning for the product-development process involves proper quantity and time allocation of coworkers, application system capacities, and other partial tasks of an individual process (Golm 1996). Therefore, the goal of capacity planning is to ensure the on-schedule processing of the entire process and the uniform utilization of resources.

3.1.1. Tasks of Process Control and Monitoring

The task of process control and monitoring is to guarantee the fulfilment of the process based on the sequence, schedule, and capacity planning determinants. The following individual tasks must then be resolved:

- Activation of processable actions
- Process monitoring of contents
- Process monitoring of time

3.2. Integrated Modeling

Modeling of virtual products includes all phases of the product life cycle, from product planning to product disposal. The aim is complete integration of all the development processes for efficient product development.

The following system characteristics are strived for through the integration of design and production planning systems:

- Increased productivity during product development
- Acceleration of the product development process
- Improvement of product and technical documentation quality

An increase in the productivity of product development phases through the integration of design and manufacturing plans is based on preventing the loss of information. A loss of information often occurs between coupled and unrelated systems because of integration difficulties. With a lack of proper integration, detection and editing of data take place numerous times for the same information content. Therefore, using product models derived from information within both the design and manufacturing data, it is possible to integrate specific work functions. The models then serve as a basis for all system functions and support in a feature approach-type form.

The feature approach is based on the idea that product formation boundaries or limits are explicitly adhered to during design and production planning stages. This ensures that the end result of the product envisioned by the designer is not lost or overlooked during the modeling phase. To realize the form and definition incorporated by the designer in a product, it is essential that an integrated design and production planning feature exist.

Accelerating the product development process is achievable through the minimization of unnecessary data retrieval and editing. Efforts to parallel the features of concurrent engineering tasks require integrated systems of design and production planning.

Higher product and documentation quality is achievable with the use of integrated systems. Through integration, all functions of a product model are made available to the user. Any errors that may occur during data transmission between separate systems are avoided.

Because of the high responsibility for cost control during product development, estimates for design decisions are extremely necessary. Cost estimates reveal the implications of design decisions and help in avoiding costly design mistakes. For effective estimation of costs to support the design, it is necessary to be able to access production planning data and functions efficiently. Integrated systems provide the prerequisites for the feedback of information from the production planners to the designers, thus promoting qualitatively better products. The following forms of feedback are possible:

- Abstract production planning experience can be made available to the designer in the form of rules and guidelines. A constant adaptation or adjustment of production planning know-how has to be guaranteed.
- Design problems or necessary modifications discovered during the production planning phases can be directly represented in an integrated model.
- Necessary modifications can be carried out in both production planning and design environments.

3.3. Methodical Orientation

The virtualization of product development is a process for the acquisition of information in which, at the end of the product development, all necessary information generated is made available. Assuming that humans are at the heart of information gathering and that the human decision making process drives product development, the virtual product-creation methods must support the decision maker throughout the product creation process.

Product-creation processes are influenced by a variety of variables. The form the developed product takes is determined by company atmosphere, market conditions, and the designer's own decisions. Also influential are the type of product, materials, technology, complexity, number of model variations, material costs, and the expected product quantity and batch sizes.

Product development is not oriented toward the creation of just any product, but rather a product that meets the demands and desires of the consumer while fulfilling the market goals of the company. The necessary mechanisms must provide a correlation between the abstract company goals and the goals of the decisions made within the product development process. For example, to ensure the achievement of cost-minimization objectives, product developers can use mechanisms for early cost estimation and selection, providing a basis for the support of the most cost-effective solution alternatives (Hartung and Elpet 1986). To act upon markets characterized by individual consumer demands and constant preference changes, it is necessary to be able to supply a variety of products within relatively short development times (Rathnow 1993; Eversheim 1989). This means that product structuring must take into account the prevention of unnecessary product variation and that parallel execution of concurrent engineering is of great importance.

Methods that are intended to support the product developer must be oriented toward not only the contents of the problem but also the designer's way of thinking. Therefore, a compromise must be made between the methodical problem solving strategy and the designer's creative thought process.

The product-development methods can be separated into process-oriented and product-oriented categories. The main concern in process-oriented product development is the design. The objective is the indirect improvement of the design or, more precisely, a more efficient design process. Product-oriented methods concern the product itself and the direct improvement of the product.

Various process-oriented methods are discussed below. Fundamental to VDI 2221 guidelines is the structuring of the product-development process into partial processes or phases. This structuring takes place independently of the developed product, the company, market conditions, and the decision maker. The demand for a general strategy results in individual steps being described at very abstract levels. Consideration of product, company, and market-related influences is incorporated into the design throughout all processes. The impact of individual influences on methods can only be clarified with examples. The worth of a new method lies in the general systemizing of the product development process. This method is not suitable for immediate derivation of concrete product development processes. Rather, it describes an ideal, flexible product-development process. The structure and content of the development process are then molded by the product, company, or market-related influences (VDI-Gesellschaft Entwicklung Konstruktion 1993).

Another example of process-oriented methods is the concurrent engineering method, which covers all topics from product development to equipment and production planning. The primary objective of simultaneous engineering is the reconfiguration of the development process, with the intention of reducing development time while improving product quality. As opposed to the traditional approach, in which a series of steps is followed and feedback occurs through long loops, the development tasks

within concurrent engineering allow for the parallel execution of many tasks. Therefore, development times are substantially reduced and the old system of following predetermined steps is avoided. This concept relies heavily on the exchange of information between the various departments. This should extend beyond company boundaries to include the equipment manufacturer in order to tie production equipment planning into the product development process. The main focus in the implementation of these methods, besides the use of computer aided technology, is the reorganization of the company structure. In the foreground are measures to stimulate the exchange of information, such as the formation of interdisciplinary teams (Eversheim et al. 1995; Krause et al. 1993; Bullinger and Warschat 1996).

The design-to-cost method is a product-development approach that bases design decisions on cost-sensitive criteria. Here, evaluation standards are not only production costs but also the costs incurred throughout the life of the product. This method is particularly applicable for complex products with relatively long life cycles. The method is broken down into target costing, cost-oriented design, and cost control. Within target costing, a goal for final costs is broken down for individual product components. The final cost is determined from the results of a market analysis or from a clear depiction of customer demands. Relative cost and manufacturing cost data can be used to aid the development of design alternatives that fall within the early cost-oriented design process. With the aid of cost estimate models, the life cycle costs of each alternative are assessed and the most cost effective variant selected. In the area of cost control, the design costs are compared to and contrasted with the original end cost objective. If the cost objective is not met, deviation analyses are necessary to determine required alternatives.

Product-oriented techniques are characterized by product formation, task formulation, and the objectives pursued. Product-oriented tasks vary considerably, according to the multitude of products and tasks. A few examples of these techniques and technique groupings are presented later in this chapter.

Design rules and guidelines specify how a product is designed according to previously determined objectives. Well-known design rules and guidelines exist particularly for production, assembly, ergonomic, and logistics-oriented processes as well as resource-efficient and recycling-oriented product design (Pawellek and Schulte 1987; Krause 1996; Pahl and Beitz 1993; Kriwet 1995).

Simulation technology has become important in the field of product development. The primary objective in the implementation of simulation technology is the early acquisition of information on product characteristics before the product even exists. The knowledge gained aids in the assessment of the respective development results. Costly and time-consuming mistakes during development phases can be recognized early and avoided. Through an iterative strategy, it is also possible to optimize systematically particular product characteristics or qualities (Frepoli and Botta 1996; Schönbach 1996).

One requirement for the application of simulation techniques is the creation of a model, which allows for the investigation and breakdown of real product tasks. With the use of computers, it is possible to design complex models that allow answers to relevant design questions to be found. These models were previously realizable only through the tedious production of prototypes. The application of simulation technology is especially helpful when numerous product variations must be considered, a situation not economically feasible with prototypes.

In the future, systems must be able to provide all relevant information in the user-desired form and make additional mechanisms available that reveal the consequences of a decision made during product development. The provision of information must include not only product specific data but also comprehensive information. Data covering all topics from design guidelines and rules to design, solution, and measurement catalogs to company individual knowhow is necessary. Solutions developed for similar products need to be accessible not only in general form but in a form that takes product-related tasks and context into account.

3.4. Rapid Prototyping

Due to the ever-increasing demand for shorter product development cycles, a new technology known as rapid prototyping (RP) has emerged. RP is the organizational and technical connection of all processes in order to construct a physical prototype. The time required from the date the order is placed to when the prototype is completed can be substantially reduced with the application of RP technology (Figure 20).

RP is made up of generative manufacturing processes, known as RP processes, and conventional NC processes as well as follow-up technologies. In contrast to conventional working processes, RP processes such as stereo lithography, selective laser sintering, fused deposition modeling, and laminated object manufacturing enable the production of models and examples without the use of forming tools or molds. RP processes are also known as free-form manufacturing or layer manufacturing.

Prototypes can be divided into design, function, and technical categories. To support the development process, design prototypes are prepared in which proportion and ergonomic models are

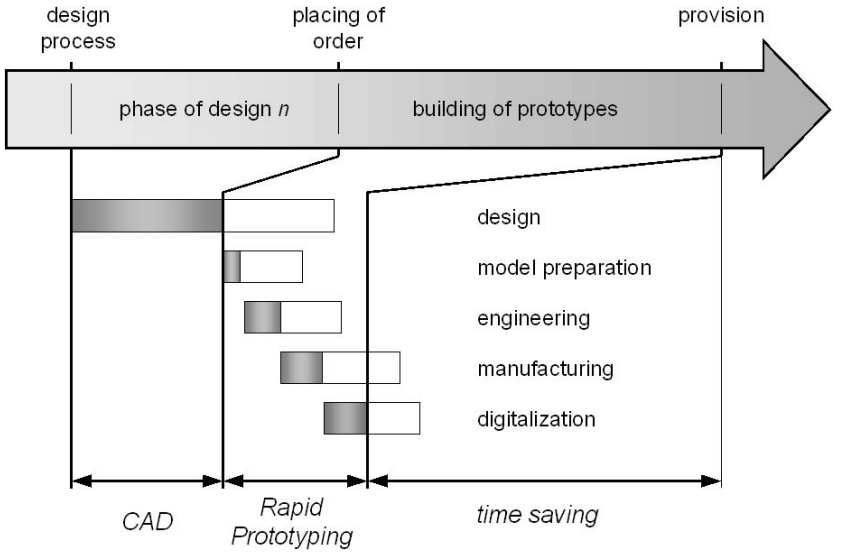

Figure 20 Acceleration Potential through CAD and RP Application.

incorporated. Design prototypes serve for the verification of haptic, esthetic, and dimensional requirements as well as the constructive conception and layout of the product. RP-produced examples are made from polycarbonates, polyamides, or wood-like materials and are especially useful for visualization of the desired form and surface qualities.

For function verification and optimization, a functional product example is required. The application of production series materials is not always necessary for this purpose. Functional prototypes should, however, display similar material strength characteristics. On the other hand, technical prototypes should be produced using the respective production series materials and, whenever possible, intended production line equipment. The latter serve for purposes such as customer acceptance checks and the verification of manufacturing processes.

Prototypes can be utilized for individual parts, product prototypes, and tool prototypes. Normally, product prototypes consist of various individual prototypes and therefore require some assembly. This results in higher levels of dimension and shape precision being required.

The geometric complexity represents an essential criterion for the selection of the suitable prototype production process. If, for example, the prototype is rotationally symmetric, the conventional NC turning process is sufficient. In this case, the presently available RP processes provide no savings potential. However, the majority of industry-applied prototypes contain complex geometrical elements such as free-form surfaces and cut-outs. The production of these elements belongs to some of the most demanding tasks in the area of prototype production and is, because of the high amount of manual work involved, one of the most time-consuming and cost-intensive procedures. RP processes, however, are in no way subjected to geometrical restrictions, so the build time and costs of producing complex geometrical figures are greatly reduced (König et al. 1994).

Another criterion for process selection is the required component measurements and quality characteristics such as shape, dimensional accuracy, and surface quality.

3.4.1. Systemization of Rapid Prototyping Processes

With the implementation of CAD/CAM technology, it is possible to produce prototypes directly based on a virtual model. The generation of the geometry using RP processes takes place quickly without the requirement of molds and machine tools. The main feature of the process is the formation of the workpiece. Rather than the conventional manufacturing process of a clamped workpiece and material removal techniques, RP processes entail the layering of a fluid or powder in phases to form a solid shape.

Using CAD models, the surfaces of the components are fragmented into small triangles through a triangulation process. The fragments are then transformed into the de facto RP standard format known as STL (stereo lithography format). The STL format describes the component geometry as a closed surface composed of triangles with the specification of a directional vector. Meanwhile, most

CAD systems now provide formatting interfaces as part of the standard software. Another feature of this process is that CAD-generated NC code describing the component geometry allows for a slice process in which layers of the object may be cut away in desired intervals or depths.

Starting with the basic contour derived from the slicing process, the workpiece is subsequently built up in layers during the actual forming process. Differences exist between the RP processes in process principles and execution.

RP processes can be classified by either the state of the raw material or the method of prototype formation. The raw materials for RP processes are in either fluid, powder, or solid states (Figure 21). As far as the method of prototype creation, the component forming can either be processed into direct, 3D objects or undergo a continuous process of layers built upon one another (Figure 22).

3.5. Digital Mock-up

Today the verification and validation of new products and assemblies relies mainly on physical mock-ups. The increasing number of variants and the need for higher product and design quality require a concurrent product validation of several design variants that are based on digital mock-ups. A digital mock-up (DMU) can be defined as ''a computer-internal model for spatial and functional analysis of the structure of a product model, its assembly and parts respectively'' (Krause et al. 1999).

The primary goal of DMU is to ensure the ability to assemble a product at each state of its development and simultaneously to achieve a reduction in the number of physical prototypes. Oriented to the product development cycle, tools for DMU provide methods and functionality for design and analysis of product components and their function. Modeling methods are divided into several categories: space management, multiple views, configuration management of product variants and versions, management of relations between components, and also incomplete models. Simulations are targeted to analyze the assembly and disassembly of a product as well as the investigation and verification of ergonomic and functional requirements. Constituent parts of a DMU tool are distinguished into either components or applications. Components are the foundation of applications and consist of modules for data organization, visualization, simulation models, and DMU/PMU correlations. Main applications are collision checks, assembly, disassembly, and simulation of ergonomics, functionality, and usage aspects. Because a complex product like an airplane can consist of more than 1 million parts, handling a large number of parts and their attributes efficiently is necessary. This requires that DMU methods are optimized data structures and algorithms.

Besides basic functions such as the generation of new assemblies, the modification of existing assembles and the storage of assemblies as product structures with related parts in heterogeneous databases, advanced modeling methods are required in order to ensure process-oriented modeling on the basis of DMU. The main methods in this context are (BRITE-EURAM 1997):

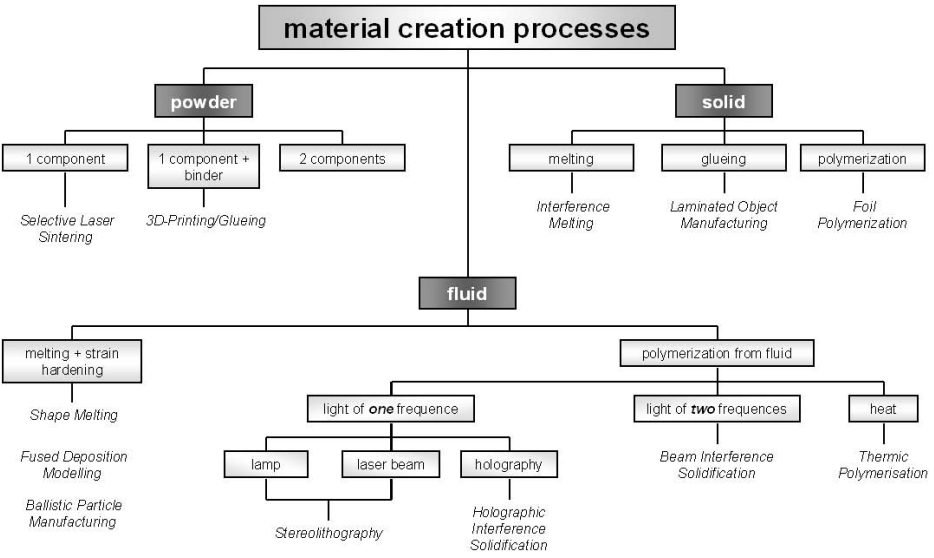

Figure 21 Classification of RP Processes with Respect to the Material-Generation Process. (From Kruth 1991)

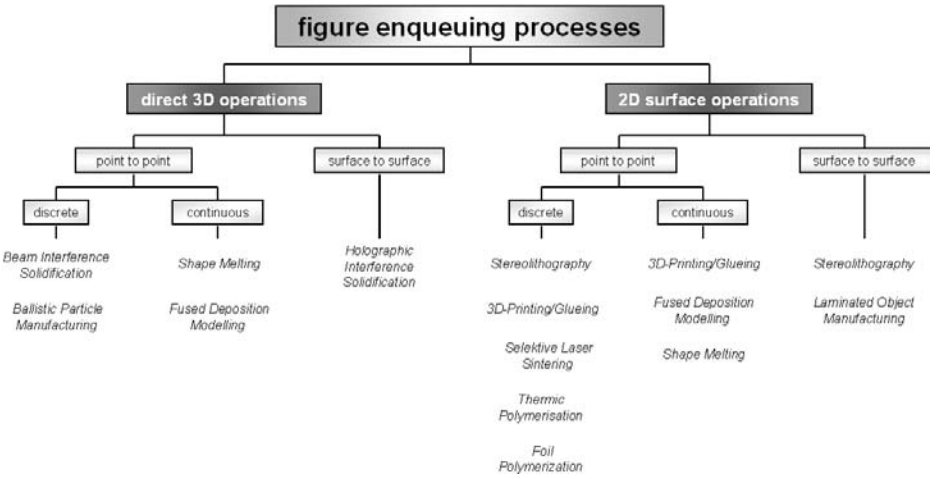

Figure 22 Classification of RP Processes with Regard to the Form-Generation Process. (From Kruth 1991)

- *Organization of spaces:* Allocating and keeping open functional and process-oriented spaces in DMU applications. The major problem is the consideration of concurrent requirements concerning the spaces.
- *Organization of views:* A view is an extract of the entire structure in a suitable presentation dedicated to particular phases and applications.
- *Handling of incomplete models:* Incomplete and inconsistent configurations during development process are allowable in order to fulfill the user's requirements regarding flexibility. Examples are symbolically and geometrically combined models with variable validity.
- *Configuration management of product structure:* Management of versions, variants, and multiuse.

Besides these methods in a distributed, cooperative environment, consequent safety management has to be taken into account. Therefore, a role- and process-related access mechanism must be implemented that allows the administrator to define restrictions of modeling related to roles. The application of such technologies enables a company to manage outsourced development services.

4. ARCHITECTURES

4.1. General Explanations

Product modeling creates product model data and is seen as a decisive constituent of the computer-supported product development activities. Product creation includes all the tasks or steps of product development, from the initial concept to the tested prototypes. During product modeling, a product model database is created and must support all relevant data throughout the product's life cycle.

Product modeling is made up of interconnected parts: the product model and the process chain. The product model is related to the product database and the management and access algorithms. The process chain, besides usually being related to the operational sequence of the product development, is in this context all the necessary product modeling processes required to turn the initial idea into a finished product. The product modeling processes consist of technical and management-related functions. The product model data are the most important factor determined from the development and planning activities.

The term *product model* can be logically interpreted to mean the accumulation of all product-related information within the product life cycle. This information is stored in the form of digitalized product model data and is provided with access and management functions. Modeling systems serve for the processing and handling of the product model data.

As with many other systems, the underlying architecture for CAD systems is important for extensibility and adaptability to special tasks and other systems. Compatibility with other systems, not just other CAD systems, is extremely important for profitable application. Product data should be

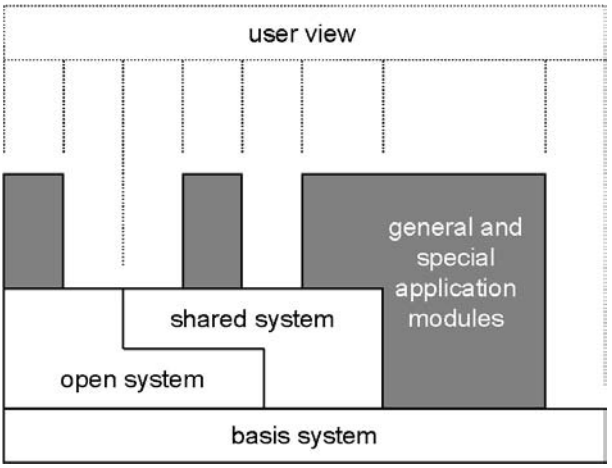

Figure 23 Classes of CAD Systems.

made universally employable throughout the product development process because bridges between media and format changes are error-prone and not often automated.

Enhancements of existing CAD systems, in the form of general and specialty application modules, are important in order to allow customer-specific adaptations to already-provided functionality.

The various classes of CAD systems, which may appear in combination with one another (Figure 23), include the basic system, general and specialty application software, and open and shared systems.

A basic CAD system is made up of a computer internal representation (CIR) of the product model, a core modeler with functionality for management and processing of the CIR, and a user interface for visualization of the CIR and interaction with the user (Figure 24).

4.2. Integration of Application Modules and Core Modeler

Many companies require not only a modeler for geometrical elements but also application modules to integrate into their product development process and for computer internal imaging of the processes. Calculation modules and simulation software belong in this category. Such application modules must integrate with the modeler to form a functional entity (Figure 25).

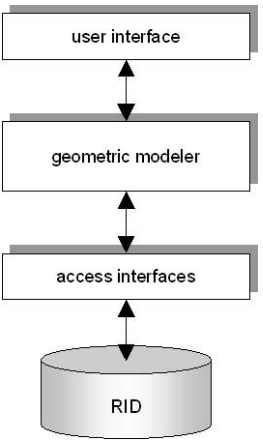

Figure 24 Basic CAD System.

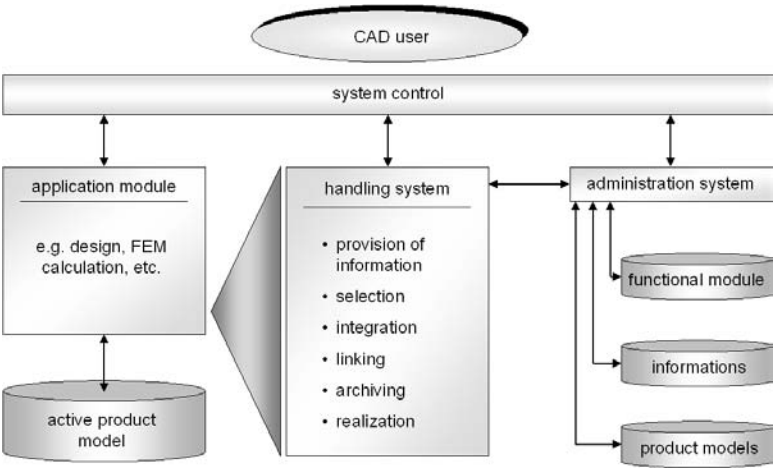

Figure 25 Modeler with Application Modules. (From Krause et al. 1990)

The application modules can be subdivided, according to their area of employment, into general and specialty modules. General application modules for widespread tasks, such as FEM modules or interfaces to widely used program systems, are commercially marketed by the supplier of the CAD system or by a system supplier of complementary software. Specially adapted extensions, on the other hand, are usually either created by the user or outsourced.

A thoroughly structured and functionally complete application programming interface (API) is a particular requirement due to the inability of the user to look deeper into the system.

Honda implemented a CAD system with around 200 application software packages (Krause and Pätzold 1992), but the user was presented with a Honda interface as a uniform medium for accessing the new plethora of programs. This enabled relative autonomy from the underlying software in that as the user, switching between systems, always dealt with the same user interface.

A further step towards autonomy, stemming from the basic system in use, is met only when application modules use an interface already provided. If this does not occur, the conversion to another base system is costly and time consuming. Sometimes it is even cheaper to install a new application module.

Often special application modules are required that cannot be integrated seamlessly into the CAD system. Therefore, various automobile manufacturers, such as Ford, General Motors, Nissan, VW, Audi, and Skoda, have implemented special surface modelers besides their standard CAD systems to enable free-form surface designs to be carried out.

4.3. Shared System Architectures

The scope and time restrictions of most design projects demand the collaboration of many designers. The implementation of shared CAD systems significantly simplifies this teamwork. Here it is possible for several designers to work on the same CIR (computer internal representation). It is not necessary to copy the CIR to various computers in order to work on it and then manually integrate the changes afterwards. The management of this process is taken over by the CAD system. These tasks, however, remain widely concealed from the user. Before this work is begun, only the design area of the respective designer must be defined in order to avoid overlapping.

Such shared CAD systems use a common database. This is usually accessible from the individual CAD stations through a client–server architecture (Figure 26). Usually an Engineering Data Management System (EDMS), implemented in conjunction with a CAD system, is used.

This technique is often found applied in local area networks (LANs), but new problems emerge when a changeover is made to wide area networks (WANs):

- The bandwidth available in a WAN is significantly lower than in a LAN and is often too small for existing shared systems.
- The data security must be absolutely ensured. Therefore, six aspects must be considered:
  - *Access control:* exclusive retrieval of data by authorized personnel
  - *Confidentiality:* prevention of data interception during transmission

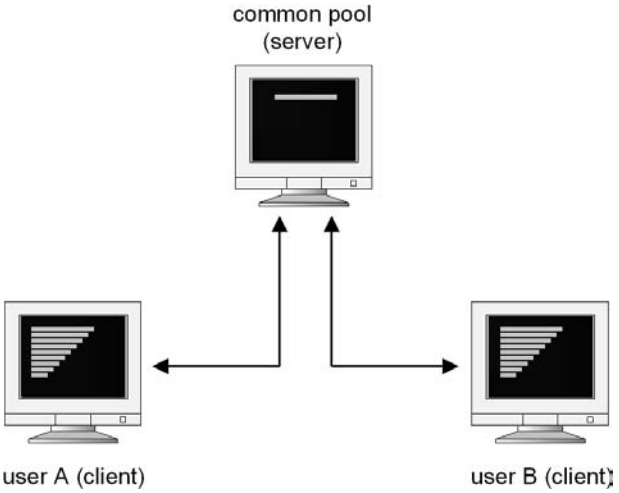

Figure 26 Shared CAD System with a Common Database and a Client-server Architecture.

- *Authentication:* the origin of the data transferred can be reliably identified
- *Integrity:* data cannot be modified during transmission
- *Nonrepudiation:* the sending of data cannot be refused or denied
- *Availability:* the data must always be available to authorized users

Newer implementations of shared systems rely on software architectures for the exchange of objects. Here, not only data is exchanged but, according to the object, also the data methods.

5. KNOWLEDGE MANAGEMENT

5.1. Origin and Background

The concept of knowledge management has been used in different disciplines, mostly in knowledge engineering (De Hoog 1997; Schreiber et al. 2000) and artificial intelligence (Göbler 1992; Forkel 1994). AI research often reduces the concept of knowledge management to the description of the development and use of expert systems (Gödicke 1992) and decision support systems. However, Davenport et al. (1996) found only one expert system application within 30 knowledge work improvement projects. Analysis of approximately 100 case studies published before February 1998 shows that IT-based approaches towards knowledge management are dominant. IT-based knowledge management approaches focus mainly on the storage (databases, DMS) and distribution (intranet and Internet applications, push and/or pull) of explicit, electronically documented knowledge, thus ignoring the tacit dimension of knowledge (Mertins 2001).

The improvements in data processing and network technologies have enabled access to data and information via the Internet at every time and every place in the world. Increasing market demands for reduction in time-to-market, more flexibility, and higher quality at lowest costs have contributed to a new discussion of the concept of knowledge management. These approaches differ from the above-mentioned ones in giving more emphasis to critical success factors such as culture and motivation of the employees and aiming to combine human-based and IT-based methods and tools for knowledge management (Davenport and Prusak 1998; Probst et al. 1998; Skyrme and Amidon 1997; Wiig 1995, 1997; Willke 1998).

5.2. Knowledge

What is knowledge? That is the question most frequently asked by people interested in knowledge management. The discussion about knowledge has a very long tradition. More than 2 thousand years ago, Socrates asked his students, ''Why do we have to know what knowledge is? How can we know what knowledge is? What do we know about knowledge?'' (see Plato, *Theaetetus*). Today there are numerous descriptions and definitions of knowledge. Romhardt (1998) finds 40 dichotomies of knowledge, such as explicit vs. implicit or tacit and individual vs. collective. Von Krogh and Venzin (1995) create seven categories of knowledge to be used in management and organization theory: tacit, em-

bodied, encoded, embrained, embedded, event and procedural. Holsapple and Whinston (1992) discuss six types of knowledge that are important for knowledge management and decision support systems: descriptive, procedural, reasoning, linguistic, assimilative, and presentation. Moreover, Schreiber et al. (2000) ask the question, ''Why bother?'' because even physicists will often have difficulty giving an exact definition of energy. This does not prevent them, however, producing energy and other products.

The concepts most often mentioned by authors in the context of knowledge management are data, information, and knowledge. Some even add wisdom. This classification, if not properly understood and used, could lead to a philosophical discussion of the ''right'' distinction between the categories. The transition from one to the other is not always clear-cut. Instead of a hierarchy, a continuum ranging from data via information to knowledge has proved to be the most practical scheme for knowledge management (Probst et al. 1998; Heisig 2000).

Data means the individual facts that are found everywhere in a company. These facts can be easily processed electronically, and gathering of large amounts of data is not problematic today. However, this process alone does not lead to appropriate, precise, and objective decisions. Data alone are meaningless. Data become information when they are relevant and fulfill a goal. Relevant information is extracted as a response to a flood of data.

However, deciding which knowledge is sensible and useful is a subjective matter. The receiver of information decides whether it is really information or just noise. In order to give data meaning and thus change it into information, it is necessary to condense, contextualize, calculate, categorize, and correct (Tiwana 2000). When data are shared in a company, their value is increased by different people contributing to their meaning.

As opposed to data, knowledge has a value that can be anywhere between true and false. Knowledge can be based on assumption, preconception, or belief. Knowledge-management tools must be able to deal with such imprecision (e.g., documentation of experiences).

> Knowledge is simply actionable information. Actionable refers to the notion of *relevant, and nothing but the relevant* information being available in the right place at the right time, in the right context, and in the right way so anyone (not just the producer) can bring it to bear on decisions being made every minute. Knowledge is the key resource in intelligent decision making, forecasting, design, planning, diagnosis, analysis, evaluation, and intuitive judgment making. It is formed in and shared between individual and collective minds. It does *not* grow out of databases but evolves with experience, successes, failures, and learning over time.'' (Tiwana 2000, p. 57)

Taking all these aspects into consideration, knowledge is the result of the interaction between information and personal experience. Typical questions for data and information are Who? What? Where? and When? Typical questions for knowledge are How? and Why? (Eck 1997).

One important differentiation is often made between tacit and explicit knowledge. Tacit knowledge is stored in the minds of employees and is difficult to formalize (Polanyi 1962; Nonaka and Takeuchi 1995). Explicit knowledge is the kind that can be codified and transferred. Tacit knowledge becomes explicit by means of externalization. With the introduction of CNC machines in mechanical workshops, experienced and highly skilled workers often felt insecure about their ability to control the process. They missed the ''right sound'' of the metal and the ''good vibrations'' of the machine. These signals were absorbed by the new CNC machines and hence workers were not able to activate their tacit knowledge in order to produce high-quality products (Martin 1995; Carbon and Heisig 1993). Similar problems have been observed with the introduction of other CIM technologies, such as CAD/CAM in the design and process-planning department and MRP systems for order management. The information supply chain could not fully substitute the informal knowledge transfer chain between the different departments (Mertins et al. 1993; Fleig and Schneider 1995). A similar observation is quoted from a worker at a paper manufacturing plant: ''We know the paper is right when it smells right'' (Victor and Boynton 1998, p. 43) However, this kind of knowledge is not found only in craftwork or industrial settings. It can be found in high-tech chip production environments (Luhn 1999) as well as social settings. From the noise of the pupils, experienced teachers can distinguish what they have to do in order to progress (Bromme 1999).

5.3. Knowledge Management Is Business and Process Oriented

Nearly all approaches to knowledge management emphasize the process character of interlinked tasks or activities. The wording and number of knowledge-management tasks given by each approach differ markedly. Probst (1998) proposes eight building blocks: the identification, acquisition, development, sharing, utilization, retention, and assessment of knowledge and the definition of knowledge goals. Another difference is the emphasis given by authors to the steps of the process- or knowledge-management tasks. Nonaka and Takeuchi (1995) describe processes for the creation of knowledge, while Bach et al. (1999) focus on the identification and distribution of the explicit, electronically documented objects of knowledge.

5.3.1. The Core Process of Knowledge Management

The analysis of different knowledge-management approaches (Probst et al. 1998; Davenport and Prusak 1998; Nonaka and Takeuchi 1995; Bach et al. 1999; Bukowitz 1999; Weggemann 1998) and the empirical results (Heisig and Vorbeck 2001) lead to the design of an integrated core process in which all activities are supported by organizational, motivational, and technical aspects. The core process can be further broken down into the core activities ''define the goals of knowledge,'' ''identify knowledge,'' ''create (new) knowledge,'' ''store knowledge,'' ''distribute knowledge,'' and ''apply knowledge.'' The quality of these stages is guaranteed by certain design fields for knowledge management. These fields include a company's process organization, available information technology, management systems, corporate culture, management of human resources, and control.

- *Create (new) knowledge:* Measures and instruments that promote the creation of knowledge include the acquisition of external knowledge (mergers, consultants, recruiting, patent acquisition), the setting up of interdisciplinary project teams that include the customers, and the application of lessons learned and methods to elicit tacit knowledge.
- *Store knowledge:* The stored knowledge in manuals, databases, case studies, reports, and even corporate processes and rules of thumb makes up one column of the other core activities. The other column consists of the knowledge stored in the brains of thousands of employees who leave their respective organizations at the end of each working day.
- *Distribute knowledge:* Provision of the right knowledge to the right person at the right time is the aim of the core task of distribution of knowledge. The methods and tools are dominated by IT applications such as the Internet or intranet. However, these tools provide added value only if trust and mutual understanding pervade the atmosphere of the entire company as well as project teams. The development of a common language is an important task. Other aspects of the distribution of knowledge are the transfer of experiences to new employees by training on the job, mentoring, or coaching techniques.
- *Apply knowledge:* According to our survey, the application of knowledge is the most essential task of knowledge management. Knowledge management mainly provides methods to overcome the barriers of the ''not invented here'' syndrome: the one-sided thinking and the development of preferred solution by existing information pathologies.

The close relationship between process and knowledge management is underscored by the critical success factors named by companies in the Europe-wide survey. Nearly one out of four companies (24%) mentioned aspects of the design of structures and processes as a critical factor in the success of knowledge management. Knowledge management is understood by practitioners from manufacturing and the service industry mainly as part of corporate culture and a business-oriented method: ''The sum of procedures to generate, store, distribute and apply knowledge to achieve organizational goals'' (Heisig and Vorbeck 2001).

Furthermore, the survey results indicate that companies focus on specific business processes to implement knowledge management. One out of every two companies starts its KM initiatives in the R&D area, two out of five focus on the process ''Understanding Markets and Customers,'' and more than one out of every three of the companies begins in the area ''Production and Delivery of Products and/or Services.'' The process ''Manage Information'' is ranked fourth in our overall sample and second in the service industry sample (Heisig and Vorbeck 2001). The companies locate their core competencies in these business processes too (Figure 27). Knowledge-management activities are started mainly within the areas identified as core competencies.

5.3.2. Design Fields of Knowledge Management

The second important step is to set up the link between knowledge management and the general organizational design areas, such as business processes, information systems, leadership, corporate culture, human resource management, and control (Figure 28).

- The business processes are the application areas for the core process of knowledge management. Existing knowledge has to be applied and new knowledge has to be generated to fulfill the needs of internal and external customers. The core activities have to be permanently aligned with the operating and value-creating business processes. Furthermore, knowledge-management activities could be linked with existing process-documentation programs (e.g., ISO certification) and integrated into business process reengineering approaches.
- Information technology is currently the main driving factor in knowledge management. This is due to considerable technological improvements in the field of worldwide data networking through Internet/intranet technologies. IT builds the infrastructure to support the core activities of storing and distributing knowledge. Data warehouses and data mining approaches will enable

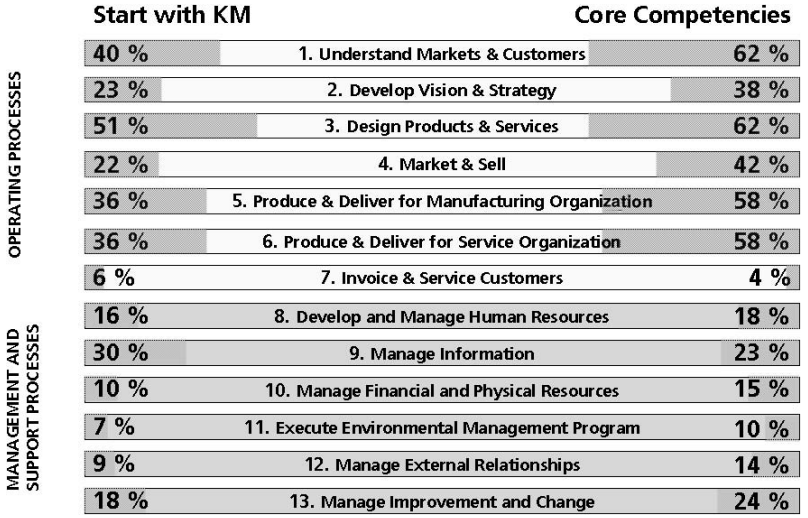

Figure 27 Where Companies Start with Knowledge Management and Where They Locate Their Core Competencies.

companies to analyze massive databases and therefore contribute to the generation of new knowledge.

- The success of knowledge-management strategies is to a large degree determined by the support through top and mid-level managers. Therefore, leadership is a critical success factor. Each manager has to promote and personify the exchange of knowledge. He has to act as a multiplier and catalyst within day-to-day business activities. Special leadership training and change programs have to be applied to achieve the required leadership style.
- If the knowledge-management diagnosis indicates that the current corporate culture will not sustain knowledge management, wider change-management measures have to be implemented.

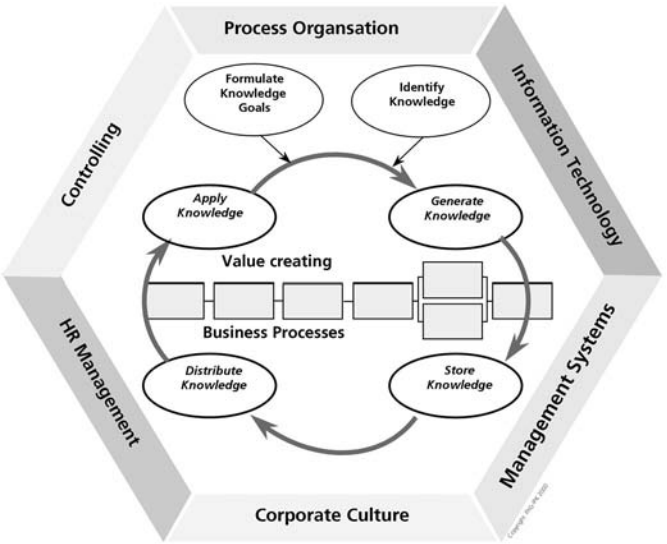

Figure 28 Core Process and Design Fields of Knowledge Management.

The required company culture could be characterized by openness, mutual trust, and tolerance of mistakes, which would then be considered necessary costs of learning.

- Personnel-management measures have to be undertaken to develop specific knowledge-management skills such as the ability to develop and apply research and retrieval strategies as well as adequately structure and present knowledge and information. Furthermore, incentives for employees to document and share their knowledge have to be developed. Career plans have to be redesigned incorporating aspects of knowledge acquisition of employees. Performance-evaluation schemes have to be expanded towards the employees' contribution to knowledge generation, sharing, and transfer.
- Each management program has to demonstrate its effectiveness. Therefore, knowledge-controlling techniques have to be developed to support the goal-oriented control of knowledge creation and application with suitable control indicators. While strategic knowledge control supports the determination of knowledge goals, operative knowledge control contributes to the control of short-term knowledge activities.

Empirical results confirmed the great potential for savings and improvements that knowledge management offers (Figure 29). Over 70% of the companies questioned had already attained noticeable improvements through the use of knowledge management. Almost half of these companies had thus saved time and money or improved productivity. About 20% of these companies had either improved their processes, significantly clarified their structures and processes, increased the level of customer satisfaction, or facilitated decisions and forecasts through the use of knowledge management (Heisig and Vorbeck 2001).

However, some differences were apparent between the answers provided by service and by manufacturing companies. Twenty-eight percent of the service firms indicated an improvement in customer satisfaction due to knowledge management, as compared with only 16% of the manufacturing companies. Twenty-three percent of manufacturing companies stressed improvements in quality, as compared to only 15% of the service companies. Answers to questions about the clarity of structures and processes showed yet another difference. Twenty-six percent of the service companies indicated improvement with the use of knowledge management, as opposed to only 14% of manufacturing companies.

5.4. Approaches to the Design of Business Process and Knowledge Management

One primary design object in private and public organizations are the business processes that structure work for internal and external clients. Known as business process reengineering (BPR) (Hammer 1993), the design of business processes became the focus of management attention in the 1990s. Various methods and tools for BPR have been developed by research institutes, universities, and consulting companies. Despite these developments, a comparative study of methods for business process redesign conducted by the University of St. Gallen (Switzerland) concludes: "To sum up,

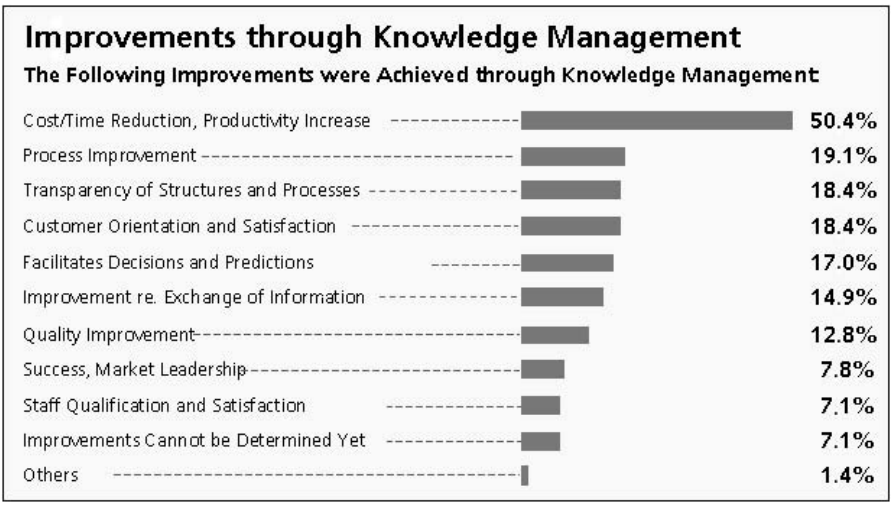

Figure 29 Improvements through Knowledge Management.

we have to state: hidden behind a more or less standard concept, there is a multitude of the most diverse methods. A standardized design theory for processes has still not emerged'' (Hess and Brecht 1995, p. 114).

> BPR's focus is typically on studying and changing a variety of factors, including work flows and processes, information flows and uses, management and business practices, and staffing and other resources. However, most BPR efforts have not focused much on knowledge, if at all. This is indeed amazing considering that knowledge is a principal success factor—or in many judgment, the major driving force behind success. Knowledge-related perspectives need to be part of BPR. (Wiig 1995, p. 257)

Nearly all approaches to knowledge management aim at improving the results of the organization. These results are achieved by delivering a product and/or service to a client. This again is done by fulfilling certain tasks, which are linked to each other, thereby forming processes. These processes have been described as business processes. Often knowledge is understood as a resource used in these processes. Nevertheless, very few approaches to knowledge management have explicitly acknowledged this relation. And even fewer approaches have tried to develop a systematic method to integrate knowledge-management activities into the business processes. The following approaches aim to support the analysis and design of knowledge within business processes:

- CommonKADS methodology (Schreiber et al. 2000)
- The business knowledge management approach (Bach et al. 1999)
- The knowledge value chain approach (Weggemann 1998)
- The building block approach (Probst et al. 1998)
- The model-based knowledge-management approach (Allweyer 1998)
- The reference model for knowledge management (Warnecke et al. 1998).

None of the approaches presented to knowledge management has been developed from scratch. Their origins range from KBS development and information systems design to intranet development and business process reengineering. Depending on their original focus, the approaches still show their current strengths within these particular areas. However, detailed criteria for the analysis and design of knowledge management are generally missing.

Due to their strong link to information system design, all approaches focus almost exclusively on explicit and documented knowledge as unstructured information. Their design scope is mainly limited to technology-driven solutions. This is surprising because the analysis of 30 knowledge work-improvement projects suggests a modified use of traditional business process design approaches and methods including nontechnical design strategies (Davenport et al. 1996). Only the business knowledge management approach (Bach et al. 1999) covers aspects such as roles and measurements.

5.5. A Method for Business Process-Oriented Knowledge Management

Since the late 1980s, the division of Corporate Management at the Fraunhofer Institute for Production Systems and Design Technology (Fraunhofer IPK) has developed the method of integrated enterprise modeling (IEM) to describe, analyze, and design processes in organizations (Figure 30) (Spur et al. 1993). Besides traditional business process design projects, this method has been used and customized for other planning tasks such as quality management (Mertins and Jochem 1999) (Web and process-based quality manuals for ISO certification) for the design and introduction of process-based controlling in hospitals and benchmarking. The IEM method is supported by the software tool MO^{2}GO (Methode zur objektorientierten Geschäftsprozessoptimierung—method for object-oriented business process optimization).

The method of integrated enterprise modeling (IEM) distinguishes between the three object classes ''product,'' ''order,'' and ''resource.'' These object classes are combined by the construct ''Action'' within a generic activity model. Five elements are provided to link the objects to the actions (Figure 31). The IEM approach offers the possibility of describing knowledge as an object within the process model. According to the overall modeling task, knowledge can be modeled as a subclass of the superordinated class ''resource'' and broken down into different sub-subclasses in the form of knowledge domains. The subclass ''knowledge'' can be linked to other ''resource'' subclasses such as ''staff,'' ''EDP-Systems,'' ''Databases,'' ''Documents,'' and so on that are relevant for the analysis and improvement of the business process. The final objective of every business process consists of the fulfillment of the internal and/or external customer demand with a product and/or service. Knowledge is required to produce and/or deliver this service or/and product and thus becomes implemented in the object ''product.'' This implemented knowledge could be divided into subclasses as well. The object ''order'' that triggers the actions could be translated into knowledge goals if appropriate.

The business-oriented knowledge-management approach starts with the selection of the business process to be improved. Davenport (1996) characterizes knowledge work processes as possessing a

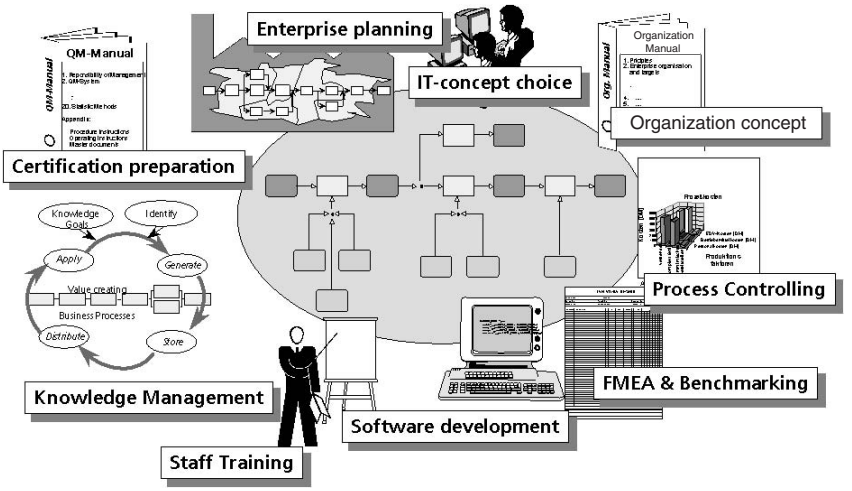

Figure 30 Application Fields of the IEM Business Process Models.

high degree of variety and exception rather than routine and requiring a high level of skills and expertise. The description of the real-world business process is carried out with the modeling constructs of the IEM method. After the description of the real-world business process, the analysis starts with the evaluation of each business task. The result is a knowledge activity profile that shows the level and quality of support provided by the current operational task towards the individual core

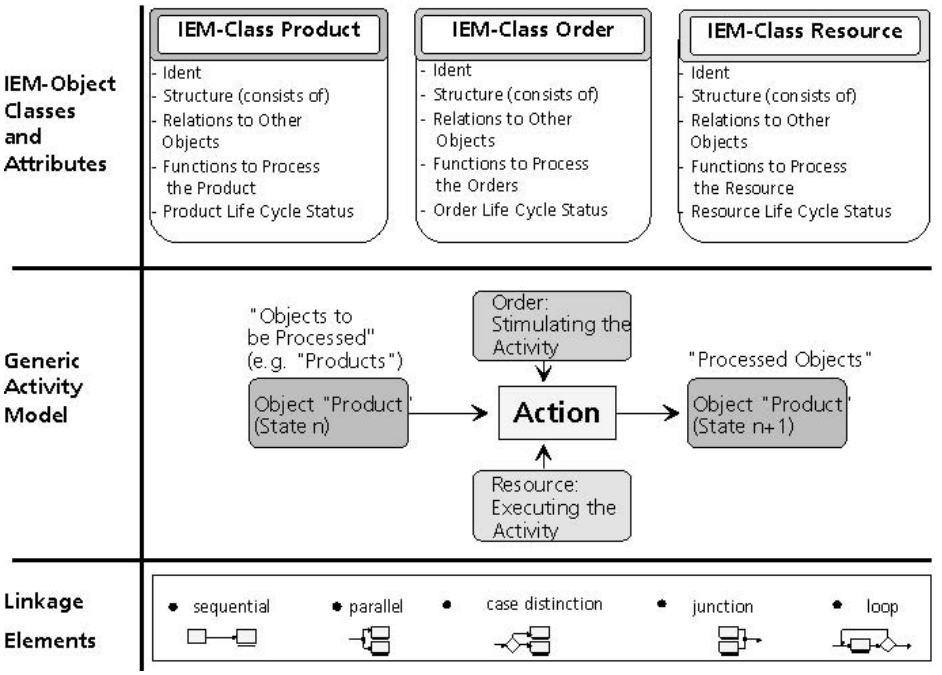

Figure 31 The Object Classes, Generic Activity Model, and Linking Elements of IEM.

tasks of knowledge management. The scope is then extended towards the analysis of the relations between the knowledge-processing tasks within the business process. This step contains the evaluation of the degree of connectivity inherent in the core process activities of knowledge management within the selected business process. The result shows whether the business processes supporting knowledge management are connected in a coherent manner. The optimization and new design of business processes aim at closing the identified gaps within the underlying core processes and sequencing the core tasks of knowledge management. One design principle is to use available procedures, methods, tools, and results from the process to design the solution. In the last step of the analysis, the focus shifts from the actions towards the resources used and the results produced within the process. The results of the analysis not only demonstrate which kind of knowledge is applied, generated, stored, and distributed but also the other resources, such as employees, databases, and documents. Due to the project aim of the improvement, the user will be able to evaluate whether the required knowledge is explicitly available or available only via the internal expert using the expert's implicit or tacit knowledge. The identified weaknesses and shortcomings in the business process will be addressed by knowledge-management building blocks consisting of process structures. The improvement measures have to integrate not only actions directed to a better handling of explicit knowledge but elements to improve the exchange of implicit knowledge.

5.6. Knowledge-Management Tools

Information technology has been identified as one important enabler of knowledge management. Nevertheless, transfer of information and knowledge occurs primarily through verbal communication. Empirical results show that between 50% and 95% of information and knowledge exchange is verbal (Bair 1998). Computer-based tools for knowledge management improve only a part of the exchange of knowledge in a company. The richness and effectiveness of face-to-face communication should not be underestimated. Computer tools promote knowledge management. The access to knowledge they enable is not subject to time or place. A report can be read in another office a second or a week later.

Therefore, a broad definition of knowledge-management tools would include paper, pencils, and techniques such as brainstorming. According to Ruggles (1997, p. 3), ''knowledge management tools are technologies, which automate, enhance and enable knowledge generation, codification and transfer. We do not look at the question if tools are augmenting or automating the knowledge work.''

E-mail and computer videoconference systems can also be understood as tools for knowledge management. However, we consider this kind of software to be the basic technology, that is, the building blocks for a knowledge-management system. Initially, groupware and intranets are only systems for the management of information. They become knowledge-management tools when a structure, defined processes, and technical additions are included, such as a means of evaluation by users.

This is not the place for a discussion about whether software can generate, codify, and transfer knowledge alone or can only aid humans in these activities. For the success of knowledge management, the social aspects of its practical use are very important. For example, a sophisticated search engine alone does not guarantee success as long as the user is not able to search effectively. It is not important for this study whether employees are supported in their knowledge management or whether the tool generates knowledge automatically on its own. This is an important point in the artificial intelligence discussion, but we do not need to go into detail here.

Syed (1998) adopts a classification from Hoffmann and Patton (1996) that classifies knowledge techniques, tools, and technologies along the axes complexity–sophistication and intensity along the human–machine continuum, indicating whether certain tools can handle the complexity of the knowledge in question and what kind of workload this means for the user (Figure 32).

5.6.1. Technologies for Knowledge Management

The following is an overview of the basic technologies used in every knowledge-management solution. The following explanation of the basic technologies helps to examine and classify tools more precisely. These are the technologies that we find today in knowledge management (Bottomley 1998). Different knowledge management tasks can be processed using these basic technologies.

Intranet technology: Intranets and extranets are technologies that can be used to build a knowledge-management system. The unified surface and access to various sources of information make this technology perfect for the distribution of knowledge throughout a company.

Groupware: Groupware is a further substantial technology that is used for knowledge-management systems (Tiwana 2000). Groupware offers a platform for communication within a firm and cooperation between employees.

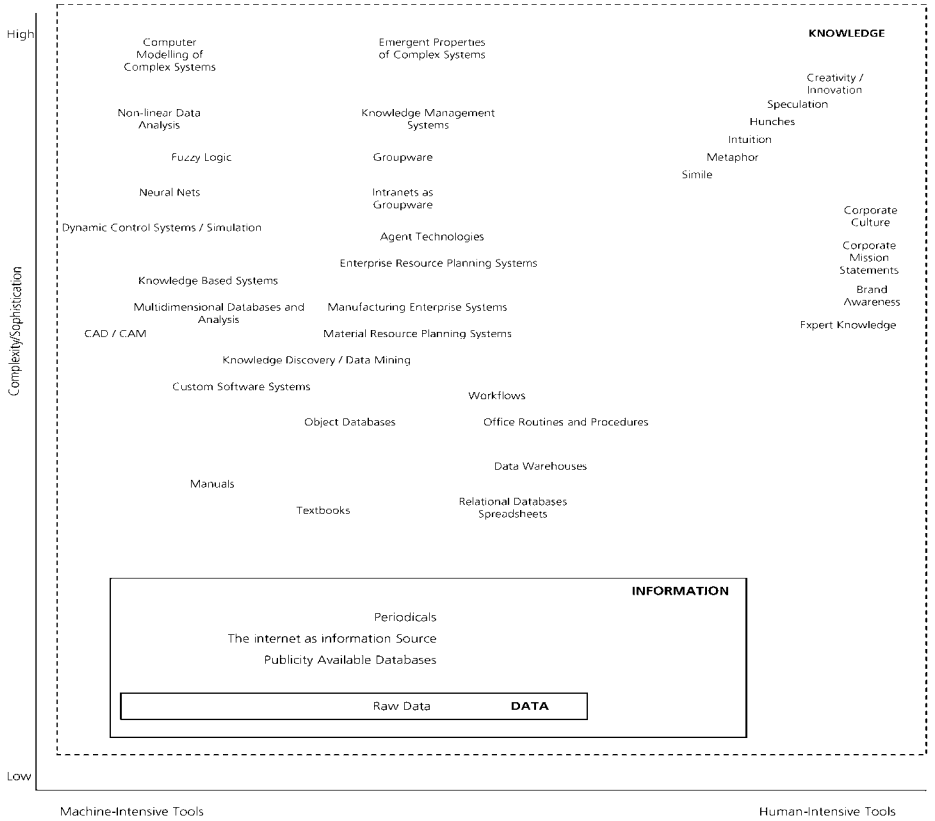

Figure 32 Knowledge Techniques, Tools, and Technologies. (From Syed 1998, p. 65, adapted from Hoffmann and Patton 1996 © 1996 by SRI Consulting, Business Intelligence Program. Reprinted by permission of SRI Consulting Business Intelligence.)

Electronic document management: Documents are a central means of storing and spreading knowledge. Procedures for using and maintaining such documents, such as a check whether an update is overdue, can be easily implemented for knowledge management systems.

Information-retrieval tools: Information retrieval offers a solution to tasks from text searches to the automatic categorization and summation of documents. Advanced search algorithms use thesauri and text mining to discover contexts that could not be found with simple queries. Semantic text analyses can also be implemented.

Workflow-management system: The business processes of a company contains a large part of knowledge. In addition, the integration of knowledge management into business processes is an important factor for success.

Data analysis: Pattern recognition and classification and forecasting are the techniques used for data analysis. Data analysis is a possible method for generating new knowledge.

Data warehousing: A modern database is where data and information are stored. Connections that are not readily apparent can be uncovered with the use of data mining and OLAP. These techniques are part of data analysis.

Agent technology: Software agents based on the essentials of artificial intelligence enable the user to search independently for information according to a personal profile and use various sources and other agents.

Help desks: Help desks are an important application area for case-based reasoning technology based on individual cases. Case knowledge can be quickly put into use in this way.

Machine learning: This technology from the field of artificial intelligence allows new knowledge to be generated automatically. In addition, processes can be automatically optimized with time with little necessity for human intervention.

Computer-based training: This technology is used to pass on knowledge to colleagues. The spread of implicit knowledge is possible with multimedia applications.

5.6.2. Architecture for Knowledge Management

Historical classification explains the special use of a certain product or how the manufacturer understands its use. The following historical roots are relevant (Bair and O'Connor 1998):

- Tools that are further developments of classical information archives or the retrieval of information.
- Solutions from the field of communication and reactivated concepts from the field of artificial intelligence come into play in the analysis of documents and in automated searches.
- Approaches to saving and visualizing knowledge also come from classical information archives.
- Tools for modeling business processes.
- Software that attempts to combine several techniques and support different tasks in knowledge management equally.

The Ovum (Woods and Sheina 1998) approach is an example of a well-structured architectural model. The initial level of the model consists of information and knowledge sources (Figure 33). These are delivered to the upper levels through the infrastructure. Next comes the administration level for the knowledge base where the access control is handled, for example. The corporate taxonomy defines important knowledge categories within the company. The next layer makes services available for the application of knowledge, such as through visualizing tools, and for collaboration, such as through collaborative filtering. The user interface is described as a portal through which the user can access the knowledge to use it in an application.

A further possibility is categorization according to the basic technology from which knowledge-management systems are constructed.

Most knowledge-management tools use existing technologies to provide a collaborative framework for knowledge sharing and dissemination. They are implemented using e-mail and groupware, intranets, and information-retrieval and document-management systems. Applications from data warehousing to help desks can be used to improve the quality of knowledge management (Woods and Sheina 1998).

5.7. Future Trends

Knowledge management is currently a buzzword on the agenda of top management and marketing and sales departments of software providers and consulting companies. Nevertheless, decision maker's awareness is increasing. Knowledge is regarded as one or even the main factor for private and public organizations to gain competitive advantage. First experience from knowledge-management projects show that a win-win situation for companies and employees is possible. By reducing double work, the company saves costs. Moreover, employees increase their experience through continuous learning and their satisfaction through solving new problems and not reinventing the wheel.

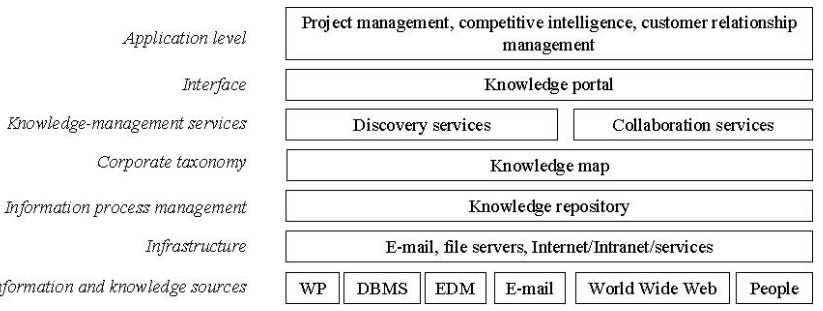

Figure 33 Ovum Knowledge-Management Tools Architectural Model. (From Woods and Sheina 1998, p. 8)

Even if knowledge management goes out of fashion as a buzzword, the essence of the idea of knowledge management—the systematic management of knowledge and experiences of the employees, suppliers, and clients—will definitely never be superfluous. Even in the dynamic new economy, experience and knowhow are still extremely important, as the example of retired experts who are very happy to pass their knowledge as ''senior experts'' on to young start-up companies shows.

With business process engineering, companies have focused their attention on eliminating non-value-adding process steps in order to improve their competitiveness by means of value-adding process steps. In the future, companies will regard their business processes as knowledge processing processes and enhance their ability to improve their use of their one and only competitive advantage—the knowhow of the people.

In the future, the basic technologies will be standard and increasingly integrated. This will require the integration of knowledge management in everyday business as well as a sense of responsibility from each individual. This will result in knowledge management becoming less discussed and more and more taken for granted.

For the exchange of knowledge to continue to improve, meta-knowledge will become increasingly important. Meta-knowledge helps to describe knowledge and specify its meaning. This form of description will have to be standardized due to the growing need for a global exchange of knowledge. This is apparent in the increased importance of Internet markets, which require a globally accepted description of products and thus knowledge.

In the IT industry, the dominant trend is toward takeovers of small, innovative companies. The market leader can then integrate new technologies into its standard product and advance that product.

Another future trend is toward knowledge management being practiced not only within companies, but between them. The Internet will reinforce the trend toward small companies being able to benefit more from the exchange of knowledge with other companies. However, some companies are becoming disillusioned regarding the use of new technologies. For example, intranet technology is taken for granted as a medium nowadays, although there is still uncertainty about what kinds of information it should be used to transfer to yield the maximum benefits. Despite continuing technological improvements in the future, people will still remain the definitive force.

CHAPTER 10

The Factory of the Future: New Structures and Methods to Enable Transformable Production

HANS-JÜRGEN WARNECKE
Fraunhofer Society

WILFRIED SIHN
Fraunhofer Institute for Manufacturing Engineering and Automation

RALF VON BRIEL
Fraunhofer Institute for Manufacturing Engineering and Automation

1. THE CURRENT MARKET SITUATION: NOTHING NEW

The renowned American organization scientist Henry Mintzberg has discovered that companies and their managers have been complaining of market turbulence and high cost and competition pressures for more than 30 years (Mintzberg 1998). Market turbulence is thus not a new phenomenon, he concludes, and companies should be able to cope with it.

However, there are only a few practical examples to back Mintzberg's claim. Practical experience and research results differ not because market turbulence forces enterprises to adapt but because the speed of change adds a new dimension to market turbulence. The results of the latest Delphi study show that the speed of change has increased considerably in the last 10 years (Delphi-Studie 1998).

The five charts in Figure 1 show the primary indicators used to measure the growing turbulence in the manufacturing environment. The change in mean product life shows that innovation speed has increased considerably in the last 15 years. This change can be validated with concrete figures from several industries. A recent Siemens survey shows that sales of products older than 10 years have dropped by two thirds over the last 15 years and now amount to only 7% of the company's total turnover. In contrast, the share of products younger than 5 years has increased by more than 50% and accounts for almost 75% of the current Siemens turnover (see Figure 2).

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

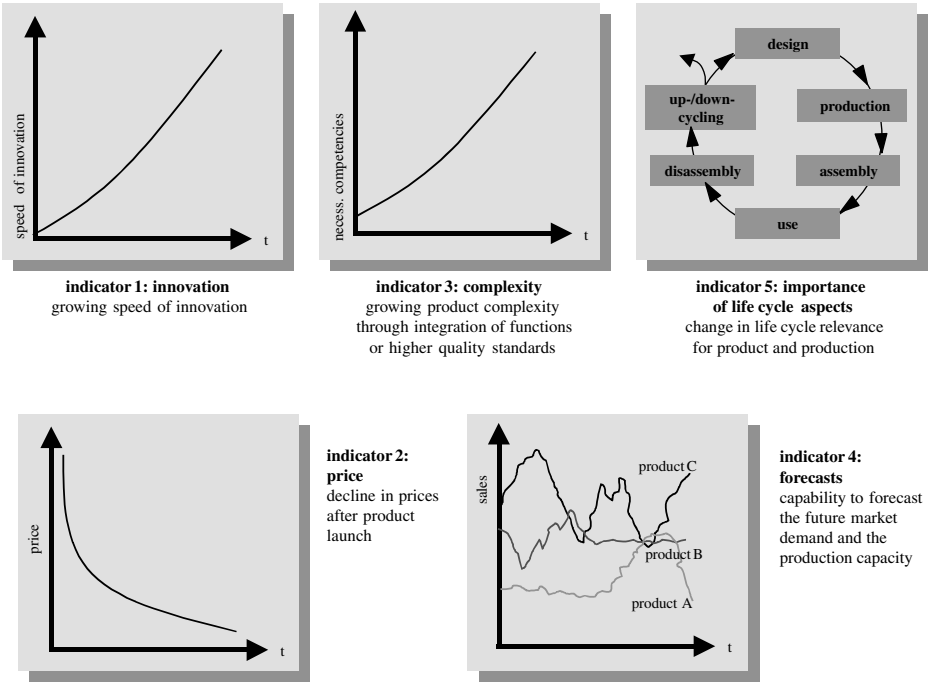

Figure 1 Indicators Measuring Market Turbulence.

However, long-range studies are not the only means to identify and verify the changes expressed by the indicators. A short-term analysis, for example, can also serve to prove that change is the main cause of turbulence. The aim of one such analysis is to predict the fluctuations in sales for a medium-sized pump manufacturer. During the first half of the year, the sales trend of some product groups

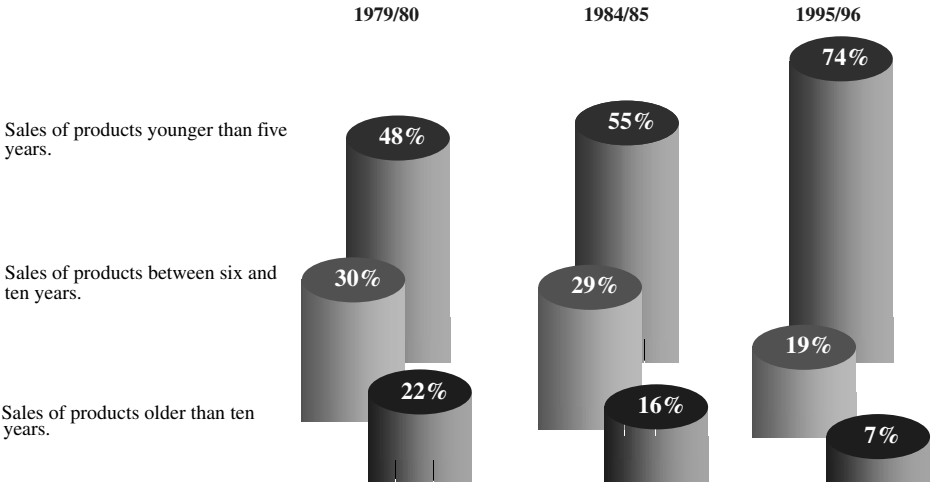

Figure 2 The Changing Life Cycle of Siemens Products. (From Kuhnert 1998)

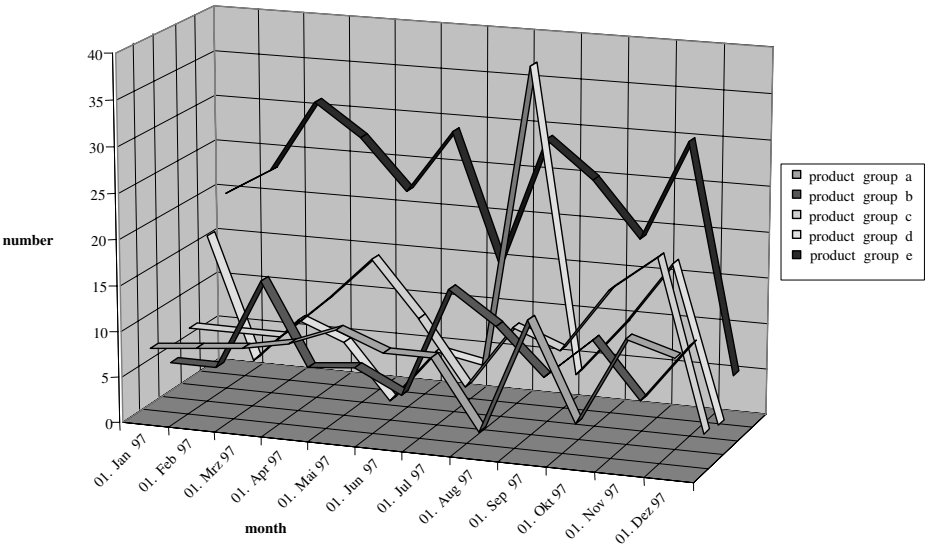

Figure 3 Fluctuations in the Order Entry of a Medium-Sized Pump Manufacturer.

could be predicted based on past results. The forecast for the second half of the year, however, though based on the same procedure, was impossible due to the divergence of monthly sales volume in certain product divisions. Therefore, an enormous adaptation effort on the part of the company was required (see Figure 3).

The overall objective is to raise a company's or factory's *transformability,* the new determinant of corporate market success. Transformability is the ability to adjust rapidly to increased turbulence and recognize changing indicators early enough to initiate proactive adaptation measures.

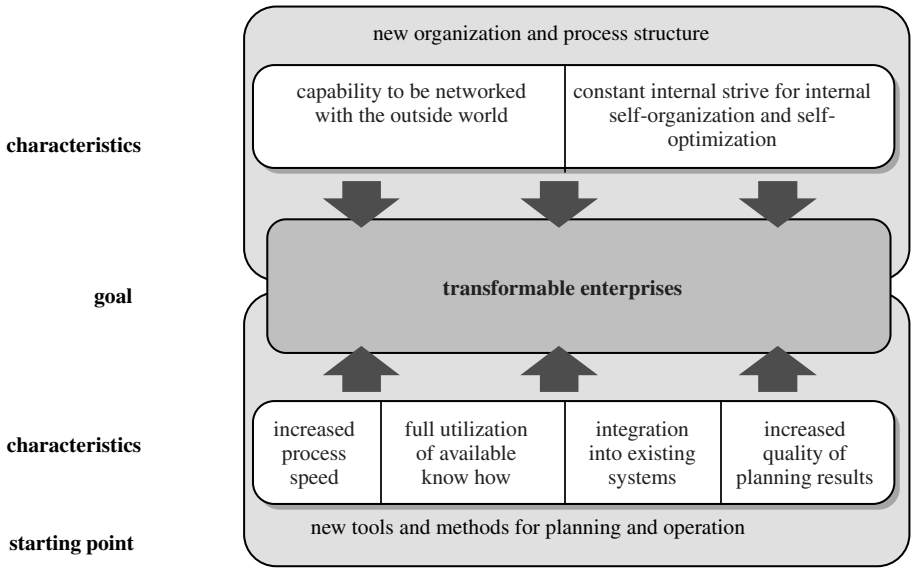

Figure 4 Contributing Factors of a Transformable Company.

2. TRANSFORMABLE STRUCTURES TO MASTER INCREASING TURBULENCE

Recent restructuring projects have shown that a company's competitiveness can be enhanced through improved technology and, in particular, through the efficient combination of existing technology with new company structures.

Factories of the future must have transformable structures in order to master the increased turbulence that began in the 1990s. Factories must also possess two important features reflecting two current trends in structural change: they must be able to enable for external structure networking and self-organize and self-optimize structures and processes internally. External networking helps to dissolve company borders that are currently insurmountable and integrate individual enterprises into company networks. Self-organization and self-optimization are intended to enhance the competencies of the value-adding units in accordance with the corporate goal and thus speed up the decision making and change processes of the enterprise.

3. CORPORATE NETWORK CAPABILITY

Corporate network capability describes the capacity of an enterprise to integrate both itself and its core competencies into the overall company network. This cooperation is continually optimized to benefit both the individual company and the network.

Companies with this capacity find that their transformability increases in two respects. First, they can focus on their core competencies and simultaneously profit from the company network's integrated and comprehensive service range. Second, the information flow in the company network is sped up by the continual networking of suppliers and customers. The advantage of the latter is that companies are provided with information concerning market changes and adjustments in consumer and supplier markets in due time. They can thus respond proactively to technological and market changes. These company networks can take four forms, as shown in Figure 5.

Companies are not limited to only one of the four types. Instead, each company can be involved in several company network types on a horizontal as well as a vertical level. In the automobile industry, for example, it is common practice for companies to cooperate in regional networks with companies on the same value-adding level and at the same time be part of the global supply chain of an automobile manufacturer. In other words, companies do not necessarily have to focus on one cooperative arrangement. Different business units might establish different cooperative arrangements.

Behr is an example of an automobile supplier with high network capability. The company's focus is vehicle air conditioning and motor cooling. Its customers include all the large European car manufacturers. In order to offer its customers a comprehensive service range, Behr is involved in nu-

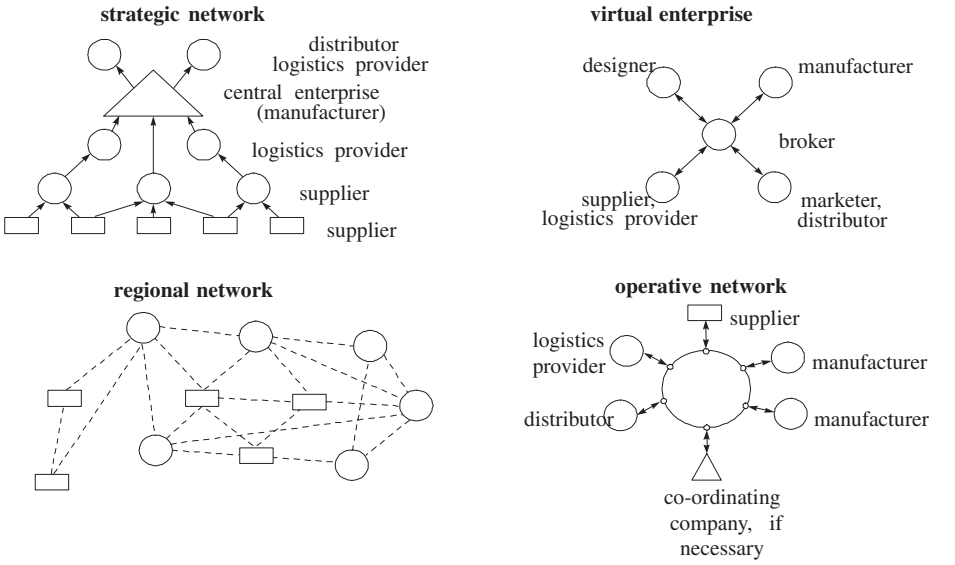

Figure 5 Basic Types of Company Networks.

merous global and local networks. In 1997 and 1998, Behr joined six cooperation projects with other automotive suppliers in which the cooperation partners were distinguished by their expertise, flat hierarchies, and accompanying short information and communication paths as well as similar corporate culture. The aim of the resulting expert network was to pool the necessary system technology and thus improve the position in the core business as well as to prepare the basis for entering new markets for components.

The project management is assumed by the partner with the greatest market share or the most comprehensive business logistics. It is also important that a continual communication flow exist, accompanied by rapid decision making processes and clearly defined interfaces that are well managed and intelligible for the customer. Accordingly, Behr and one of its cooperation partners have taken the initiative to jointly develop and supply front-end modules. The module is composed of the cooling system's heat transfer, the air-conditioning condenser, cooling fan, air deflector, lighting, bumpers, and radiator grill. Together, the cooperation partners are able to provide 75% of the module components. Through this network, Behr was able to increase its market presence and revenue.

3.1. Internal Self-Organization and Self-Optimization

In corporate self-organization and self-optimization, the authority to make decisions is shifted directly to the value-adding units, creating semiautonomous organizational units. Therefore, apart from the actual output process, semiautonomous units have to integrate management and planning functions as well as coordinate functions to ensure global optima and avoid local optima.

The advantages of semiautonomous structures with regard to improved labor productivity have been confirmed by numerous studies and accepted by most experts (Westkämper et al. 1998). Advantages include increased corporate transformability, which can be achieved through a quicker information flow in semiautonomous units, and the involvement of the process owners in the decision making process from an early stage. The latter also leads to better staff motivation, which positively affects transformability.

An important task for semiautonomous organizational units is to coordinate themselves with the common target system in the course of self-optimization (see Figure 7). Making a profit is the main goal of this target system. However, the system must still be coordinated with the interests of the employees. In addition, the goals must affect wages in order to increase the credibility of the goal system.

The Fraunhofer Institute for Production and Automation (IPA) has carried out more than 100 industrial projects in which it applied the principle of the fractal company to introduce semiautonomous organization structures coordinated by means of a common target system. More than 20 of

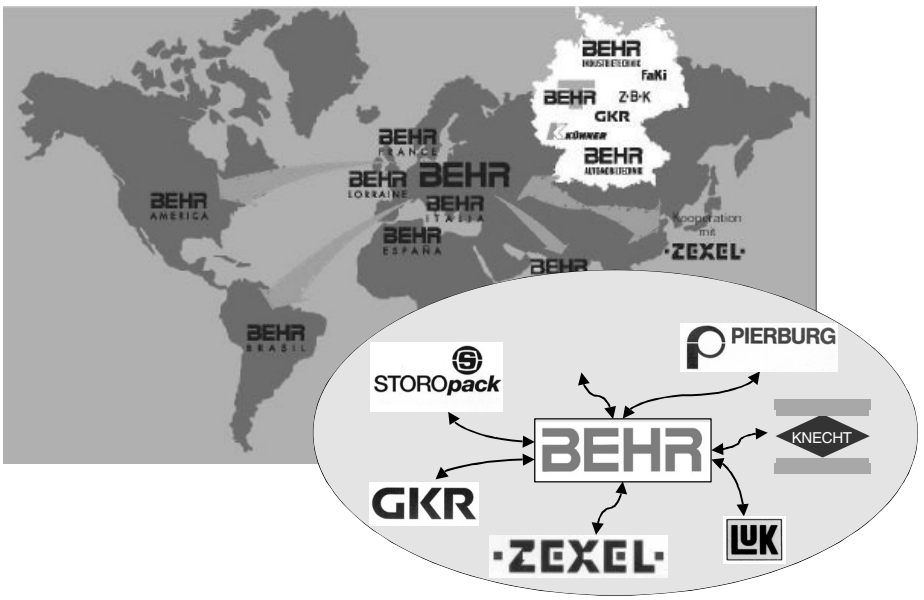

Figure 6 The Behr Company as an Example of a Networked Structure.

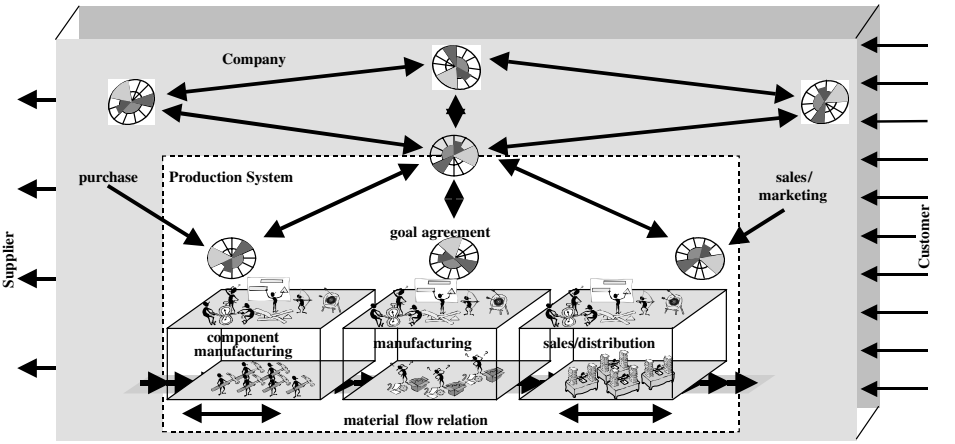

Figure 7 Common Target System to Coordinate Semiautonomous Organizational Units.

these projects have been further analyzed, showing increased corporate transformability and a significant change in organizational parameters.

A manufacturer of packaging machinery was among the companies analyzed. It exemplifies the changes in the organizational structure and the transition to self-optimizing structures. Before the organizational changes were implemented, the company had a classical functional organization structure (see Figure 9). This structure led to a high degree of staff specialization, which was unsatisfactory in terms of the value-adding processes. For example, six departments and a minimum of 14 foremen and their teams were involved in shipping a single packaging machine.

In the course of the change process, semiautonomous units were created based on the idea of the fractal company. These units performed all functions necessary for processing individual customer orders. Part of the new structure included organizational units that focused on product groups for customized assembly processes. The interfaces of the latter no longer serve to carry out individual

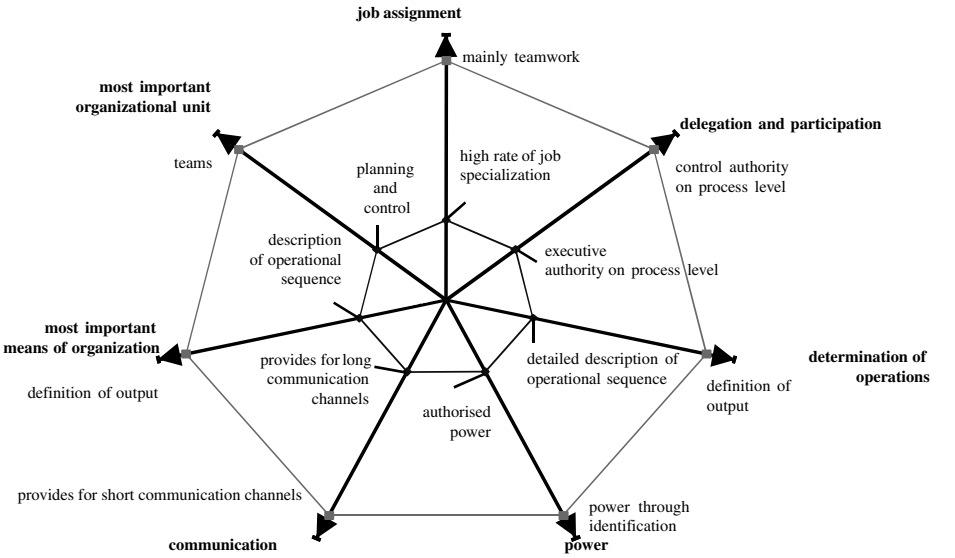

Figure 8 Basic Change in Self-optimizing Structures. (From Kinkel and Wengel 1998)

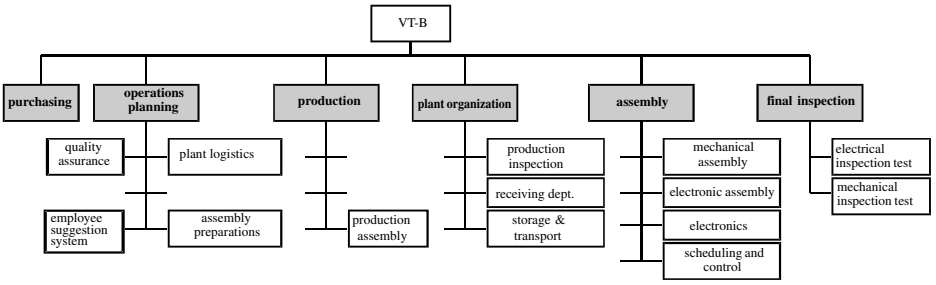

Figure 9 Traditional Corporate Structure Exemplified by a Manufacturer of Packaging Machinery.

customer orders but are instead needed for long-term planning and maintaining the production process (see Figure 10).

Reducing the interfaces in the planning process and at the same time adjusting the planning and control principles to the new corporate responsibility structure cut the cycle time for producing a machine by 60%.

4. NEW METHODS FOR PLANNING AND OPERATING TRANSFORMABLE STRUCTURES

In the future, companies will need new planning methods to increase their transformability and adaptability to a changing business environment. These methods and tools will speed up processes but also increase performance quality and integrate existing methods. The following four methods allow to the transformability of an enterprise to be increased. They differ in the extent of their market penetration, their market maturity, and their operative range. All methods are based on the new corporate structure and attempt to improve the related processes (see Figure 11).

4.1. Process Management through Process Modeling, Evaluation, and Monitoring

If future enterprises are no longer structured according to Tayloristic functions but focus on added value, then new methods and procedures will be required for mapping and evaluating these processes.

To achieve increased transformability, it is necessary to check the process efficiency continuously with regard to the current speed of change. If processes are to be successfully and comprehensively

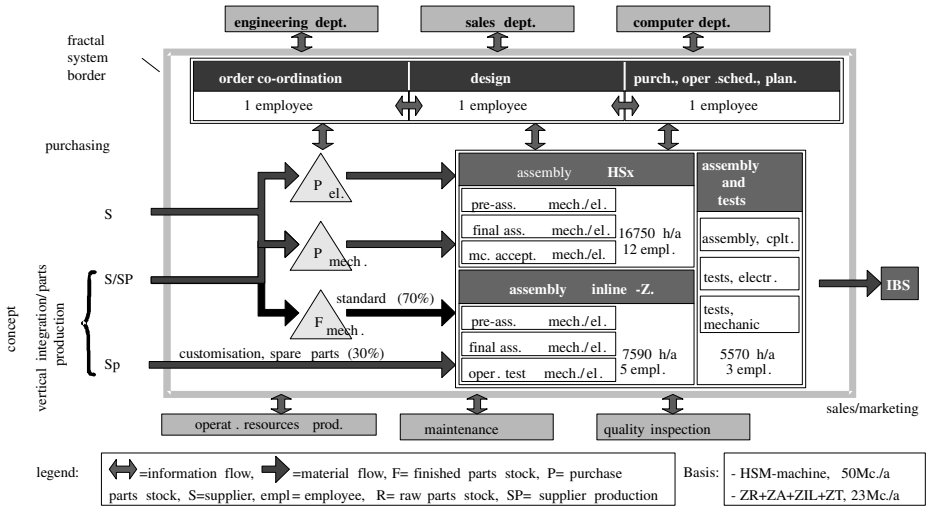

Figure 10 Functional Integration after Transformation.

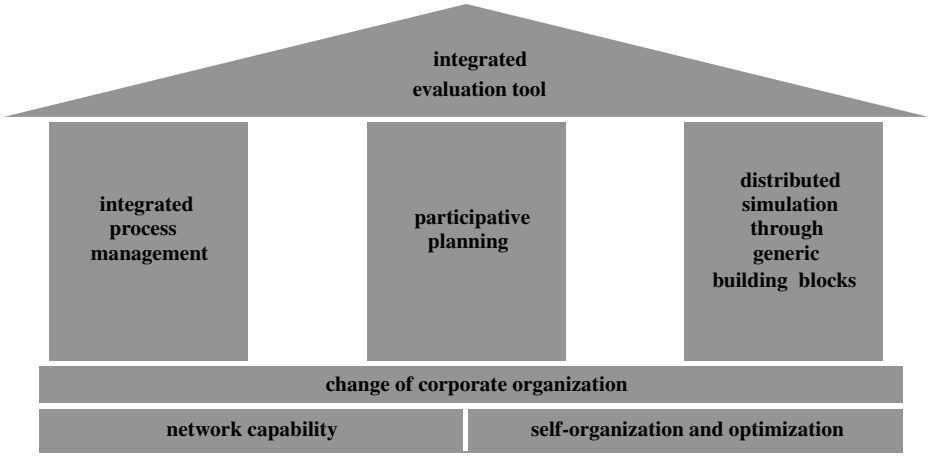

Figure 11 The Structure of the Methods Presented.

managed, it is not sufficient to map the process once but rather use an integrated and holistic approach. It is necessary that process modeling be understood by all those involved in the process. At the process evaluation and optimization stage, the structures of the process model are evaluated and optimized from different points of view before being passed on to the continuous process monitoring stage (see Figure 12).

A great number of modeling tools for process modeling are currently available on the market and applied within companies. These tools all have the capacity to map the corporate process flow using predefined process building blocks. Depending on the necessary degree of specification, the processes can be depicted in greater detail over several levels. Each process module can be equipped with features such as frequency, duration, and specific conditions to enable evaluation of the work flow as a whole. In addition, the process steps can be linked through further modules such as required resources and required and created documents. However, none of the tools can provide specific instructions as to the extent of the models' detail. The specification level depends, for the most part, on the interest of the persons concerned, including both the partners in the corporate network and the semiautonomous organizational units within the individual companies. In any case, the interfaces between the organizational units and the network partners must be adequately specified so that the required results to be delivered at the interfaces are known. However, a detailed description of individual activities in the organizational units is not necessary.

The evaluation and optimization of processes can be based on the performance results provided at the interfaces. Performance results means primarily to the expected quality, agreed deadlines, quantities and prices, and maximal costs. So that the process efficiency and the process changes with regard to the provided results can be evaluated, the immediate process figures have to be aggregated and evaluated in terms of the figures of other systems. This leads to new cost tasks. An important leverage point in this respect is the practical use of process cost calculation and its integration into process management(von Briel and Sihn 1997).

At the monitoring stage, it is necessary to collect up-to-date process figures. Based on these key figures, cost variance analyses can be carried out that allow the relevant discrepancies between desired and actual performance to be determined and illustrated by means of intelligent search and filter functions. The relevant figures are then united and aggregated to create global performance characteristics. Due to the locally distributed data and their heterogeneous origins, monitoring processes that encompass several companies is problematic. To solve this problem, the Fraunhofer Institute developed the supply chain information system (SCIS), which is based on standard software components and uses the Internet to enable the continuous monitoring of inventory, quality, and delivery deadlines in a multienterprise supply chain. The person responsible for the product stores the data of each supplier separately in a database. This product manager is therefore in a position to identify and mark critical parts on the basis of objective criteria (ABC analyses, XYZ analyses) and practical experience. It is then possible to determine dates (e.g., inventory at a certain point in time) for critical parts and carry out time analyses (e.g., deadline analyses for a certain period of time, trend analyses). These analyses are used to identify logistical bottlenecks in the supply chain. Moreover, the analyses can be passed on to the supply chain partners, thus maintaining the information flow within the supply chain.

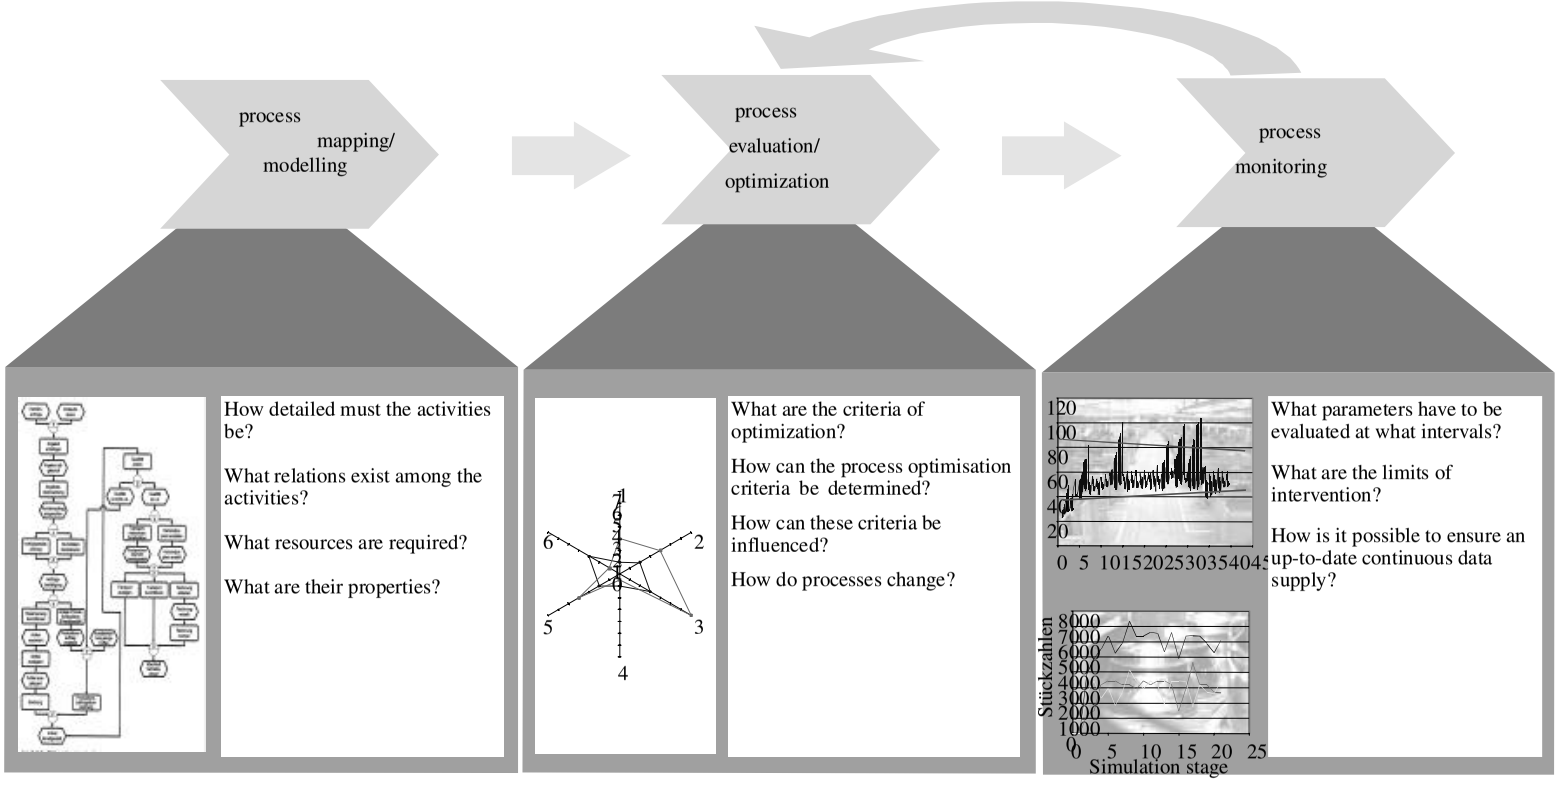

Figure 12 Model of Holistic Process Optimization.

4.2. Integrated Simulation Based on Distributed Models and Generic Model Building Blocks

Simulation is another important method for increasing the transformability of systems. With the help of simulation, production systems can be evaluated not only during standard operation but during start-up and fluctuation periods. Simulation is therefore an ideal planning instrument for a turbulent environment characterized by specific phenomena. However, in practice, the use of simulation is increasing only slowly due to the need for accompanying high-performance computer systems and reservations regarding the creation of simulation models, pooling of knowhow, and maintenance of the models. The main problem remains the nonrecurring creation of simulation modules and the need to create a problem-specific overall model.

Two simulation methods can be used to speed up the planning process. The first method generates company- and industry-specific modules that can be put together to create individual simulation models. This is achieved by simply changing the parameters without having to build a completely new planning model. The modules can be continuously created until the user no longer needs to adapt the individual modules but merely has to modify the parameters of the overall model (see Figure 13).

The model of a production system developed by the Fraunhofer Institute shows that two basic building blocks suffice to create a structured model of 10 different types and 25 pieces of machinery. Within two weeks, 25 variations of the production system could be analyzed in collaboration with the production system staff.

The second method enhances the creation of simulation models by allowing distributed models to be built that interact through a common platform or protocol. Thus, various problem-specific tools can be put into action so that there is no need to apply a single tool for all problems. Moreover, the modeling effort and maintenance costs are shared by all participants. Accordingly, every semiautonomous corporate unit and partner in the corporate network can maintain and adapt its own model. On the other hand, because a common platform ensures that the models are consistent and executable, corporate management doesn't lose control over the overall model. The introduction of HLA communication standards for an increasing number of simulation systems fulfills the principal system requirements for networked simulation.

4.3. Participative Planning in the Factory of the Future

The participative planning method is used to reduce the number of interfaces that arise when a complex planning task is solved—that is, one that involves many planning partners and their individual knowhow. It also improves information flow at the interfaces, allows planning processes to be carried out simultaneously, and prevents double work in the form of repeated data input and data transfer. Participative planning is based on the theory that cooperation considerably increases efficiency in finding solutions for complex problems.

The basic principle of participative planning is not new. It was used in factory and layout planning long before the introduction of computer assistance. Previously, team meetings used paper or metal

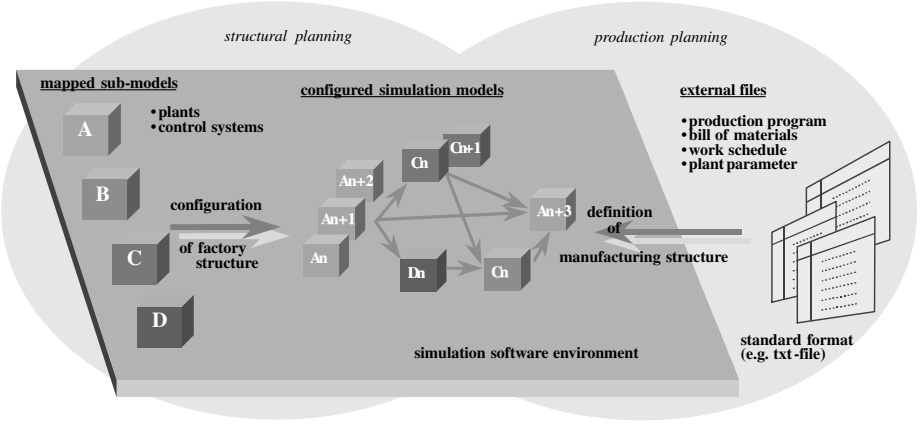

Figure 13 Modeling with Predefined Building Blocks.

components to represent machinery or production areas. These items could be fastened or glued to the factory's layout plan. This procedure has remained more or less the same in participative planning, the only difference being that interactive factory planning uses virtual elements that exist solely in the computer model and do not need to be glued or pinned. These objects not only possess proper geometrical characteristics but also include additional information concerning object values.

The basic tool of participative planning, the interactive planning table, is based on an idea from the Institute for Hygiene and Applied Physiology and the Institute for Design and Construction at the ETH Zurich. A projector is used to project a 2D image of the planning area via a mirror onto an ordinary table. Simultaneously, a 3D model of the planning area is presented on the wall. The same mirror returns the picture on the table to a camera mounted beside the projector. Thus, feedback on the changes performed on the table is made available. The interactive mechanism of the planning table works by means of metal building bricks with reflective upper surfaces that make it possible for the camera to register the movements of the bricks. Two main forms of interaction exist. One uses one of two brick sizes and the other, the classical way, uses a mouse and keyboard (see Figure 14).

The interactive planning method leads to a significant reduction of planning time while maintaining planning quality. Accordingly, this planning model especially applies to planning cases in which the highest possible planning quality is imperative due to low profit margins and high investment costs, when several partners with different knowhow levels participate in the planning and the planning takes place under high time pressure. Given the increased speed of change, this will apply to an increasing number of planning cases.

4.4. The Integrated Evaluation Tool for Companies

Many enterprises argue that decisions must affect the revenue figures more quickly and in turn influence the corporate profit situation and business value. Hardly any company data are more controversial than the accounting figures. The main criticism of these figures is that for the most part, they are based on past results. Moreover, because the results are aggregated and based on many different accounting parameters, it is not possible to derive clear-cut measures in due time. This means there is too much time between the occurrence and recognition of weak spots in the corporate revenue figures.

However, an integrated evaluation tool has to include accounting figures, which form the basis for corporate decision making and also determine the key data that allow changes to be registered before they take effect in accounting. The balanced scorecard (Kaplan and Norton 1996), a method developed for practical use by Kaplan, provides an easy-to-understand method that enables accounting figures to be combined with other process data (see Figure 15).

The balanced scorecard identifies vital figures for answering the following questions:

2-D projection
Abeamer is used to project an image of the planning area on to an ordinary table.

3-D projection
In addition, a three-dimensional view of the planning area will be projected on the wall.

Image return
The picture reflected on the table is returned via a camera mounted beside the beamer.

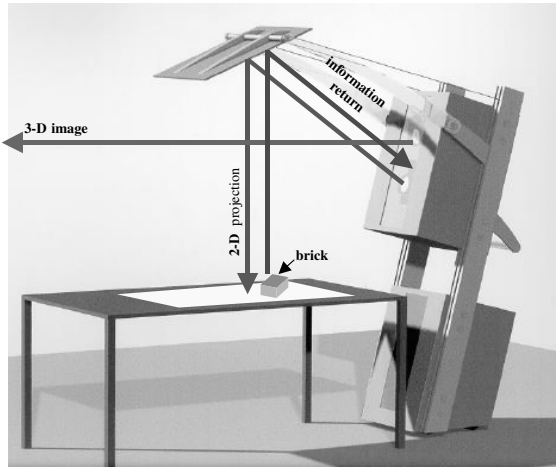

Figure 14 The Technology Behind the Factory Planning Table.

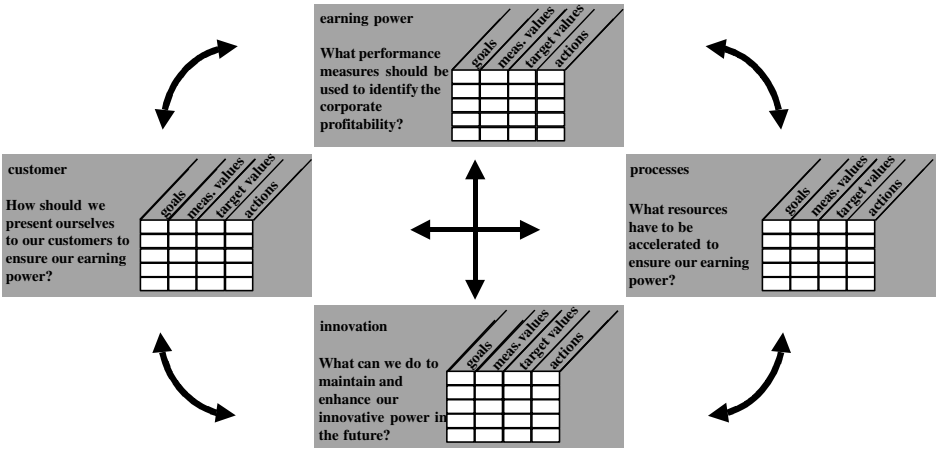

Figure 15 The Principal Structure of the Balanced Scorecard.

- How does the current profit situation of the company compare to the market situation?
- How is the company's market attractiveness rated by its customers?
- What is the current situation in the company's value-adding processes?
- What improvements can be made in corporate processes and products, and what is the innovative power of the company?

This tool helps a company recognize changes in the corporate situation at an early stage and initiate appropriate actions due to the depth and variety of the questions and their differing time horizon. The balanced scorecard thus serves as an early warning system for a company so that it can actively respond to market changes. The tool also allows the current profit and market situation of the company to be taken into consideration. Thus, the balanced scorecard helps the company avoid the short-range view of the profit situation and expand it to include vital aspects of corporate management.

5. CONCLUSION

Based on Peter Drucker's now generally recognized thesis that only the uncertain is certain in the future markets of manufacturing enterprises (Drucker 1992), it appears safe to forecast that manufacturing structures will change fundamentally. In this context, the transformability of future manufacturing structures will become an important feature, enabling quick and proactive response to changing market demands.

In the scenario of transformable manufacturing structures, the focus will no longer be on the "computer-directed factory without man" of the 1980s but on the accomplishment of factory structures that employ of the latest technology. Human beings, with their unique power for associative and creative thinking, will then take a crucial part in guaranteeing the continuous adaptation of factory structures.

Implementing transformability requires the application of new manufacturing structures in factories and enterprises. These structures are distinguished by their capacity for external networking and increased internal responsibility. Combining these new structures with new design and operation methods will lead to factories exceeding the productivity of current factory structures by quantum leaps. However, this vision will only become reality if both strategies—new structures and methods—are allowed to back up each other, not regarded as isolated elements.

CHAPTER 9
Enterprise Modeling

AUGUST-WILHELM SCHEER
FRANK HABERMANN
OLIVER THOMAS
Saarland University

1. MODELING BASICS

1.1. Creating a Model World

Enterprises are sociotechnological real-world systems. A system is a composition of elements and their relationships. Examples of elements of the system enterprise are employees, products, activities, machines, computers, and software, which interact in manifold ways. They can be described by their structures (static view) as well as their behavior (dynamic view). Because enterprises are very complex, in many cases analysis cannot be done directly on the real-world-system.

Enterprise modeling aims at reducing the complexity of the system to be studied. Only specific aspects of an enterprise are examined, such as data structures, input–output relationships, and logistic

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

processes. Such subsystems of the real world are called ''mini world'' or ''model domain.'' Thus, models are descriptions of the most important characteristics of a focused domain. The creative process of building such an abstracted picture of a real-world system is called modeling (see Figure 1).

In addition to the actual purpose of modeling, the modeling methods applied also determine the focus of the model. This is particularly true when a certain type of method has already been defined. Models reproduce excerpts of reality. They are created by abstracting the properties of real objects, whereas their essential structures and behavior remain intact (homomorphy). Not only the content-related purpose of the model but also the permissible illustration methods determine to what extent nonessential characteristics may be abstracted. For example, if an object-oriented modeling approach or a system-theoretic approach is selected, modeling only leads to objects applicable to the syntax or the semantics of these particular methods. In order to avoid lock-in by certain methods, architectures and methodologies are developed independently of any particular method, while supporting a generic business process definition.

The following sections we will discuss modeling methods and architectures in greater detail.

1.2. Levels of Abstraction

Abstraction is the basic concept of modeling. In system theory, we know many perspectives of abstraction. Thus, we can concentrate either on the structure or behavior of enterprises; on certain elements of the enterprise, such as data, employees, software, products; or on a bounded domain, such as sales, accounting, manufacturing. Typically, in enterprise modeling projects, several of these perspectives are combined. For instance, a typical modeling project might be ''Describe the sales data structures.''

However, the term *level of abstraction* describes the relationships between a model system and the respective real-world system. That is, it describes the steps of abstraction. From low to high abstraction we can distinguish at least three levels in modeling: instances, application classes, and meta classes.

At the instance level, each single element of the real world is represented through one single element in our model. For example, in the case of modeling an individual business process, every element involved in the business process is instantiated by the affixed name, such as customer (no.) 3842, material M 32, or completed order O 4711, etc. (see Figure 2).

Enterprise modeling at the instance level is used for controlling individual business processes. In manufacturing, this is for creating work schedules as the manufacturing process descriptions for individual parts or manufacturing orders. In office management, individual business processes are executed through workflow systems. Therefore, they must have access to information regarding the respective control structure and responsible entities or devices for every single business case.

At the application class level, we abstract from instance properties and define classes of similar entities. For example, all individual customers make up the class ''customer,'' all instances of orders constitute the class ''order,'' and so on (see Figure 2). Every class is characterized by its name and the enumeration of its attributes, by which the instance is described. For example, the class ''cus-

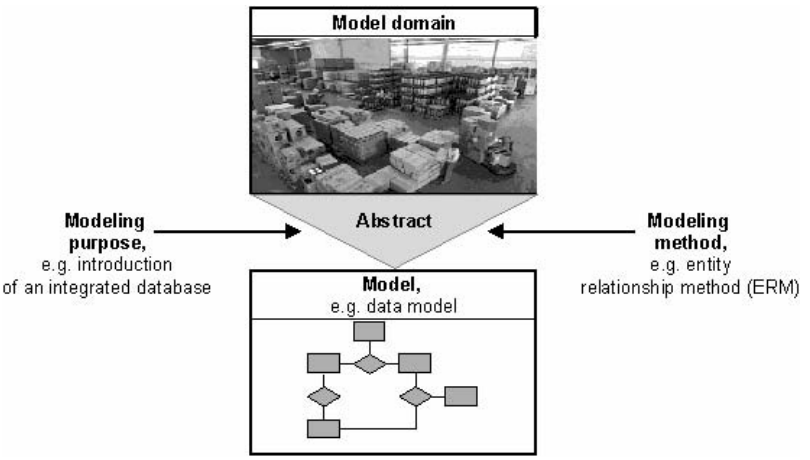

Figure 1 Modeling.

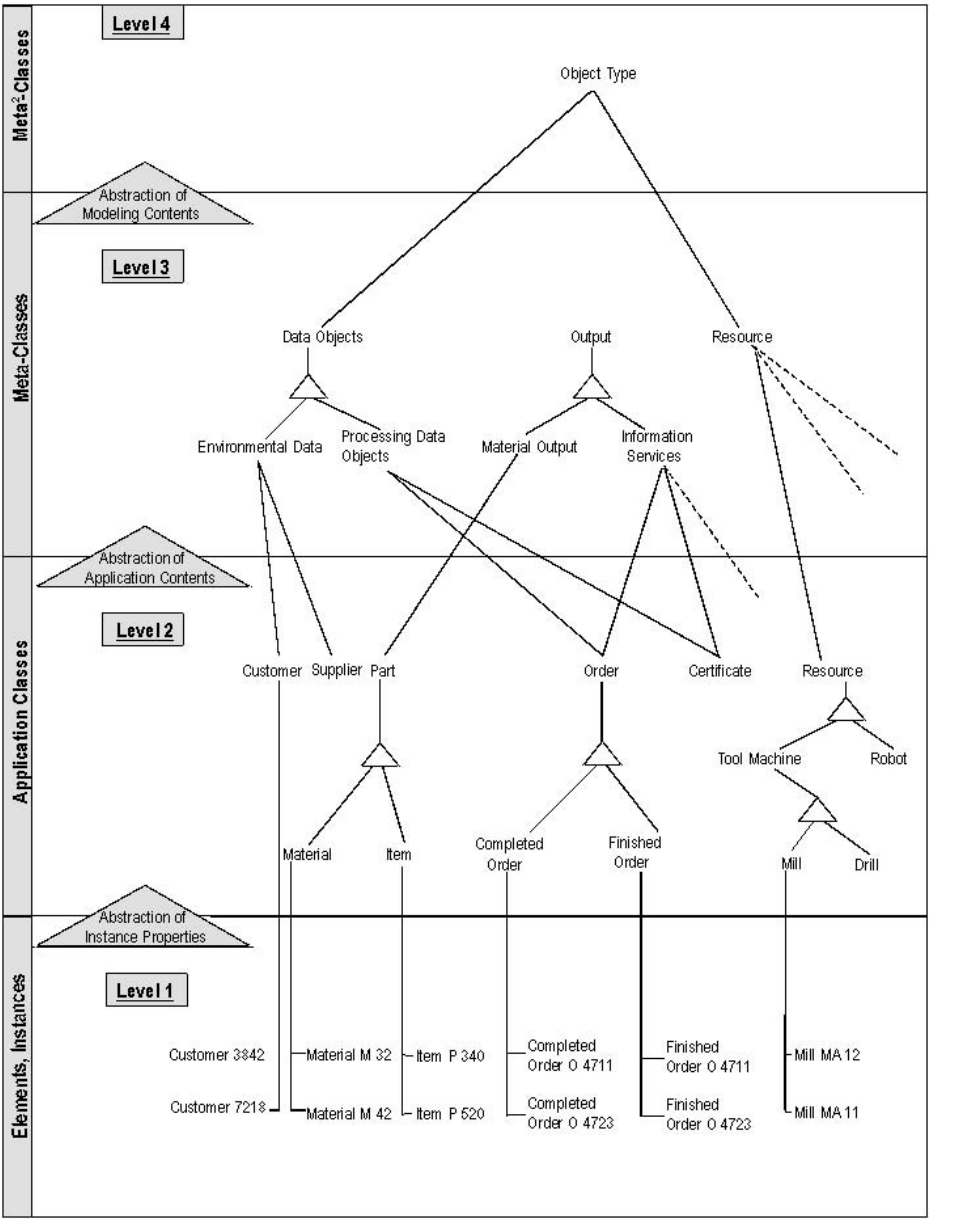

Figure 2 Levels of Abstraction.

tomer'' is characterized by the attributes customer number, customer name, and payment period. The instances of these characteristics are the focus of the description at Level 1.

Finding classes is always a creative task. It thus depends on the subjective perspective of the modeler. Therefore, when defining, for example, order designations, we will only abstract specific properties of cases 4711 or 4723, respectively, leading to the classes ''completed order'' or ''finished order.'' At Level 2, we will abstract the ''completed'' and ''finished'' properties and create the parent class ''order'' from the subset. This operation is known as generalization and is illustrated by a triangular symbol.

When quantities are generalized, they are grouped to parent quantities. This makes order instances of Level 1 instances of the class ''order'' as well. The class ''order'' is designated as the property ''order status,'' making it possible to allocate the process state ''completed'' or ''finished'' to every instance. Materials and items are also generalized, making them ''parts'' and ''resources.''

Thus, Level 2 contains application-related classes of enterprise descriptions. On the other hand, with new classes created from similar classes of Level 2 by abstracting their application relationships, these are allocated to Level 3, the meta level, as illustrated in Figure 2. Level 2 classes then become instances of these meta classes. For example, the class ''material output'' contains the instances ''material'' and ''item'' as well as the generalized designation ''part.'' The class ''information services'' contains the class designation ''order,'' along with its two child designations, and the class designation ''certificate.'' The creation of this class is also a function of its purpose. Thus, either the generalized classes of Level 2 or their subclasses can be included as elements of the meta classes.

When classes are created, overlapping does not have to be avoided at all costs. For example, from an output flow point of view, it is possible to create the class ''information services'' from the classes ''order'' and ''certificate.'' Conversely, from the data point of view, these are also data objects, making them instances of the class ''data objects'' as well.

The classes at modeling Level 3 define every object necessary for describing the facts at Level 2. These objects make up the building blocks for describing the applications at Level 2. On the other hand, because the classes at Level 2 comprise the terminology at Level 1, objects at Level 3 are also the framework for describing instances.

This abstraction process can be continued by once again grouping the classes at Level 3 into classes that are then allocated to the meta^2 level. Next, the content-related modeling views are abstracted. In Figure 2, the general class ''object type'' is created, containing all the meta classes as instances.

1.3. Principles of Modeling

Enterprise modeling is a creative process and can therefore not be completely directed by rules. However, if certain standards are observed, it is indeed possible to classify and understand third-party models. Furthermore, it is also a good idea to establish certain quality standards for enterprise models.

Figure 3 illustrates the relationship between principles and enterprise modeling. A principle is a fundamental rule or strategy that guides the entire process of enterprise modeling. Thus, modeling

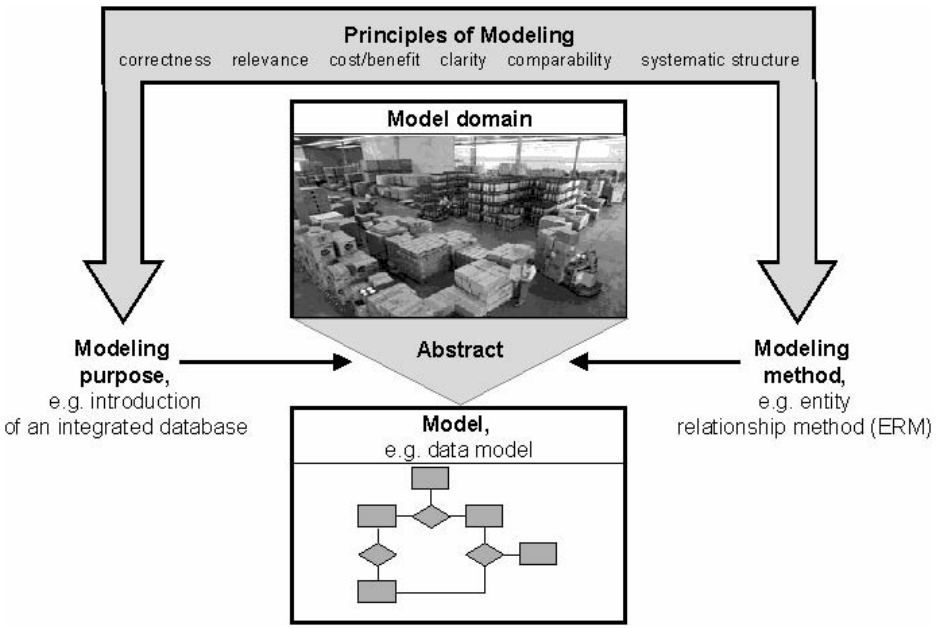

Figure 3 Principles of Modeling.

principles concern the association between the domain and the respective model as well as the selection of appropriate modeling methods and tool support. A modeling method is a set of components and a description of how to use these components in order to build a model. A modeling tool is a piece of software that can be used to support the application of a method. We will discuss modeling methods and tools in more detail in the following chapters.

1.3.1. Principle of Correctness

The correctness of models depends on correct semantics and syntax, that is, whether syntax of the respective metamodel is complete and consistent. Semantic correctness of a model is measured by how closely it complies with the structure and behavior of the respective object system. In real-world applications, compliance with these requirements can be proven only after simulation studies have been carried out or other similar efforts have been made. Some modeling tools provide a simulation function that can be used for this purpose.

1.3.2. Principle of Relevance

Excerpts of the real-world object system should only be modeled provided they correspond with the purpose of the model. Models should not contain more information than necessary, thus keeping the cost vs. benefit ratio down to an acceptable level.

1.3.3. Principle of Cost vs. Benefit

One of the key factors ensuring a good cost vs. benefit ratio is the amount of effort necessary to create the model, the usefulness of modeling the scenario, and how long the model will be used.

1.3.4. Principle of Clarity

''Clarity'' ensures that a model is understandable and usable. It also determines how pragmatic the relationship between the model and the user is. Because models contain a large amount of information regarding technical and organizational issues, only specialists are usually able to understand them quickly. Once models are broken down into subviews, individual views are easier to comprehend.

1.3.5. Principle of Comparability

Models created in accordance with a consistent conceptual framework and modeling methods are comparable if the objects have been named in conformity with established conventions and if identical modeling objects as well as equivalent degrees of detailing have been used. In models created with different modeling methods, it is important to make sure that their metamodels can be compared.

1.3.6. Principle of Systematic Structure

This principle stipulates that it should be possible to integrate models developed in various views, such as data models, organizational models, and business process models. This requires an integrated methodology, that is, an architecture providing a holistic metamodel (see Section 4).

2. MODELING BENEFITS

Enterprise models are used as instruments for better understanding business structures and processes. Thus, the general benefit of enterprise modeling is in business administration and organizational processes. Focusing computer support in business, we can use enterprise models additionally to describe the organizational impacts of information technology. Consequently, the second major benefit of enterprise modeling is for developing information systems.

2.1. Benefits for Business Administration and Organizational Processes

Corporate mission statements entail the production and utilization of material output and services by combining production factors. Multiple entities and devices are responsible for fulfilling these tasks. In accordance with corporate objectives, their close collaboration must be ensured. In order for human beings to be able to handle complex social structures such as enterprises, these structures must be broken down into manageable units. The rules required for this process are referred to as ''organization.''

Structural or hierarchical organizations are characterized by time-independent (static) rules, such as by hierarchies or enterprise topologies. Here, relationships involving management, output, information, or communication technology between departments, just to name a few, are entered. Org charts are some of the simple models used to depict these relationships.

Process organizations, on the other hand, deal with time-dependent and logical (dynamic) behavior of the processes necessary to complete the corporate mission. Hierarchical and process organizations are closely correlated. Hierarchical organizations have been a key topic in business theory for years.

However, due to buzzwords such as business process reengineering (BPR), process organizations have moved into the spotlight in recent years.

Reasons for creating business process models include:

- Optimizing organizational changes, a byproduct of BPR
- Storing corporate knowledge, such as in reference models
- Utilizing process documentation for ISO-9000 and other certifications
- Calculating the cost of business processes
- Leveraging process information to implement and customize standard software solutions or workflow systems (see Section 2.2).

Within these categories, other goals can be established for the modeling methods. In business process improvement, we must therefore identify the components that need to be addressed. Some of the many issues that can be addressed by business process optimization are:

- Changing the process structure by introducing simultaneous tasks, avoiding cycles, and streamlining the structure
- Changing organizational reporting structures and developing employee qualification by improving processing in its entirety
- Reducing the amount of documentation, streamlining and accelerating document and data flow
- Discussing possible outsourcing measures (shifting from internal to external output creation)
- Implementing new production and IT resources to improve processing functions

In these examples, we are referring to numerous modeling aspects, such as process structures, hierarchical organizations, employee qualification, documents (data), and external or internal output as well as production and IT resources. Obviously, an enterprise model, particularly a business process model for the purpose of optimization, must be fairly complex. Moreover, it should address multiple aspects, for which numerous description methods are necessary. These various purposes determine the kind of modeling objects as well as the required granularity.

2.2. Benefits for Developing Information Systems

Information systems can be designed as custom applications or purchased as off-the-shelf standard solutions. After the initial popularity of custom applications, integrated standard solutions are now the norm. With the advent of new types of software, such as componentware (where software components for certain application cases are assembled to form entire applications), a blend between the two approaches has recently been making inroads.

The development of custom applications is generally expensive and is often plagued by uncertainties, such as the duration of the development cycle or the difficulty of assessing costs. Thus, the tendency to shift software development from individual development to an organizational form of industrial manufacturing—in ''software factories''—is not surprising.

In this context, multiple methods for supporting the software development process have been developed. They differ according to their focus on the various software development processes and their preferred approach regarding the issue at hand, such as data, event, or function orientation, respectively.

Due to the wide range of methods that differ only slightly from one another, this market is cluttered. In fact, the multitude of products and approaches has actually impeded the development of computer-aided tools based on these methods. We therefore recommend a methodology (study of methods) covering various development methods. The following are typical questions that leverage the framework capabilities of a methodology:

1. Are there really so many totally different ways of designing a computer-aided information system?
2. If not, how similar are these methods? If so, why are there so many different ways?
3. Is there an optimal way of developing an information system?
4. Where does the development process start and where does it end?
5. What does the finished product of the design process look like?
6. How many steps are necessary to obtain a development result?
7. Should only one particular kind of information system be used or are several methods required, each for a different system? According to which criteria should the methods be selected?

The purpose of these questions is to classify and evaluate the various modeling methods. After these issues are addressed, there is, however, a second group of reasons for dealing with information system design methodologies (ISDMs), resulting from the fact that usually several business partners are involved in complex development projects. Sometimes they use different development methods, or the results of their work might overlap. Only an architecture integrating the individual methods, confirming agreement or pointing out any overlap, can lead to mutual understanding.

The alternative to individual software development is to buy a standardized business administration software solution. Such solutions include modules for accounting, purchasing, sales, production planning, and so on. Financial information systems are characterized by a markedly high degree of complexity. Many corporate and external business partners are involved in the implementation of information systems. This becomes apparent in light of seamlessly integrated data processing, where data is shared by multiple applications. Examples include comprehensive IS-oriented concepts implemented in enterprises, CIM in manufacturing companies, IS-supported merchandise management systems for retailers, and electronic banking in financial institutions.

Until the mid-1990s, the ratio between the effort of implementing financial packaged applications in organizations and their purchase price was frequently more than 5:1. This ratio is so high because off-the-shelf systems are more or less easy to install, yet users must also determine which goals (strategies) they wish to reach with the system, how the functionality of the system can achieve this, and how to customize, configure, and technically implement the package.

With hardware and software costs rapidly decreasing, that ratio became even worse. Small and medium-sized enterprises (SMEs) are not able to pay consultants millions of dollars for implementation. Hence, architectures, methods, and tools have become increasingly popular because they can help reduce the cost of software implementation and at the same time increase user acceptance of standard software solutions.

Several modeling approaches are possible:

- Reduce the effort necessary for creating the target concept by leveraging ''best-practice case'' knowledge available in reference models.
- Create a requirements definition by leveraging modeling techniques to detail the description.
- Document the requirements definition of the standard software by means of semantic modeling methods, making the business logic more understandable.
- Use semantic models to automate reconciliation of the requirements definition of the target concept with the standard software as much as possible, cutting down on the need for specific IS skills.
- Leverage semantic models as a starting point for maximum automation of system and configuration customizing.

3. MODELING VIEWS AND METHODS

3.1. Process-Oriented Enterprise Modeling

Generally speaking, a business process is a continuous series of enterprise activities, undertaken for the purpose of creating output. The starting point and final product of the business process are the output requested and utilized by corporate or external customers. Business processes often enable the value chain of the enterprise as well as focusing on the customer when the output is created.

In the following, we explain the key issues in modeling business processes with a simple example from customer order processing. First, let us outline the scenario:

> A customer wants to order several items that need to be manufactured. Based on customer and item information, the feasibility of manufacturing this item is studied. Once the order has arrived, the necessary materials are obtained from a supplier. After arrival of the material and subsequent order planning, the items are manufactured according to a work schedule and shipped to the customer along with the appropriate documentation.

This scenario will be discussed from various points of view. As we have already seen, in system theory we can distinguish between system structures and system behavior. We will begin by describing the responsible entities and relationships involved in the business process. Then, by means of function flow, we will describe the dynamic behavior. Output flows describe the results of executing the process, and information flows illustrate the interchange of documents involved in the process.

Functions, output producers (organizational units), output, and information objects are illustrated by various symbols. Flows are depicted by arrows.

3.1.1. Organization Views

Figure 4 depicts the responsible entities (organizational units) involved in the business process, along with their output and communication relationships, illustrated as context or interaction diagrams. The

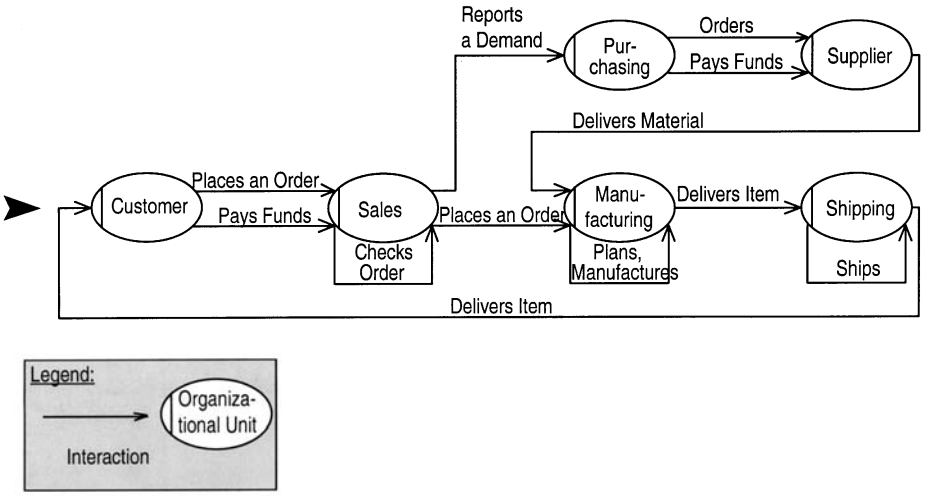

Figure 4 Interaction Diagram of the Business Process "Order Processing."

sequence in which processes are carried out is not apparent. Nevertheless, this provides an initial view of the business process structure. In complex processes, the myriad interchanges among the various business partners can become somewhat confusing. In addition to the various interactions, it is also possible to enter the activities of the responsible entities. This has been done in only a few places.

The class of organization views also includes the hierarchical organization structure (org charts). Org charts are created in order to group responsible entities or devices that are executing the same work object. This is why the responsible entities, responsible devices, financial resources, and computer hardware are all assigned together to the organization views.

3.1.2. Function Views

Figure 5 describes the same business process by depicting the activities (functions) to be executed, as well as their sequence. The main issue is not responsible entities, as with the interaction diagram, but rather the dynamic sequence of activities. For illustration purposes, the organizational units are also depicted in Figure 5. Due to redundancies, their interrelationship with the interaction diagram is not as obvious. As function sequences for creating output, function flows characterize the business process. The output flows themselves will be displayed individually.

The class of function views also includes the hierarchical structure of business activities transforming input into output. According to the level of detail, they are labeled "business processes," "processes," "functions," and "elementary functions."

Because functions support goals, yet are controlled by them as well, goals are also allocated to function views—because of the close linkage. In application software, computer-aided processing rules of a function are defined. Thus, application software is closely aligned with "functions" and is also allocated to function views.

3.1.3. Output Views

The designation "output" is very heterogeneous. Business output is the result of a production process, in the most general sense of the word. Output can be physical (material output) or nonphysical (services). Whereas material output is easily defined, such as by the delivery of material, manufactured parts, or even the finished product, the term *services* is more difficult to define because it comprises heterogeneous services, such as insurance services, financial services, and information brokering services. Figure 6 illustrates this simplified classification of "output"—that is, also "input"—as a hierarchical diagram.

Concerning our business process example, the result of the function "manufacture item" in Figure 7 is the material output, defined by the manufactured item. Likewise, quality checks are carried out and documented during the manufacturing process. All data pertinent to the customer are captured in "order documents," themselves a service by means of the information they provide. After every intercompany function, output describing the deliverable is defined, which in turn is entering the next

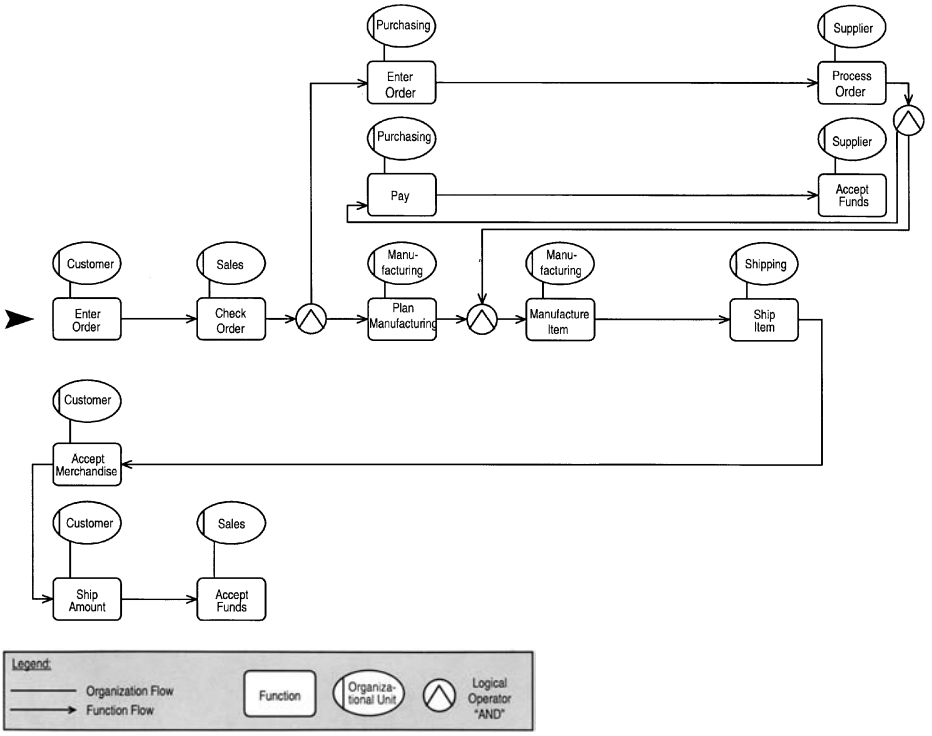

Figure 5 Function Flow of the Business Process "Order Processing."

process as input. To avoid cluttering the diagram, the organizational units involved are not depicted. It is not possible to uniquely derive the function sequence from the illustration of the output flow.

3.1.4. Data Views

The designations "data" and "information" are used synonymously. In addition to information services, other information, used as environment descriptions during the business processes, constitutes

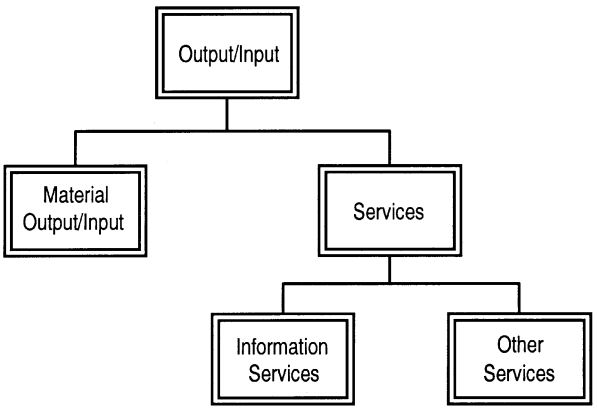

Figure 6 Types of Input–Output.

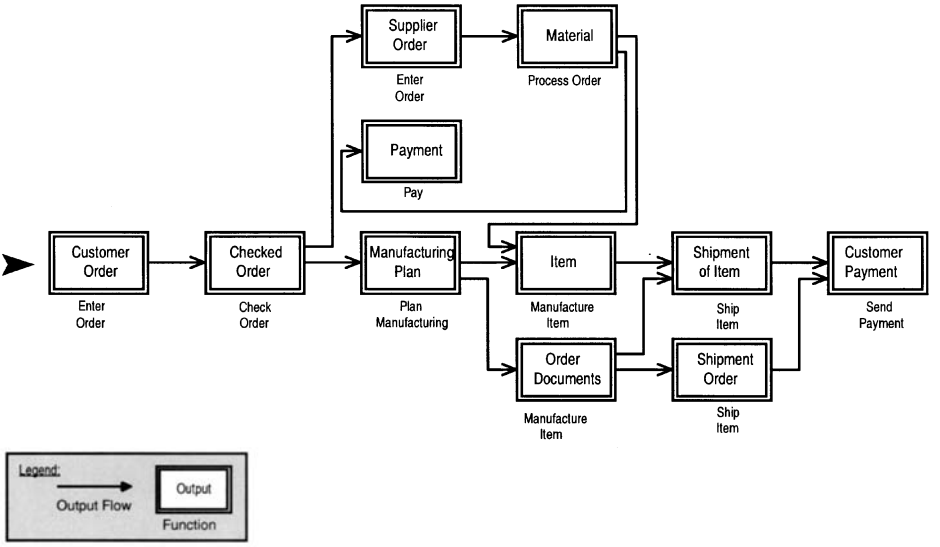

Figure 7 Output Flow of the Business Process "Order Processing."

process components. Figure 8 illustrates the information objects of our business process example, along with the data interchanged among them. Objects listed as information services have double borders. Information objects describing the environment of the business process are shown as well, such as data regarding suppliers, items, or work schedules. These data are necessary to create infor-

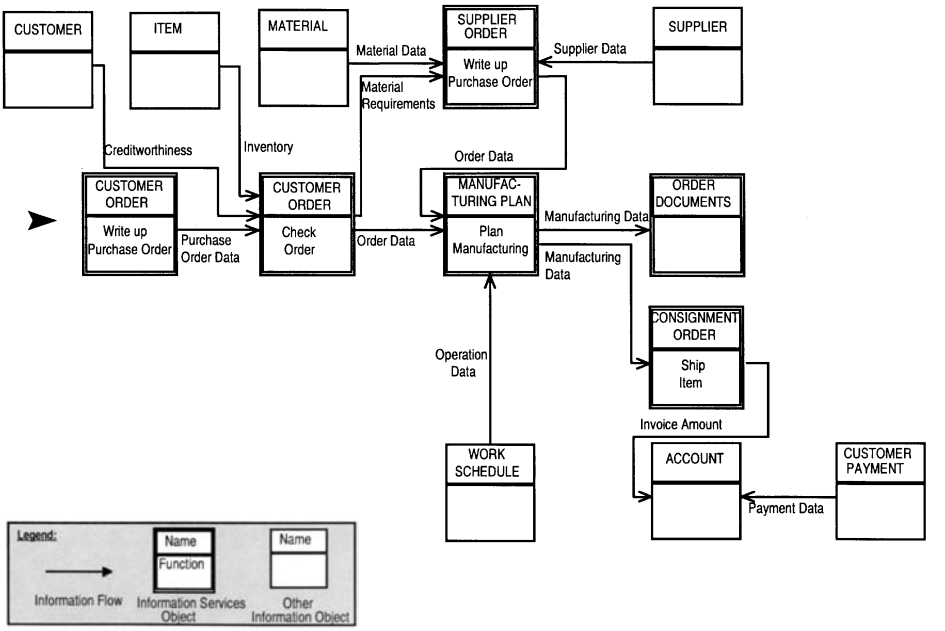

Figure 8 Information Flow of the Business Process "Order Processing."

mation services. For example, when orders are checked, the customer's credit is checked and inventory is checked for availability.

Because data flow is triggered by the functions that are linked to the information objects, it is more or less possible to read the function flow in Figure 8. However, if multiple functions are applied to an information object or multiple data flows are requested by a function, the function process cannot be uniquely deduced.

Besides information flow modeling, the (static) description of data structures is a very important modeling task. Static enterprise data models are used to develop proper data structures in order to implement a logically integrated database. Chen's entity relationship model (ERM) is the most widespread method for the conceptual modeling of data structures.

3.1.5. Process View

Building various views serves the purpose of structuring and streamlining business process modeling. Splitting up views has the added advantage of avoiding and controlling redundancies that can occur when objects in a process model are used more than once. For example, the same environmental data, events, or organizational units might be applied to several functions. View-specific modeling methods that have proven to be successful can also be used. Particularly in this light, view procedures differ from the more theoretical modeling concepts, where systems are divided into subsystems for the purpose of reducing complexity. In principle, however, every subsystem is depicted in the same way as the original system. This is why it is not possible to use various modeling methods in the same system.

It is important to note that none of the flows (organization, function, output, and information flow, respectively) illustrated above is capable of completely modeling the entire business process. We must therefore combine all these perspectives. To this end, one of the views should be selected as a foundation and then be integrated into the others. The function view is closest to the definition of a business process and is therefore typically used as a starting point. However, in the context of object-oriented enterprise modeling information, flows can serve as a starting point as well.

Figure 9 provides a detailed excerpt of our business process example, focusing the function "manufacture item" with all flows described above.

The method used to describe the process in Figure 9 is called event-driven process chain (EPC). The EPC method was developed at the Institute for Information Systems (IWi) of the Saarland

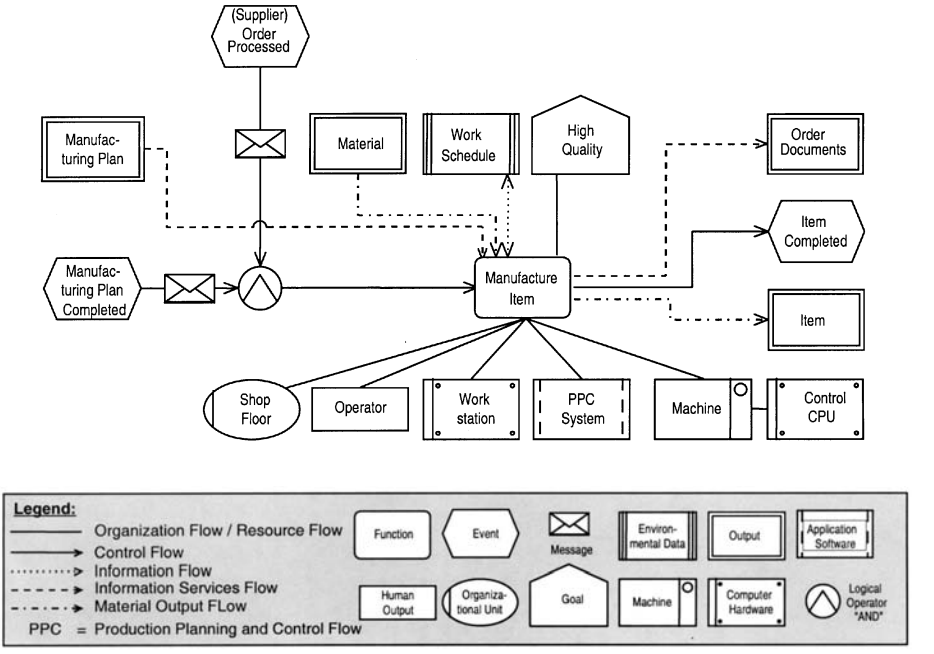

Figure 9 Detailed Excerpt of the Business Process "Order Processing."

University, Germany, in collaboration with SAP AG. It is the key component of SAP R/3's modeling concepts for business engineering and customizing. It is based on the concepts of stochastic networks and Petri nets. Simple versions exclude conditions and messages and include only E(vent)/A(ction) illustrations.

Multiple functions can result from an event. On the other hand, multiple functions sometimes need to be concluded before an event can be triggered. Logical relationships are illustrated by "and" ($\wedge$), "inclusive-or" ($\vee$) and "exclusive-or" (XOR) symbols. Figure 10 gives some typical examples of event relationships. When there are more complex relationships between completed functions and functions that have just been launched (such as different logical relationships between groups of functions), decision tables for incoming and outgoing functions, respectively, can be stored in an event.

3.2. Object-Oriented Enterprise Modeling

Object-oriented enterprise modeling starts with analyzing the entities of the real world. In the object-oriented model, these entities will be described through objects. The object data (attributes) represent characteristics of the real system and are accessible only by means of object methods. By their definition, attributes and methods objects are entirely determined. Objects that share the same characteristics are instances of the respective object class. Classes can be specialized to subclasses as well as generated to superclasses. This is called inheritance—each subclass will inherit the attributes and methods from its superclass.

We can equate the term *method* used in object-oriented analysis with the term *function.* Due to the fact that classes are frequently data classes (such as "customers," "suppliers," "orders," etc.), they represent the link between data and function view. We have already experienced object-oriented class design when we discussed the levels of abstraction and the examples of the modeling views (see Section 1.2 as well as Section 3.1), so we can skim the properties of creating object-oriented classes.

Object-oriented modeling is not based on a standardized method. Rather, a number of authors have developed similar or complementary approaches. The various graphical symbols they use for their approaches make comparisons difficult. The Unified Modeling Language (UML), introduced by

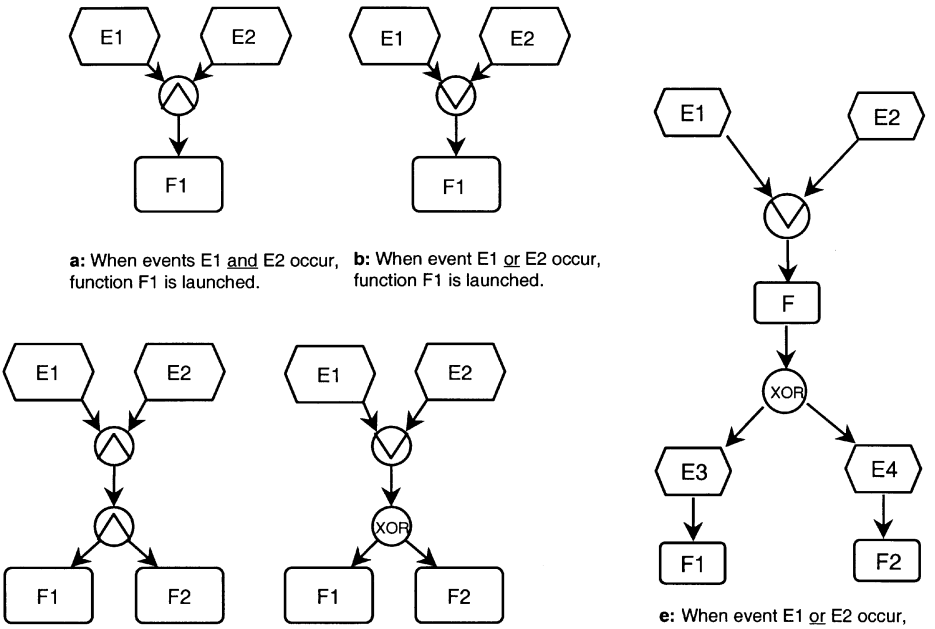

Figure 10 Event Relationships in EPC.

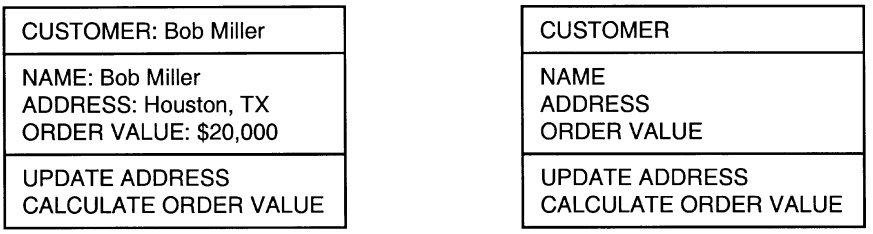

Figure 11 Object and Object Class.

Rumbaugh, Booch, and Jacobsen aims to streamline and integrate various object-oriented approaches, which is why we will use these symbols.

Objects, each with its own identity and indicated by an ID number, are described by properties (attributes). The functions (methods) that can be applied to the object define their behavior. Objects represent instances and are illustrated by rectangles. Objects with identical attributes, functionality, and semantics are grouped into object classes or regular classes. The quantity of customers thus forms the class "customer" (see Figure 11).

By naming attributes and methods, classes define the properties and the behavior of their instances, that is, objects. Because attributes and methods form a unit, classes realize the principle of encapsulation. In addition to attribute and method definitions for objects, we can also use class attributes and class methods that are valid only for the classes themselves, not for the objects. An example would be "number of customers" and "creating a new customer."

One significant property of the object-oriented approach is inheritance, giving classes access to the properties (attributes) and the behavior (methods) of other classes. Inherited attributes and methods can be overwritten and redefined by the inheriting class. Inheritance takes place within a class hierarchy with two types of classes, namely overriding classes and subordinate classes, as is shown by generalizing and specializing operations in data modeling. A class can also inherit properties from several overriding classes (multiple inheritance), with the resulting class diagram forming a network. Figure 12 gives an example of inheritance among object classes.

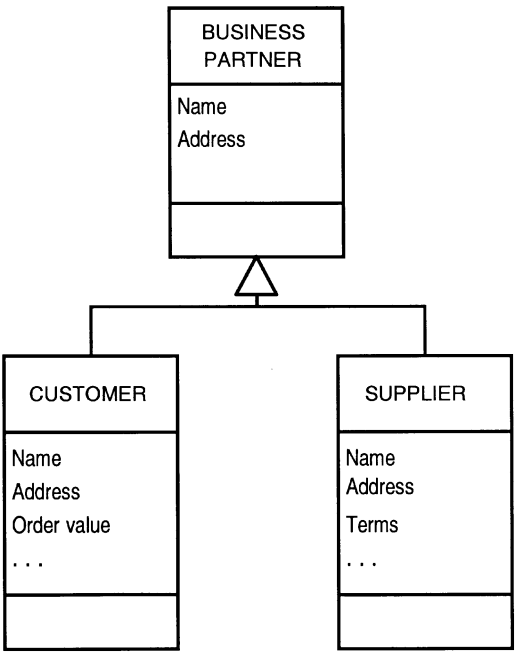

Figure 12 Inheritance.

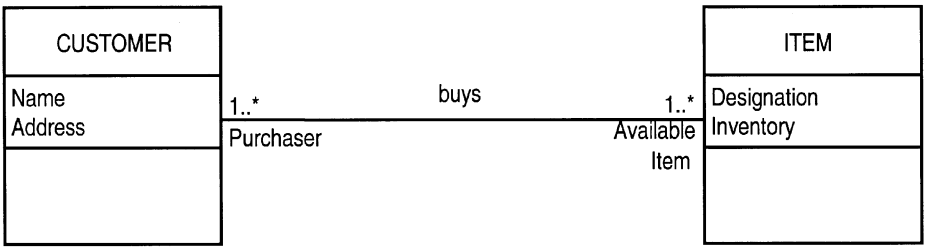

Figure 13 Association.

In addition to the generalizing relationships between classes, there are also relationships (i.e. associations) between objects of equal class ranking or between objects of the same class. These associations equate to relationships in entity relationship models, although here they are illustrated by only one line. These illustrations should be read from left to right. Cardinalities are allocated to an association. At each end of the association, role names can be allocated to the associations. If associations contain attributes, they are depicted as classes (see the class "purchasing process" in Figure 13).

Aggregations are a special kind of association describing the "part of" relationships between objects of two different classes. Role names can be applied to aggregations as well. If attributes are allocated to an aggregation, this leads to a class, as shown by the class "structure," in an aggregation relation for a bill of materials (see Figure 14).

Class definition, inheritance, associations, and aggregations make up the key structural properties of object-oriented modeling. Overall, the UML provides seven methods for describing the various static and dynamic aspects of enterprises. Nevertheless, even with methods such as use case diagrams and interaction diagrams, it is difficult to depict process branching, organizational aspects, and output flows. Therefore, one of the main disadvantages of the object-oriented approach is it does not illustrate business process in a very detailed manner.

4. MODELING ARCHITECTURES

4.1. Architecture of Integrated Information Systems (ARIS)

In the architecture of integrated information systems (ARIS), we can distinguish two different aspects of applications:

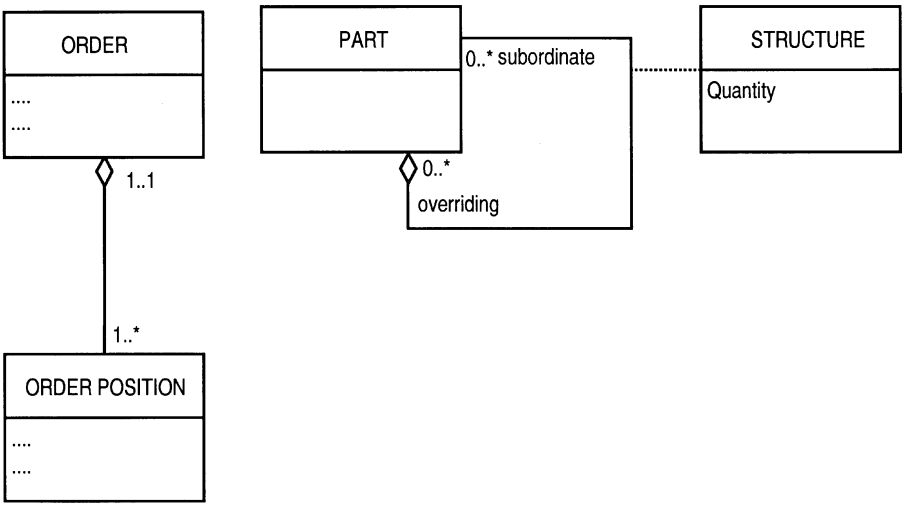

Figure 14 Aggregation.

1. The ARIS concept (ARIS house), an architecture for modeling enterprises, particularly describing business processes
2. The ARIS house of business engineering (HOBE), representing a concept for comprehensive computer-aided business process management.

Both applications are supported by the ARIS Toolset software system, developed by IDS Scheer AG. We will discuss tool support for enterprise modeling in Section 5.

The ARIS concept consists of five modeling views and a three-phase life cycle model. The integration of both leads to 15 building blocks for describing enterprise information systems. For each block the ARIS concept provides modeling methods, meta structures of which are included in the ARIS information model.

As we have already discussed static and dynamic modeling views (see Section 3.1), we can skim over the creation of modeling views. ARIS views are created according to the criterion of semantic correlation similarity, that is, enterprise objects that are semantically connected are treated in the same modeling view. The ARIS modeling views are (see Figure 15):

- *Data view:* This view includes the data processing environment as well as the messages triggering functions or being triggered by functions. Events such as "customer order received,"

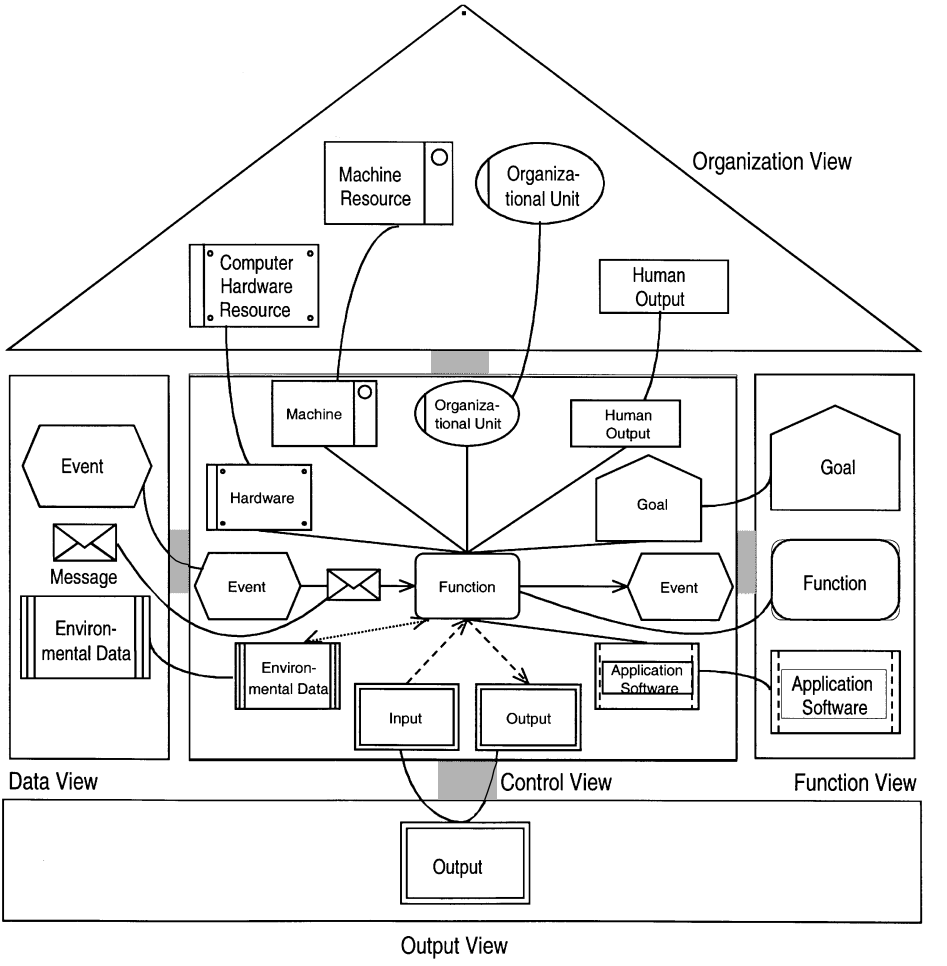

Figure 15 Views of the ARIS Concept.

''completion notice received,'' and ''invoice written'' are also information objects represented by data and therefore modeled in the data view.

- *Function view:* The business activities to be performed and their relationships form the function view. It contains the descriptions of each single activity (function) itself, the associations between super- and subordinate functions, and the logical sequence of functions. Enterprise goals that guide the performance of the functions and the application systems that support their execution are also components of this view.
- *Organization view:* Departments, office buildings, and factories, are examples of organizational units that perform business functions. They are modeled according to criteria such as ''same function'' and ''same work object.'' Thus, the structure as well as the interaction between organizational units and the assigned resources (human resources, machine resources, computer hardware resource) are part of the organization view.
- *Output view:* This view contains all physical and nonphysical output that is created by business functions, including services, materials, and products as well as funds flows. Because each output is input for another function—even if this function is probably carried out by an external partner—input–output diagrams are also components of this view.
- *Control view/process view:* In the views described above, the classes are modeled with their relationships relative to the views. Relationships among the views as well as the entire business process are modeled in the control or process view. This enables a framework for the systematic inspection of all bilateral relationships of the views and the complete enterprise description using a process-oriented perspective.

The ARIS concept provides a set of methods that can be used to model the enterprise objects and their static and dynamic relationships. For each view at least one well-proven method is provided. Because ARIS is an open architecture, new modeling methods, such as UML methods, can easily be integrated into the meta structure. Figure 16 gives examples of ARIS methods for conceptual modeling.

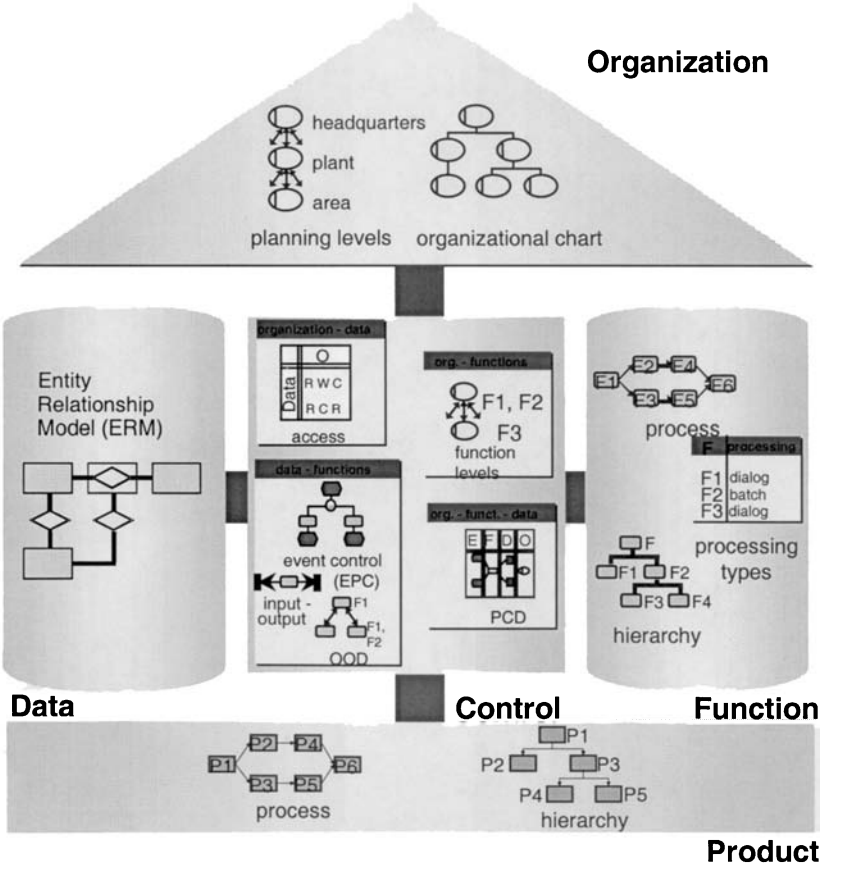
Up to now, we have discussed enterprises, particularly business processes, from a management point of view, that is, without any particular focus on information technology. The aforementioned application programs (components of the function view), computer hardware (a component of the organization view), and data media (components of the data view) contain only system names, not IT descriptions. These are included in the ARIS concept by evaluating the IT support provided by each ARIS view.

- Function views are supported by the application programs, which may be described in more detail by module concepts, transactions, or programming languages.
- Organization views, along with their production resources and the computer resources responsible, may be detailed further by listing network concepts, hardware components, and other technical specifications.
- Data views may be detailed more precisely by listing data models, access paths, and memory usage.
- Output views group the various types of output, such as material output and information services. Here again there is a close alignment with the supporting information technology. In material output (e.g., entertainment technology, automobiles, and machine tools), more and more IT components (e.g., chip technology), along with the necessary hardware, are used. Other service industries, such as airline reservations, are closely linked with IT as well.
- The fact that the respective views can be combined within the control view means that there is a definite link with IT, as demonstrated by the above arguments.

Using a phase model, enterprise models are thus transformed step by step into information and communication technology objects (see Figure 17).

The starting point of systems development is the creation of an IS-oriented initial strategic situation in Phase 1. ''IS-oriented'' means that basic IT effects on the new enterprise concepts are already taken into account. Some examples of these relationships might be creating virtual companies through communication networks, PC banking, integrated order processing and product development in industry (CIM), or integrated merchandise management systems (MMS) in retail.

Strategic corporate planning determines long-term corporate goals, general corporate activities, and resources. Thus, planning has an effect on the long-term definition of enterprises, influencing corporate goals, critical success factors, and resource allocation. The methods in question are similar to management concepts for strategic corporate planning. Provided actual business processes have already been described, this occurs in a general fashion. At this stage, it is not advisable to split up functions into ARIS views and then describe them in detail.



Legend:

ERM = Entity Relationship Model
Fn = Function n
E = Event
D = Data
O = Organizational Unit
Pn = Product n
R = Read
W = Write
C = Create
PCD = Process Chain Diagram
EPC = Event-driven Process Chain
OOD = Object Oriented Design

Figure 16 ARIS Methods for Conceptual Modeling.

In Phase 2, the requirements definition, individual views of the application system are modeled in detail. Here as well, business-organizational content is key. Examples of business processes should be included at this level. However, in this phase more conceptual modeling methods should be used than in the strategic approach because the descriptions for the requirements definition are the starting point for IT implementation. Modeling methods that are understandable from a business point of view should be used, yet they should be sufficiently conceptual to be a suitable starting point for a

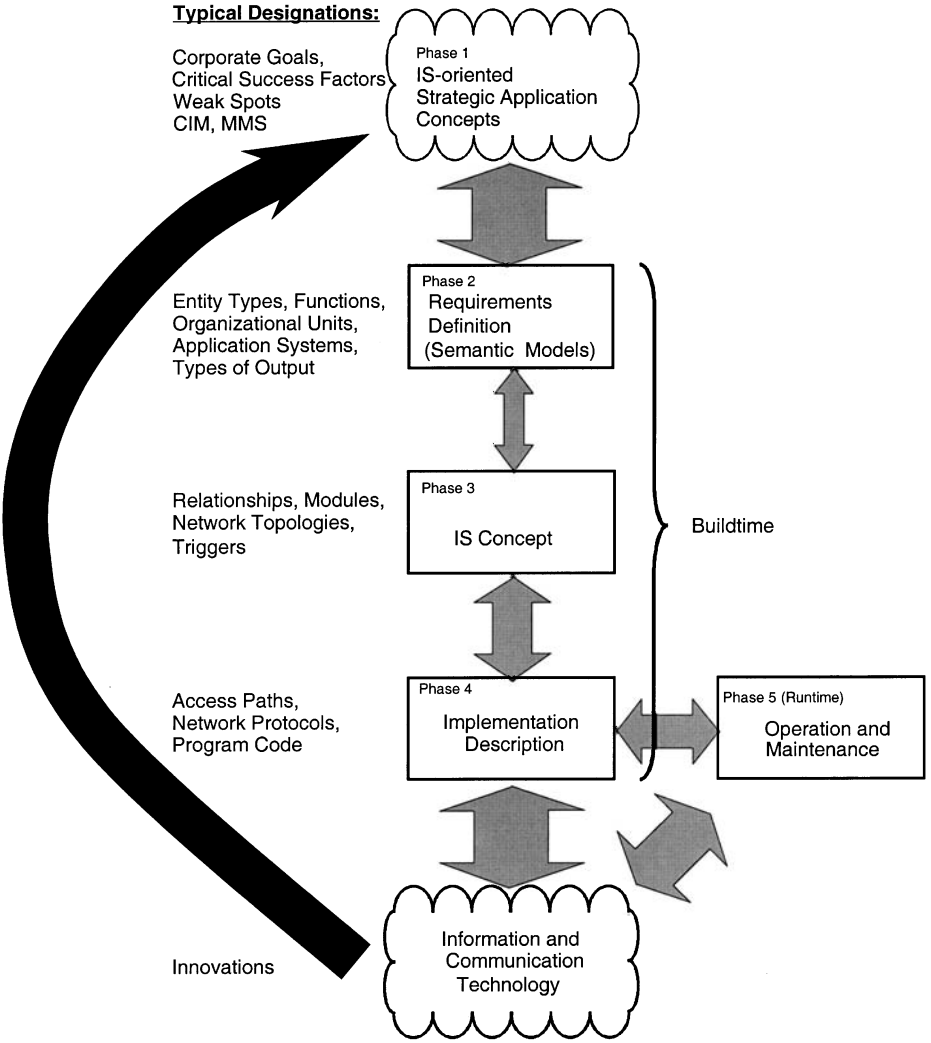


Figure 17 ARIS Phase Model.

consistent IT implementation. Therefore, it makes sense to include general IT objects, such as databases or programs, at this level.

Phase 3 calls for creating the design specification, where enterprise models are adapted to the requirements of the implementation tool interfaces (databases, network architectures, or programming languages, etc.). At this time, actual IT products are still irrelevant.

Phase 4 involves the implementation description, where the requirements are implemented in physical data structures, hardware components, and real-world IT products.

These phases describe the creation of an information system and are therefore known as buildtime. Subsequently, the completed system becomes operable, meaning it is followed by an operations phase, known as runtime. We will not address the operation of information systems, that is, runtime, in great detail.

The requirements definition is closely aligned with the strategic planning level, illustrated by the width of the arrow in Figure 17. However, it is generally independent of the implementation point of view, as depicted in the narrow arrow pointing to the design specification.

Implementation description and operations, on the other hand, are closely linked with the IT equipment and product level. Changes in the system's IT have an immediate effect on its type of implementation and operation.

The phase concept does not imply that there is a rigid sequence in the development process, as in the waterfall model. Rather, the phase concept also includes an evolutionary prototyping procedure. However, even in evolutionary software development, the following description levels are generally used. Phase models are primarily used because they offer a variety of description objects and methods.

The ARIS concept in Figure 18 is enhanced by the phases of the buildtime ARIS phase model. After a general conceptual design, the business processes are divided into ARIS views and documented and modeled from the requirements definition to the implementation description. These three description levels are created for controlling purposes as well. This makes it possible to create the links to the other components at each of the description levels.

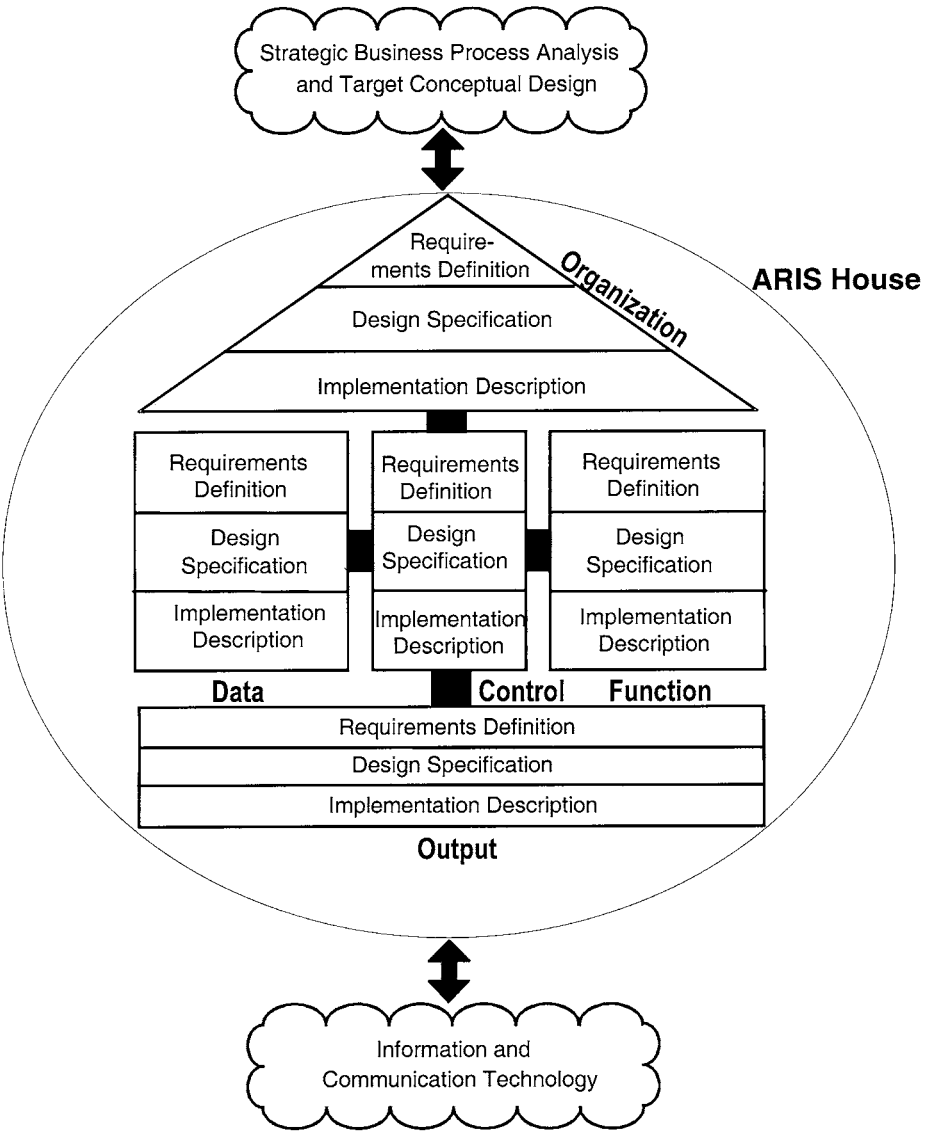

Figure 18 ARIS Concept with Phase Model.

The ARIS concept paves the way for engineering, planning, and controlling enterprises, particularly business processes. The ARIS house of business engineering (HOBE) enhances the ARIS concept by addressing comprehensive business process management from not only an organizational but an IT perspective. We will outline how ARIS supports business management in the design and development stages, using ARIS-compatible software tools.

Because business process owners need to focus on the ''one-shot'' engineering and description aspects of their business processes, ARIS HOBE provides a framework for managing business processes, from organizational engineering to real-world IT implementation, including continuous adaptive improvement. HOBE also lets business process owners continuously plan and control current business procedures and devote their attention to continuous process improvement (CPI). Comprehensive industry expertise in planning and controlling manufacturing processes is a fundamental component of HOBE. Objects such as ''work schedule'' and ''bill of material'' provide detailed description procedures for manufacturing processes, while production planning and control systems in HOBE deliver solutions for planning and controlling manufacturing processes. Many of these concepts and procedures can be generalized to provide a general process management system.

- At level I (process engineering), shown in Figure 19, business processes are modeled in accordance with a manufacturing work schedule. The ARIS concept provides a framework covering every business process aspect. Various methods for optimizing, evaluating, and ensuring the quality of the processes are also available.
- Level II (process planning and control) is where business process owners' current business processes are planned and controlled, with methods for scheduling and capacity and (activity-based) cost analysis also available. Process monitoring lets process managers keep an eye on the states of the various processes.
- At Level III (workflow control), objects to be processed, such as customer orders with appropriate documents or insurance claims, are delivered from one workplace to the next. Electronically stored documents are delivered by workflow systems.
- At Level IV (application system), documents delivered to the workplaces are specifically processed, that is, functions of the business process are executed using computer-aided application systems (ranging from simple word processing systems to complex standard software solution modules), business objects, and Java applets.

HOBE's four levels are linked with one another by feedback loops. Process control delivers information on the efficiency of current processes. This is where continuous adaptation and improve-

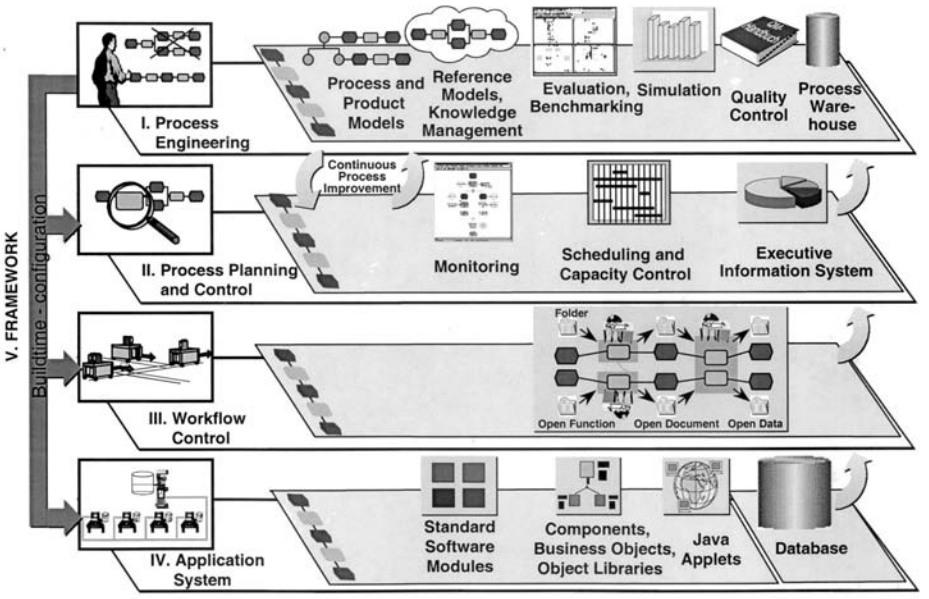

Figure 19 ARIS House of Business Engineering.

ment of business processes in accordance with CPI begins. Workflow control reports actual data on the processes to be executed (amounts, times, organizational allocations) to the process control level. Application supporting modules are then started by the workflow system.

In the fifth component of the HOBE concept, Levels I through IV are consolidated into a framework. Frameworks contain information on the respective architecture and applications, configuring real-world applications from the tools at levels II and III as well as application information from the reference models (level I). Frameworks contain information on the composition of the components and their relationships.

4.2. Information Systems Methodology (IFIP-ISM)

Olle et al. (1991) give a comprehensive methodology for developing more traditional information systems. The designation ''methodology'' is used at the same level as ''architecture.'' The seven authors of the study are members of the International Federation for Information Processing (IFIP) task group, in particular of the design and evaluation of information systems working group WG 8.1 of information systems technical committee TC 8. The research results of the study are summarized in the guideline ''Information Systems Methodology.''

The design of the methodology does not focus on any particular IS development methods. Rather, it is based on a wide range of knowledge, including as many concepts as possible: IDA (interactive design approach), IEM (information engineering methodology), IML (inscribed high-level Petri nets), JSD (Jackson system development), NIAM (Nijssen's information analysis method), PSL/PSA (problem statement language/problem statement analyzer), SADT (structured analysis and design technique) as well as Yourdon's approach of object-oriented analysis.

This methodology is described by metamodels of an entity relationship concept. It features the point of view and stages of an information system life cycle, distinguishing data-oriented, process-oriented, and behavior-oriented perspectives (see Figure 20). Creating these perspectives is less a matter of analytical conclusion than simply of reflecting a goal of addressing the key issues typical in traditional IS developing methods.

Entity types and their attributes are reviewed in the data-oriented perspective. The process-oriented perspective describes events (business activities), including their predecessor or successor relationships. Events and their predecessor or successor relationships are analyzed in the behavior-oriented perspective.

From a comprehensive 12-step life-cycle model we will select three steps, information systems planning, business planning, and system design, and then examine the last two in detail in terms of their key role in the methodology.

Information systems planning refers to the strategic planning of an information system. In business analysis, existing information systems of an entire enterprise or of a subarea of the enterprise are

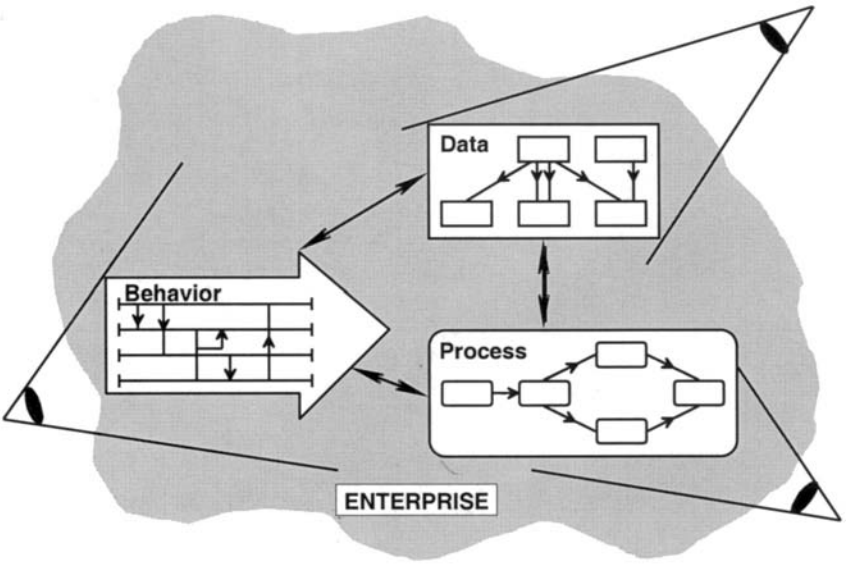

Figure 20 Perspectives of the IFIP Architecture. (From Olle et al. 1991, p. 13)

analyzed. The respective information system is designed in the step system design. This concept also includes a comprehensive procedural model, including a role concept for project organization.

With regard to ARIS, this concept has some overlapping areas. In others there are deviations. What both concepts have in common is their 2D point of view, with perspectives and development steps. There are differences in their instances, however. For example, Olle et al. do not explicitly list the organization view but rather review it along with other activities, albeit rudimentarily. The process definition more or less dovetails with ARIS's function definition. Data and functions or events and functions are also strictly separated from one another. The three perspectives linked together are only slightly comparable to ARIS control view. The step system design blends together the ARIS phases of requirements definition and design specification, with the emphasis on the latter.

4.3. CIM Open System Architecture (CIMOSA)

The ESPRIT program, funded by the European Union (EU), has resulted in a series of research projects for developing an architecture, Computer Integrated Manufacturing Open System Architecture (CIMOSA), for CIM systems. CIMOSA results have been published by several authors, including Vernadat (1996). This project originally involved 30 participating organizations, including manufacturers as the actual users, IT vendors, and research institutes. Although the project focused on CIM as an application goal, its mission was to provide results for general enterprise modeling. One of CIMOSA's goals was also to provide an architecture and a methodology for vendor-independent, standardized CIM modules to be "plugged" together, creating a customer-oriented system ("plug and play").

The CIMOSA modeling framework is based on the CIMOSA cube (see Figure 21).

CIMOSA distinguishes three different dimensions, described by the three axes of the cube. The vertical direction (stepwise derivation) describes the three description levels of the phase concept:

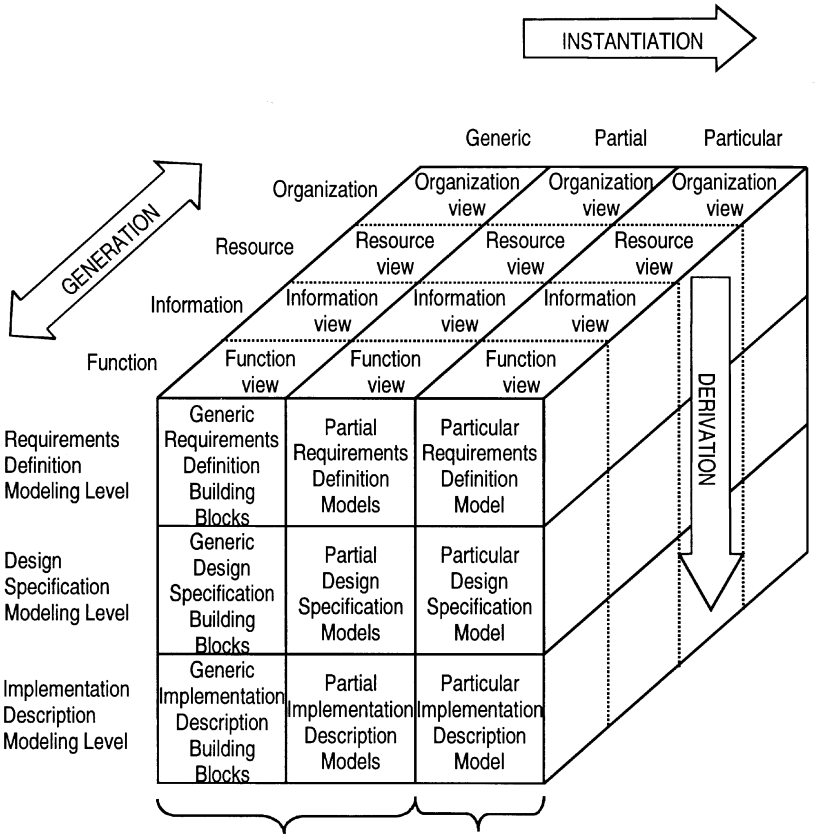

Figure 21 The CIMOSA Modeling Architecture. (CIMOSA cube). (From Vernadat 1996, p. 45)

requirements definition, design specification, and implementation description. These levels are for the most part identical with those of the ARIS life cycle.

In the horizontal dimension (stepwise instantiation), concepts are individualized step by step. First, basic requirements (generic requirements, building blocks) are defined, then particularized in the next step according to industry specific requirements (partial requirements). In Step 3, they are broken up into enterprise-specific requirements (particular requirements).

This point of view makes it clear that initially, according to CIMOSA, general building blocks should be used to define standards, after which the building blocks are grouped into industry specific reference models. In the last step, they are used for developing enterprise-specific solutions. In ARIS, the degree of detailing an information model is defined while the granularity issues are addressed.

By directly entering content-related reference models, the CIMOSA architecture, it becomes clear, combines general methodological issues regarding information systems and application-related CIM domains.

The third dimension, stepwise generation, describes the various views of an information system. This point of view has goals similar to ARIS regarding the creation of views, although not all the results are the same. CIMOSA divides description views into function view, information view, resource view, and organization view. Function view is the description of events, although it also includes a combination of other elements such as events and processes, including performance and exception handling. Information view refers to the data view or object definition. Resource view describes IT and production resources, and organization view implies the hierarchical organization.

CIMOSA also breaks up the entire context into various views, although it lacks a level for reassembling them, as opposed to ARIS with its control and process views. This results in the fact that in CIMOSA, descriptions of the individual views are combined with one another. For example, when resources are being described, they are at the same time also allocated to functions. The CIMOSA modeling concept does not feature an output view.

The CIMOSA concept develops an architecture suitable for describing information systems, into which content in the form of standardized reference models, all the way to actual software generation, can be entered. Despite the above-mentioned drawbacks, it considers important points. Based on this concept, modeling methods are classified in CIMOSA and described by metamodels, all the while adhering to an event-driven, business process-oriented view. Furthermore, enterprises are regarded as a series of multiple agents communicating with one another.

Despite the considerable financial and intellectual efforts spent on CIMOSA, its practical contribution so far has been minimal. Business users involved in the project have so far reported few special applications resulting therefrom, with the exception of the car manufacturer Renault with a repair service application for manufacturing plants and the tooling company Traub AG with an application for optimizing individual development of tools. To date, a CIMOSA-based modeling tool has not been used much in practice.

The main reason for the lack of success in real-world applications is presumably its very theoretical design, which does not incorporate commercially available IT solutions (standard software, for example). Considering the general lack of interest in CIM concepts, the extremely specialized focus of this approach seems to be working to its disadvantage.

4.4. Zachman Framework

A framework for describing enterprises, quite popular in the United States, was developed by J. A. Zachman. This concept is based on IBM's information systems architecture (ISA) but has been enhanced and presented by Zachman in numerous talks and seminars.

This approach (see Figure 22) consists of six perspectives and six description boxes. In the ARIS terminology, Zachman's description boxes would equate to views and perspectives would equate to the levels of the life-cycle model.

Perspectives are listed in brackets along with the respective role designations of the party involved: scope (planner), enterprise model (owner), system model (designer), technology model (builder), components (subcontractor), and functioning system (user).

The areas to be viewed are designated by interrogatives with the respective actions listed in brackets: what (data), how (function), where (network), who (people), when (time), and why (rationale). Perspectives and files to be viewed are at a right angle to one another. Every field in the matrix is described by a method.

Contrary to ARIS, the Zachman framework is not capable of being directly implemented into an information system and the relationships between the description fields are not entered systematically. Furthermore, the relationship of Zachman's framework with the specific creation of output within the business process is not apparent.

Initial approaches for supporting tools are becoming apparent, thanks to cooperation with Framework Software, Inc.

FOCUS

PERSPECTIVE	Generic Framework	WHAT *(Dato)*	HOW *(Function)*	WHERE *(Network)*	WHO *(People)*	WHEN *(Time)*	WHY *(Rationale)*
	Element Bond Element	Entity Relationship Entity	Process Input-Output Process	Node Line Node	Agent Work Agent	Event Cycle Event	End Means End
	SCOPE *(Planner)*	Entity List	Process List	Location List	Organization List	Major Event List	Objective List
	ENTERPRISE MODEL *(Owner)*	Enterprise Entity Enterprise Rule Enterprise Entity	Enterprise Process Resource Enterprise Process	Enterprise Location Enterprise Channel Enterprise Location	Organization Work Organization	Enterprise Event Enterprise Cycle Enterprise Event	Objective Strategy Objective
	SYSTEM MODEL *(Designer)*	Entity Type Relationship Type Entity Type	System Process User View System Process	Site Link Site	Role Presentation Role	System Event System Cycle System Event	Criterion Choice Criterion
	TECHNOLOGY MODEL *(Builder)*	Data Structure Referential Integrity Data Structure	Application Device Format Application	Connection Point Communication Line Connection Point	User Technical Interface User	Technical Event Technical Cycle Technical Event	Condition Action Condition
	COMPONENTS *(Sub-contractor)*	Data Container Aquisition Data Container	Module/Object Couple/Message Module/Object	Address Protocol Address	Individual Transaction Individual	Component Event Component Cycle Component Event	Sub-condition Step/Task Sub-condition
	FUNCTIONING SYSTEM *(User)*	Information Integrity Information	Procedure Request Procedure	Client/Server Access Client/Server	Worker Work Session Worker	Operating Event Operating Cycle Operating Event	Target Option Target

5. MODELING TOOLS

5.1. Benefits of Computerized Enterprise Modeling

Modeling tools are computerized instruments used to support the application of modeling methods. Support in designing enterprise models through the use of computerized tools can play a crucial role in increasing the efficiency of the development process. The general benefits of computer support are:

- All relevant information is entered in a structured, easy-to-analyze form, ensuring uniform, complete documentation. The incorporation of a user-friendly graphical interface offers a comfortable means of creating and modifying the necessary diagrams. Changes in one part of the documentation are automatically updated in other locations and thus need only be performed once.
- Referencing stored design to its creation date enables the different versions to be managed in a comfortable fashion. Versions are overwritten only if the user expressly wishes it; otherwise, each modification is maintained as an independent version.
- The use of a tool facilitates conformance to a fixed procedural model. Consistency checks ensure that modeling activities are not permitted until the preceding level has been completely processed.
- The internal consistency of the draft model can be validated by using rule-based systems. The general system requirements must also be entered within the framework of tool application in order to ensure external consistency. This necessitates the use of a powerful tool that provides structured support for the entire life cycle.
- Generation algorithms enable graphical representations to be derived from existing database structures. Likewise, the graphical tool interface enables the information objects to be categorized in a meaningful, content-related manner. However, since the aim of providing application-oriented data structuring is again based on content-related perspectives, it would be difficult for a tool to provide further support. In particular, reclassifying basic information units such as attributes into information objects that are more meaningful from a subject-oriented perspective is the virtual equivalent of redesigning the model.

5.2. Characterization of Modeling Tools

We can distinguish different groups of tools for enterprise modeling (see Figure 23). In relation to the different tasks of enterprise modeling, each group shows its special support profile.

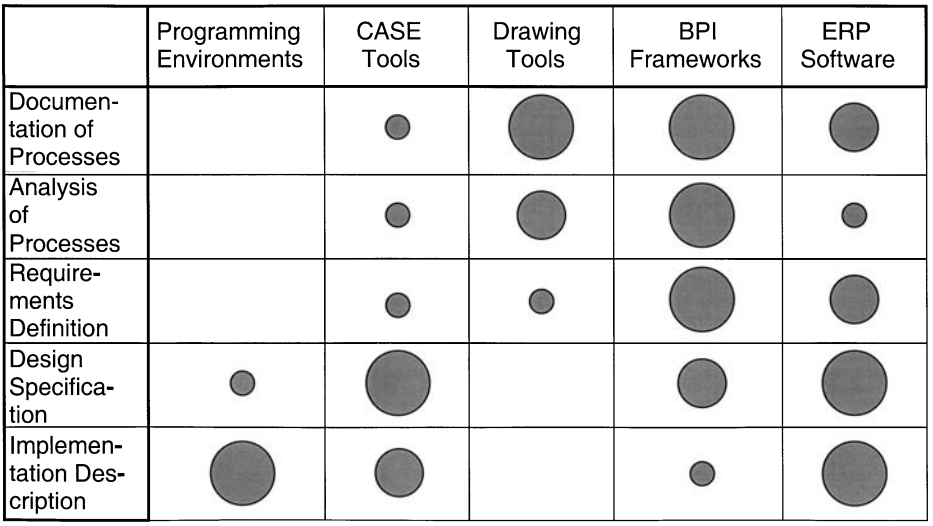

Figure 23 Modeling Tools.

The first group that can be seen as modeling tools in a broader sense are programming environments. Programming environments such as Borland JBuilder and Symantec Visual Café for Java clearly emphasize the phase of implementation description. They describe a business process by the language of the software application that is used to support the process performance. In few cases, programming languages provide limited features for design specification.

CASE tools such as ADW, on the other hand, support a specific design methodology by offering data models and function models (e.g., the entity relationship method (ERM) and structured analysis and design technique [SADT]). Their metastructure has to reflect this methodology. Thus, they automatically provide an information model for the repository functionality of this system. Because CASE tools cannot really claim to offer a complete repository, they are also called encyclopedias.

In contrast, drawing tools such as VISIO and ABC FlowCharter support the phases of documentation and, to a certain extent, analysis of business structures and processes. The emphasis is on the graphical representation of enterprises in order to better understand their structures and behavior. In most of the cases, drawing tools do not provide an integrated meta model, that is, repository. Consequently, drawing tools cannot provide database features such as animating and simulating process models, analyzing process times, and calculating process costs.

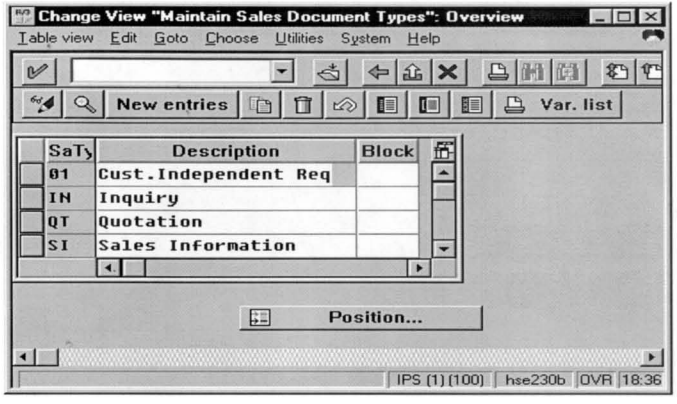
Business process improvement (BPI) frameworks such as ARIS offer a broader set of modeling methods, which are described together in one consistent metamodel. As a result, each model is stored in the framework's repository and thus can be retrieved, analyzed, and manipulated and the model history can be administered (see Section 4.1).

The last group encompasses standard software systems, such as enterprise resource planning (ERP) systems like those from SAP, Baan, or Oracle. ERP systems offer greater flexibility with respect to customization, provide support for data management, and include functionality for creating and managing a (sub)repository. The main weakness is in active analysis of business structures—that is, ERP tools typically do not offer tools for simulation process alternatives.

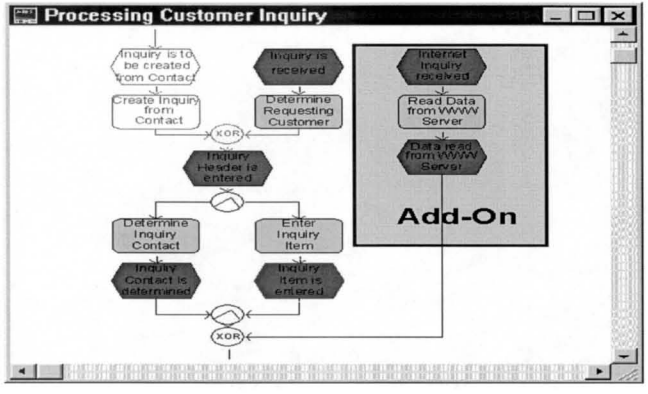
Because all the modeling tools presented focus on different aspects, none of the systems is suitable for handling the entire systems development process. However, ERP systems are opening up more and more to the modeling and analysis level, endeavoring to support the whole system life cycle.

The integration between ARIS and SAP R/3, for example, demonstrates seamless tool support from the documentation to the implementation phase. In an excerpt from the SAP R/3 reference model, Figure 24 shows a customizing example with the ARIS Toolset. For clarification purposes, the four windows are shown separately. In a real-world application, these windows would be displayed on one screen, providing the user with all the information at once.

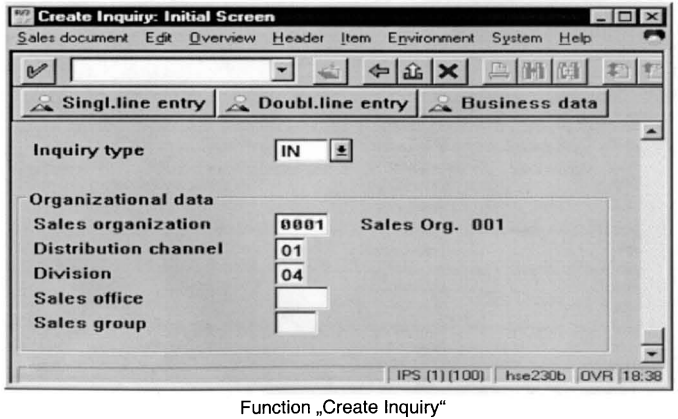
The upper-right window shows an excerpt from the business process model in the ARIS modeling tool, illustrating the part of the standard software process that can be hidden. An additional process branch, not contained in the standard software, must be added.



Customizing: Maintain Sales Document Types



Process Model



Function „Create Inquiry"

Process: Processing Customer Inquiry						
Function	As-is/Target	Unresolved Issues	Inter-face	In Charge	Date	Effort
1. Determine Ordering Customer	From now on, ordering Customers will be queried in Accordance with ISP Country Codes	CPD Customer necessary	Customer Master Data (internal)	C. Jones	May 29	Standard
2. Determine Inquiry Contact	Define third-party as new Partner Type in customized Version	None	Customer Master Data (internal)	P. Miller	May 29	Standard
3. Enter Inquiry Item	Use AFN Item Type as Standard	None	Customer Master Data (internal)	P. Miller C. Jones	May 30	Standard

Documentation of Results

Figure 24 Customizing SAP R/3 with ARIS Toolset.

The function ''create inquiry'' asks users which screen is being used in SAP R/3. Using the process model as a modeling tool and by clicking on the function (or starting a command), users can seamlessly invoke SAP R/3. This screen is shown at the bottom left.

The Implementation Management Guide (IMG) customizing tool is activated for customizing the function. In the upper-left hand window, it depicts the function parameters that are available.

With the modeling tool, results of discussions, parameter decisions, unresolved issues, and the like are stored in the function, as depicted in the bottom-right window. This enables detailed documentation of business and IT-specific business process engineering. This documentation can be used at a later point in time for clarifying questions, using this knowhow for follow-up projects, and monitoring the project.

6. MODELING OUTLOOK

In the mid-1990s, the BPR debate drew our attention from isolated business activities to entire value chains. Yet ''entire'' process management in most of the cases focused on the information flow within departmental, corporate, or national boundaries. Obstacles within those areas appeared hard enough to cope with. Therefore, interorganizational communication and cooperation were seldom seriously put on the improvement agenda. Consequently, enterprise models, particularly business process models were also restricted to interorganizational aspects.

In the meantime, after various BPR and ERP lessons learned, companies seem to be better prepared for business scope redefinition. More and more, they sense the limitations of interorganizational improvement and feel the urge to play an active role in the global e-business community. That means not only creating a company's website but also designing the back-office processes according to the new requirements.

Obviously, this attitude has effects on business application systems, too. While companies are on their way to new business dimensions, implemented ERP systems cannot remain inside organizational boundaries. On the technical side, ERP vendors are, like many other software vendors, forced to move from a traditional client–server to a browser–web server architecture in order to deliver e-business capabilities. Hence, for their first-generation e-business solutions almost all big ERP vendors are using a mixed Java/XML strategy. On the conceptual side, ERP vendors are facing the even bigger challenge of providing instruments for coping with the increasing e-business complexity. Business process models appear to be particularly useful in this context. While e-business process models are fundamentally the same as interorganizational process models, integration and coordination mechanisms become even more important:

- Due to increasing globalization, e-business almost inevitably means international, sometimes even intercultural, business cooperation. While ERP systems were multilingual from the very first, the human understanding of foreign business terms, process-management concepts, legal restrictions, and cultural individualities is much more difficult. Because models consist of graphic symbols that can be used according to formal or semiformal grammars, they represent a medium that offers the means to reduce or even overcome those problems.
- Many improvement plans fail because of insufficient transparent business processes and structures. If people do not realize the reengineering needs and benefits, they will not take part in a BPR project and accept the proposed or made changes. While this is already a serious problem within organizational boundaries, it becomes even worse in the case of interorganizational, that is, geographically distributed, cooperation. In the case of business mergers or virtual organizations, for example, the processes of the partners are seldom well known. Yet, in order to establish a successful partnership, the business processes have to be designed at a very high level of detail. Thus, business process models can help to define the goals, process interfaces, and organizational responsibilities of interorganizational cooperation clearly.
- Up to now, we have mainly discussed strategic benefits of modeling. However, at an operational level of e-business, models are very useful, too. In business-to-business applications such as supply chain management we have to connect the application systems of all business partners. This means, for example, that we have to fight not only with the thousands of parameters of one single ERP system but with twice as many, or even more. Another likely scenario is that the business partners involved in an interorganizational supply chain are using software systems of different vendors. In this case, a business process model can first be used to define the conceptual value chain. Secondly, the conceptual model, which is independent from a certain software, can be connected to the repositories of the different systems in order to adopt an integrated software solution.

These few examples already demonstrate that enterprise models play a major role in the success of e-business. Some software vendors, such as SAP and Oracle, have understood this development and are already implementing their first model-based e-business applications.

CHAPTER 11

Enterprise Resource Planning Systems in Manufacturing*

Mary Elizabeth A. Algeo
Edward J. Barkmeyer
National Institute of Standards and Technology

1. INTRODUCTION

Enterprise resource planning (ERP) is a class of commercially developed software applications that integrate a vast array of activities and information to support tactical-level operations and operations planning for an industrial enterprise. The term *ERP* refers to the software and not to the related business processes. However, as software, it enables better execution of certain processes. Although often presented as a single package, an ERP system is an envelope around numerous applications and related information. For manufacturers, those applications typically support the operations processes of materials sourcing, manufacturing planning, and product distribution. To its end users, an individual application of an ERP system may appear seamless; however, to those who procure, implement, and/or maintain ERP systems, they are complex software systems that require varying levels of customization and support both centrally and across applications. While ERP systems are commercial applications developed by individual vendors, they can hardly be considered off-the-shelf. They are part of a continuing trend of outsourcing IT solutions in which part of the solution is bought, part is configured, and part is built from scratch. In general, as the scope and complexity of integrated applications have increased from systems supporting a single business unit to systems supporting an entire enterprise and its relationships with business partners, the portions of an IT solution that are bought and configured have increased while the percentage of custom-built software has decreased. Given their broad organizational and functional scope, ERP systems are unlike any other contemporary commercial manufacturing applications. They provide ''transaction management,'' both from the business perspective and from a database perspective. Additionally, they provide a basic level of decision support. Optionally, they enable development of software for higher levels of decision support, which may be offered by ERP vendors or third-party vendors. It is clear that ERP, as a subject, is very complex. Its use marries technology, business practices, and organizational structures. The purpose of this chapter is to present a high-level view of ERP in order to frame a discussion of technological challenges and research opportunities for improving ERP interoperability. Although ERP is relevant to many types of industries (e.g., goods and services) and organizations (e.g., for-profit and not-for-profit), the discussion in this chapter is limited to ERP in manufacturing enterprises. More specifically, the focus of this chapter is ERP that supports the principal operations of a manufacturing enterprise: planning, procuring, making, and delivering products. An ERP system may support other enterprise functions, such as finance management, human resource management, and possibly sales and marketing activities. Detailed analysis of those functions is beyond the scope of this chapter; however, the linkages of those functions with manufacturing-specific functions are not.

This overview looks at ERP by itself and as part of a larger entity (Figure 1). Section 2 discusses ERP internals such as core functions, implementation elements, and technology issues. Additionally,

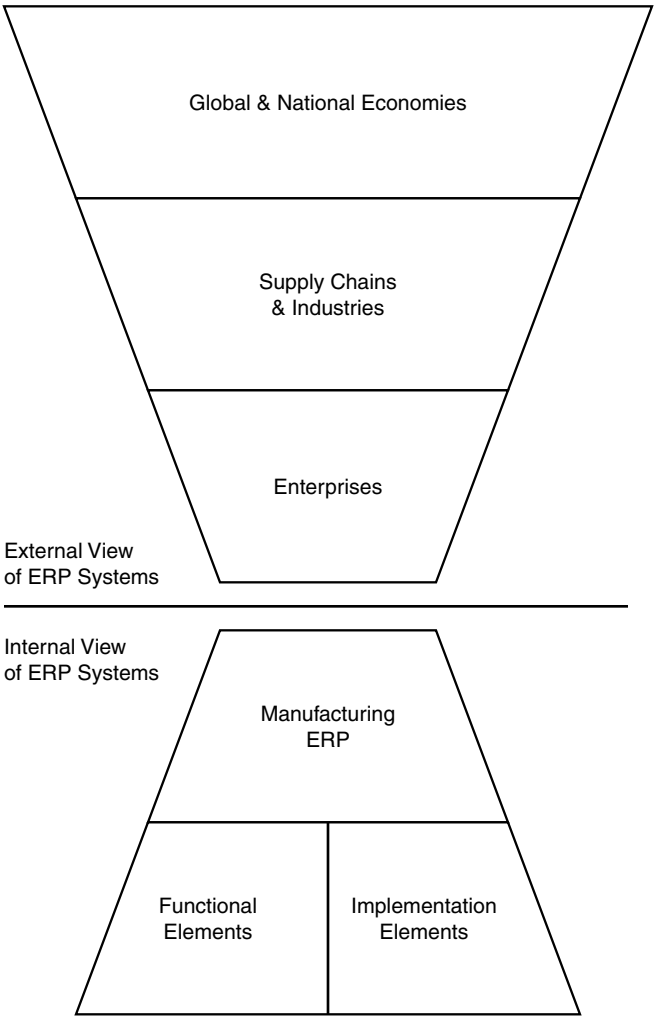

Figure 1 External and Internal Views of ERP.

Section 2 identifies critical integration points for ERP and other applications within manufacturing enterprises. Section 3 discusses ERP and its relationship to three larger entities, namely the U.S. economy, supply chains, and individual manufacturers. Section 4 presents issues and possible resolutions for improving ERP performance and interoperability.

This chapter is the result of a two-year study funded by two programs at the National Institute of Standards and Technology: the Advanced Technology Program's Office of Information Technology and Applications and the Manufacturing Systems Integration Division's Systems for Integrating Manufacturing Applications (SIMA) Program.

The concepts presented in this chapter were gathered from a variety of sources, including literature reviews, manufacturing industry contacts, ERP vendor contacts, consultants specializing in the applications of IT to manufacturing, relevant professional and trade associations, and standards organizations.

1.1. Major Business Functions in Manufacturing Enterprises

Manufacturers typically differentiate themselves from competitors along the three major business functions through which they add value for their customers. Customer relationship management

(CRM), the first dimension of competitive advantage, seeks to add value for customers through those processes that involve direct contact with customers before, during, and after sales. The idea is to understand the prevalent needs and concerns of individual customers and groups of customers. Product development, the second dimension of competitive advantage, focuses on product—what and how to produce an object to satisfy the customer's *want.* Operations, the third dimension of competitive advantage, focuses on satisfying *demand*—how much to make, when to make, and where to make—by producing and delivering products in an effective and efficient manner.

Needs, wants, and *demands* are basic concepts underlying modern, market-based economies (Kotler and Armstrong 1999). Needs beget wants, which beget demand. Needs are states of felt deprivation. They are a basic part of our human condition and are physical, social, and individual in nature. The customer's needs include product capabilities, product servicing, user instruction, and business relationships. Wants are the forms taken by human needs as shaped by culture and individual personality. They are described in terms of objects that will satisfy needs. Demands are human wants that are backed by buying power. Identifying needs and translating them into wants in terms of product and process definitions are the objectives of product development. Satisfying demand, given supply conditions as well as product and process definitions, is the objective of operations. This high-level partitioning of manufacturing business functions into CRM, product development, and operations has growing acceptance in manufacturing and related industries (Hagel and Singer 1999). This acceptance has been fostered by the realization that the underlying activities of these high-level functions are those that add value for the customer.

The complex activities of product development seek to satisfy customer want by translating the abstract to the physical through the product development process. As such, in commercial manufacturing enterprises, product development typically starts with an analysis of market opportunity and strategic fit and, assuming successful reviews through intermediate phases, ends with product release. Among other things, product release serves as a signal to operations to begin production and distribution as the necessary design and manufacturing engineering specifications are ready for execution in a production environment.

Operations, on the other hand, consists of processes for satisfying customer demand by transforming products—in raw, intermediate, or final state—in terms of form, location, and time. To accomplish this objective both effectively and efficiently—and thus meet specific, customer- focused, operational objectives—a manufacturing enterprise must have timely and accurate information about expected and real demand as well as expected and real supply. A manufacturer then considers this information on supply and demand with the current and expected states of its enterprise. It is ERP that allows a manufacturer to monitor the state of its enterprise—particularly the current and near-term expected states. In fact, ERP systems often serve as the cornerstone in the emerging information architectures that support balancing external and internal supply and demand forces. ERP systems play both direct and indirect roles in this trend among manufacturing enterprises towards a synchronized, multilevel, multifacility supply chain planning hierarchy.

1.2. Manufacturing Operations Planning

Figure 2 illustrates the emerging synchronized, multilevel, multifacility supply chain planning hierarchy with ERP as its foundation. The goal of this architecture is to enable more efficient and effective execution across plants, distribution systems, and transportation systems. Independently, these planning activities focus on the strategic, the tactical, and the operational (i.e., execution) levels. Collectively, they support the translation of strategic objectives into actions on the plant floor, in warehouses, and at shipping points throughout the extended enterprise. In addition, they provide top management with up-to-date, synchronized information regarding the state of the entire enterprise.

This synchronization is accomplished by transforming information in a meaningful way from one level within the supply chain planning hierarchy to the next. At the strategic level, top management evaluates numerous factors to determine the design or redesign of the supply chain network as well as time-independent sourcing, production, deployment, and distribution plans. These factors typically include the enterprise's business philosophy as well as company, market, technological, economic, social, and political conditions. Supply chain planning at the strategic level involves ''what if'' analysis particularly with respect to the first three factors: business philosophy, company conditions, and market conditions. A business philosophy might specify maximizing net revenues or return on assets. Assessment of company conditions considers existing and potential aggregates of fixed (i.e., plant), financial, and human resources. When evaluating market conditions, top management analyzes aggregate product/part demand as well as the anticipated capacity of suppliers and transportation channels—also in aggregate terms. Optimization at this level, which usually employs mathematical programming methods, typically yields the location, size, and number of plants, distribution centers, and suppliers as well as product and supply volumes.

Supply chain operations planning at the tactical level determines the flow of goods over a specific time horizon. Mathematical programming methods yield time-dependent integrated sourcing, pro-

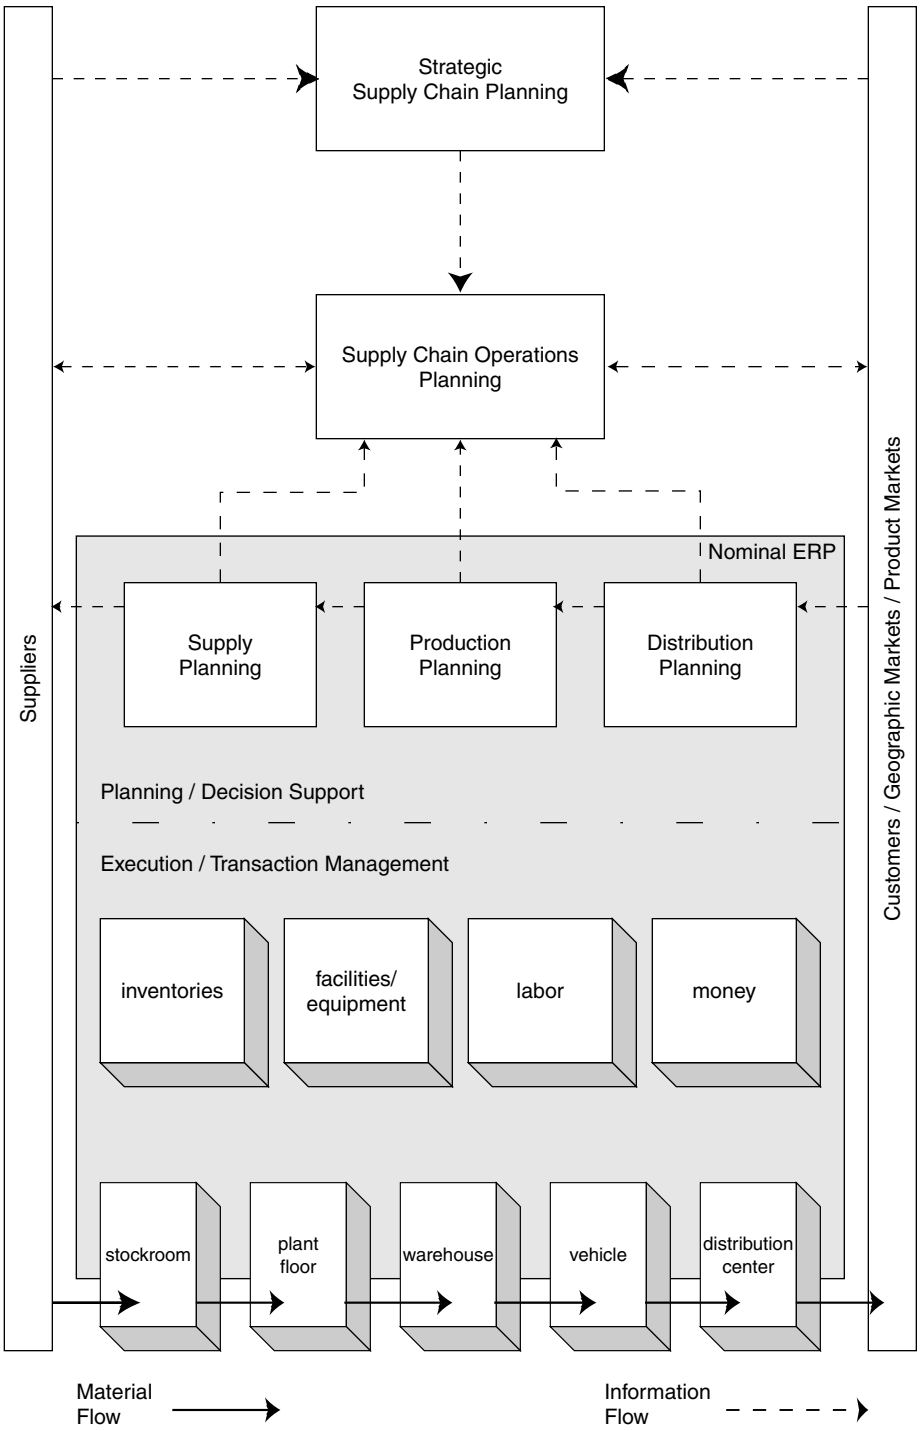

Figure 2 Intraenterprise View of Supply Chain Planning Hierarchy.

duction, deployment, and distribution plans typically designed to satisfy a financial management objective such as minimizing total supply chain costs or maximizing net revenues by varying product mix. Often, once these plans are established, a more detailed level of tactical planning occurs to optimize supply, production, and distribution independently. Frequently, the objective at this lower level of tactical planning is to minimize costs related to inventories and/or major equipment changeovers.

Supply chain planning at the operational level is, in essence, supply scheduling that occurs on a facility-by-facility basis. As such, separate but coordinated schedules are generated for plants, warehouses, distribution centers, and vehicle systems. Planning at this level differs from tactical and strategic levels in that demand actually exists—that is, orders have been placed. These orders need to be scheduled based on the immediate state of resources (i.e., materials, equipment, and labor). The diverse nature of facilities means that the specifics of optimization vary widely at this level, but the objective typically is to maximize throughput in a given facility.

Individually, these layers serve to separate concerns and enable the definition of tractable planning problems for which mathematical and managerial solutions can be obtained. Collectively, these layers of supply chain planning enable manufacturing enterprises more effectively and efficiently to balance supply, resources, and demand. The upper layers buffer the lower layers from sudden shifts in the market, thus allowing for smoother changes in the enterprise's plants, distribution channels, and transportation systems.

1.3. Partitioning the Domain of Manufacturing

The domain of manufacturing is in fact an aggregate of many subdomains of many types. There is no single correct method for decomposing that complex and dynamic aggregate. The method of decomposition depends on the particular objective at hand. Generally speaking, there are four common approaches to partitioning the manufacturing domain. Each looks at a different aspect of the manufacturing enterprise:

1. *Nature of the product:* This approach categorizes manufacturing industries by the general nature of the product itself—fertilizers, pharmaceuticals, metals, automotive parts, aircraft, etc. This is the approach used by industry classification systems such as the North American Industry Classification System (NAIC) (Office of Management and Budget 1997) and its predecessor, the Standard Industrial Classification (SIC) (Office of Management and Budget 1988). In general, this approach is a good mechanism for characterizing market communities, and thus economic estimators, but it is not a particularly good mechanism for characterizing ERP requirements or planning approaches.
2. *Nature of the customer:* Because most manufacturing output is consumed by other industries, many manufacturers are part of the supply chains ending in original equipment manufacturers (OEMs) in a single major industry: automotive, aerospace, shipbuilding, household appliances, computers, etc. The members of the chain produce different kinds of products, using different processes, with different business behaviors, but the behavior of the supply chain itself often is dominated by the demands of the OEMs.
3. *Nature of the process:* This approach characterizes a domain by the organization of the manufacturing facility and the general nature of the manufacturing processes it employs: continuous process, assembly line, discrete batch, job shop, and construction. There is some correlation between the process type and the product type, in that most manufacturers of a given product type tend to use a particular process organization. In general, process type strongly influences the manufacturing-specific aspects of ERP, including both information capture and planning approaches. On the other hand, large manufacturers often use several different process styles for different products and different components of larger products.
4. *Nature of the business in terms of customer orders:* This characterization includes make-to-stock, make-to-order, assemble-to-order, and engineer-to-order. It has a great deal to do with what the detailed business operations are and how operational and tactical planning is done. Clearly this categorization has a tremendous influence on the ERP requirements and on the behavior of the enterprise in its supply chain. More than any other, this characterization determines the nature of the delivery activities and the dependence on supplier relationships.

These last two categories, as differentiators for ERP, warrant more detailed discussion.

1.3.1. Nature of Process

Continuous process refers to a facility in which products are made by an essentially continuous flow of material through some set of mixing, state transformation, and shaping processes into one or more final products. The final form may itself be intrinsically discrete, or it may be discretized only for

packaging and shipment. Examples are wet and dry chemicals, foods, pharmaceuticals, paper, fibers, metals (e.g., plate, bar, tubing, wire, sheet), and pseudocontinuous processes such as weaving, casting, injection molding, screw machines, and high-volume stamping.

Assembly line refers to a facility in which products are made from component parts by a process in which discrete units of product move along an essentially continuous line through a sequence of installation, joining, and finishing processes. Examples are automobiles, industrial equipment, small and large appliances, computers, consumer electronics, toys, and some furniture and clothing.

Discrete batch, also called *intermittent,* refers to a facility in which processes are organized into separate work centers and products are moved in lots through a sequence of work centers in which each work center is set up for a specific set of operations on that product and the setup and sequence is specific to a product family. This describes a facility that can make a large but relatively fixed set of products but only a few types of product at one time, so the same product is made at intervals. This also describes a facility in which the technology is common—the set of processes and the ordering is relatively fixed, but the details of the process in each work center may vary considerably from product to product in the mix. Examples include semiconductors and circuit boards, composite parts, firearms, and machined metal parts made in quantity.

Job shop refers to a facility in which processes are organized into separate work centers and products are moved in order lots through a sequence of work centers in which each work center performs some set of operations. The sequence of work centers and the details of the operations are specific to the product. In general, the work centers have general-purpose setups that can perform some class of operations on a large variety of similar products, and the set of centers used, the sequence, the operations details, and the timing vary considerably over the product mix. Examples include metal shops, wood shops, and other piece-part contract manufacturers supporting the automotive, aircraft, shipbuilding, industrial equipment, and ordnance industries.

Construction refers to a manufacturing facility in which the end product instances rarely move; equipment is moved into the product area and processes and component installations are performed on the product in place. The principal examples are shipbuilding and spacecraft, but aircraft manufacture is a hybrid of construction and assembly line approaches.

1.3.2. Nature of the Business in Terms of Customer Orders

Make-to-stock describes an approach in which production is planned and executed on the basis of expected market rather than specific customer orders. Because there is no explicit customer order at the time of manufacture, this approach is often referred to as a push system. In most cases, product reaches retail outlets or end customers through distribution centers and manufacturing volumes are driven by a strategy for maintaining target stock levels in the distribution centers.

Make-to-order has two interpretations. Technically, anything that is not made-to-stock is made-to-order. In all cases there is an explicit customer order, and thus all make-to-order systems are described as pull systems. However, it is important to distinguish make-to-demand systems, in which products are made in batches, from option-to-order systems, in which order-specific features are installed on a product-by-product basis. The distinction between make-to-demand batch planning and on-the-fly option selection using single setup and prepositioning is very important to the ERP system.

A *make-to-demand* manufacturer makes fixed products with fixed processes but sets up and initiates those processes only when there are sufficient orders (i.e., known demand) in the system. This scenario may occur when there is a large catalog of fixed products with variable demand or when the catalog offers a few products with several options. The distinguishing factor is that orders are batched and the facility is set up for a run of a specific product or option suite. The planning problem for make-to-demand involves complex trade-offs among customer satisfaction, product volumes, materials inventories, and facility setup times.

Option-to-order, also called *assemble-to-order,* describes an approach in which production is planned and executed on the basis of actual (and sometimes expected) customer orders, in which the product has some predefined optional characteristics which the customer selects on the order. The important aspects of this approach are that the process of making the product with options is predefined for all allowed option combinations and that the manufacturing facility is set up so the operator can perform the option installation on a per-product basis during manufacture. This category also applies to a business whose catalog contains a family of fixed products but whose manufacturing facility can make any member of the family as a variant (i.e., option) of a single base product. The option-to-order approach effects the configuration of production lines in very complex ways. The simplest configurations involve prepositioning, in which option combinations occur on the fly. More complex configurations involve combinations of batching and prepositioning.

Engineer-to-order describes an approach in which the details of the manufacturing process for the product, and often the product itself, must be defined specifically for a particular customer order and only after receipt of that order. It is important for other business reasons to distinguish contract engineering, in which the customer defines the requirements but the manufacturer defines both the

product and the process, from contract manufacturing, in which the customer defines the product details and the manufacturer defines the process details. But the distinction between contract engineering and contract manufacturing is not particularly important for ERP, as long as it is understood that both are engineer-to-order approaches. In these scenarios, some set of engineering activities must take place after receipt of customer order and before manufacturing execution, and then certain aspects of manufacturing planning can begin.

1.3.3. Combining Nature of Process and Nature of Business in Terms of Customer Orders

Many attempts to characterize manufacturing roll up some combination of the four major categorization approaches (product, customer, process, business) into a single categorization scheme in order to make certain useful generalizations. But because resource planning and ERP systems must deal with important details of the organization's business process, these generalizations do not provide good guidelines for studying the variations in planning and execution information. In particular, no generalization about industries applies to all manufacturing organizations in that industry, and there is no way to roll up the nature of the process with the nature of the business in terms of customer orders. For example, all four business patterns can be observed in the continuous (and pseudocontinuous) processing industries. Even though engineer-to-order (customer-specific recipe) is fairly rare in the chemical and raw metal industries, it is the norm (customer-specific mold) in the injection-molding and casting industries. It does make sense, however, to cross the nature of the process with the nature of the business in terms of customer orders to identify those combined characteristics that have the most significant influence on ERP system requirements. Table 1 identifies 14 distinct categories, out of a possible 20, for which there are known manufacturers in specific industries.

2. AN INTERNAL VIEW OF ERP SYSTEMS

This section describes what ERP systems do and how they do it. Sections 2.1 through 2.3 describe the core functional elements of ERP systems: human resource management, finance management and accounting, contracts management, materials acquisition, materials inventory, maintenance management, order entry and tracking, manufacturing management, process specification management, warehousing, and transportation. Sections 2.4 through 2.6 describe implementation aspects, particularly ERP systems architecture, configuration management tools, and Internet interfaces.

2.1. Scope of ERP Systems in Manufacturing Enterprises

As illustrated in the portion of Figure 2 bounded by the gray box, the functionality of ERP systems encompasses certain interactions among the following elements:

- Four categories of resources (inventories, facilities/equipment, labor, and money)
- Two generic activities (planning/decision support and execution/transaction management)
- Three types of manufacturing operations activities (supply, production, and delivery)
- Five major types of physical facilities (stockroom, plant floor, warehouse, vehicle/depot, and distribution center) through which material flows in manufacturing enterprises

Because there is considerable variation among manufacturers as to which functions in which facilities fall within the scope of an ERP implementation, the gray box does not envelop all physical facilities. Typically, in some way or another, all transactions—all changes of state and many deci-

TABLE 1 Examples per Process and Customer Order Characteristics

	Make-to-Stock	Make-to-Demand	Option-to-Order	Engineer-to-Order
Continuous	refineries	solvents, plastics, alloys	fuels	casting, injection molding
Assembly line	appliances	electric motors, valves	autos, computers	aircraft
Discrete batch	electronic components	windows, auto parts	*no known*	semiconductors, circuit boards
Job shop	*none*	*none*	*none*	metal parts, composites
Construction	*none*	*no known*	aircraft	ships

sions—are captured in an ERP system. Each of these facilities may use additional systems for planning and analysis, execution level scheduling, control, and automated data capture. Some of the planning, analysis, scheduling, and management systems are part of, or tightly connected to, the ERP systems; others are more loosely connected. This variation results from two major factors: systems that are closely coupled to equipment, most of which are highly specialized, and systems that manage information and business processes specific to a particular industry that the ERP vendor may not offer. Because of the historic emphasis on reducing inventory costs, the management of stockroom is, in almost all cases, an intrinsic part of an ERP system. To the contrary, plant floor activity control is almost never a part of ERP. Management of execution activities within warehouses, vehicles/depots, and distribution centers may be handled in a centralized fashion by an ERP system or in a decentralized fashion by an applications specific to those facilities.

2.2. Transaction Management and Basic Decision Support: The Core of ERP

Transactions are records of resource changes that occur within and among enterprises. Through the use of a logically (but not necessarily physically) centralized database, it is the management of these transactions that constitutes the core of an ERP system. More specifically, this transaction database captures all changes of state in the principal resources of the manufacturing enterprise. It also makes elements of the current state available to personnel and software performing and supporting the operations of the enterprise. This scope encompasses all of the numerous resources (i.e., materials inventories, facilities/equipment, labor, and money) and product inventories of all kinds. It also includes the states and results of many business processes, which may not be visible in physical instances (e.g., orders, specifications). The detailed breakdown of this broad scope into common separable components is a very difficult technical task, given the many interrelationships among the objects, significant variations in the business processes, and the technical origins of ERP systems. Nonetheless, it is possible to identify general elements from that complexity and diversity. The functions of a manufacturing enterprise that are supported by transaction management correspond to the major types of resources as follows:

- For inventories, materials inventory and materials acquisition
- For facilities/equipment, manufacturing management, process specification management, maintenance management, warehousing and transportation
- For labor, human resource management
- For money, financial management and accounting
- For product, order entry and tracking

These functions, in whole or in part, make up the core of ERP. The following sections describe each function and its relationship to core ERP. These functions are then discussed in terms of finer-grain execution and planning activities.

2.2.1. Materials Inventory

This function is made up of all information on stores of materials and allocations of materials to manufacturing and engineering activities. That includes information on materials on hand, quantities, locations, lots and ages, materials on order and in transit, with expected delivery dates, materials in inspection and acceptance testing, materials in preparation, and materials allocated to particular manufacturing jobs or product lots (independent of whether they are in stock).

ERP systems routinely capture all of this information and all transactions on it. It is sometimes combined with materials acquisition information in their component architecture.

Execution activities supported by materials inventory include receipt of shipment, inspection and acceptance, automatic (“low-water”) order placement, stocking, stores management, internal relocation, issuance and preparation, and all other transactions on the materials inventory. Except for some stores management functions, all of these are revenue producing.

Planning activities supported by materials inventory include supply planning, manufacturing planning, and manufacturing scheduling.

2.2.2. Materials Acquisition

This function deals primarily with information about suppliers and materials orders. It includes all information about orders for materials, including recurring, pending, outstanding, and recently fulfilled orders, and long-term order history. Orders identify internal source and cost center, supplier, reference contract, material identification, quantity, options and specifications, pricing (fixed or variable), delivery schedule, contacts, change orders, deliveries, acceptances, rejects, delays, and other notifications. It may also include invoices and payments. This also includes special arrangements, such as consignment and shared supply schedules.

ERP systems support part of an enterprise's materials acquisition function by handling all of this information for active suppliers and orders and journalizing all transactions. But they regularly purge closed orders and relationships, using the journal or some other export mechanism to move this information to an archival or data warehouse system. ERP systems generally maintain simple materials specifications directly but typically carry only references to more complex specification documents in some other product data management (PDM) or document management system.

Execution activities supported by materials acquisition include internal requests, placement of external orders and changes, receipt and acceptance of materials, and all other transactions against materials orders. All of these are revenue-producing activities.

Planning activities supported by materials acquisition include supply chain development, supplier identification and qualification, supply planning, manufacturing planning, and cash-flow projections.

2.2.3. Order Entry and Tracking

These functions focus on the customer order through its life cycle. Order entry is the mechanism by which the decision to make product enters the ERP system. It begins with the capture of customer order, including all specifications and options, quantities, packaging requirements, and delivery requirements. It ends with the creation of one or more corresponding manufacturing orders and delivery orders. At that point it becomes order tracking, which follows the customer order through the fulfillment processes (for the surrogate orders) and finally through the payment processes. It is important to note that although manufacturing may be driven directly by customer order, there is a decision point between the entry of the customer order and the release of the associated manufacturing orders, and in most ERP systems they are maintained as separate objects. While this release is often automated, it is a critical business control point and the automation reflects the business rules for the release.

The execution activities supported by order entry and tracking include the revenue-producing activities of customer order capture, production start, and delivery start.

The planning activities supported by order entry and tracking include tactical planning for all of engineering, manufacturing, and delivery, according to the nature of the business as described in Section 1.3.2.

2.2.4. Manufacturing Management

This function deals primarily with the tracking of work through the manufacturing facilities and the management of manufacturing resources that are used in performing that work.

The manufacturing resources include personnel, equipment, and materials. Because each of these is also the subject of another ERP domain (human resources, maintenance, inventory), there is *always* overlap among the concerns. And because many ERP systems developed from manufacturing resource planning (MRP II) systems, which dealt with various aspects of those resources listed above, there is no agreement about where the boundaries are. The one concern that is clearly unique to manufacturing management is the assignment of resources to specific work items. But at some level of planning that depends on resource availability and resource capabilities, which are the boundary areas.

The tracking of work begins with tentative and actual placement of manufacturing orders through the order entry component described above. In general, the manufacturing order information is a part of the manufacturing management component. Planning processes determine which resources (materials, equipment, labor) will be assigned to fulfilling these orders in which time frames and these assignments are captured. Execution processes draw materials (usually tracked as lots) and use equipment and personnel to perform the work. These usages and the flow of work through the facility are captured. Finished goods leave the manufacturing domain for some set of distribution activities, and at this point the completion of the manufacturing orders is tracked.

The execution processes supported by manufacturing management are the revenue-producing processes that convert materials into finished goods, but that support is limited to tracking those processes.

The planning processes supported by manufacturing management are all levels of manufacturing resource planning and scheduling, except for detailed scheduling, as noted above.

2.2.5. Process Specification Management

This function deals with the information associated with the design of the physical manufacturing processes for making specific products. As such, it is an engineering activity and like product engineering, should be almost entirely out of the scope of core ERP systems. But because several information items produced by that engineering activity are vital to resource planning, ERP systems maintain variable amounts of process specification data. In all cases, the materials requirements for a product lot—the ''manufacturing bill of materials''—are captured in the ERP system. And in all cases, detailed product and materials specifications, detailed equipment configurations, detailed operations procedures, handling procedures, and equipment programs are outside the core ERP infor-

mation bases. These information sets may be maintained by ERP add-ons or third-party systems, but the core contains only identifiers that refer to these objects.

For continuous-process and assembly-line facilities, the major process engineering task is the design of the line, and that is completely out of scope for ERP systems. What ERP systems maintain for a product mix is the line configurations (identifiers) and equipment resources involved, staffing and maintenance requirements, the set of products output, the production rates and yields, and the materials requirements in terms of identification and classification, start-up quantities, prepositioning requirements, and feed rates.

For batch facilities, the major process engineering tasks are the materials selection, the routing (i.e., the sequence of work centers with particular setups), and the detailed specifications for operations within the work centers. The materials requirements, the yields, and the routings for products and product mixes are critical elements of the ERP planning information. The detailed work center operations are unimportant for planning, and all that is captured in the ERP core is the external references to them, the net staffing and time requirements, and the assigned costs of the work center usages.

For job shop facilities, the major process engineering tasks are materials selection, the routing, and the detailed specifications for operations within the work centers. The materials requirements and yields for specific products are critical elements of the ERP planning information. The routing is often captured as a sequence of work center operations—unit processes, each with its own equipment, staffing and time requirements, associated detail specification identifiers, and assigned cost. The detailed unit process specifications—operator instructions, setup instructions, equipment control programs—are kept in external systems.

No execution processes are directly supported by process specification management. All levels of resource planning are directly and indirectly supported by this information.

2.2.6. Maintenance Management

This function includes all information about the operational status and maintenance of equipment, vehicles, and facilities. *Operational status* refers to an availability state (in active service, ready, standby, in/awaiting maintenance, etc.), along with total time in service, time since last regular maintenance, and so on. The ERP system tracks maintenance schedules for the equipment and actual maintenance incidents, both preventive and remedial, and typically an attention list of things that may need inspection and refit. Any maintenance activities include both technical data (nature of fault, repair or change, parts installed, named services performed, etc.) and administrative data (authorization, execution team, date and time, etc.). In addition, this component tracks the schedules, labor, and work assignments of maintenance teams, external maintenance contracts and calls, and actual or assigned costs of maintenance activities.

In those organizations in which machine setup or line setup is performed by a general maintenance engineering group rather than a setup team attached to manufacturing operations directly, it is common to have such setups seen as part of the maintenance component rather than the manufacturing component. Similarly, operational aspects of major upgrades and rebuilds may be supported in the maintenance component of the ERP system. These are areas in which the behavior of ERP systems differs considerably.

This component supports sourcing, manufacturing, and delivery activities indirectly. Maintenance, per se, is purely a support activity.

Planning activities supported by maintenance management include all forms of capacity planning, from manufacturing order release and shipment dispatching (where immediate and expected availability of equipment are important) up to long-term capacity planning (where facility age and statistical availability are important).

2.2.7. Warehousing

This function deals with the information associated with the management of finished goods and spare parts after manufacture and before final delivery to the customer.

For products made-to-stock, this domain includes the management of multiple levels of distribution centers, including manufacturer-owned/leased centers, the manufacturer's share of concerns in customer-owned/leased centers, and contracted distribution services. The primary concerns are the management of space in the distribution centers and the management of the flow of product through the distribution centers. Thus, there are two major elements that are sometimes mixed together: the management of the distribution center resources (warehouse space, personnel, and shipping and receiving facilities) and the management of finished product over many locations, including manufacturing shipping areas, distribution centers per se, and cargo in-transport. Distribution center and product (family) includes tracking actual demand experience, projected demand and safety stocks, units on hand, in-flow and back-ordered, and units in manufacture that are earmarked for particular distribution centers. The primary object in product distribution tracking is the shipment because that

is the unit of product management at the factory, in transportation, and through all distribution centers, except possibly the one nearest the final customers. For shipments, what is tracked is the product content, the ultimate recipient, the current location, and the associated delivery/shipping orders.

For certain products made-to-order (both made-on-demand and option-to-order), the distribution center approach is used because it facilitates planning and use of delivery resources and usually because a sizable part of the manufacturer's product line (such as spare parts) is made to stock. In these cases, the information managed is similar to the made-to-stock case, but actual demand and safety stock concerns are replaced by tracking specific customer orders. Customer orders are part of shipments up to the final distribution center, and final delivery to customer is tracked from there.

For most products made-to-order, the warehousing component manages information only for finished goods in factory holding areas awaiting shipment and shipments that are in transportation to the customer. In this case, each shipment is associated with a particular customer at creation, and it may be associated with one or more manufacturing orders even before manufacturing starts. For shipments, what is tracked is the product content, the customer order, the current location, and the associated delivery/shipping orders. In many make-to-order cases, the manufacturing holding areas are managed as manufacturing resources instead of warehousing resources, and the shipments are managed as part of order tracking, thus eliminating the warehousing component.

Execution activities supported by warehousing are the revenue-producing delivery of finished goods via distribution centers and the support activities of distribution center management. The primary planning activities supported by warehousing are distribution planning and distribution requirements planning.

2.2.8. Transportation

This function includes all aspects of movement of parts and finished goods among manufacturing facilities and distribution centers as well as final delivery to customers. It can be subdivided into the management of vehicle fleets, transportation service contracts, and shipping orders.

All manufacturers manage shipping orders—the decision to move shipments of parts and finished goods from one facility to another in the process of fulfilling customer orders. What is captured for the order is the associated shipments, the starting and ending locations, the means of transfer, the nominal pickup and delivery times, and the associated authorizations. The means of transfer can be by owned vehicles or transportation service contracts, or a combination.

For transportation service contracts, what is tracked is the contractual information, the shipping and housing orders placed under those contracts, the states of those orders and corresponding states of the internal shipping orders, and the shipments themselves. In addition, the system tracks other actions under the contract, including payment authorizations, change orders, delays, misdeliveries, damaged and misplaced goods, and shipments not accepted.

The management of vehicle fleets, for enterprises that have their own, entails the capture of maintenance and spare parts information and the capture of vehicle staffing, routes and schedules, and current orders, states, and locations. In general, the activities are the same as those of contract shipping organizations, but the manufacturer's transportation fleet has only one customer and usually a small and mainly predefined set of destinations.

Execution activities supported by transportation include movement of parts between manufacturing centers and movement of spare parts and finished products to customers and distribution centers, all of which are revenue producing. The supporting activities of managing transportation fleets and services are also supported.

Planning activities supported by transportation include delivery planning, transportation resource planning, and transportation route planning.

2.2.9. Human Resource Management

The human resource management (HRM) component includes the management of all information about the personnel of the manufacturing enterprise—current and former employees, retirees and other pensioners, employment candidates, and possibly on-site contractors and customer representatives. For employees, the information may include personal information, employment history, organizational placement and assignments, evaluations, achievements and awards, external representation roles, education, training and skills certification, security classifications and authorizations, wage/salary and compensation packages, pension and stock plan contributions, taxes, payroll deductions, work schedule, time and attendance, leave status and history, company insurance plans, bonding, and often medical and legal data. For contract personnel, some subset of this information is maintained (according to need), along with references to the contract arrangement and actions thereunder.

The HRM system is often also the repository of descriptive information about the organizational structure because it is closely related to employee titles, assignments, and supervisory relationships.

The execution activities supported by the HRM system are entirely support activities. They include the regular capture of leave, time, and attendance information and the regular preparation of data

sets for payroll and other compensation actions and for certain government-required reports. They also include many diverse as-needed transactions, such as hiring and separation actions of various kinds, and all changes in any of the above information for individual personnel. But the HRM system supports *no* revenue-producing function directly, and it often plays only a peripheral role in strategic planning.

2.2.10. Finance Management and Accounting

This function includes the management of all information about the monies of the enterprise. The primary accounting elements are grouped under accounts payable (all financial obligations of the organization to its suppliers, contractors, and customers); accounts receivable (all financial obligations of customers, suppliers, and other debtors to this organization); and general ledger (the log of all real and apparent cash flows, including actual receipts and disbursements, internal funds transfers, and accrued changes in value). In reality, each of these is divided into multiple categories and accounts. While smaller organizations often do finance management under the heading *general ledger,* larger ones, and therefore ERP systems, usually separate the finance management concerns from general ledger transactions. They include fixed asset management (acquisition, improvement, amortization, depreciation of plants, facilities, and major equipment); financial asset management (cash accounts, negotiable instruments, interest-bearing instruments, investments, and beneficial interests [e.g., partnerships]); and debt management (capitalization, loans and other financing, and ''assignments of interest'' [e.g., licenses, royalties]).

The major enterprise execution activities supported by the finance management component are contracting, payroll, payment (of contractual obligations), invoicing, and receipt of payment. Payroll is a supporting activity, but payment and receipt are revenue producing.

The primary financial planning activities supported are investment planning, debt planning, and budget and cash flow planning and analysis.

2.3. Interaction Points

It is the intent of many ERP vendors to provide the information systems support for all the business operations of the manufacturing enterprise, and ERP systems have gone a long way in that direction. But there are still several areas in which the manufacturing organization is likely to have specialized software with which the ERP system must interface. The primary mission of the ERP system is to provide direct support to the primary operations activities (materials acquisition, manufacturing, product delivery) and to the planning and management functions for those operations. The software environment of a large manufacturing enterprise includes many other systems that support nonoperations business functions. This includes product planning and design, market planning and customer relations, and supply chain planning and development. Additionally, software that supports the detailed manufacturing processes and the control of equipment is so specialized and therefore so diverse that no ERP provider could possibly address all customer needs in this area.

On the other hand, the wealth of data managed within the ERP core, as well as its logical and physical infrastructure and the demand for those data in many of these related processes, open the door for integrating these other functions with the ERP system. This is the situation that leads to demands for open ERP interfaces.

Moreover, as the ERP market expands to medium-sized enterprises, the cost of the monolithic ERP system has proved too high for that market, leading ERP vendors to adopt a strategy using incremental ERP components for market penetration. This strategy in turn requires that each component system exhibit some pluggable interface by which it can interact with other component systems as they are acquired. While ERP vendors have found it necessary to document and maintain these interfaces, thus rendering them open in a limited sense, none of the vendors currently has an interest in interchangeable components or standard (i.e., public open) interfaces for them. But even among components there are ''forced'' ERP boundaries where the medium-sized enterprise has longer-standing enterprise support software (e.g., in human resources and finance). These also offer opportunities for standardization.

At the current time, the most significant ERP boundaries at which standard interfaces might be developed are depicted in Figure 3.

2.3.1. Contracts Management

Contractual relationships management deals with the information associated with managing the formal and legal relationships with suppliers and customers. It consists of tracking the contract development actions; maintaining points of contact for actions under the agreements; and tracking all formal transactions against the agreements—orders and changes, deliveries and completions, signoffs, invoices and payments, disputes and resolutions, and so on. ERP systems rarely support the document management function, tracking the contract document text through solicitation, offer, counteroffer, negotiation, agreement, amendments, replacement, and termination. They leave that to a legal or

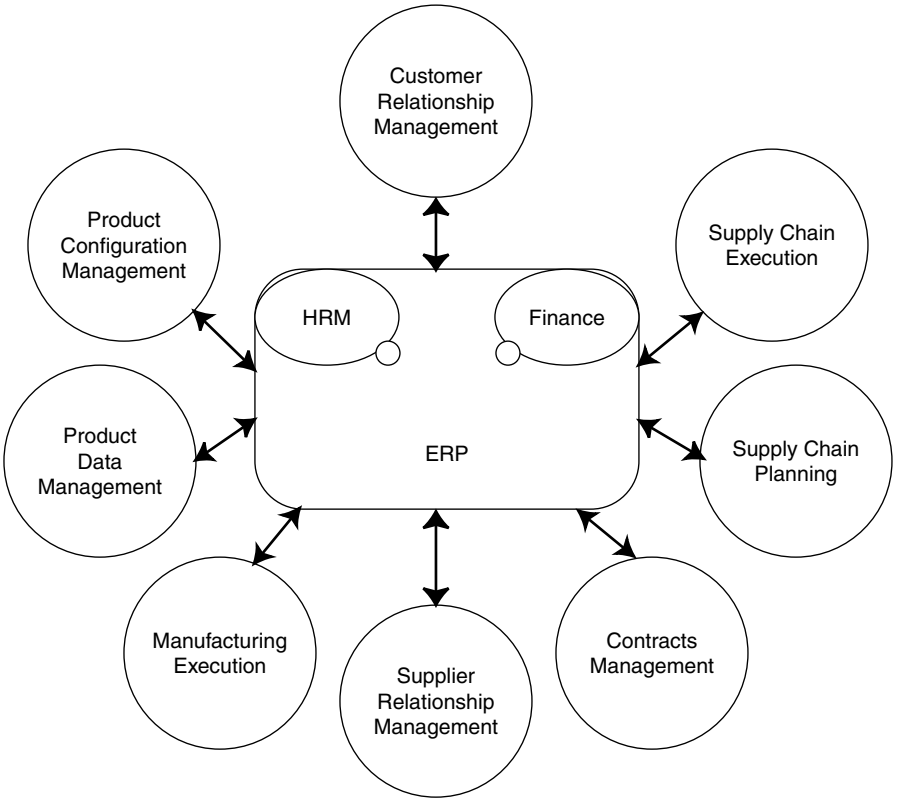

Figure 3 Opportunities for Standard ERP Interfaces.

business document management system and carry only references into that system where needed. They do routinely capture all transactions against agreements, but they often capture them in different places. Only a few centralize all these transactions under contracts management.

2.3.2. Supplier Relationship Management

This activity includes information on contractual arrangements with suppliers and points of contact, relationship history (orders, fulfillments, disputes, resolutions), business evaluations, and technical evaluations of products and capabilities, including certifications for specific materials. For specific materials (or product families), there are approved supplier lists that identify suppliers from whom the organization may order that material, often with preference ranking or ranking criteria.

2.3.3. Customer Relationship Management

As mentioned previously, the objective of CRM is to add value for customers through those processes that involve direct contact with customers before, during, and after sales. This function encompasses marketing and sales activities related to the identification and characterization of markets, the characterization of product opportunities within those markets that are consistent with the strategies and expertise of the enterprise, and the development of those markets into a customer base that generates recurring demand for the products of the enterprise. ERP systems may support demand planning activities that make projections for existing products with target volumes and time requirements as well as projections for new products or product modifications. ERP systems may also support customer inquiries as to product lines and company capabilities as well as inquiries and negotiations for alternative supply arrangements. As discussed in Section 2.2.3, ERP systems always support customer orders for existing products, customer order changes and cancellations, and inquiries about customer order status.

2.3.4. Product Configuration Management

A product configurator tracks the design of product options from desired features to manufacturing specifications. It captures product planning, pricing, and engineering decisions about option implementations and interoption relationships. The sales configurator component tells the sales staff what option combinations a customer can order and how to price them. The manufacturing configurator converts the option set on a customer order to a specification for bill of materials, station setup, prepositioning requirements, batching requirements, and process selections.

In ''to-order'' environments, an ERP system may include a product configuration function. A product configurator captures customer-specified product options in make-to-demand, option-to- order, and engineer-to-order environments. In those environments, product configurators connect the front office with the back office. In make-to-demand and option-to-order environments, product configurators link sales with manufacturing operations. In engineer-to-order environments, product configurators are a conduit between sales and engineering.

2.3.5. Product Data Management

While ERP systems are the principal repository for all operations data, they contain only fragments of product and process engineering data. One of the reasons for this is that the ERP core is short transactions with concise data units, while engineering data management requires support for long transactions with large data files. As ERP systems have grown over the last 10 years, PDM systems have grown rapidly as the product engineering information management system, especially in mechanical and electrical parts/product industries. The rise of collaborative product and process engineering in the automotive and aircraft industries has led to increasing capture of process engineering information in the PDM. Product engineering software tools, particularly CAD systems, are used to design tooling and other process-specific appliances, and these tools often have modules for generating detailed process specifications from the product definitions (e.g., exploded bills of materials, numerical control programs, photomasks). These tools expect to use the PDM as the repository for such data. Moreover, increased use of parts catalogs and contract engineering services has led to incorporation of a significant amount of part sourcing information in the PDM. Many ERP vendors are now entering the PDM product market, and the interface between PDM and ERP systems is becoming critical to major manufacturers and their software providers.

2.3.6. Supply Chain Execution

Although ERP systems may offer a one-system solution to supporting the operations of a given enterprise, one cannot expect that solution to extend beyond the walls. The information transactions supporting the materials flows from suppliers to the manufacturing enterprise and the flows of its products to its customers are becoming increasingly automated. Although basic electronic data interchange (EDI) transaction standards have been in existence for 20 years, they are not up to the task. They were intentionally made very flexible, which means that the basic structure is standard but most of the content requires specific agreements between trading partners. Moreover, they were made to support only open-order procurement and basic ordering agreements, while increased automation has changed much of the behavior of open-order procurement into automated catalogs and automated ordering and made several other supplier–customer operation techniques viable in the last several years. Thus, there is a need for ERP systems to operate, via upgraded e-commerce interfaces, with the ERP systems of the partners in the supply chain.

2.3.7. Supply Chain Planning

Until recently, ERP-supported planning algorithms focused on the internal behavior of the enterprise in managing its production and distribution, treating both customers and suppliers largely as black boxes with documented behaviors. The new concept is resource and market planning that focuses on the participation of the enterprise in various supply chains; thus, it can be effective only if it is part of a joint planning effort of multiple partners in those chains—the enterprise, its peers in the chain, its customers in the chain, and its suppliers. The joint planning activity must be supported by information interchanges between the decision-support software in (or linked to) the separate ERP systems of the partners. Algorithms for performing such joint planning are emerging, and first-generation software to support those algorithms is now available under the title advanced planning and scheduling (APS). Further development of these algorithms and interfaces is a necessary element of the future of ERP systems.

2.3.8. Manufacturing Execution

At some point, the gathering of manufacturing resource status information and work-in-process information becomes specific to the resource and the particular manufacturing task. It requires spe-

cialized systems to implement the specialized data-capturing technology and convert those data into resource planning, job planning, and tracking information. Further, particularly in discrete batch and job shop environments, the resource scheduling process itself becomes deeply involved with the details of the manufacturing tasks and the resource setups. Finally, a great deal of information gathered on the manufacturing floor is used to improve the process and product engineering as well as the characterization of machine capabilities, process yields, product quality, and so on. This domain is now loosely called manufacturing execution systems. Such systems deal with the details of data gathering, conversion, and assessment for specific purposes and industries. Future ERP systems must expect to interface with such companion factory management systems in a significant number of customer facilities. The need is to share resource planning information, resource status information, and order/job/lot release and status information.

2.3.9. Human Resource Management

Although it is considered a part of ERP, human resource management (HRM) systems have already penetrated the medium-sized enterprise market in many industries, of which manufacturing is only a subset. As ERP systems grow out of the manufacturing industry to other business areas, the need for interfacing with established HRM systems becomes apparent. And this makes standard interfaces to the HRM component more attractive to ERP and HRM vendors and customers.

2.3.10. Finance

In a similar way, most businesses, large and small, have long since built or acquired financial management software to support their business practices. Moreover, those practices and the related legal requirements vary significantly from country to country and, to a lesser extent, from state to state. For ERP systems, this means no ''one size fits all'' customers or even all business units of a single customer. Thus, interfaces to specialized and in-place financial software packages will continue to be a requirement.

2.4. Elements of ERP Implementations

The previous section addressed the functional aspects—the ''what''—of ERP systems. This section deals with the ''how'' of ERP, specifically the generic software elements of current commercial ERP systems. It does not address the rationale used by a specific manufacturing enterprise to manage its own ERP selection, deployment, and upkeep. However, it covers briefly some of the tools for managing an ERP system. Additionally, it describes the generic architectures used by ERP vendors.

The basic elements of an ERP implementation include the core transaction system, packaged decision support applications provided by the ERP vendor, in-house or third-party extended applications, and a collection of tools for managing various aspects of the system (Figure 4). Each of these software elements reside in a computing environment that is typically distributed and possibly multiplatform.

2.4.1. Core ERP—Transactions

The ERP core consists of one or more transaction databases as well as transaction services. As described in Section 2.2, these services include capturing, executing, logging, retrieving, and monitoring transactions related to materials inventories, facilities/equipment, labor, and money.

2.4.2. Packaged Decision Support Applications

In addition to transaction management, ERP vendors provide decision support applications that offer varying degrees of function-specific data analysis. The terms *decision support application* and *decision support systems* (DSS) refer to software that performs function-specific data analysis irrespective of enterprise level. That is, decision support includes applications for supply, manufacturing, and distribution planning at the execution, tactical, and strategic levels of an enterprise. There is considerable variability among ERP vendors regarding the types of decision support applications that they include as part of their standard package or as add-ons. At one end of the spectrum, some vendors provide very specific solutions to niche industries based on characteristics of the operations environment (i.e., process and business nature) as well as enterprise size in terms of revenue. For example, an ERP vendor at one end of the spectrum might focus on assembly line/engineer-to-order environment with decision support functionality limited to manufacturing and distribution planning integrated with financials. At the other end of the spectrum, an ERP vendor could offer decision support functionality for supply, manufacturing, and distribution planning at all enterprise levels for a host of operations environments for enterprises with varying revenues. While such a vendor offers an array of decision support tools, one or more tactical level, function-specific applications (i.e., supply, manufacturing, distribution) are typically part of a standard ERP implementation (Figure 2). The others

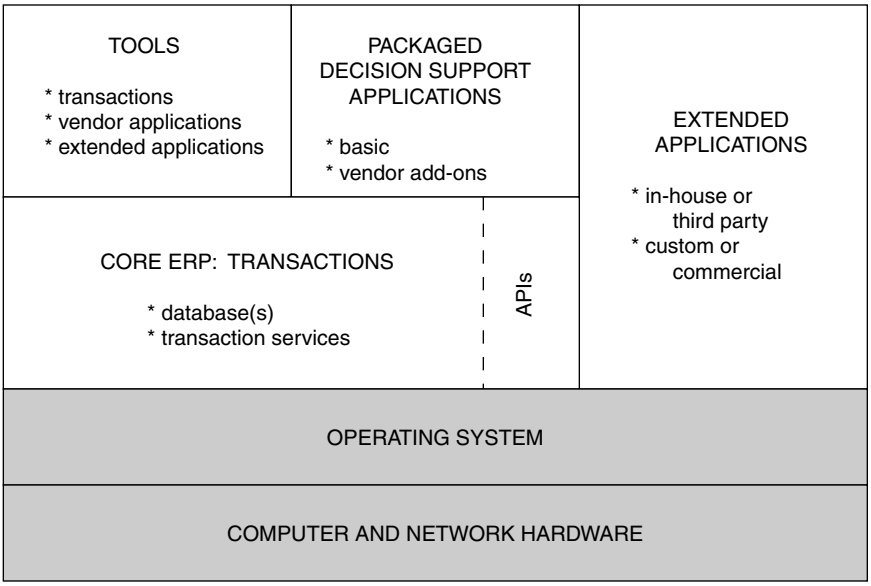

Figure 4 Basic Implementation Elements of ERP Systems.

tend to be considered add-ons. While a vendor may offer these add-ons, a manufacturer may opt to forgo the functionality they offer altogether or implement them as extended applications, either developed in-house or procured from third-party software vendors.

2.4.3. Extended Applications

The wealth of data in ERP systems allows many manufacturing enterprises to use ERP as an information backbone and attach extended applications to them. The motivation for such applications is that manufacturers typically see them as necessary to achieve differentiation from competitors. These applications may be developed in-house or by a third party. A third party may be a systems integrator who develops custom software, or it may be a vendor who develops specialized commercial software. As discussed in Section 2.3, these add-ons may provide additional functionality for customer and supplier relationship management, product data management, supply chain planning and execution, and human resource management. Regardless of the source, these applications must integrate with the ERP. Application programmer interfaces (APIs) are the common mechanism for integrating extended applications with the ERP backbone, and specifically the ERP core. Even among their partners and strategic allies (i.e., certain systems integrators and third-party software vendors), ERP vendors discourage the practice of integrating their standard applications with extended applications because of potential problems with upward compatibility. Because APIs to the ERP core have a longer expected lifetime, APIs are presently the most common approach to accessing information in the ERP system.

2.4.4. Tools

Given the enormous scope of the system, ERP can be a challenge to set up and manage. As such, ERP and third-party vendors provide software tools for handling various aspects of these complex systems. These tools generally fall into two categories: application configuration tools, which support the setup and operation of the ERP system itself, and enterprise application integration (EAI) tools, which support integration of the ERP system into the enterprise software environment.

2.4.4.1. ERP Configurators In an effort to decrease the amount of time and effort required to install, operate, and maintain an ERP system, vendors may provide a variety of application configuration tools. These tools vary in complexity and sophistication, but they all perform essentially the following tasks:

- *Define the computing topology:* Query the manufacturing administrator about the enterprise computing environment, the operating platforms, and the number, locations, and kinds of user workstations. Direct the setup program to install the appropriate versions of the ERP core and packaged modules on the server and workstation platforms.
- *Define the information base:* Query the manufacturing administrator about the specifics of their business information environment and assist in developing specialized information models (based on the vendor's generic ERP models) to support those business specifics. Automatically configure the ERP databases and transaction formats accordingly.
- *Define tasks and workflows:* Query the manufacturing administrator about the specifics of their business processes, map individual tasks to users across organizations, applications, and systems, and assist in developing specialized workflow models and decision support models. Then automatically configure the ERP workflow/task models, decision support invocations, and report formats.
- *Define security and control requirements:* Query the manufacturing administrator for user classifications by task responsibilities and authorizations. Define the user privileges, activity logging requirements, and security controls.

2.4.4.2. Enterprise Application Integration Unlike application configuration tools, which are part of an ERP vendor's suite and centered on the ERP system as the integrator of business processes, enterprise application integration (EAI) tools are actually a non-ERP-specific category of software tools whose primary function is to support business processes by linking up distinct software systems in the overall enterprise computing environment. As such, they view ERP as one part of a manufacturer's entire IT solution. But many of these tools come with predefined interfaces to specific ERP systems (some are provided by ERP vendors) and are designed primarily to link other software systems and applications with the ERP system.

This is a relatively new and fragmented class of software, employing a number of techniques of varying sophistication and providing quite variable capabilities. One view of EAI is as "a selection of technologies to address a number of applications integration problems" (Gold-Bernstein 1999). In this perspective, EAI technologies include platform integration solutions (messaging, message queueing, publish-and-subscribe, and object request brokers), message brokers (translations and transformation, intelligent routing, and application adapters), some graphical user interface (GUI) tools to define routing and mapping rules, and process automation and workflow.

A simplified view of a typical EAI architecture is provided in Figure 5. The EAI package consists of a number of application-specific adapters, each of which is capable of extracting data from and providing data to a particular application software package in some form convenient to that application. The adapter may also communicate directly with a central EAI engine that moves data sets between the adapters in some message form. In many cases the message is just a file, while in some cases the sole function of the adapter is to command the application to input or output a particular file. In some architectures, the adapter is responsible for converting the application information to or from a common interchange model and format used by the EAI package. In others, each adapter produces information in a convenient form and the engine is responsible for the conversion of the messages or files between the adapters, using a common reference model or an application-to-application-specific translation, or both.

Most EAI packages are designed primarily to solve intraenterprise communication problems. Many provide some mechanisms for Web-based access as a means of interaction with customers and suppliers.

2.5. ERP Architectures

For purposes of illustration, the ERP community refers to tiers when describing the general logical architectures of ERP systems. While the notion of tiers generally implies a hierarchy, such is not the case with tiers in present-day ERP architectures. Advances in distributed computing technologies enable more open communication among components. Instead, these tiers are the basic types of logical elements within an ERP implementation and thus provide a means for describing various ERP execution scenarios.

Figure 6 illustrates the five tiers of ERP architectures: core/internal (often called data), application, user interface, remote application, and remote user interface. A common intraenterprise scenario involves the data, application, and user interface tiers. This scenario does not preclude application-to-application interaction. Similarly, common interenterprise scenarios include an internal user or application requesting information from an external application or an external user or application requesting information from an internal application. The Internet is the conduit through which these internal/external exchanges occur. Additionally, in many ERP systems web browsers have emerged as the platform for both local and remote user interfaces.

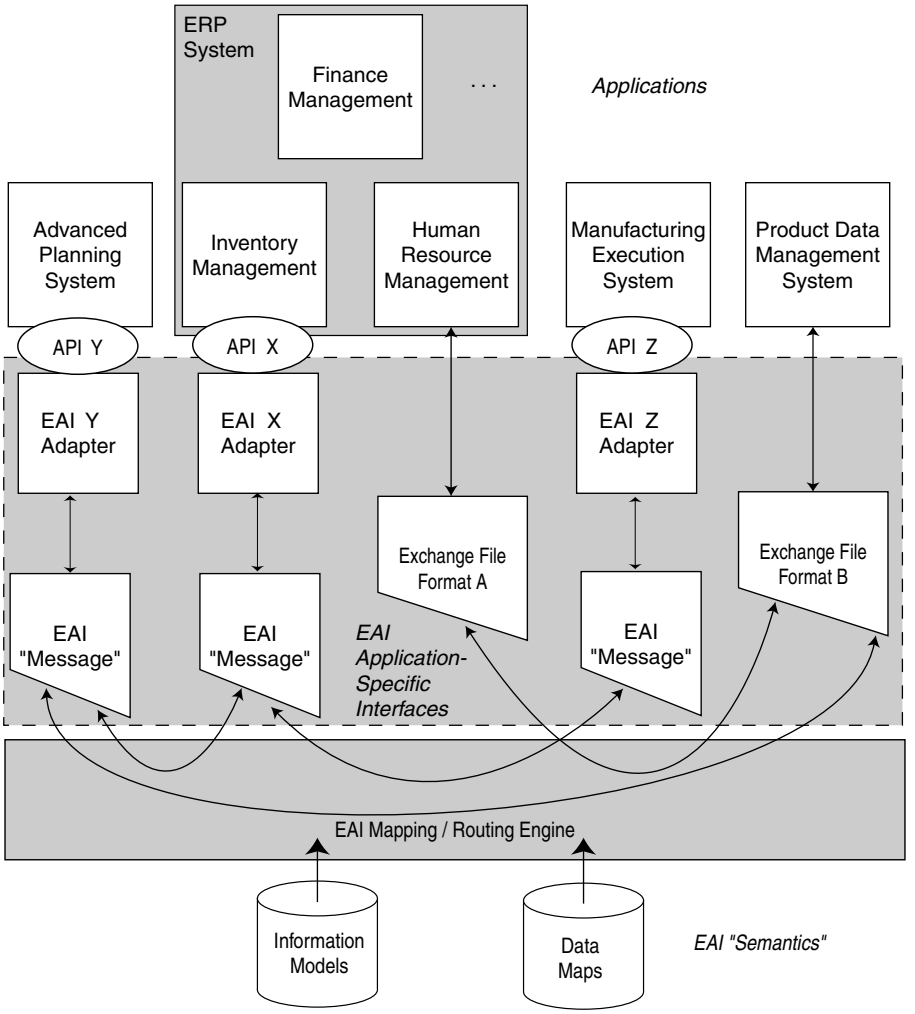

Figure 5 EAI Systems Architectures.

2.6. ERP and the Internet

The emergence of the Internet as the primary conduit for exchange of ERP-managed information among trading partners has spawned the term *Internet-based ERP.* This term does not convey a single concept but may refer to any of the following:

- Internal user-to-ERP-system interfaces based on web browsers
- External user-to-orders interfaces based on web browsers
- Interfaces between decision support software agents of different companies that support supply chain operations
- Interfaces between decision support software agents of different companies that support joint supply chain planning

The increasingly commercial nature of the Internet and the development of communication exchange standards have had significant impact on ERP systems. In describing this impact, the term *tier* is used in the context of ERP architecture (Section 2.5).

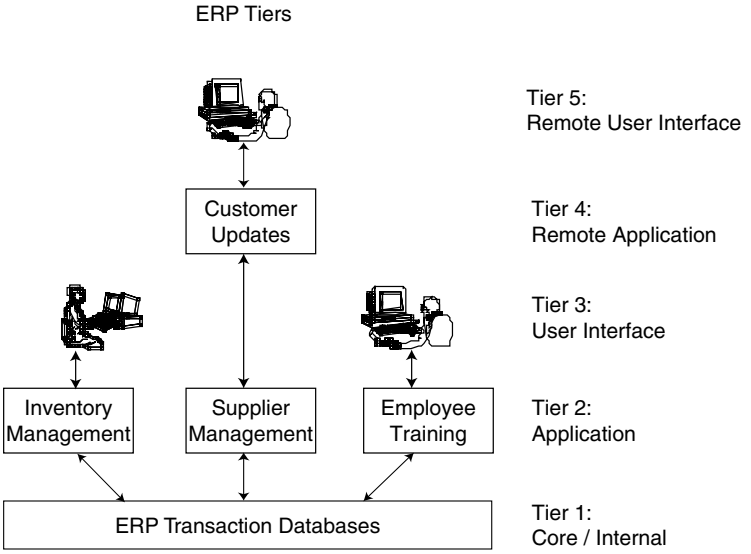

Figure 6 Tiers in ERP Architectures.

2.6.1. Internal User-to-ERP Interfaces

Also called application hosting, this approach employs user interfaces (Tier 3) based on Internet/Web technologies, notably Java, the Hypertext Markup Language (HTML), and the Extensible Markup Language (XML). In this scenario, ERP vendors as well as systems integrators take on a new role as application service providers (ASPs). This is an important change in the product architecture of ERP, in that the ERP vendor no longer has to maintain the dedicated workstations or the workstation software for users so connected. It also means that the ERP vendor cannot price that part of its services by station but instead uses transaction volume metrics. This differs from other impacts by being purely intranet-based (i.e., all such connections are from within the enterprise and thus subject to alternative controls and security mechanisms).

2.6.2. External User-to-ERP Interfaces

In this scenario, a remote user (Tier 5), via an interface based on Web technologies, accesses application service modules (Tier 2). This is a widely used approach among ERP vendors and CRM vendors. It differs from the first by having many electronic business technical concerns, including access authorization and data filtering, secure sockets, and contract and payment references. The critical question here is whether the functions supported include order entry or just order tracking and how the Web services are related to internal orders management. The CRM system may act as a staging system with no direct connect between the Web interface and the ERP system itself.

2.6.3. B2B Supply Chain Operations Interfaces

This scenario involves communication between a remote application and a local application (i.e., Tier 4 and Tier 2). The actual exchange is usually based on EDI or some XML message suites,* using file transfers, electronic mail, or some proprietary messaging technology to convey the messages. This scenario is significantly different from the above in that neither of the communicating agents is a user with a browser. Rather, this is communication between software agents (decision support modules) logging shipment packaging, release, transportation, receipt, inspection, acceptance, and possibly payment on their respective ERP systems (with some separate Tier 3 user oversight at both ends). Special cases of this include vendor-managed inventory and consignment management, which illustrate the use of the Internet in direct support of an operations process.

*E.g., RosettaNet (RosettaNet 2000), CommerceNet (CommerceNet 2000), Electronic Business XML (Electronic Business XML 2000), Open Applications Group Interface Specification (OAGIS) (Open Applications Group 2000).

2.6.4. Joint Supply Planning (Advanced Planning and Scheduling) Interfaces

This scenario also involves communication between a remote application and a local application (i.e.,Tier 4 and Tier 2) with the exchange based on a common proprietary product or perhaps an XML message suite. Again the communicating agents are software systems, not users with browsers, but their domain of concern is advanced planning (materials resource planning, distribution resource planning, etc.) and not shipment tracking. There are very few vendors or standards activities in this yet because this represents a major change in business process. This scenario illustrates use of the Internet in direct support of a tactical planning process.

3. AN EXTERNAL VIEW OF ERP SYSTEMS

This section illustrates ERP systems in a larger context. Section 3.1 provides some current thinking on the apparent macroeconomic impacts of IT, with a yet-to-be-proven hypothesis specific to ERP systems. Section 3.2 describes the relationship of ERP specifically with respect to electronic commerce, supply chains, and individual manufacturing enterprises.

3.1. ERP and the Economy

Much has been written and said about the emerging digital economy, the information economy, and the New Economy. It is the authors' view that the information economy must support and coexist with the industrial economy because certain fundamental needs of mankind are physical. However, while these economies coexist, it is clear that the sources of wealth generation have changed and will continue to change in fundamental ways. In the last 50 years, the U.S. gross domestic product (GDP), adjusted for inflation, has grown more than 500% (Figure 7). While each major industry has grown considerably during that period, they have not grown identically. Confirming that the economy is a dynamic system, the gross product by industry as a percentage of GDP (GPSHR) saw significant changes in the last half of the 20th century (Figure 8). GPSHR is an indication of an industry's contribution (or its value added) to the nation's overall wealth. While most goods-based industries appear to move towards a kind of economic equilibrium, non-goods industries have seen tremendous growth. The interesting aspect of ERP systems is that they contribute to both goods- and non-goods-based industries in significant ways. In fact, for manufacturers, ERP plays a critical role in extending the existing industrial economy to the emerging information economy. In the information economy, ERP accounts for a significant portion of ''business applications'' sales, not to mention the wealth generated by third parties for procurement, implementation, integration, and consulting. While these are important, in this chapter we focus on the use of ERP in manufacturing. Therefore, the following sections describe how ERP and related information technologies appear to impact the goods-producing sectors of the current U.S. economy.

Macroeconomics, the study of the overall performance of an economy, is a continually evolving discipline. Still, while economists debate both basic and detailed macroeconomic theory, consensus exists on three major variables: output, employment, and prices (Samuelson and Nordhaus 1998). The primary metric of aggregate output is the gross domestic product (GDP), which is a composite of personal consumption expenditures, gross private domestic investment, net exports of goods and services, and government consumption expenditures and gross investment. The metric for employment is the unemployment rate. The metric for prices is inflation. While these variables are distinct, most macroeconomic theories recognize interactions among them. It appears that the use of information technology may be changing economic theorists' understanding of the interactions among economic variables, particularly for predicting gross domestic product, unemployment, and inflation. It is important to gain a deeper understanding of these changes because their impact would affect government policy decisions, particularly those involving monetary policy and fiscal policy.

In the current record domestic economic expansion, real output continues to increase at a brisk pace, unemployment remains near lows not seen since 1970, and underlying inflation trends are subdued. During this period, inflation has been routinely overpredicted while real output has been underpredicted. Conventional economic theory asserts that as real output increases and unemployment decreases, significant pressures mount and force price increases. Yet, in this economic expansion, inflation remains in check, *apparently* due in part to IT-enabled growth in labor productivity (Greenspan 1999). In the early 1990s, the labor productivity growth rate averaged less than 1% annually. In 1998, that rate had grown to approximately 3%. So what has happened in this decade? In the last 10 years, information technology has enabled companies, most notably manufacturers, to change the way they do business with access to better information (often in real time) and better decision-support technologies. These changes have improved the way manufacturers respond to market wants (i.e., for products) and market demands (wants for products backed by buying power). ERP systems play a significant part in satisfying the latter by enabling better planning and execution of an integrated order fulfillment process. In short, ERP software enables these improvements by providing decision makers in an enterprise with very accurate information about the current state of the enterprise.

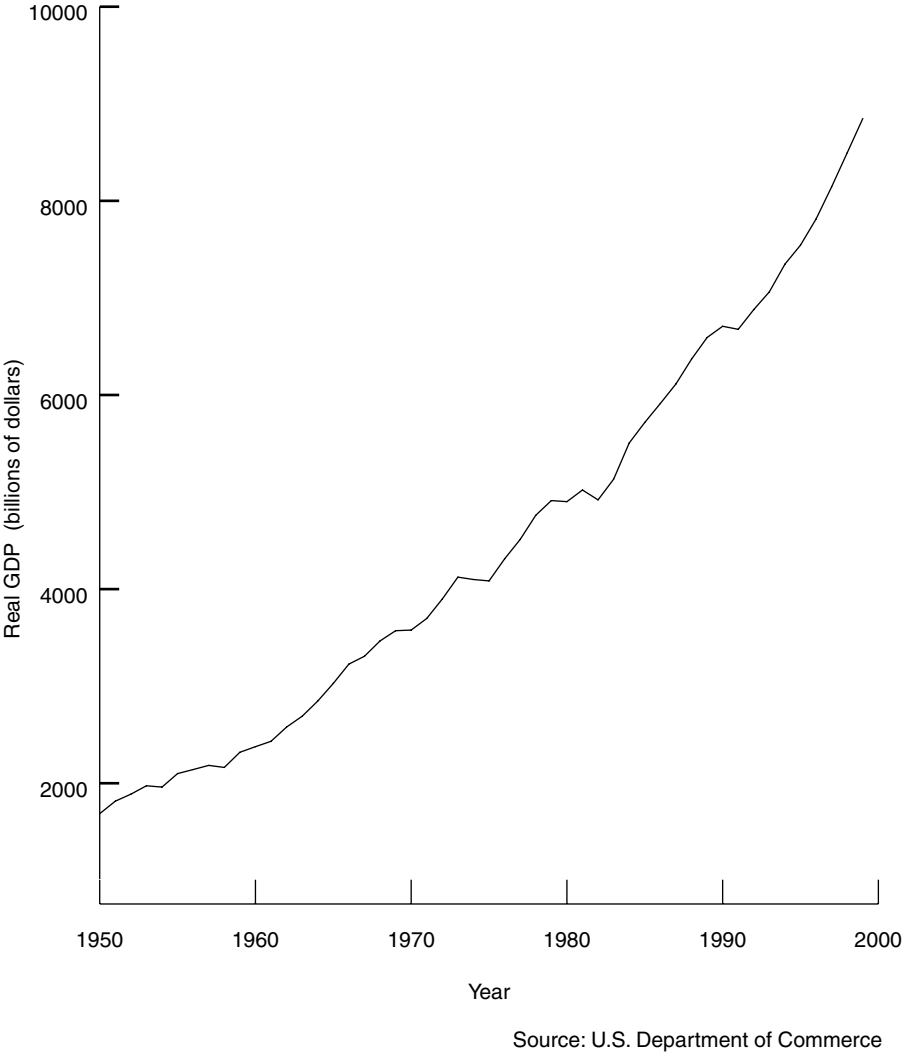

Figure 7 GDP Growth, 1950–1999.

Moreover, an increasing number of manufacturers have direct access to demand information from their customers and resource information from their suppliers. In many cases, the customer's demand information and the supplier's resource information originate in their respective ERP systems. Just as these data are more accurate for the customer/manufacturer/supplier enterprise, so too is the resulting information flowing up and down the supply chain. For the manufacturer between them, this information enables decision makers to base decisions on accurate external information, as well as accurate internal information. The following remarks by Federal Reserve Chairman Alan Greenspan perhaps best capture the essence of this phenomenon (Greenspan 1999):

> As this century comes to an end, the defining characteristic of the current wave of technology is the role of information. Prior to the advent of what has become a veritable avalanche of IT innovations, most of twentieth century business decision-making had been hampered by limited information. Owing to the paucity of timely knowledge of customers' needs and of the location of inventories and materials flows throughout complex production systems, businesses required substantial programmed redundancies to function effectively.

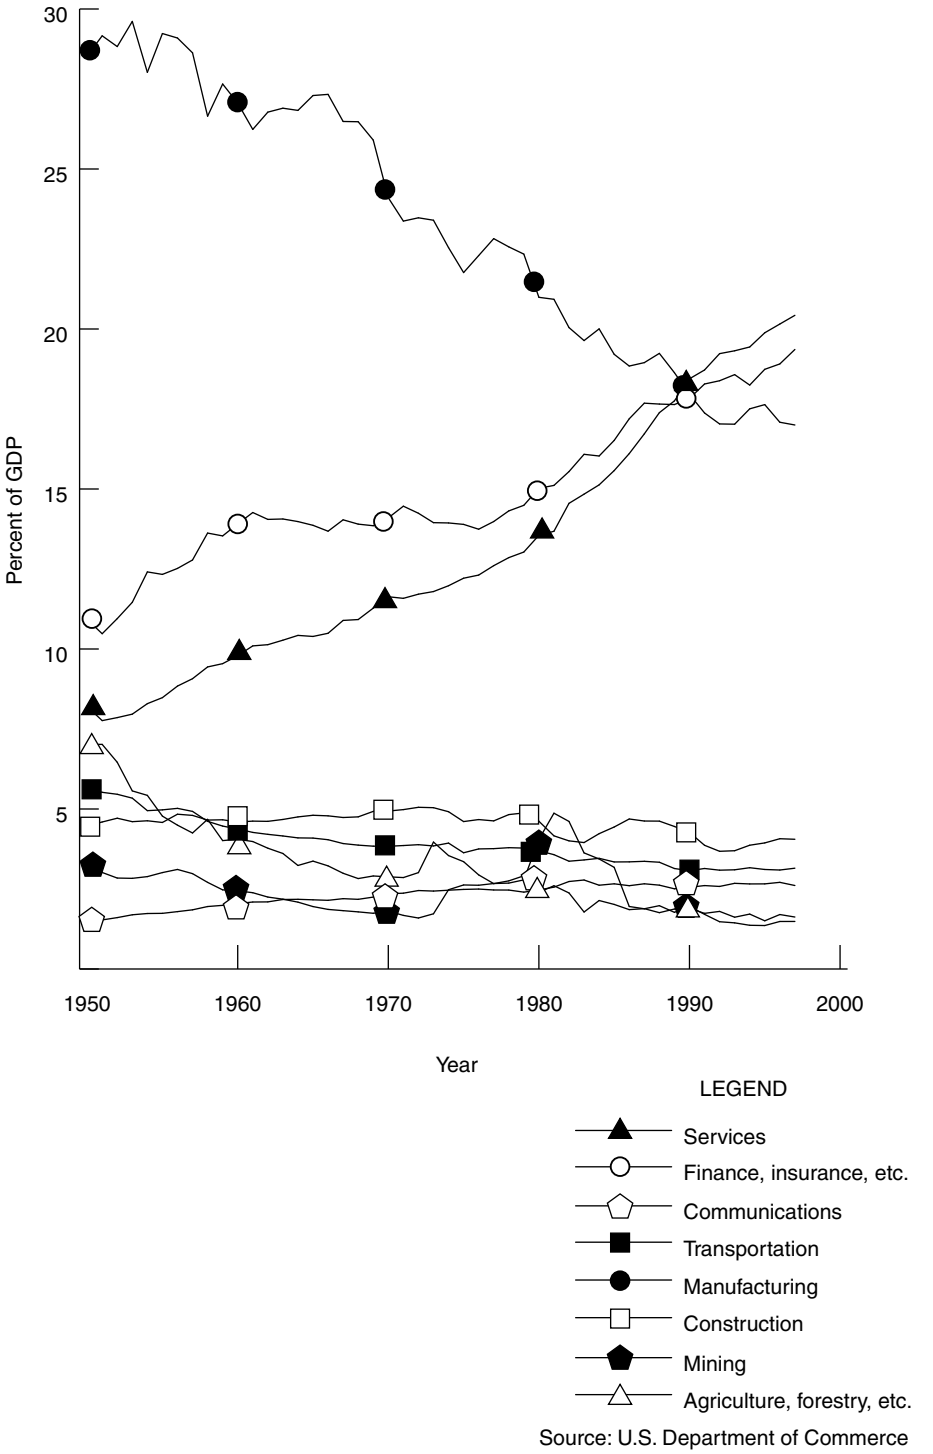

Figure 8 Gross Product Originating by Industry Share of GDP, 1950–1997.

> Doubling up on materials and people was essential as backup to the inevitable misjudgments of the real-time state of play in a company. Judgments were made from information that was hours, days, or even weeks old. Accordingly, production planning required adequate, but costly, inventory safety stocks, and backup teams of people to maintain quality control and for emergency response to the unanticipated and the misjudged.
>
> Large remnants of information void, of course, still persist and forecasts of future events on which all business decisions ultimately depend are still inevitably uncertain. But the recent years' remarkable surge in the availability of real-time information has enabled business management to remove large swaths of inventory safety stocks and work redundancies. . . .
>
> Moreover, information access in real-time resulting from processes such as, for example, checkout counter bar code scanning and satellite location of trucks, fostered mark reductions in delivery lead times on all sorts of goods, from books to capital equipment. This, in turn, has reduced the overall capital structure required to turn out our goods and services, and, as a consequence, has apparently added to growth of multi-factor productivity, and thus to labor productivity acceleration.
>
> Intermediate production and distribution processes, so essential when information and quality control were poor, are being bypassed and eventually eliminated.

ERP systems, in part, enable those activities described by Chairman Greenspan by providing two core functions: transaction management and near-term decision support. The objective of transaction management is to track the effect of execution activities on inventories, resources, and orders, while the objective of intermediate-term decision support is to use that and other information to generate accurate plans for sourcing, production, and delivery.

3.2. ERP, Supply Chains, and Electronic Commerce

ERP systems do not provide a complete solution for supply chain management (SCM) or electronic commerce. However, especially for manufacturers, the functionality provided by ERP is a necessary (although by no means sufficient) element of both SCM and, therefore, electronic commerce. This section provides definitions of electronic commerce and SCM and explains the relationships among these concepts and ERP.

3.2.1. Electronic Commerce

Ask 10 people to define electronic commerce and you'll likely get 10 different definitions that reflect the particular biases of those asked. Recognizing the existence of these broad interpretations, this chapter uses an inclusive definition developed by the Gartner Group (Terhune 1999):

> Electronic commerce is a dynamic set of technologies, integrated applications, and multi-enterprise business processes that link enterprises together.

The concept of electronic commerce centers on the use of technology, and those technologies tend to be infrastructural in nature. Some obvious current technological issues include network-related subjects (the Internet, the Web, and extranets), security, interoperability of applications software, and the exchange of application-based information within and across enterprises. These integrated applications, which collectively comprise an enterprise's electronic business or (e-business) environment, include EDI software, supply chain management, ERP, customer relationship management, and enterprise application integration software. Issues in multienterprise business processes revolve around the different interactions that occur across enterprises. Electronic commerce changes, in part or in whole, the mode of these interactions from paper and voice to networked, digital information flows. The nature of these interactions, and the relationships among trading partners in general, range from coercive to collaborative depending on the general structure and practices of a given industry, the goods and/or services produced, and the impact of information technology on the distribution channels through which those goods and services flow. Recognizing and understanding these distinctions are critical for evaluating the existing and potential impact of electronic commerce across industries.

Manufacturing industries face particular challenges in realizing the benefits of electronic commerce because of the coupling of goods and information and the coordination required across those domains. Information-intensive industries (e.g., banking, traveling, advertising, entertainment) experience the effects of electronic commerce before materials-intensive industries such as manufacturing, construction, and agriculture. In information-intensive industries, products and services lend themselves to the technology. In many of these cases, electronic commerce technology simply becomes a new distribution channel for the information product or service. The manufacturing situation is significantly more complex because it requires reconciliation of goods *and* information. The objective is not to develop new distribution channels per se (the information network does not move goods); the objective is to improve the flow of goods by using the information technology to improve the business practices. Optimizing the flow of goods through distribution channels is one particular type of electronic commerce improvement. By so doing, trading partners can root out the inefficiencies within channels and make them more adaptive to changes in the market. It is precisely those inefficiencies and adaptability that are the foci of SCM.

3.2.2. Supply Chain Management

Supply chain management is one of several electronic commerce activities. Like electronic commerce, SCM has acquired buzzword status. Nonetheless, a common understanding of SCM has emerged through the work of industry groups such as the Supply Chain Council (SCC), the Council on Logistics Management (CLM), and the APICS organization, as well as academia.

> SCM is the overall process of managing the flow of goods, services, and information among trading partners with the common goal of satisfying the end customer. Furthermore, it is a set of integrated business processes for planning, organizing, executing, and measuring procurement, production, and delivery activities both independently and collectively among trading partners.

It is important to note a critical distinction here, especially since that distinction is not explicit in the terminology. While *SCM* is often used synonymously with *supply chain integration* (SCI), the two terms have connotations of differing scopes. As stated previously, SCM focuses on planning and executing trading partner interactions of an operations nature—that is, the flow of goods in raw, intermediate, or finished form. SCI is broader; it includes planning and executing interactions of any kind among trading partners, and it refers in particular to the development of cooperating technologies, business processes, and organizational structures.

The operations-specific objectives of SCM can only be achieved with timely and accurate information about expected and real demand as well as expected and real supply. A manufacturer must analyze information on supply and demand along with information about the state of the manufacturing enterprise. With the transaction management and basic decision support capabilities described earlier, ERP provides the manufacturer with the mechanisms to monitor the current and near-term states of its enterprise. As depicted in the synchronized, multilevel, multifacility supply chain planning hierarchy of Figure 2, ERP provides the foundation for supply chain management activities. Section 1 described the various levels of the hierarchy, and Section 2 described the details of transaction management and decision support.

4. ERP CHALLENGES AND OPPORTUNITIES

While evidence suggests that ERP systems have brought about profound positive economic effects by eliminating inefficiencies, there is still room for substantial improvement. The technical challenges and opportunities for ERP systems arise from how well these systems satisfy the changing business requirements of the enterprises that use them. Case studies in the literature highlight the unresolved inflexibility of ERP systems (Davenport 1998; Kumar and Van Hillegersberg 2000). The monolithic nature of these systems often hampers, or even prevents, manufacturers from responding to changes in their markets. Those market changes relate to ERP systems in two important ways: the suitability of decision support applications to an enterprise's business environment and the degree of interoperability among applications both within and among enterprises.

These two issues lead to three specific types of activities to improving ERP interoperability: technology development, standards development, and business/technology coordination.

4.1. Research and Technology Development

4.1.1. Decision Support Algorithm Development

Manufacturing decision support systems (DSSs), especially those that aid in planning and scheduling resources and assets, owe their advancement to progress in a number of information technologies, particularly computational ones. The early versions of these applications—namely materials requirements planning (MRP) and manufacturing resource planning (MRP II)—assumed no limitations on materials, capacity, and the other variables that typically constrain manufacturing operations (e.g., on-time delivery, work-in-process, customer priority). The emergence of constraint-based computational models that represent real-world conditions has enabled manufacturers to better balance supply and demand. In spite of the improvement in DSSs, significant opportunities still exist. Different models apply to different business environments. With the rapid pace of change, the commercial viability of the Internet, and the push to "go global," there are new variables to examine and new models to develop. Instead of convergence to any single optimization function, there will likely be specialization to classes of functions. That specialization has begun as illustrated in Figure 2 and described in Section 3.2 Continued specialization (not simply customization) is likely and necessary. Those classes will account for the variety of ways that manufacturing enterprises choose to differentiate their operations from those of their competitors. While cost reduction has been the focus of the current generation of DSSs, models that also address revenue enhancement and response time are expected to be the focus of future generations.

4.1.2. Component Decomposition Analysis

As decision support technology evolves, so too does ERP system functionality. While advances in software functionality affect an enterprise's continuous IT improvement strategy, they do not comprise all of that strategy. Migration is another critical aspect of continuous IT improvement. That is, replacing and upgrading an existing system—in whole or in part—must be possible for an enterprise to move from one functional state to another. In general, ERP vendors have focused on providing functionality at the expense of replaceability and upgradability (Sprott and Wilke 1998). Consequently, lock-in effects are major concerns for manufacturing and nonmanufacturing enterprises alike.

Possessing the concepts of services and encapsulation, components are touted as the solution to this problem. A component delivers functionality to a user or another software entity through one or more well-defined interfaces. Encapsulation means that a component is a separate entity, thus making it easier with which to manage, upgrade, and communicate. Yet components alone do not guarantee interoperability, especially in complex e-business and electronic commerce environments. For ERP systems to be interoperable, there must be widespread agreement on the services that ERP applications provide and on the boundaries of encapsulation. Numerous approaches to defining services and interfaces exist, including vendor-specific conventions, intraenterprise conventions, industry-specific standards, and technology-specific standards.

These approaches all lack broad perspective and thus do not meet the challenges of enabling ERP interoperability in e-business and electronic commerce environments. To achieve interoperability with the vendor-specific conventions, a single ERP vendor must dominate not just the ERP system market but the markets of all the other systems that (need to) interoperate with ERP. Intraenterprise conventions work up to the bounds of the enterprise, as long as there are no major internal changes (such as mergers or acquisitions). The approach based on industry-specific standards fails to realize that the focal point of operations is business process and that information varies according to the characteristics of those processes. Industries obviously are defined by product, not business process, and commonality of product does not translate into commonality of business process. Operations-wise, what makes sense for one supply chain member (e.g., an original equipment manufacturer [OEM]) does not necessarily make sense for another (e.g., a lower-tier supplier). The fourth approach, technology-specific standards, tends to yield limited solutions because it focuses on syntax and not semantics. Without agreement on the meaning of the information to be exchanged and the function that the information supports, the challenges of reconciliation persist. Many technology-focused efforts fail to perform sufficient domain-specific information requirements analysis.

Because electronic commerce dramatically changes the nature of power and control in supply chains, component decomposition analysis must address the three emerging models of business-to-business (B2B) markets. The first approach is an OEM-controlled model such as those recently announced by U.S. automakers and defense contractors (Stoughton 2000). The second is supplier-controlled model such as those in metals, chemical, and paper industries. The third is an open model that allows control to be shared among all supply chain players. Many think that the open model will prevail in the long run. However, industries will not collectively reach that point at the same rate or at the same time. To realize this model, it is necessary to look beyond industry-specific exchange of operations data. It is necessary to analyze business processes and characterize them at appropriate levels of detail. These characterizations would highlight the different kinds of components and thus the information that needs to be exchanged in different scenarios.

4.2. Standards Development

Standards play an important role in achieving interoperability. With respect to ERP systems, opportunities exist for establishing standard interface specifications with other manufacturing applications.

4.2.1. ERP–PDM Interfaces

As discussed in Section 2.3.5, there is an obvious interaction point between ERP and PDM systems. Thus, there is a need for interfaces between the two systems to share separately captured engineering and sourcing specifications. In the longer run, the goal should be to have PDM systems capture all the product and process engineering specifications and to extract resource requirements information for use in ERP-supported planning activities. Conversely, sourcing information, including contract engineering services, should be captured in the ERP system. To do this, one needs seamless interactions as seen by the engineering and operations users.

4.2.2. ERP–MES Interfaces

As presented in Section 2.3.8, future ERP systems must expect to interface with such companion factory management systems in a significant number of customer facilities. There is the need to share resource planning information, resource status information, order/job/lot release, and status infor-

mation. However, developing such interfaces is not a straightforward exercise. The separation of responsibilities and the information to be exchanged vary according to many factors both at the enterprise level and the plant level. Prestandardization work is necessary to identify and understand those factors.

4.2.3. Supply Chain Operations Interfaces

Supply chain information flows between the ERP systems of two trading partners have been the subject of standardization activities for 20 years, with a spate of new ones created by Internet commerce opportunities. Most of these changes concentrate on basic ordering agreement and open procurement mechanisms. Requirements analysis of this information is necessary before actual standards activities commence. As the business practices for new trading partner relationships become more stable, standards for interchanges supporting those practices will also be needed. Changes in business operations practices as well as in decision support systems have changed the information that trading partners need to exchange. This includes shared auctions, supply schedule, vendor-managed inventory, and other operational arrangements, but the most significant new area is in joint supply chain planning activities (i.e., advanced planning and scheduling).

4.3. Establishing Context, Coordination, and Coherence for Achieving Interoperability

Several developments in the past decade have combined to extend the locus of information technology from research labs to boardrooms. The commercialization of information technology, the pervasiveness of the Internet, and the relatively low barriers to market entry for new IT companies and their technologies all serve to create an environment of rapid growth and change. The ERP arena, and electronic commerce in general, suffer from a proliferation of noncooperative standards activities, each aimed at creating interoperability among a handful of manufacturers with specific software tools and business practices. There is an imperative to reduce competition among standards efforts and increase cooperation.

Understanding the complex environment that surrounds ERP and other e-business and electronic commerce applications is a critical challenge to achieving interoperability. Topsight is a requirement for meeting this challenge. The objective of topsight is to establish context, coordination, and coherence among those many activities that seek standards-based interoperability among manufacturing applications. While the hurdles that exist in the current environment are considerable, there is significant need—as well as potential benefit—for an industry-led, multidisciplinary, and perhaps government-facilitated effort to provide direction for the development and promulgation of ERP and related standards.

The notion of topsight for improving interoperability among specific applications is not new. The Black Forest Group, a diverse assembly of industry leaders, launched the Workflow Management Coalition (WfMC), which has produced a suite of specifications for improving interoperability among workflow management systems. A similar ERP-focused standards strategy effort would strive to understand better the diversity of operations and operations planning in order to improve interoperability among ERP and related systems.

For a topsight effort to succeed in an arena as broad as ERP, particularly one that is standards-based, there must be a cross-representation of consumers, complementors, incumbents, and innovators (Shapiro and Varian 1999).

As consumers of ERP systems, manufacturers and their trading partners face the risk of being stranded when their systems do not interoperate. The lack of interoperability in manufacturing supply chains can create significant costs (Brunnermeier and Martin 1999), and those costs tend to be hidden. More accurate cost structures must be developed for information goods, particularly for buy-configure-build software applications. Unlike off-the-shelf software applications, ERP systems are more like traditional assets, in the business sense, with capital costs and ongoing operational costs.

Complementors are those who sell products or services that complement ERP systems. Given the role that ERP plays in electronic commerce, this group is very large. It includes both software vendors and systems integrators and management consultants. Some of the software that complements ERP was discussed previously in Section 2.3. Others include additional categories of software necessary for achieving e-business: EDI/e-commerce, business intelligence, knowledge management, and collaboration technologies (Taylor 1999).

Incumbents are the established ERP vendors, and they make up a market that is very dynamic and diverse (Table 2). Achieving consensus of any kind with such a diverse market is a considerable challenge. To achieve ERP interoperability requires, among others, deeper understanding of common elements. That understanding can be acquired by detailed functional and information analysis of the ERP systems.

The notion of innovators in the standards process focuses on those who collectively develop new technology. While many individual technology development activities associated with ERP and electronic commerce might be considered innovative, there have been few explicit collective development

TABLE 2 The Current State of ERP Market

ERP Vendor Categories	Total Annual Revenue	Cross-Functional Scope	Manufacturing Environment Scope	Targeted Industry Scope
Tier 1 ERP Vendors	more than $2 billion	broad, manufacturing, materials, human resource, financial SCM and CRM	broad, continuous, assembly line, discrete batch, job shop, construction	broad, larger and mid-market manufacturers across numerous industries
Tier 2 ERP Vendors	between $250 million and $2 billion	moderate, but expanding beyond one or two functional areas, some adding SCM and/or CRM	variable, some support one or two manufacturing environments while others support more	moderate, larger and mid-market manufacturers across several industries
Tier 3 ERP Vendors	less than $250 million	narrow, fill void of Tier 1 and Tier 2	narrow, typically supports one type of manufacturing environment	narrow, smaller manufacturers in niche industries

efforts. Most ERP vendor partnerships tend to be confined to making existing products work together through application programmer interfaces. They generally do not involve the joint creation of new (and often complementary) technologies. The dynamics that compel banks and credit card companies to pursue smart card development do not exist in the ERP environment. However, there are others who meet this definition of innovator. Academia is one group of innovators whose relationship with ERP vendors tends not to make headlines. Still, many of the technologies in today's ERP systems have academic roots. The perspective of university researchers across numerous disciplines would add significant value to a topsight effort.

5. CONCLUSIONS

ERP is a very complex subject. It marries technology, business practices, and organizational structures. ERP systems are commercially developed software applications that integrate a vast array of activities and information necessary to support business operations and operations planning at the tactical level. ERP is software and not a business process or a set of business processes. However, as software, it enables better execution of certain processes. Although often presented as a single package, an ERP system is an envelope around numerous applications and related information. For manufacturers, those applications typically support the operations processes of materials sourcing, manufacturing planning, and product distribution. To its end users, an individual application of an ERP system may appear seamless; however, to those who procure, implement, and/or maintain ERP systems, they are complex software systems that require varying levels of customization and support both centrally and across each application. While ERP systems are commercial applications developed by individual vendors, they can hardly be considered off-the-shelf. They are part of a continuing trend of outsourcing IT solutions in which part of the solution is bought, part is configured, and part is built from scratch. Given their broad organizational and functional scope, ERP systems are unlike any other contemporary commercial manufacturing applications. They provide transaction management from both the business perspective and a database perspective. Additionally, they provide a basic level of decision support. Optionally, they enable higher levels of decision support that may be offered by ERP vendors or a third-party vendor.

This chapter presented an overview of ERP from the outside and from the inside. The outside view clarified the connection between ERP, electronic commerce, and supply chain management. The inside view describe the functional and implementation elements of ERP systems, particularly in the context of manufacturing enterprises, and identified the points at which ERP interacts with other software applications in manufacturing enterprises. Finally, we looked at open research problems surrounding ERP and identified those that are important to fitting ERP systems into current and future business processes.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION AND DEFINITION

Automation has many facets, both in the service industry and in manufacturing. In order to provide an in-depth treatment of the concepts and methods of automation, we have concentrated in this chapter on assembly and robotics. Industrially produced, finished products consist mainly of several individual parts manufactured, for the most part, at different times and in different places. Assembly tasks thus result from the requirement of putting together individual parts, dimensionless substances, and subassemblies into assemblies or final products of higher complexity in a given quantity or within a given unit of time. Assembly thus represents a cross-section of all the problems in the production engineering field, very different activities and assembly processes being performed in the individual branches of industry.

Assembly is "the process by which the various parts and subassemblies are brought together to form a complete assembly or product, using an assembly method either in a batch process or in a continuous process" (Turner 1993). VDI Guideline 2860 defines assembly as "the sum of all processes needed to build together geometrically determined bodies. A dimensionless substance (e.g. slip materials and lubricants, adhesives, etc.) can be applied additionally."

The production system in a company can be divided into different subsystems. The assembly area is linked to the other subsystems by the material and information flow (see Figure 1).

Assembly is concerned with bringing together individual parts, components, or dimensionless substances into complex components or final products. DIN 8593 differentiates the following five main functional sections:

1. Supply
2. Adjustment
3. Inspection
4. Assembly work
5. Help functions

The composition of these activities varies greatly, depending on the industry and product. The structure of assembly systems is based on different organization types, depending on the batch size, the product, and the projected turnover. Assembly is divided into:

- Point assembly (often called site assembly)
- Workshop assembly
- Group assembly
- Line assembly

The evaluated scope for automation is expressed by this list in ascending order.

This chapter provides a general overview of the assembly field. Special emphasis is given to the selection and design of the appropriate assembly approach, assembly design, and assembly techniques.

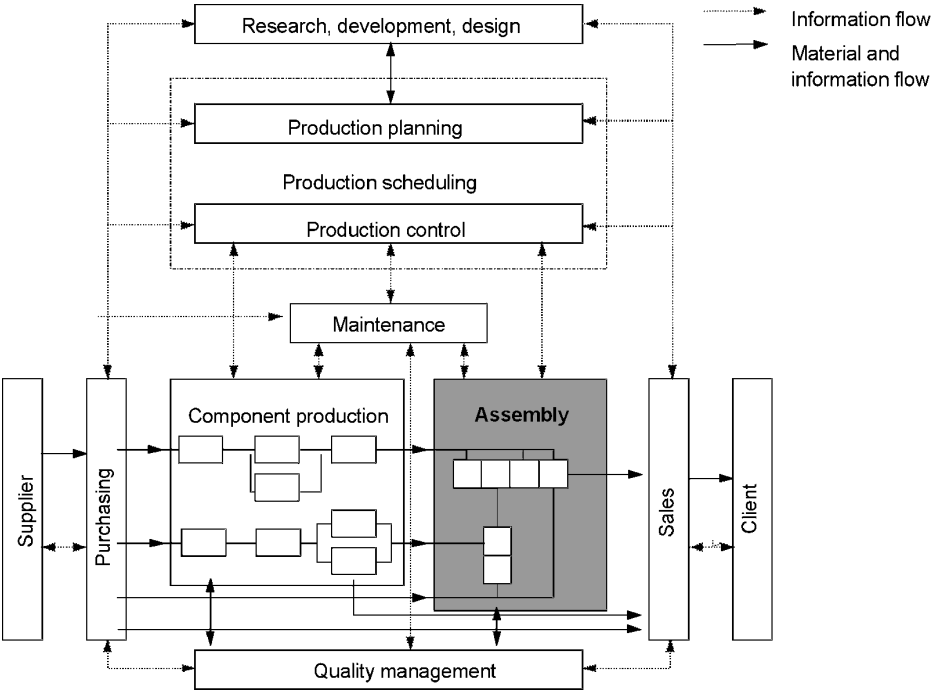

Figure 1 Assembly as a Subsystem of the Production System.

2. CLASSIFICATION OF ASSEMBLY TYPES AND CHOICE OF ASSEMBLY METHODS

Investigations into automation assembly procedures should first try to ascertain whether and in what scope automation assembly systems can be applied efficiently. This requires a very careful analysis of the assembly tasks as well as a thorough examination of possible alternatives and their profitability.

The total assembly cost of a product is related to both the product design and the assembly system used for its production. Assembly costs can be reduced to a minimum by designing the product so that it can be assembled economically by the most appropriate assembly system. Assembly systems can be classified into three categories:

1. Manual assembly
2. Special-purpose assembly
3. Flex-link (programmable) assembly

In manual assembly, the control of motion and the decision making capability of the assembly operator, assuming that the operator is well trained, are far superior to those of existing machines or artificial intelligence systems. Occasionally, it does make economic sense to provide the assembly operator with mechanical assistance, such as fixtures or a computer display detailing assembly instructions, in order to reduce the assembly time and potential errors.

Special-purpose assembly systems are machines built to assemble a specific product. They consist of a transfer device with single-purpose work heads and feeders at the various workstations. The transfer device can operate on a synchronous indexing principle or on a free-transfer nonsynchronous principle.

Flex-link assembly systems, with either programmable work heads or assembly robots, allow more than one assembly operation to be performed at each workstation and provide considerable flexibility in production volume and greater adaptability in designing changes and different product styles.

Capital-intensive assembly, such as when automatic assembly systems are applied, produces the required low unit costs only when relatively large quantities are produced per time unit and a long

amortization time is selected. Due to its flexibility, however, an assembly system able to assemble various products is more economical despite its larger investment volume. A flexible assembly system is also capable of assembling smaller batches cost-effectively, thus meeting the increasing market demands for product variety and shorter product life.

The type of automated assembly system is essentially determined by the workpieces to assemble. The most influential factors are the workpiece's total weight, size, amount, and number of types and variants.

Assembly systems are mainly automated for small-volume products or components with a total weight of a few kilograms. The cycle times for automated assembly systems vary between tenths of seconds and minutes.

The various types of automated assembly systems arise due to the combination of the different types of assembly stations and work transfer devices, which, in turn, are dependent on the requirements of the workpieces to assemble. Flexibility, that is, being adaptable to different conditions and assembly tasks, should also be a characteristic of assembly systems. An adequate configuration of the assembly station as well as respective work transfer devices will help meet the different flexibility requirements.

Assuming that the product design is compatible with automated assembly, there are several different ways to characterize the operation and configuration of the automated system. One way consists of classifying the system by the type of work transfer used by the system. These types are shown in Figure 2.

In transfer systems linked to rigid work transfer systems, the workpieces and/or partly assembled components run through the assembly process on workpiece carriers in clocked cycles. The assembly stations are placed on a circuit or next to each other parallel to the transfer device. Rigid work transfer systems have the following features:

- Joint or jointly controlled handling and/or passing-on devices
- A uniform cycle for all assembly stations set by the pace of the station with the longest cycle time
- Assembly of the manufacturing equipment in specified uniform intervals
- The shutdown of one assembly station results in the stoppage of the whole assembly installation

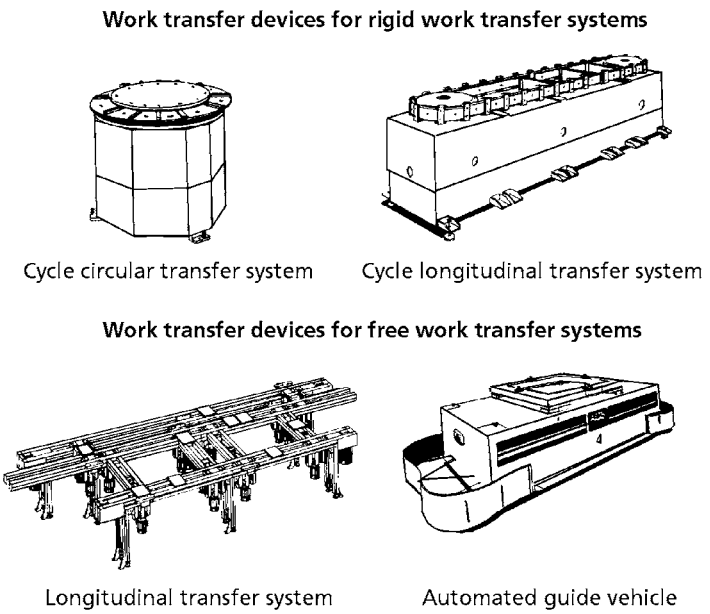

Figure 2 Alternative Work Transfer Systems for Different Assembly Configurations.

For transfer systems to flex-link systems, flexibility is achieved in the way the individual stations of an assembly system are linked—for example, for a junction in the material flow or the evening out of capacity fluctuations and/or technical malfunctions of the individual assembly stations.

Flex-link systems also allow a different level of automation at each of the assembly stations. Depending on the respective assembly tasks, the automation level can be stipulated according to technical and economic factors. In addition, step-by-step automation of the assembly system is possible because individual manual assembly equipment can still be replaced by automatic assembly station later on.

Some features of flex-link assembly stations are:

- Independent handling and manufacturing equipment that is linked to the interfaces for control purposes
- Single disengagement of the processing and handling cycles that allows different cycle times at each of the assembly stations
- Magazines as malfunction buffers between the assembly stations for bridging short stoppage times
- Freedom of choice in the placement and sequence of the assembly stations.

For longitudinal transfer systems, the transfer movement usually results from the friction between the workpiece carrier and the transfer equipment (belt, conveyor, etc.). The workpiece carriers transport the workpieces through the assembly system and also lift the workpieces in the assembly stations. The workpiece carrier is isolated and stopped in the assembly station in order to carry out the assembly process. The coding of the workpiece is executed by mechanical or electronic write/read units on which up-to-date information about the assembly status or manufacturing conditions can be stored.

Due to flex-linking, the number of linked assembly stations can be very high without impairing the availability of the whole system. Flexible modular assembly systems with well over 80 assembly stations for automated assembly of complex products are therefore not uncommon.

3. DESIGN OF MANUAL ASSEMBLY SYSTEMS

The manual assembly systems are divided into two main categories, manual single-station assemblies and assembly lines.

The manual single-station assembly method consists of a single workplace in which the assembly work is executed on the product or some major subassembly of the product. This method is generally used on a product that is complex or bulky and depends on the size of the product and required production rate. Custom-engineered products such as machine tools, industrial equipment, and prototype models of large, complex consumer products make use of a single manual station to perform the assembly work on the product.

Manual assembly lines consist of multi-workstations in which the assembly work is executed as the product (or subassembly) is passed from station to station along the line (see Figure 3).

At each workstation, one or more human operators perform a portion of the total assembly work on the product by adding one or more components to the existing subassembly. When the product comes off the final station, work has been completed.

Manual assembly lines are used in high-production situations where the sequences to be performed can be divided into small tasks and the tasks assigned to the workstations on the line. One of the key advantages of using assembly lines is the resulting specialization of labor. Because each worker is given a limited set of tasks to perform repeatedly, the worker becomes a specialist in those tasks and is able to perform them more quickly and consistently.

4. DESIGN OF AUTOMATIC ASSEMBLY SYSTEMS

The automation scope of assembly systems includes the following priorities:

- Reduction in the cost of assembly
- Increasing productivity
- Improved product quality

Improved motivation of the staff, improved clearness, shorter processing times, and improved ergonomical workstations as well as better organization are further advantages.

The movement towards automation of manufacturing and assembling sequences takes place progressively. Mechanized facilities can be automated only if specific prerequisites are fulfilled and if employing complex industrial goods seems profitable. Because assembly systems require maximum flexibility, the degree of automation is still relatively low.

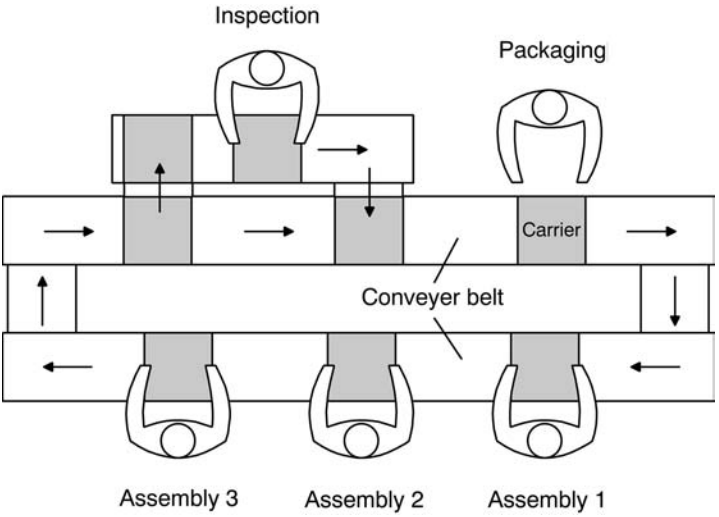

Figure 3 Example of a Manual Assembly Line.

In principle, automatic assembly systems can be further classified into the following subcategories:

- Short-cycle assembly machines
- Flexible, modular assembly systems
- Flexible assembly systems with industrial robots

Short-cycle assembly machines are actually single-purpose machines because each of them is specially designed for one assembly task only. They work in cycles ranging from less than 1 sec up to approximately 5 sec and are also used for mass-production assembly (over 1 million units annually).

Short-cycle assembly machines are often constructed modularly with standardized components for the work transfer devices and the handling and joining equipment. This allows the existing assembly machines to be partially adjusted to the new situation by modifying, converting, or retooling for changes to the assembly product.

Assembly processes are monitored by means of integrated control devices (mechanical keys, inductive feeders, etc.) in the assembly stations or partly in separate stations. This is a very important function from a quality-assurance point of view. For short-cycle assembly machines, either force-moved or pneumatic-driven motion facilities are used in the assembly stations.

The essence of flexible, modular assembly systems is that all subsystems are constructed in a modular way. The modularity pertains not only to the actual assembly stations and the sequencing devices, stands, and so on, but to the work transfer devices, control and regulation. The variety of combinations made possible by the module allows the automation of a wide range of assembly tasks. The modular conception of these systems ensures

- Easy modification and supplementary possibilities
- The capability of changing to adjust to different sets of circumstances
- A high level of reusability
- Expansion of the control technology

The investment risk is thus reduced.

Flexible, modular assembly systems (see Figure 4) usually work in cycles of a few seconds and are often used for the automated assembly of product variants for large to medium numbers of units. The principle of the flex-link assembly stations is applied for flexible, modular assembly systems because this is the only way to realize flexibility in the linking of individual assembly stations. Longitudinal transfer systems are used as work transfer devices. In order to prevent individual cycle times, technical malfunctions, capacity fluctuations, and other factors of certain assembly stations from affecting the next stations, a buffer function in the transfer line between the assembly sta-

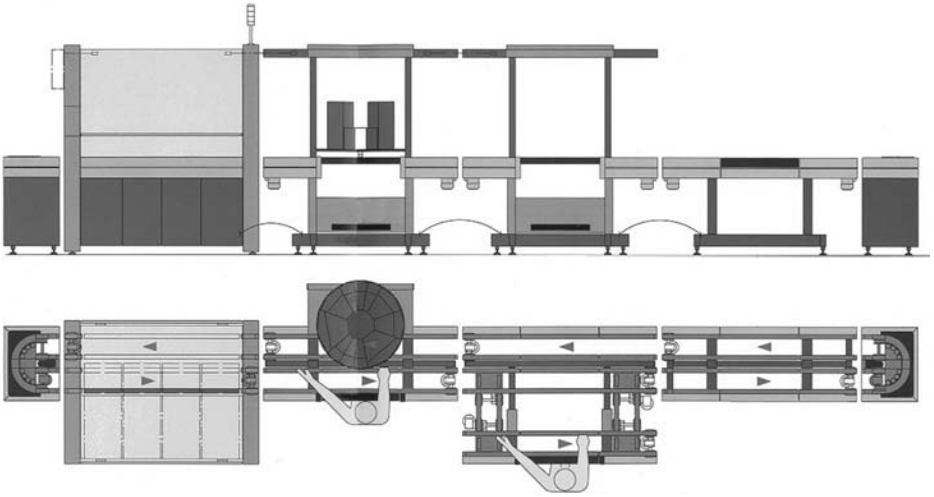

Figure 4 Flexible, Modular Assembly System. (*Source:* teamtechnik)

tions allows several workpiece carriers to stack up. The distance between the individual assembly stations is not determined by the transfer device but by an optimal buffer capacity.

Flexible assembly systems with industrial robots can be divided into three principal basic types with specific system structures:

1. Flexible assembly lines
2. Flexible assembly cells
3. Flex-link assembly systems

The largest number of industrial assembly robots is used in flexible assembly lines (see Figure 5). Flexible assembly lines are more or less comparable to flexible, modular assembly systems with regard to construction, features, and application. The cycle times for flexible assembly lines generally vary between 15 and 30 sec. The main area of application for these systems is the automated assembly of products with annual units of between 300,000 and 1 million.

The application of flexible assembly lines is economically viable especially for assembling products with several variants and/or short product lives because the flexibility of assembly robots can

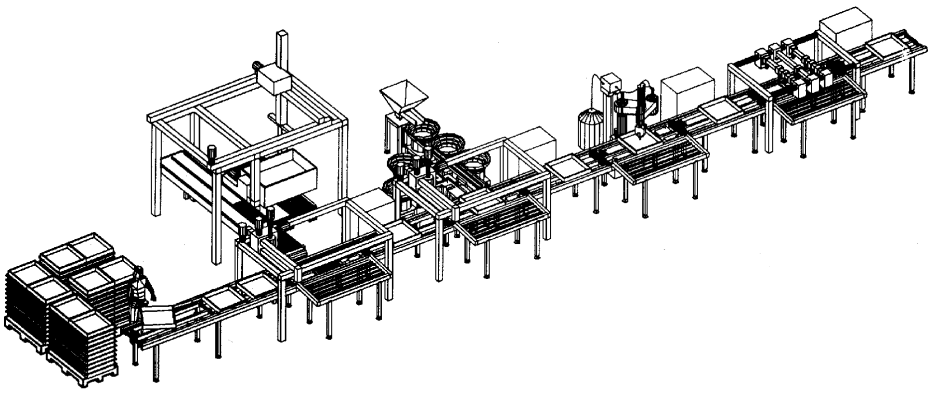

Figure 5 Flexible Assembly Line.

be best utilized for the execution of different assembly procedures for the individual product variations or follow-up products.

Assembly robots can also execute several assembly processes within an assembly cycle. This allows a high level of utilization for the assembly system, in particular for smaller amounts of workpieces, which is important for economic reasons. Depending on the cycle time range, an assembly robot can be allocated with a maximum of five to six assembly procedures in a flexible assembly line.

Flexible assembly cells (see Figure 6) are complex automated assembly stations with one or two assembly robots for large work loads (larger than for assembly stations or flexible assembly lines) where an exact limitation is very difficult and seldom expedient. A certain number of periphery devices are necessary to carry out several assembly processes of complete assembly sequences or large portions of them. Task-specific assembly devices such as presses and welding stations are also integrated if required. These periphery devices significantly limit the possible workload of the flexible assembly cells, to a maximum of 8–10 different workpieces per assembly robot. There are several reasons for this:

- Only a limited number of periphery devices can be placed in the assembly robot's workspace.
- The greater the number of subsystems, the greater the risk of interference to the whole system.
- A large number of periphery devices reduces the accessibility of the system for maintenance, repair, and troubleshooting work.

A large number of the industrial applications of flexible assembly cells are conducted as island solutions, that is, without being linked to other assembly stations. Flexible assembly cells as assembly islands are used for the automated assembly of subassembly components or simple products with usually less than 20 different parts. This system works best technically and economically with cycle times from 25–120 sec. This allows it to be applied in situations requiring an annual number of units to be assembled of between 50,000 and 500,000, depending on the scope of the assembly tasks and the number of shifts with which the system will be run.

The application of flexible assembly cells is not possible when the product or component consists of more than 20 parts. Industrial assembly very often concerns products or components composed

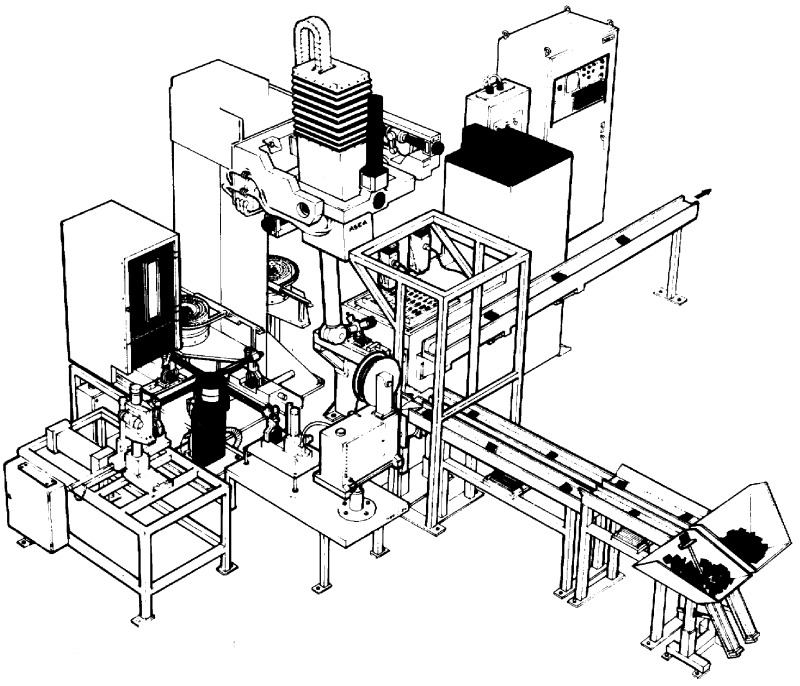

Figure 6 Flexible Assembly Cell.

of many more parts with annual units below 500,000. In order to assemble these products automatically, it is possible to distribute the assembly procedures among several flex-link assembly systems.

There are two typologies of linking flexible assembly systems: permanent and flex-link sequences. Linking with a permanent linking sequence means that each assembly system is linked in a set sequence to each other, such as with longitudinal transfer systems (see Figure 7). The permanent linking sequence allows these assembly systems to execute only a smaller number of assembly tasks with different assembly sequences. They are therefore suitable for the automated assembly of variants and types with comparable assembly sequences and several similar products or components with comparable assembly sequences.

Particularly for small annual workpiece amounts, it is economically necessary to assemble several different products or components in one flexible automated assembly system in order to maintain a high level of system utilization. Because sometimes very different assembly processes must be realized, a linking structure (flex-link sequence), independent from certain assembly processes, is necessary. Assembly systems of this type are able to meet the increasing demands for more flexibility.

In flex-link assembly systems, the workpieces are usually transported by workpiece carriers equipped with workpiece-specific lifting and holding devices. The transfer movement usually results from the friction between the workpiece carrier and the transfer equipment (belt, conveyor, plastic link chain, etc.). The transfer device moves continuously. However, the workpiece carriers are stopped during the execution of the assembly processes. In the assembly station, each of the workpiece carriers is stopped and indexed. If high assembly forces are required, the workpiece carriers must be lifted from the transfer device.

The coding of the workpiece carrier is executed by means of mechanical or electronic write/read units. In this way, it is possible to record up-to-date information about the assembly status or manufacturing procedure on every workpiece carrier and to process this information through the assembly control system. Figure 8 shows a workpiece carrier with a coding device.

5. PERFORMANCE EVALUATION AND ECONOMIC JUSTIFICATION IN SELECTING THE ASSEMBLY SYSTEM

Various methods have been developed and proposed for performance evaluation and system selection. Simplified mathematical models have been developed to describe economic performance, and the effects of several important variables have been analyzed:

1. Parts quality (PQ), represented by this factor, is the average ratio of defective to acceptable parts.
2. Number of parts in each assembly (NA).
3. Annual production volume per shift (VS).

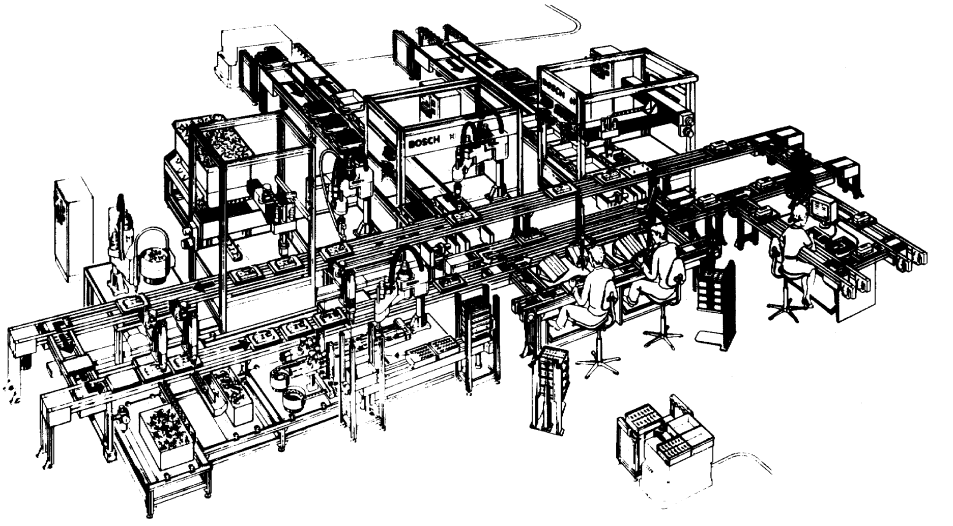

Figure 7 Flex-link Assembly System.

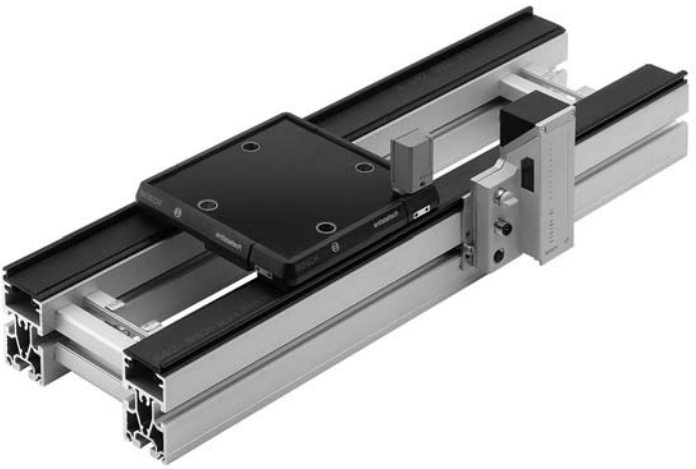

Figure 8 Example of a Workpiece Carrier with a Coding Device. (*Source:* Robert Bosch GmbH)

4. Product style variation (SV) is defined as the ratio of the total number of parts available (NT) to the number NA actually used in each product.
5. Design changes (ND) is the number of parts that are changed (necessitating new feeders and workheads, etc.) during the life of the assembly system.
6. Number of products to be assembled (NP).
7. Economic climate (RI). Economic market conditions are expressed by the capital cost of the equipment relative to an equivalent operator rate.
8. QE is defined as the cost of the capital equipment that can economically be used to do the work of one operator on one shift per year.

The economic climate for investment in automation can be expressed by the ratio RI:

$$\mathrm{RI} = \mathrm{SH}\,\frac{\mathrm{QE}}{\mathrm{WA}} \tag{1}$$

where SH = number of shifts
WA = annual cost of one assembly operator

When this ratio is low, investment in automation is less likely to be profitable.

In addition to the eight variable factors above, it should be remembered that manual assembly systems will be necessary if special fitting or adaptation of parts is required or if there are wide fluctuations in demand for the product, such that its automated system will not be able to respond in time to the new requirements. In addition, intangible benefits of automation, which are difficult to quantify (e.g., shortage of qualified workers) or high consistency requirements must be taken into account.

The cost of assembly (CA) for a complete assembly is given by

$$\mathrm{CA} = \mathrm{TP}\left(\mathrm{WT} + \frac{\mathrm{CE} \times \mathrm{WA}}{\mathrm{SH} \times \mathrm{QE}}\right) \tag{2}$$

where TP = average time between delivery of complete assemblies for a fully utilized system
WT = total rate for the machine operators
CE = total capital cost for all equipment including engineering setup and debugging cost

For the purpose of comparing the economics of assembly systems, the cost of assembly per part

will be used and will be nondimensionalized by dividing this cost per part by the rate for one assembly time per part, TA. Thus, the dimensionless assembly cost per part (CD) is given by:

$$\mathrm{CD} = \frac{\mathrm{CA}}{\mathrm{NA} \times \mathrm{WA} \times \mathrm{TA}} \tag{3}$$

Substituting Eq. (2) into (3) gives

$$\mathrm{CD} = \frac{\mathrm{TP}}{\mathrm{TA}} \left(\mathrm{WR} + \frac{\mathrm{CE/NA}}{\mathrm{SH} \times \mathrm{QE}} \right) \tag{4}$$

where

$$\mathrm{WR} = \frac{\mathrm{WT}}{\mathrm{WA} \times \mathrm{NA}} \tag{5}$$

and is the ratio of the cost of all operators compared with the cost of one manual assembly operator and expressed per part in the assembly. The dimensionless assembly cost per part for an assembly operator working without any equipment will be one unit, which forms a useful basis for comparison purposes. For a particular assembly system Eq. (4) holds true only if the required average production time (TQ) for one assembly is greater than or equal to the minimum production time (TP) obtainable for the system. This means that if TP $\leq$ TQ (because the system is not fully utilized), then TQ must be substituted for TP.

6. ASSEMBLY: SCOPE FOR RATIONALIZATION

The early history of assembly process development is closely related to the history of the development of mass production methods. Thus, the pioneers of mass production are also considered the pioneers of modern assembly. Their ideas and concepts significantly improved the manual and automated assembly methods employed in large-volume production. In the past decade, efforts have been directed at reducing assembly costs by the application of flexible automation and modern techniques.

In the course of the development of production engineering, mechanization and automation have reached a high level in the fields of parts production, which permits the efficient production of individual parts with a relatively low proportion of labor costs. In the field of assembly, by contrast, automation remains limited to large-volume production. In medium and short-run production, rationalization measures have been taken mainly in the area of work structuring and workstation design. For the following reasons, automation measures have scarely begun in assembly:

1. Assembly is identified by product-specific, and thus quite variable, work content (handling, joining, adjusting, testing activities). Once solutions have been found, however, they can be applied to other products or companies only with great difficulty, in contrast to parts manufacturing.
2. Assembly, as the final production stage, must cope extensively with continuously shifting market requirements in regard to timing, batch sizes, derivatives, and product structure.

Although the automation trend in the assembly field has been growing remarkably over the past years, many industrial sectors still have relatively unexploited potential for rationalization. Compared to other manufacturing branches, such as parts manufacturing, assembly is characterized by a relatively low degree of automation. It accounts for only 60–90% of the manufacturing sequences of parts manufacturing, spot welding, and press shop in the automotive industry, for example. Specifically in assembly, however, this percentage decreases dramatically to less than 15% because of the complexity of the assembly tasks. The vehicle assembly as a whole (inclusive of final assembly) is quite cost-intensive in terms of employed labor force, representing 30% portion of the whole vehicle cost of production. Because of the high assembly costs, the automation of further subassembly tasks is therefore considered a major objective towards which the most effort is being directed.

Over the past years, automation technologies have been evolving dramatically in terms of flexibility and user-friendly operation as for their use in assembly systems. Automated devices, especially industrial robots, have also become less and less cost-intensive. Prices have been reduced up to 50% in some cases. For this reason, the scope for rationalization and application in assembly is as promising as ever.

An automation study was conducted by the Fraunhofer IPA in order to ascertain which industrial branches are characterized by exceptional scope for rationalization in the assembly. The results of this investigation are shown in Figure 9.

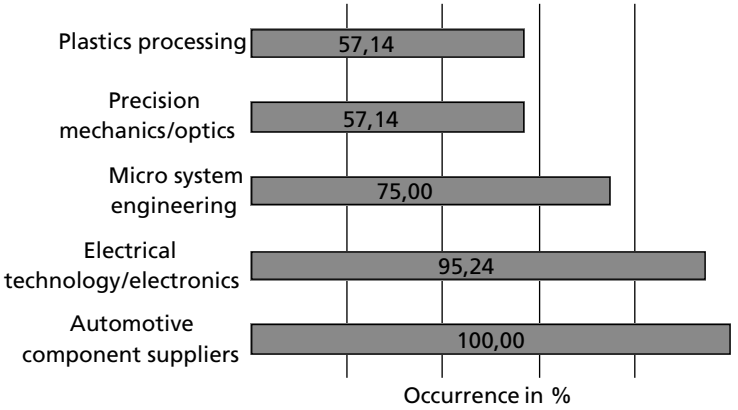

Figure 9 Industrial Branches Characterized by Exceptional Scope for Rationalization in Assembly.

The objectives achieved by the industrial application of automated solutions are shown in Figure 10. The investigation gave evidence that the cost-reduction objective, followed by quality improvement, was considered the first priority.

The most important preconditions to the realization of the still unexploited potential for rationalization in assembly are illustrated in Figure 11.

Despite the fact that assembly-oriented product design is perhaps the most important prerequisite for simple and automatic assembly, as has been well known for years, the enormous scope for rationalization of this field is very far from exhausted. Yet even though it is undeniable that the high manufacturing cost of a product becomes evident in assembly, the largest portion of it is due to construction. Investigations into different manufacturing areas have produced evidence that approximately 75% of the whole assembly costs originate in the early stages of product design and construction. The most important rules and methods of assembly-oriented product design are described in the following chapter.

The precondition to assembly systems covered next in the study is hardware and software modularization. The interconnecting implementation of standardized components, allowing assembly systems for the most varied assembly tasks to be designed simply and quickly, makes it possible to

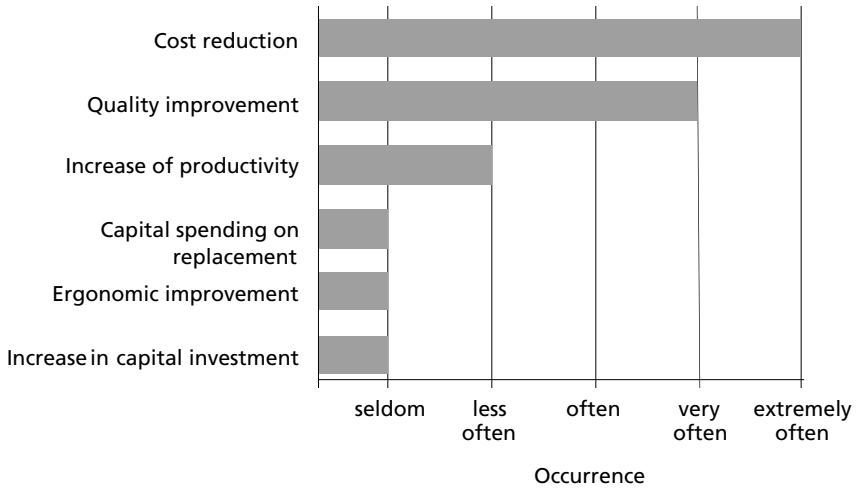

Figure 10 Objectives Pursued by Assembly Automation Projects.

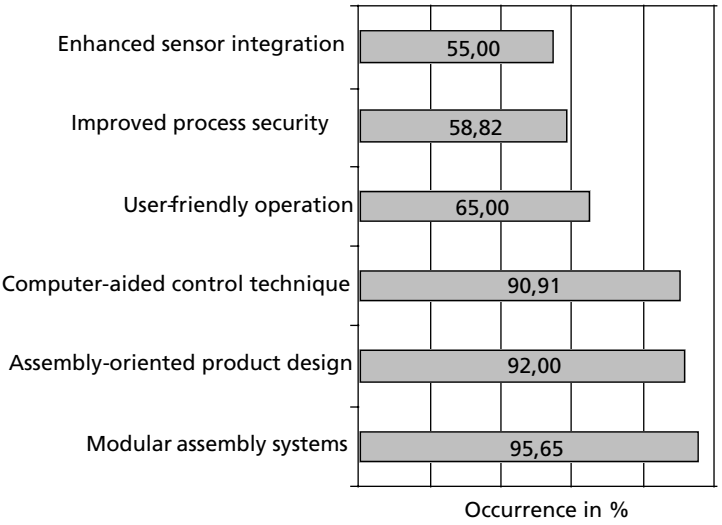

Figure 11 Preconditions to the Realization of the Assembly scope for Rationalization.

strive for the required flexibility. The investment risk decreases in proportion to the high recoverability of most components because the volume of investment would be well paid off in the case of product change if a large portion of the assembly components could be reused.

New requirements for the control technique are imposed by modularization, such as modular configuration and standardized interfaces. Conventional SPS control systems are largely being superseded by industrial PC. The result is decentralization of intelligence achieved by integration, for example, its transfer to the single components of the assembly systems. Assembly systems can thus be realized more quickly and cost-effectively. Further possibilities for rationalization could be exploited by simplification of the operation as well as programming of assembly systems, still characterized by a lack of user-friendliness. The service quality and operation of assembly systems could be greatly improved by the use of graphically assisted control panels allowing for better progress monitoring.

Industrial robots are being used more and more in flexible automation for carrying out assembly sequences. Flexibility is guaranteed by free programmability of the device as well as by the ever-increasing integration of intelligent sensory mechanisms into the systems. The application of image-processing systems directly coupled with robot control is expected to grow faster and faster in the next years. The increasing implementation of sensor technologies is due to the rapid development of computer hardware, allowing for better performance at lower prices.

Further on, the degree of automation in the assembly can be enhanced by improving the logistics and material flow around the workplaces as well as by reducing secondary assembly times. Logistical aspects can be improved by optimizing the layout of workplaces, paying special regard to the arm sweep spaces. Specific devices for local parts supply can help to reduce secondary assembly times consistently. They should be specially designed for feeding marshalled components correctly oriented as close as possible to the pick-up station to enable workers to grasp them ''blindly'' and quickly. Rigid workplace limitations can be relaxed by introducing the compact layout (see Figure 12), allowing workers to walk from one workstation to the next and carry out different assembling tasks corresponding to overlapping sequences. This allows the number of workers along the same assembly line to be varied flexibly (according to the task to perform) even though the whole assembly sequence is still divided proportionately among the workers employed.

As for the organizational and structural aspects in the assembly, recent research approaches and developments have revealed new prospects of better ''hand-in-hand'' cooperation between workers and robots along assembly lines or at workstations. Industrial robots, being intended to help workers interactively in carrying out assembly tasks, need not be isolated or locked any longer. For this purpose, man–machine interfaces should be improved and safety devices redeveloped. Further on, robots should learn to cope with partially undefined external conditions. This is still a vision at present, but it shows future opportunities for realizing the unexploited potential for rationalization in the assembly field.

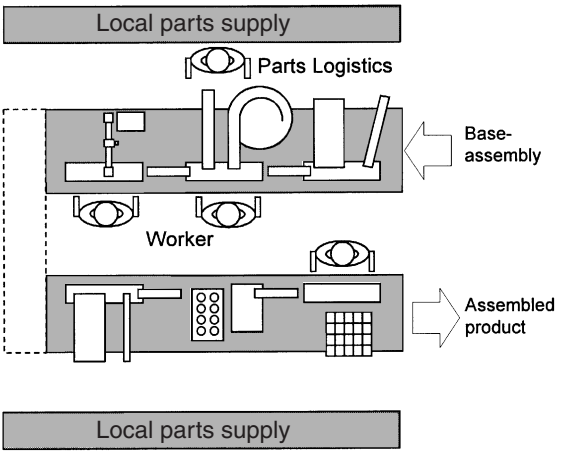

Figure 12 Layout of a Flexibly Varying Assembly System.

7. ASSEMBLY ENGINEERING: ESSENTIAL TECHNOLOGIES

The three essential technologies for assembly engineering explained in this section are product design for assembly, simultaneous engineering, and automation of connecting techniques.

7.1. Design for Assembly (DFA) and Assemblability Evaluation

7.1.1. Design for Assembly

When a product is designed, consideration is generally given to the ease of manufacture of its individual parts and the function and the appearance of the final product. One of the first steps in the introduction of automation in the assembly process is to reconsider the design of the product to make it simple enough to be performed by a machine.

The subject of design for automatic assembly can be conveniently divided into three sections: product design, design of subassemblies for ease of assembly, and design of parts for feeding and orienting.

The greatest scope for rationalization is in the measures affecting the whole product assembly system. However, these can only be executed for subsequent products, that is, in the long-term. Individual subassemblies can be made easier to assemble for existing products as long as this does not affect the function and the interfaces to the rest of the product remain the same. The success of these rationalization measures, however, is not as great as that concerning the whole assembly system. Measures affecting individual parts have the least potential for rationalization because only small modifications can be made. However, they can be realized quickly with existing products so that the positive effect of the measures can be perceived very quickly (Figure 13).

Various points concerning parts and product design for assembly are summarized below.

Assembly rules for product design and design of subassemblies:

1. Minimize the number of parts.
2. Ensure that the product has a suitable part on which to build the assembly, with accessibility from all sides and sufficient room for assembly.
3. Ensure that the base part has features that will enable it to be readily located in a stable position in the horizontal plane.
4. If possible, design the product so that it can be built up in layer fashion, each part being assembled from above and positively located so that there is no tendency for it to move under the action of horizontal forces during the machine index period.
5. Form subassemblies that can be assembled and inspected independently.
6. Try to facilitate assembly by providing chamfers or tapers that will help to guide and position.
7. Avoid time-consuming fastening operations (e.g., screwing, soldering) and separate joining elements and safety elements (e.g., rivets, safety panes).
8. Avoid loose, bendable parts (e.g., cable).

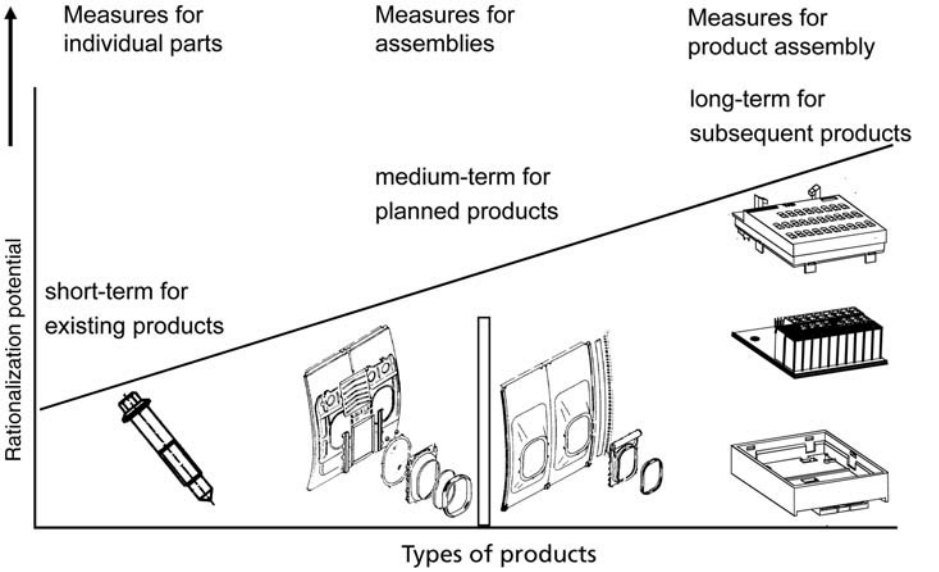

Figure 13 Measures for Easy-to-Assemble Product Design.

Assembly rules for the design of parts:

1. Avoid projections, holes, or slots that will cause tangling with identical parts when placed in bulk in the feeder. This may be achieved by arranging that the holes or slots are smaller than the projections.
2. Attempt to make the parts symmetrical to avoid the need for extra orienting devices and the corresponding loss in feeder efficiency.
3. If symmetry cannot be achieved, exaggerate asymmetrical features to facilitate orienting or, alternatively, provide corresponding asymmetrical features that can be used to orient in the parts.

In addition to the assembly design rules, a variety of methods have been developed to analyze component tolerance for assembly and design for assembly by particular assembly equipment.

7.1.2. Assemblability Evaluation

The suitability of a product design for assembly influences its assembly cost and quality. Generally, product engineers attempt to reduce the assembly process cost based on plans drawn by designers. The recent trend has been toward product assemblability from the early design phase in order to respond to the need for reduction in time and production costs.

The method of assemblability evaluation is applied by product designers for quantitatively estimating the degree of difficulty as part of the whole product design process. In 1975, the Hitachi Corporation developed the pioneering method of assemblability evaluation called the Assemblability Evaluation Method (AEM). AEM analyzes the assembly structure using 17 symbols, thus aiming to give designers and production engineers an idea of how easily procedures can be assembled (see Figure 14). It points out weak areas of design from the assemblability viewpoint. The basic ideas of the AEM are:

1. Qualification of difficulty of assembly by means of a 100-point system of evaluation indexes
2. Easy analysis and easy calculation, making it possible for designers to evaluate the assemblability of the product in the early stage of design
3. Correlation of assemblability evaluation indexes to assembly cost

AEM focuses on the fundamental design phase. The approach is to limit the number of evaluation items so that designers can apply them in practice. The reason for concentrating on the early design phase was to achieve greater savings by considering assemblability issues as priorities from the very

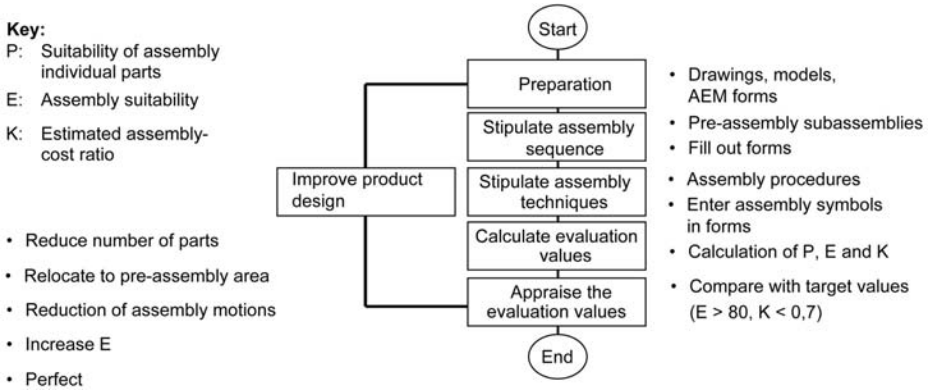

Figure 14 Evaluation of Assembly Suitability According to Hitachi (AEM).

beginning. As a result, however, the accuracy of this evaluation cannot be very high compared to more detailed analyses.

7.1.3. Boothroyd–Dewhurst DFA Method

The Boothroyd–Dewhurst method is widely used. The objective of this method is to minimize the amount of assembly required for existing products or product constructions. This should be achieved first and foremost by reducing to a minimum the number of individual parts that have to be assembled. The shape of the individual parts for handling and assembly is also optimized. The procedure can be divided into three steps:

1. Selection of an assembly principle
2. Analysis of the assembly task (Figure 15)
3. Improvement of design

In the Boothroyd–Dewhurst method, the assembly times and costs as well as the design efficiency (DE) play a decisive role in determining the assembly suitability. The DE is calculated by multiplying the number of individual parts by the calculated costs and comparing this figure with the theoretical minimum number of individual parts multiplied by the ideal costs for assembly. This means that the factor DE always has a value between 0 (very bad) and 1 (ideal assembly system for this product).

The theoretical minimum number of individual parts is determined by examining whether two assembly parts that are associated with another

- Must move toward each other relatively
- Must be made of different materials
- Must be separated from other assembly parts for assembly or dismantling

If none of these three requirements have to be satisfied, both assembly parts may be combined.

Based on the costs and the DE factor, a decision is made on whether reconstruction is possible. A reconstructed product is then reanalyzed in the same way. Figure 16 shows the original variants and a reconstructed valve. Originally, the lid had to be kept low against the screw compression spring so that both screws could be assembled. Designing the lid with snap connectors for attachment to the casing and the integration of guides to help the screw compression spring into the piston suggested that the number of parts could be reduced from seven to four and the expensive screwing assembly task could be eliminated.

The Boothroyd–Dewhurst method aims primarily at reducing assembly costs by means of an integrated construction system. Other measures, such as product structuring, sorting, the construction of subassemblies and the differential construction technique are not considered. The evaluation of the suitability of the assembly system requires that the product be a constructed one. This means that assembly suitability is taken into consideration only very late in the construction process. The Boothroyd–Dewhurst DFA method is also available for PCs.

7.2. Simultaneous Engineering

In the planning and realization of assembly systems, it is not only the selection of the correct operating materials which is important for the project success but also the optimal composition of the project

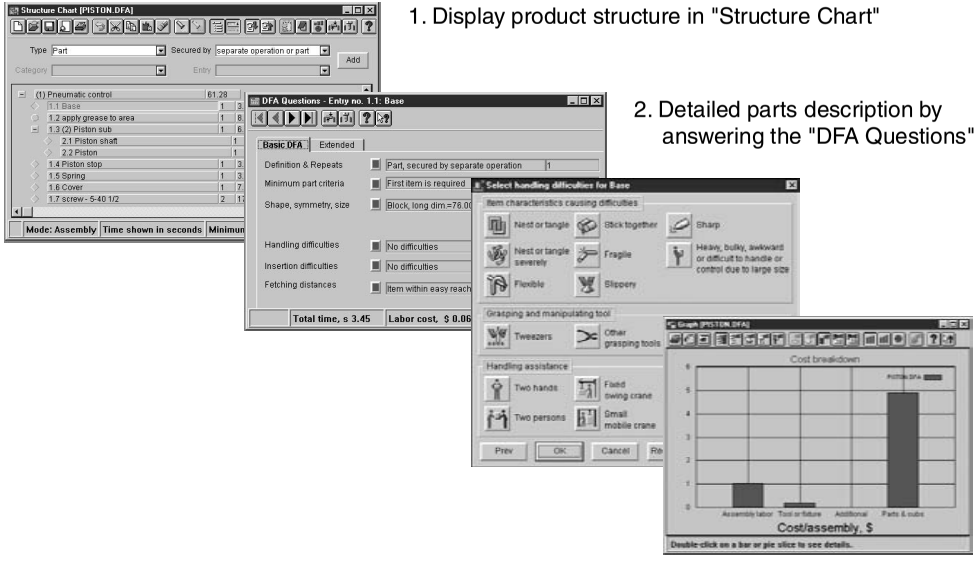

Figure 15 Analysis of the Assembly Tasks According to the Boothroyd–Dewhurst Method.

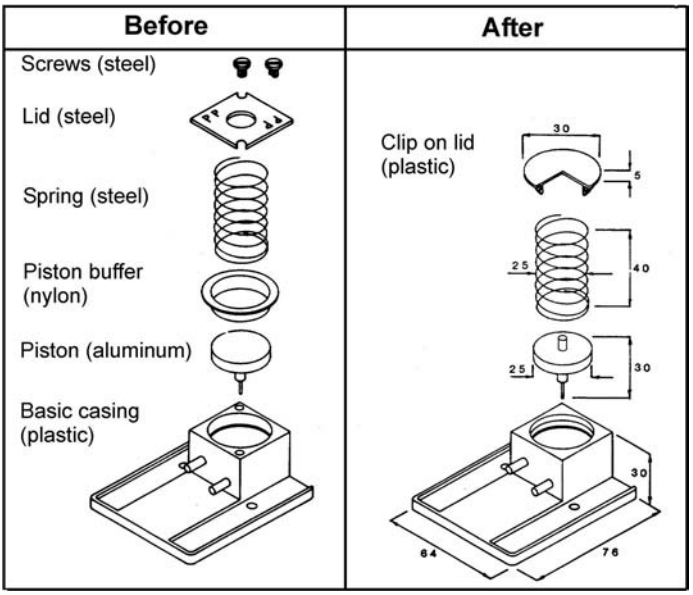

Figure 16 Easy-to-Assemble Product Design for a Pneumatic Piston.

groups. Teamwork, also called simultaneous engineering, is certainly the most decisive precondition for an optimal and mutually coordinated design of the product and assembly system. The team is made up of product developers, assembly system planners, quality management, purchasing, and sales and can vary depending on the project tasks and decisions to take. However, steps must be taken to ensure that all members of the team are aware of the rules of simultaneous engineering.

Another opportunity for interdisciplinary work arises when there is pressure to shorten product development times. By involving the assembly system planner in the construction process, it is possible to begin much earlier with the assembly system design. Some of the development and planning work may then be executed parallel to one another. The development and realization times are shortened and the costs for the whole project are usually reduced. Additionally, the products can be brought onto the market much earlier due to the shorter development times.

Figure 17 shows a few examples of how simultaneous engineering can help shorten the product development times for new products in comparison with preceding models.

Experience from numerous projects has also shown that, by means of simultaneous engineering, the number of product changes during the development phase can be significantly reduced.

Simultaneous engineering is not really a new way of thinking. However, in recent times it has been applied more consistently and systematically than ever. This is particularly true in Europe. Many Japanese companies have been practising simultaneous engineering successfully since the mid-1970s.

7.3. Connecting Technologies

The establishment of connections is one of the most common assembly tasks. The automation of this task is thus one of the central problems confronting assembly rationalization.

7.3.1. Screws

Among the most important assembly procedures is the making of screw connections. The connecting process ''screwing'' has therefore been examined in detail, and the use of flexible handling appliances such as screw assembly systems has further been tested in typical industrial tasks. The problems of positioning errors, controlled correction of the screwing tool, and diameter flexibility for handling different screw sizes without changing tools have been solved through the development of special hardware modules. The system offers the possibility, in assembling metric screws, of increasing the joining speed, handling screws with different heads (including Phillips), self-tapping in wood and/or plastic, and mounting hexagon head cap screws of different diameters without changing tools.

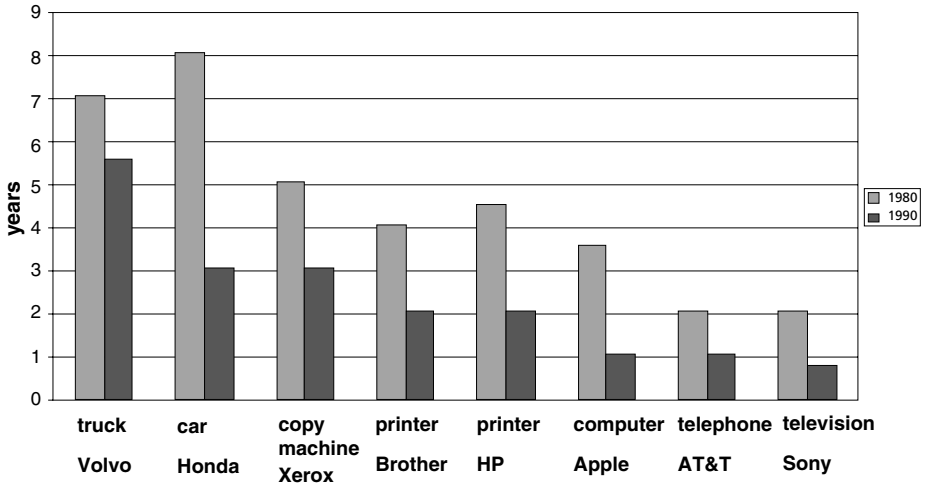

Figure 17 The Change in Product Development Times When Using Simultaneous Engineering. (*Source:* Prof. Dr. Gerpott)

7.3.2. Rivets

Like screwing, riveting is one of the classic connecting techniques. In recent times, rivets have in fact been gaining in popularity again through the development of new types and manipulation tools and the increasing replacement of steel and iron by other materials.

The greatest market potential among the different types of rivets is forecast for blind rivets. Access to the workpieces being joined is required from only one side, thereby offering the ideal conditions for automation. A blind riveter for industrial robots has been developed based on a standard tool that, apart from its size and weight, is also notable for its enhanced flexibility. With the aid of a changeover device, for example, different rivet diameters and types of blind rivet can be handled.

7.3.3. Self-Pierce Riveting

In contrast to traditional riveting, self-pierce riveting does not require pilot drilling of the steel plate at the joint. The most frequent technique is self-pierce riveting with semitubular rivets, characterized by the rivet punching out only the punch side of the sheet. Joining simply results from noncutting shaping of the die side and widening of the rivet base on the sheet die side. The necessary dies are to be matched with the rivet length and diameter, workpiece thickness, as well as number of interlayer connections, thickness variants, and materials. The workpiece punch side is flat when countersunk punching head rivets are used, whereas the die side is normally uneven after die sinking.

Punching rivet connections with semitubular rivets are gastight and waterproof. Punching rivets are mainly cold extruded pieces of tempering steel, available in different degrees of hardness and provided with different surfaces. Ideal materials for application are therefore light metals and plastics or combinations of both. Punching rivet connections with semitubular rivets show a far better tensile property under strain than comparable spot welding connections.

7.3.4. Press-fitting

Press-fitting as a joining process does not require any additional elements, making it particularly desirable for automation. At the same time, however, high seam joining and bearing pressures occur that may not be transferred to the handling appliance.

A press-fitting tool was therefore developed with allowance for this problem. It confines the bearing pressures within the tool with very little transfer to the handling appliance. Various process parameters, such as joining force, joining path, and joining speed, can be freely programmed so as to increase the flexibility of the tool. A tolerance compensation system is also integrated in the tool that compensates any positioning errors (axis and angle shift). For supply of the connecting elements the tool also has interfaces to interchangeable part-specific magazines (revolving and cartridge magazines) and the possibility of supply via formed hoses.

7.3.5. Clinching

Clinching is a way of joining sheet metal parts without connecting elements. A specially designed press-driven set of dies deforms the parts at the joint to provide a friction-locked and keyed connection.

Because no connecting elements are required, the problem of organizing, preparing, and feeding these parts does not apply. For this reason, this relatively recent connecting technique is being used for an increasing number of applications.

A robot-compatible, freely programmable tool has been developed for flexibly automated clinching. This tool is notable for its compact outer dimensions and low handling weight. With this robust but sensitive robot, tool joining forces up to 50 kN can be generated. Different sets of dies for the specific connecting task in question can also be used by means of the automated changeover system. The sensor system integrated in the tool allows precise and individual process control. Rapid working strokes and joining force can all be freely programmed. The quality and success of the join at each point are checked and documented.

8. INDUSTRIAL ROBOTS

8.1. Definitions

Industrial robots have become an important and indispensable component in today's world of flexible automation. After the initial technical problems and high financial risk that impeded the willingness to invest, they have become an important means of automation in recent years.

The large number of handling devices in use can be divided into parts handlers and industrial robots (programmable handling devices).

Parts handlers are used in a variety of industrial sectors. They are mainly equipped with handling devices with grippers that execute set motion processes in specified cycles. The motion processes are controlled by means of limit stops or control cams. These components present the biggest disadvantage of the parts handler because of the amount of effort required to retool the device if the process is changed.

Industrial robots are defined by ISO 8373 as automatically controlled, reprogrammable, multipurpose manipulators that are programmable in three or more axes and may either be fixed in place or mobile for use in industrial automation applications.

The number of installed industrial robots in all sectors of the most important industrial nations is shown in Figure 18.

The automotive, electrical, and electronic industries are the largest users of robots. The predominant applications are welding, assembling, painting, and general handling tasks. Flexibility, versatility, and the cost of robot technology have been driven strongly by the needs generated by these industries, which still account for more than 75% of the world's stock of robots. In their main application areas, robots have become a mature product exposed to enormous competition by international robot manufacturers, resulting in rapidly falling unit costs. However, the robot unit price accounts for less than 30% of the average work cell investment. A considerable share of total investment cost is attributed to engineering and programming the robot and putting it into operation.

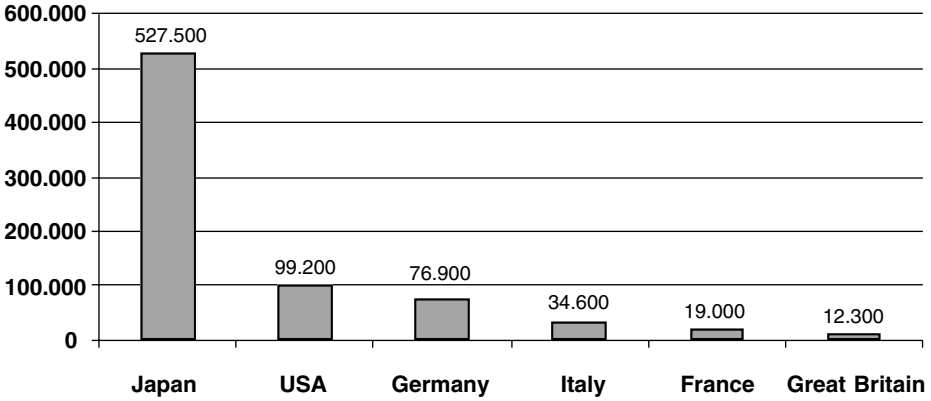

Figure 18 Estimate of the Number of Installed Industrial Robots in the Year 2000.

8.2. Classification and Types of Robots

Each of the industrial robot elements is linked to one another by linear guides and revolute joints in a kinematic chain, and the actuation of these elements forms the axes of the robot. Kinematics is the spatial allocation of the movement axes in order of sequence and construction.

Figure 19 illustrates the mechanical configurations of different types of robots.

The main axes help to position the final effector (tool or workpiece) spatially. The hand or adjacent axes are primarily responsible for the orientation of the tool and are therefore usually made of a series of revolute joints.

The following information may be useful for the selection of the industrial robot best suited to the respective application:

- The load-bearing capacity is the largest weight that has to be handled at the specified motion speed in relation to the robot flange. If the work speed or the reach is decreased, a larger weight can be moved.
- The mechanical structure refers to the kinematic chain as an ordered sequence and the type of motion axis on the robot.
- The number of axes is the sum of all the possible movements by the system. The higher the degree of freedom, the lower the system accuracy and the higher the costs. Therefore, it is advisable to limit the number of axes to the amount required.
- The work space is calculated from the structure of the kinematics and its dimensions. Its shape is also dependent on the movement areas of the individual axes and actuators.
- The positional accuracy determines the deviation during the run up to freely selected positions and orientations. The repetitive accuracy is the difference when the run-up to a spatial point is repeated.

Within a wide range of contructional types and variants, four versions have proved to be particularly suitable in practical operation:

1. Cartesian robots
2. Articulated robots
3. SCARA robots
4. Parallel robots

An extreme rigid structure is the first characteristic of Cartesian robots, whose single axes move only in the direction of the Cartesian space coordinates. For this reason, Cartesian robots are particularly suitable for operating in large-sized working areas. Major applications include workpiece palletizing and commissioning.

Standard articulated robots consist of six axes. They are available on the market in a large variety of types and variants. Characterized by a cylindrical working area occupying a relatively small volume, articulated robots easily allow failures to be repaired directly. Articulated robots are used primarily for spot welding, material handling, and painting as well as machining.

SCARA robots have a maximum of four degrees of freedom but can also be equipped with just three for very simple tasks. These robots are used for assembly tasks of all types, for simple loading and unloading tasks, and for fitting of electronic components to printed circuit boards.

The six linear driving axes of parallel robots are aligned between the base plate and the robot gripper so as to be parallel. Therefore, positioning accuracy and a high degree of rigidity are among the characteristics of parallel robots. The working area is relatively small. Parallel robots are particularly suitable for tasks requiring high accuracy and high-range forces, such as workpiece machining.

8.3. Major Robot Components

8.3.1. Power Supply

Three main power sources are used for industrial robot systems: pneumatic, hydraulic, and electric. Some robots are powered by a combination of electric and one other power source. Pneumatic power is inexpensive but is used mostly for simpler robots because of its inherent problems, such as noise, leakage, and compressibility. Hydraulic power is also noisy and subject to leakage but is relatively common in industry because of its high torque and power and its excellent ability to respond swiftly to motion commands. It is particularly suited for large and heavy part or tool handling, such as in welding and material handling, and for smooth, complex trajectories, such as in painting and finishing. Electric power provides the cleanest and most quiet actuation and is preferred because it is self-contained. On the other hand, it may present electric hazards in highly flammable or explosive environments.

Robot	Axes		Examples
Principle	Kinematic Structure	Workspace	Photo

Cylindrical Robot			
Spherical Robot			
SCARA Robot			
Articulated Robot			
Parallel Robot			

Figure 19 Classification of Industrial Robots by Mechanical Structure.

The typical series of sequences to be carried out by the electrical drive of a robot axis is shown in Figure 20.

The reference variables, calculated in interpolation cycles by the motion-controlling device, are transmitted to the axle controller unit. The servodrive converts the electric command values into couple of forces to be transmitted to the robot axle through the linkage. The internal control circuit is closed by a speed indicator, the external one by a path-measuring system.

8.3.2. Measuring Equipment

Measuring devices able to provide the axis controller unit with the suitable input quantity are required for robot position and speed control. Speed measurement is carried out directly over tachometer generators or indirectly over differential signals of angular position measuring systems. Optoelectronical incremental transducers, optoelectronical absolute transducers, as well as resolvers are among the most common devices for robotic angular measuring. For the path measurement of linear motions, the measuring techniques used by incremental and absolute transducers are suitable as well.

8.3.3. Control System

The major task of the robot control system consists of piloting one or more handling devices according to the technologically conditioned handling or machining task. Motion sequences and operations are fixed by a user program and are carried out by the control system unit. The necessary process data are provided by sensors, which therefore make it possible for the unit to adapt to a certain extent the preset sequences, motions, and operations to changing or unknown environmental conditions.

Figure 21 shows the components of a robot controller system.

Data exchange with superset control system units is actuated through a communication module, such as for loading the user program in the robot control unit or exchanging status data. The process control device organizes the operational sequence of the user program which provides instructions for the motion, gripper, sensors, and program flow. The robot axes as well as the auxiliary axes involved in the task to perform are driven by the motion-controlling device.

There are three kinds of motion control:

1. Point-to-point positioning control
2. Multipoint control
3. Continuous path control

The axis controller carries out the task of driving the robot axes according to the reference variables. The sequential progression from one axis position to the next is monitored and readjusted comparatively to the actual positions. An appliance (teach pendent) allows the robot to be operated and programmed by hand. The operator can easily access all control functions in order to run the robot in manual mode or determine the program flow.

The control system also determines two major performance measures of the robot: its accuracy and repeatability. The first indicates the precision with which the robot can reach a programmed

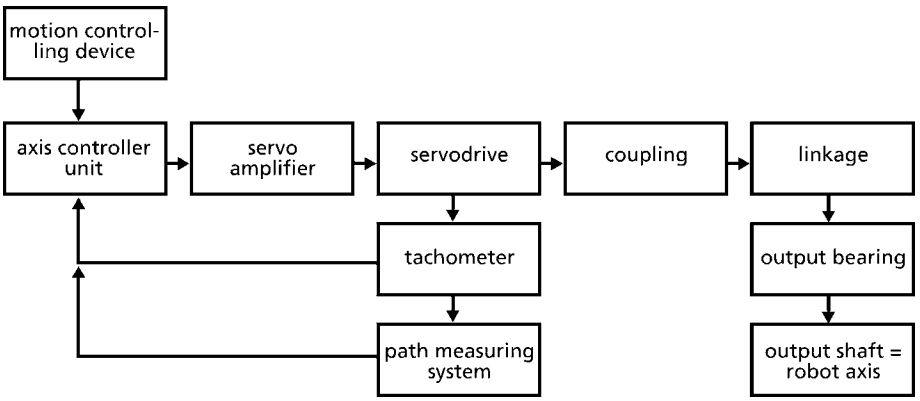

Figure 20 Electrical Drives of Robot Axis.

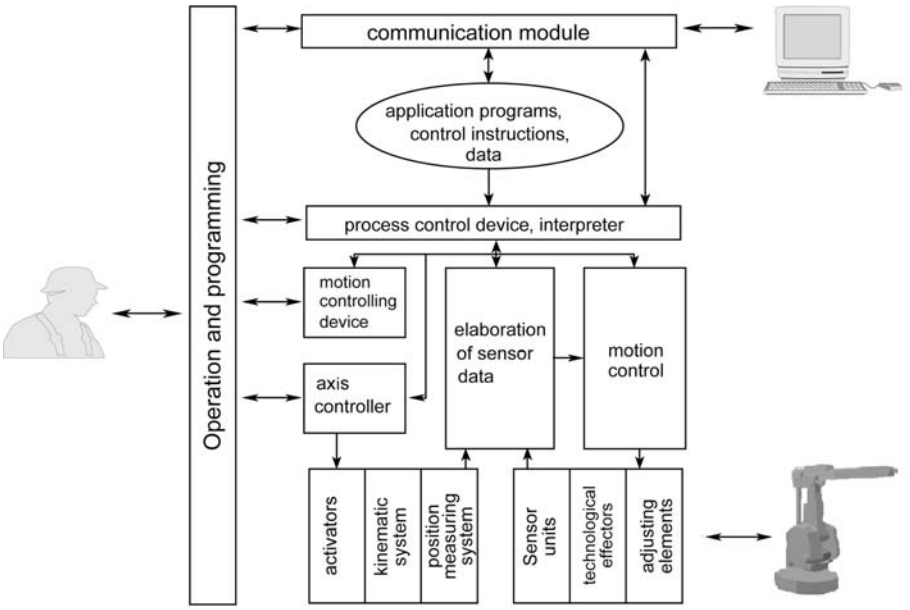

Figure 21 Components of a Robot Controller System.

position or orientation. The second indicates the tolerance range over which a programmed motion can be repeated several or many times. While the accuracy of robots is difficult to establish in a standard way, repeatability has been standardized. Typically, industrial robots will have a repeatability better than ± 0.01 in. and more precise robots will be within ± 0.003 in.

8.3.4. Gripper

The gripper is the subsystem of an industrial robot able to transfer the power transmission from the workpiece to the industrial robot to make sure the robot has recorded the workpiece's exact position. A gripping system has to carry out the following tasks:

- Temporarily maintaining the allocation of the workpiece and the gripping device, defined on the basis of the gripping center line
- Recording the static forces and moments produced by the workpiece
- Recording the kinetic forces and coupling of forces produced by the acceleration during the operating sequence
- Recording process-bound forces (e.g., joining forces)

According to the complexity of the gripping task, the robot gripper can be equipped with several subsystems. A driving mechanism (electric, pneumatic, or hydraulic) is required if the gripping force is produced kinematically, which is often the case with mechanical grippers. A holding system allows the workpiece position to be fixed opposite the gripping kinematic device. The gripping area is among the major criteria for evaluating the flexibility of a gripping device.

The object (workpiece) to be manufactured, the space available in the building, and the required cycle time of handling and assembly systems play a major role in the decision which robotic gripper to use. If, for example, the standard gripper version proves to be inadequate for specific operations, it can be equipped with interchangeable gripping systems by the creation of standardized interfaces.

8.4. Programming and Robot Simulation

8.4.1. Programming

The robot control system contains a programming method by teaching, by using a teach pendent, by showing and actually leading the robot manipulator through the desired motions, or by programming.

A programming method is the planned procedure that is carried out in order to create programs. According to IRDATA, a program is defined as a sequence of instructions aimed at fulfilling a set of manufacturing tasks. Programming systems allow programs to be compiled and also provide the respective programming assistance (see Figure 22).

If direct methods (online programming methods) are used, programs are created by using the robot. The most common method is teach-in programming, in which the motion information is set by moving towards and accepting the required spatial points, assisted by the teach pendent. However, the robot cannot be used for production during programming.

One of the main features of indirect methods (offline programming methods) is that the programs are created on external computers independent of the robot control systems. The programs are generated in an offline programming system and then transferred into the robot's control system. The key advantage of this method is that the stoppage times for the robot systems can be reduced to a minimum by means of the configuration of the programs.

Hybrid methods are a combination of direct and indirect programming methods. The program sequence is stipulated by indirect methods. The motion part of the program can be defined by teach-in or play-back methods or by sensor guidance.

8.4.2. Robot Simulation

Computer-assisted simulation for the construction and planning of robot systems is becoming more and more popular. The simulation allows, without risk, examination and testing on the model of new experimental robot concepts, alternative installation layouts or modified process times within a robot system. ''*Simulation* is the imitation of a system with all its dynamic processes in an experimental model which is used to establish new insights and to ascertain whether these insights can be transferred to real situations'' (VDI Guideline 3633).

The starting point for the development of graphic 3D simulation systems was the problem of planning the use of robots and offline programming. Independent modules or simulation modules integrated into CAD system were created. To enable a simulation to be conducted, the planned or real robot system must first be generated and depicted as a model in the computer. The abstraction level of the simulation model created must be adjusted to the required imitation: ''as detailed as necessary, as abstract as possible.'' Once the model has been completed, an infinite number of simulations can be carried out and modifications made. The objective is to improve the processes and eliminate the possibility of planning mistakes.

Figure 23 shows an example of the visualization of a robot welding station.

Simulation is now considered one of the key technologies. Modern simulation systems such as virtual reality are real-time oriented and allow interaction with the operator. The operator can change the visual point of view in the graphical, 3D picture by means of input devices (e.g., data gloves) and thus is able to take a look around in the ''virtual world.'' The virtual objects can be interactively manipulated so that modifications can be executed more quickly, safely, and comfortably.

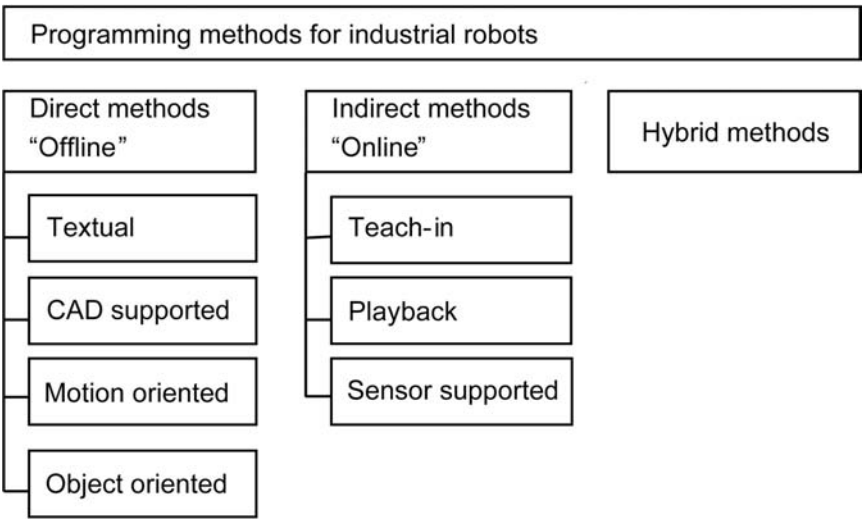

Figure 22 Overview of Programming Methods for Industrial Robots.

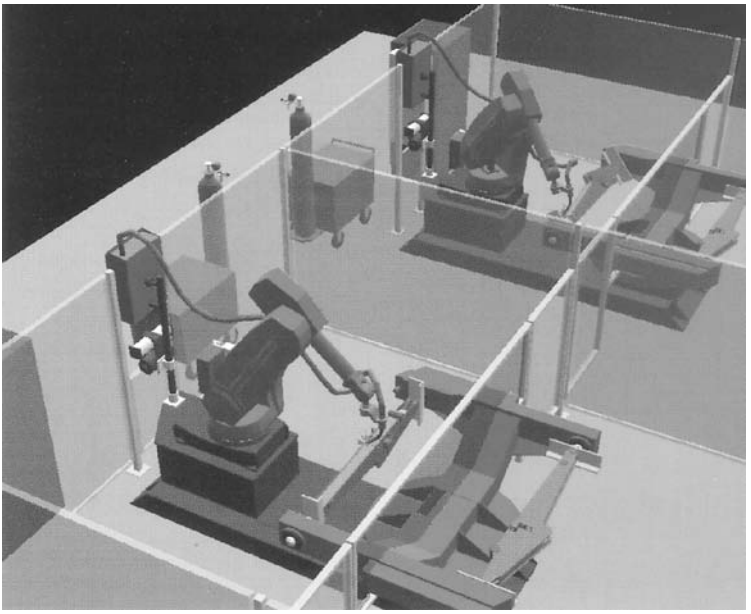

Figure 23 3D Simulation of a Robot Welding Station.

The main advantages and disadvantages of simulation can be summed up as follows:

- Dynamic analysis of modeled processes and verification of executed modifications
- Increased planning security due to the evaluation of the project planning before realization
- Reduction in planning time
- Reduction in development costs for the realization of robot systems
- Expenditure savings due to reduction of run-through times and stock levels and optimization of resource utilization

8.5. New Applications

In the 1980s, as industrial robots became a recognized indicator of modern production facilities, thought was also given to the use of robots outside the factory. The term *service robots* was coined for such new robot systems, which, however, still have no valid international definition today. The International Federation of Robotics (IFR) November 1997, Stockholm, Sweden suggested the following definition in 1997: ''A service robot is a robot which operates semi or fully autonomously to perform services useful to the well-being of humans and equipment, excluding manufacturing operations.''

Because of the multitude of forms and structures as well as application areas, service robots are not easy to define. IFR has adopted a preliminary system for classifying service robots by application areas:

- Servicing humans (personal, safeguarding, entertainment, etc.)
- Servicing equipment (maintenance, repair, cleaning, etc.)
- Performing autonomous functions (surveillance, transport, data acquisition, etc.)

Following are examples of application fields for service robots.

8.5.1. Courier and Transportation Robots

The HelpMate, introduced in 1993, is a mobile robot for courier services in hospitals. It transports meals, pharmaceuticals, documents, and so on, along normal corridors on demand (see Figure 24). Clear and simple user interfaces, robust robot navigation, and the ability to open doors or operate

Figure 24 Mobile Robot for Courier Services in Hospitals. (*Source:* PYXIS)

elevators by remote control make this a pioneering system in terms of both technology and user benefit.

8.5.2. Cleaning Robots

A service robot climbs surfaces on suction cups for cleaning (see Figure 25), inspection, painting and assembly tasks. Tools can be mounted on the upper transversal axis. Navigation facilities allow accurate and controlled movement.

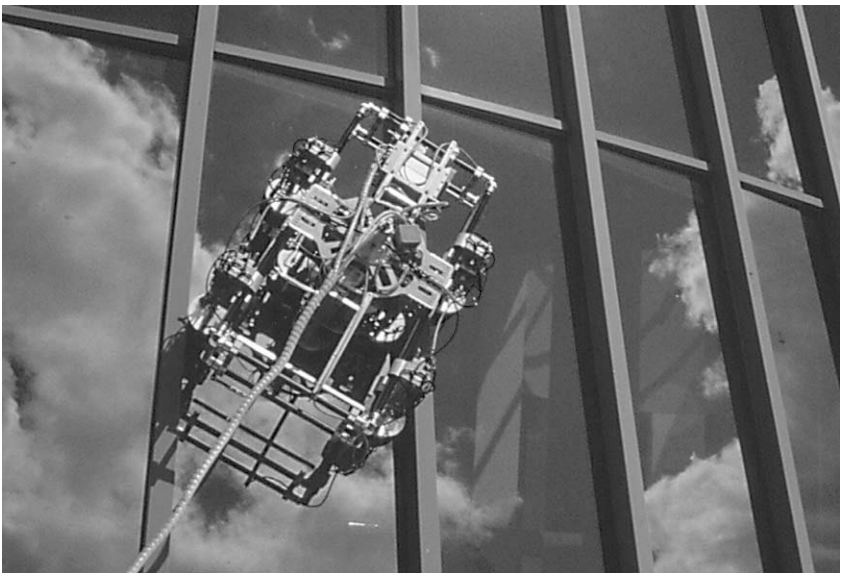

Figure 25 Cleaning Robot. (*Source:* IPA)

8.5.3. Refueling by Robot

Refueling a car by robot is as convenient and simple as entering a parking lot. Upon pulling up to the refueling station, the customer inserts a card and enters the PIN code and the refueling order. The robot locates the car, opens the tank flap, and docks onto the tank cap. Once the cap is open, the robot pumps the right grade and amount of fuel into the tank (see Figure 26).

8.5.4. Medical Robot

This mechatronic assistant system was developed by Siemens AG and Fraunhofer IPA. It is used for different operation tasks. The system consists of an operation robot (hexapod) whose kinematics concept is based on the Stewart platform. These kinematics allow extreme accuracy in micrometer ranges and a high level of stiffness despite the robot's relatively small size (see Figure 27).

The operator controls the operation robot from an ergonomic operation cockpit similar to a flight simulator. Tactile back-coupling of the motions helps the operator operate the system. The operation cockpit is also assembled on a hydraulic hexapod.

8.5.5. Assistance and Entertainment

This mobile robot has been created to communicate with and entertain visitors in a museum (see Figure 28). It approaches the visitors and welcomes them to the museum. Speech output is accompanied by movement of the robot head. The robot gives guided tours in the museum. Moving its head up and down symbolizes the robot looking at the object it is currently talking about. Explanations are further accompanied by pictures or video sequences shown on the screen of the robot.

9. TECHNOLOGIES FOR ASSEMBLY OPERATIONS

Several technologies highly relevant to assembly are discussed briefly below.

9.1. Feeding Systems

Sorting and feeding devices are an important component in the automated assembly of products. Their task is to sort out the often unsorted supplied workpieces and to deliver the right amount to the assembly station at the right time. The most commonly used feeding systems are vibratory bowl feeders, capable of sorting nearly 90% of all components automatically.

The unsorted workpieces that have been fed in are moved by triggered vibration energy to the edge of the bowl. They then run onto a sloped helical channel on the inside or outside wall of the bowl and are moved upwards over mechanical baffles. These baffles have the task of orienting the

Figure 26 Refueling Station. (*Source:* IPA)

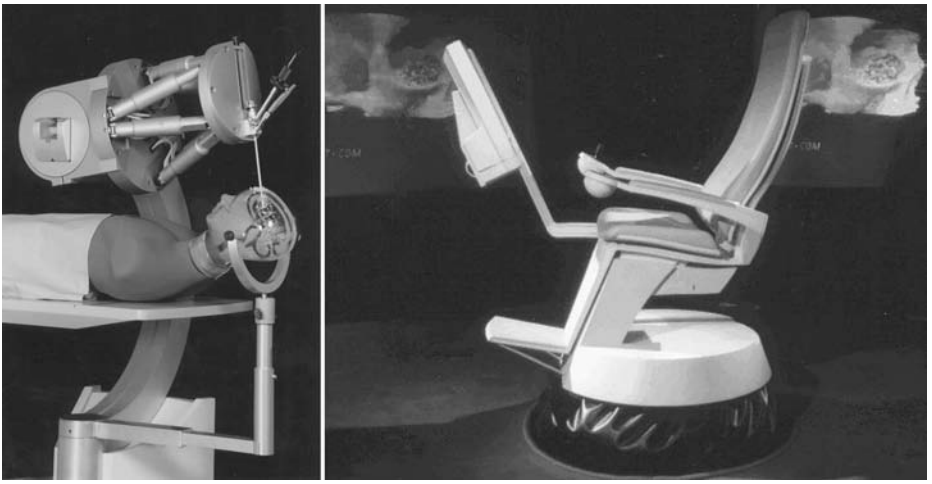

Figure 27 Operation Robot (Model number Vision OP 2015).

disoriented workpieces during the transfer movement by means of turning, twisting, tilting, or setting upright the workpieces and/or throwing back wrongly oriented workpieces into the bin. However, mechanical baffles are set up for only one type of workpiece and much retooling is required if the workpiece is changed. These pieces of equipment are therefore suitable only for large series assembly.

To increase flexibility, mechanical baffles are being replaced more and more with optical parts-recognition systems in the vibratory bowl feeder. The geometry of the various workpieces can be programmed, stored in, and retrieved from the control system if there is a change of product. This means that retooling can be kept to a minimum.

Image processing as a sensor for guiding robots is also being applied more and more in flexible workpiece-feeding systems. Isolation of unsorted workpieces is conducted on a circular system of servocontrolled conveyor belts. The correctly oriented workpieces on one of these conveyor bands

Figure 28 Entertainment Robots in the Museum of Communication, Berlin. (*Source:* IPA)

are recognized by a camera and the coordinates are determined. The robot can grab only recognized workpieces; the other workpieces remain in the circular system.

The various feeding and sorting systems are depicted in Figure 29.

9.2. Magazines

Parts that cannot be easily bowl-fed can be stored in an oriented fashion in a magazine. Magazining is the storage of workpieces in a special order for stock purposes before and after the manufacturing equipment. Magazines for the simple storage of workpieces are containers with grid elements, slot-in boards, and so on. When magazines for automatic handling are used, the magazine and forwarding functions usually blend into one function. The various types of magazine are depicted in Figure 30.

Static magazines (e.g., stack magazines) are widely used especially in component manufacturing. The magazines are simply constructed and make use of the falling or rolling motion of the workpieces. Pallet magazines are used for the storage of workpieces that are mainly in sheet arrangements and

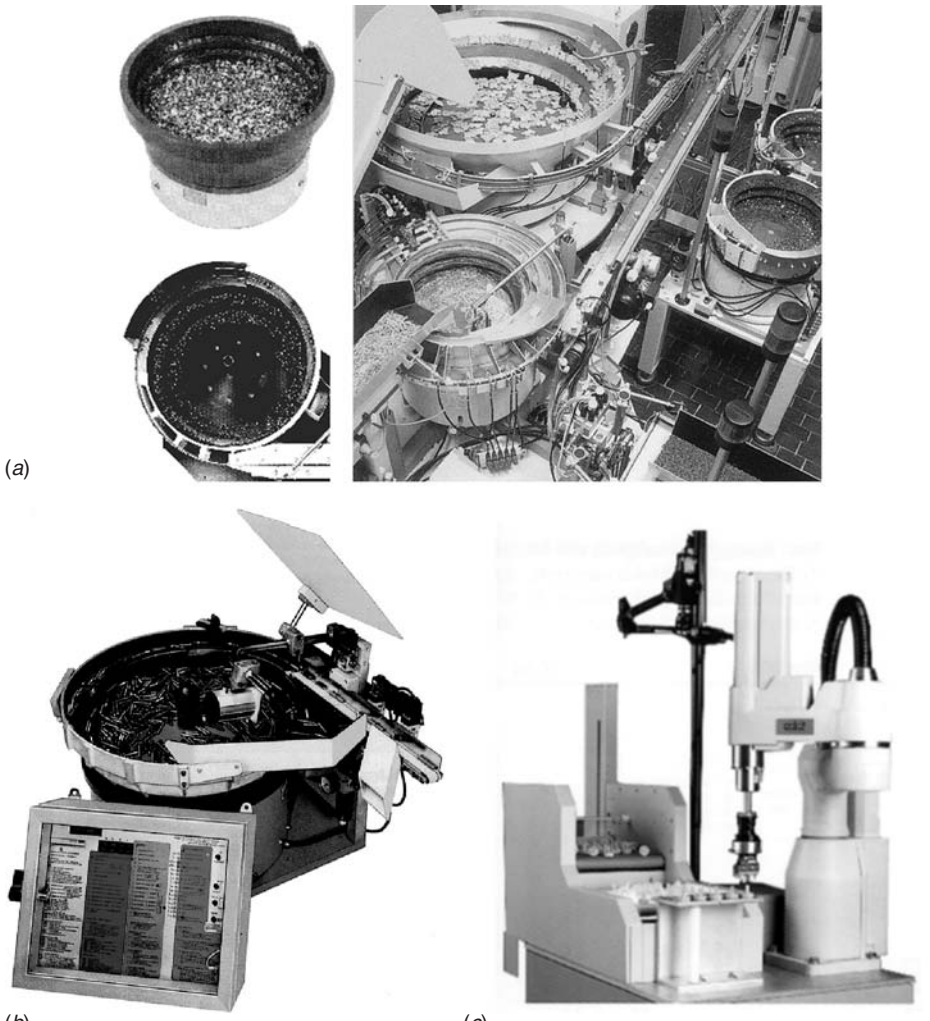

Figure 29 Examples of Standard and Flexible Part-feeding Devices. (*a*) Bowl feeders with mechanical baffles. (*Source:* RNA, MHK, Bihler) (*b*) Bowl feeder with parts-recognition system. (*Source:* MRW) (*c*) FlexFeeder. (*Source:* Adept)

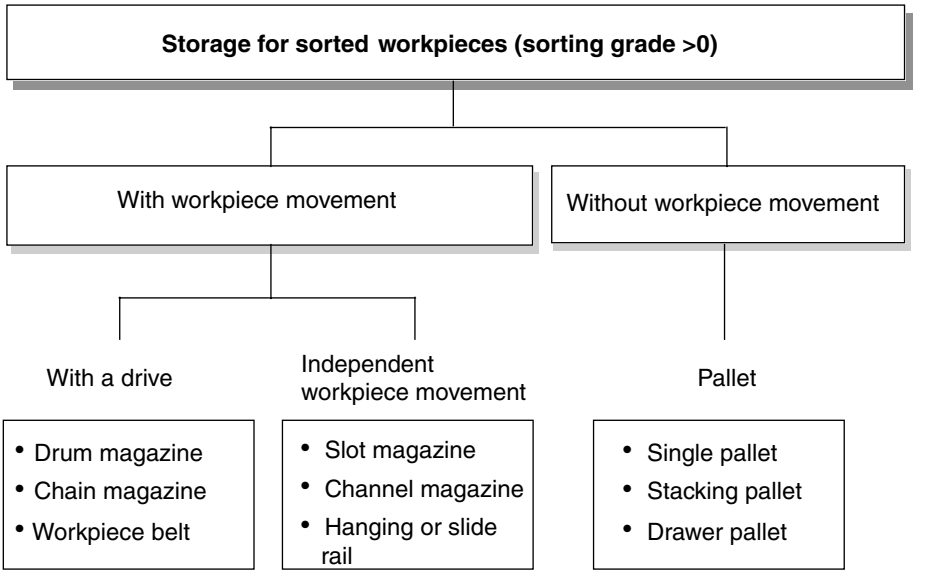

Figure 30 Types of Magazines.

in a certain order. Workpiece positioning is conducted by means of a form closure. Pallet magazines are usually stackable. The pallets can be coded for controlling tasks in the material flow. They are usually used in flex-link assembly systems.

Driven and/or movable magazines are preferable when dealing with larger workpieces. These magazines are capable not only of storage but also of forwarding and/or transferring the workpieces.

9.3. Fixturing

Fixtures are the bases that securely position workpieces while the assembly system performs operations such as pick-and-place and fastening. They are generally heavy and sturdy to provide the precision and stability necessary for automated assembly. They carry a variety of substructures to hold the particular workpiece. While each fixture is different, depending on the workpiece it handles, several commonsense rules for their design are suggested:

1. Design for assembly (DFA) usually results in simpler fixture design. Simple vertical stacking of parts, for example, generally allows minimal fixtures.
2. Do not overspecify fixtures; do not demand fixture tolerances not required by product tolerances. Fixture cost is proportional to machining accuracy.
3. Fixture weight is limited by conveyor and drive capabilities. The transfer conveyor must be able to carry the fixtures. And because fixture bases get rough treatment, include replaceable wear strips where they contact the conveyor. Replacing wear strips is cheaper than replacing bases. In addition, plastic bumpers cut wear, noise, and shock.
4. Use standard toolroom components when possible. Drill bushings, pins, and clamps are available from many sources. Use shoulder pins in through-holes instead of dowel pins positioned by bottoming in the hole. Through-holes are easier to drill and do not collect dirt.
5. Make sure any fragile or vulnerable parts are easily replaceable.

9.4. Sensors and Vision Systems

Sensors provide information about the automated system environment. They are the link between the technical process and its control system and can be seen as the sense organ of the technical system. They are used for a number of tasks, such as material flow control, process monitoring and regulation, control of industrial robot movements, quality inspections and industrial metrology, and for security protection and as safeguards against collisions.

The variety of sensors can be divided into technology applications as depicted in Figure 31.

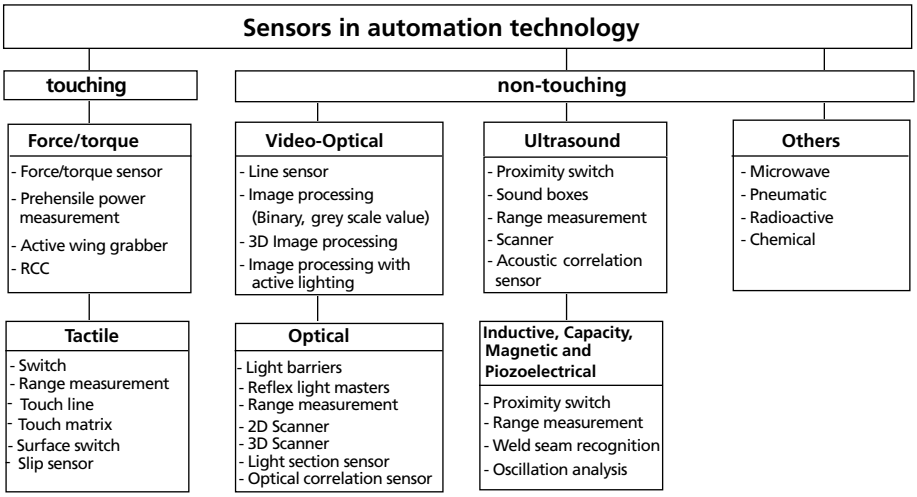

Figure 31 Systemization of Sensors by Technologies.

9.4.1. Tactile Sensors

Tactile touching sensors allow simple information from the environment to be recorded by touching the objects directly. In the simplest case, the sensor is a switch that sends a binary signal when set or not set. A variety of miniaturized switches are combined with line and matrix arrangements with integrated sensor data preprocessing to enable the creation of a tactile pattern recognition similar to the human sense of touch.

9.4.2. Force/Torque Sensors

Force/torque sensors allow reaction forces and torques that occur during handling or processing procedures to be recorded. For example, when two parts with a low positional tolerance are joined in an assembly system, the respective motional corrections can be automatically executed due to reaction forces. A completed recording is usually conducted with rotational measurement strips and contains three forces and torques. Depending on the task, a smaller number may also be sufficient.

9.4.3. Video-optical Sensors

With video-optical systems, tapes of camera pictures and subsequent image processing on a computer allow statements to be made about the type, number, and position of objects at a workpiece scene. These objects are then taught to the image processing system in a specific learning process (see Figure 32).

The reflection of an illuminated workpiece passes through a lens onto the CCD chip in the camera. A 2D discrete position image is created. The camera electronically turns this image into a video signal. The image-processing computer uses a frame grabber to turn the video signal into digital images and store these in the memory. Image-processing procedures can access these image data. Despite the large amount of hardware required, the main component of image-processing systems is the image-processing software.

Image-processing systems are extremely sensitive to changes in lighting conditions. Lighting therefore plays a decisive part in the evaluation of the images. Different specific lighting procedures for gathering spatial information have been developed, such as:

- The transmitted light procedure
- The silhouette-projection procedure
- The light section procedure (triangulation)
- The structured light procedure
- The coded lighting procedure
- The Stereo image processing

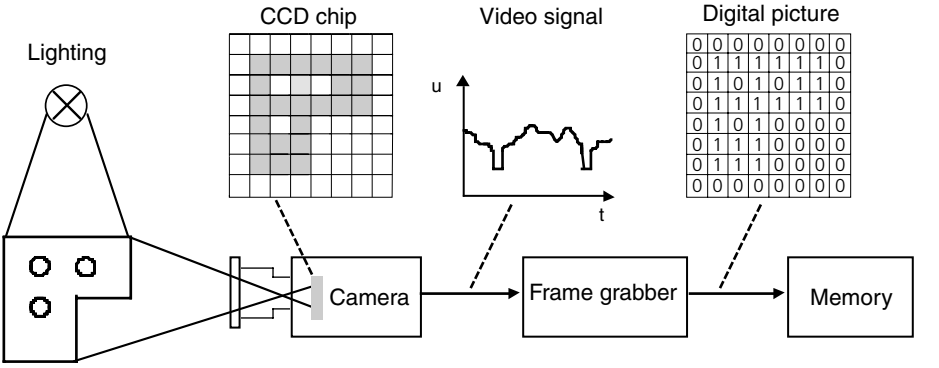

Figure 32 Basic Structure of an Image-processing System.

9.4.4. Ultrasound Sensors

An ultrasound sensor transmits a short high-frequency sound signal. If this signal is reflected by an object to the sensor and the echo is received by the sensor, it is possible to determine the distance to the object from the transfer time of the ultrasound impulse. The rate of measurement is physically limited due to the transfer time of the sound in the air. The range of sensors typically varies between 0.5 m and 6 m due to the attenuation of the sound in the air.

10. COMPUTER-AIDED METHODS FOR ASSEMBLY SYSTEMS

A large number of analytical models have been developed for planning manual and general assembly systems. Another objective has been to measure and evaluate the performance and productivity of assembly system design by applying simulation. Two essential technologies are explained in this section.

10.1. Layout Planning and Optimization

Nobody these days could imagine new products being designed and constructed without software tools. However, in the field of assembly line planning for new products, a lot of paperwork still has to be done. Most companies use computers only for documentation purposes and visualization of planning results. This means that many companies still use standard office tools for this field of activity and even execute the concept for the layout of assembly lines with a simple graphic tool. The high number of different tools and interfaces means that an actual data status for all project participants is impossible.

Meanwhile, some tools are available that are specially designed for the planning of assembly structures. The advantage of these tools is that they make continuous planning of assembly plants possible. All planning increments are entered into a central database that can show the actual status at any time.

The product structure is first defined in the tool, and then design proposals for the product are created by the software. The objective of these proposals is to create a consistent design for product assembly. MTM and UAS analysis are also supported by the software. The cycle time and the number of workstations are determined on the basis of the time data. The work steps for each station are also defined. After this, rough plans for each station can be made. This can be done using the database, which can be placed directly in the workstation. The database contains many common data such as workbenches, pressings, and robots. These are displayed as 3D graphics with additional parameters such as price and dimensions.

In addition, ergonomic investigations can be carried out in every workstation. The results of the time analyses and the appropriation of the parts can also be checked and optimized in the 3D model of the workstations (Figure 33).

The independent stations are finally united in a complete layout of the system, and the interlinking system and the bumpers are defined. In a final simulation of the material flow, the buffer sizes can be optimized and bottlenecks eliminated. The planning results are available as data and also as a 3D model of the assembly line. This provides all participants with enough data upon which to base their decisions (see Figure 34).

Figure 33 Software-Based Optimization of a Manual Assembly Station.

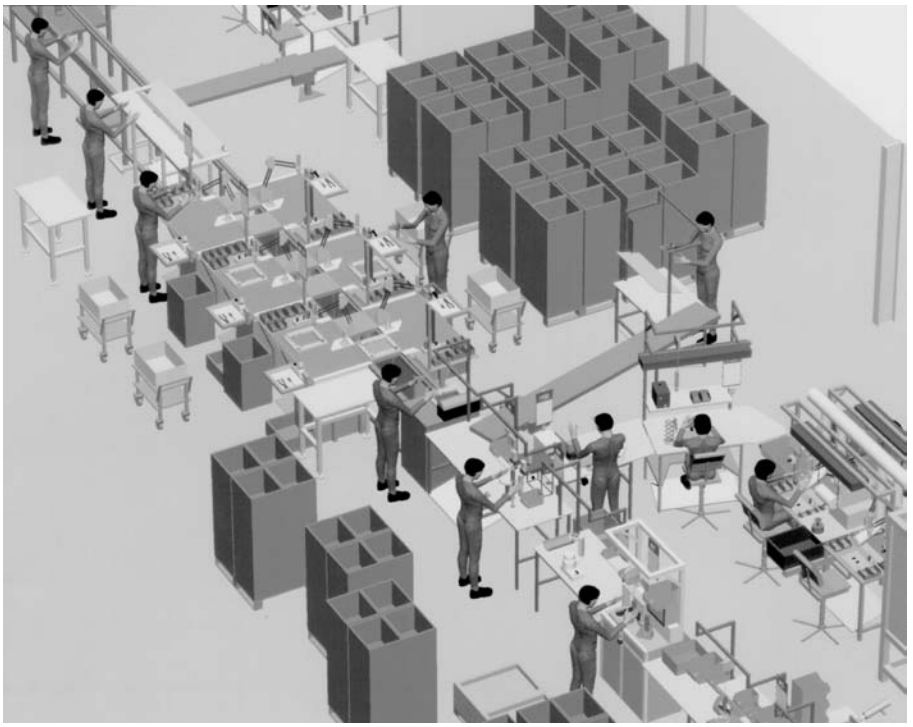

Figure 34 Software-Based Design of an Assembly Line. (*Source:* Vossloh Schwabe GmbH)

Cost analyses and efficiency calculations can also be executed with the software support. The use of software tools for the planning of assembly lines can reduce planning time and increase the quality of the results.

10.2. Simulation of Material Flow

The objective of material flow simulation is to predict the effect of actions before they are executed in order to be able to react if the results do not meet expectations. For making decisions especially in complex problems, the operations research procedure is also available. This procedure supposedly finds the most optimal solution on its own, which the simulation cannot accomplish. However, the immense number of model restrictions for complex problems with regard to model shaping and the great amount of calculation required make this practically unusable. In contrast, material flow simulation requires only a reasonable amount of modeling and calculation effort.

There are basically two application fields for material flow simulation: simulation for new plans and simulation aimed at optimizing existing systems. For new plans, the simulation aims to increase the planning security by determining initially whether the system works at all, whether the cycles of the individual stations are correct, where possible bottlenecks are in the system, and how malfunctions in individual stations affect the whole system. During the subsequent planning optimization process, the effects of malfunctions mainly determine the buffer size, which can vary considerably from the static buffer deviations. Furthermore, steps can be taken to review which measures will be needed to increase capacity by 10%, 20%, and more without the necessity of further shifts. This allows a change in the level of demand during the product's life cycle to be taken into consideration.

During operation after a product modification, new work tasks, or the assembly of a further variation on the existing system have been introduced, often a manufacturing system will no longer achieve the planned production levels and a clear deviation between target and actual production figures will become evident over a longer period of time. Due to the complexity of the manufacturing process, it is often not clear which actions would have the greatest effect. Simulation can determine, for example, what level of success an increase in the number of workpiece carriers or the introduction of an additional work cell would have. This helps in the selection of the optimal measures needed to increase productivity and the required levels of investment. Simulation of an existing system also has the major advantage that existing data pertaining to system behavior, such as actual availability, the average length of malfunctions, and the dynamic behavior of the system, can be used. These data can be determined and transposed to the model relatively easily, which makes the model very realistic.

For a simulation study to be executed, a simulation model must first be made that represents a simplified copy of the real situation. The following data are required: a scaled layout of the production, the cycle times of each of the processing steps, the logistic concept including the transportation facilities and the transportation speeds, the process descriptions, and data on the malfunction profiles, such as technical and organizational interruption times and the average length of these times. Once these data has been entered into the model, several simulations can be executed to review and, if necessary, optimize the behavior of the model.

The following example shows the possibilities of material flow simulation. In the model of an assembly system which is designed to produce 140 pieces/hr, the number of the workpiece carriers is increased. The result is a higher production level at some of the examined stations, but at some locations the higher number of workpiece carriers cause a blockage of stations that have successor stations with a higher cycle time. Thus, the increase of workpiece carriers has to be done in small steps with a separate simulation after each step to find the optimum. In this example, a 10% increase in the number of workpiece carriers and the installation of a second, parallel screwing station lead to a production increase from 120 to 150 pieces/hr.

The model reaches its optimum when each of the parameters is specifically modified and a combination of different measures is achieved. Aside from the creation of the model itself, this is the real challenge.

11. ASSEMBLY IN INDUSTRY: APPLICATIONS AND CASE STUDIES

Assembly is fundamental in almost all industrial activities. Assembly applications in several important industries are illustrated in the following case studies.

11.1. Automotive Assembly

More than half of the industrial robots throughout the world are used in the automotive industry. These robots are utilized in a number of different manufacturing sectors. The main areas of application are in car-body construction, mainly in spot welding and painting. Assembly lines are also being more and more robotized in the automotive industry. This is essential in the case of complex joining processes requiring a high standard of quality, which can be guaranteed only by robots.

But in order to promote automation in automotive assembly effectively, two conditions must be met first:

1. Assembly-oriented automotive design
2. Preassembly of as many subunits as possible

A few application areas of automatic assembly in the automotive industry (see Figures 35, 36, 37) are shown in the following examples.

11.2. Assembly of Large Steering Components

This non-synchronous pallet-based, power and free system manufactures a large steering component for the automotive industry (see Figure 38). Cycle time is approximately 20 seconds, three shifts per day. Unique pallet design helped this customer automate the assembly process while minimizing material handling of the final product. An important issue for the manufacturing process was the testing of each unit throughout the assembly sequence. Tests performed are leak, torque, function, and final performance. The automation system also featured manual stations for placing specific parts and for rework and evaluation.

11.3. Automatic Removal of Gearboxes from Crates

The combination of innovative sensory analysis with modern industrial robots is opening up more new fields of application for automation technology. Automatic unloading of workpieces from crates is a problem that automation technology researchers have been addressing for a long time. However, only recently have usable systems for the rough production environment been developed. The requirements for these unloading systems are:

- Localization accuracy better than 5 mm
- Cycle time maximum 24 sec (in accordance with subsequent manufacturing processes)
- No predefined lighting conditions for the recognition sensors
- Lowest possible tooling-up requirements for new types of workpiece
- If possible, no additional pieces of equipment for the recognition sensors in the work cell

Figure 35 Robotized Spot Welding Line (*Source:* KUKA Roboter GmbH)

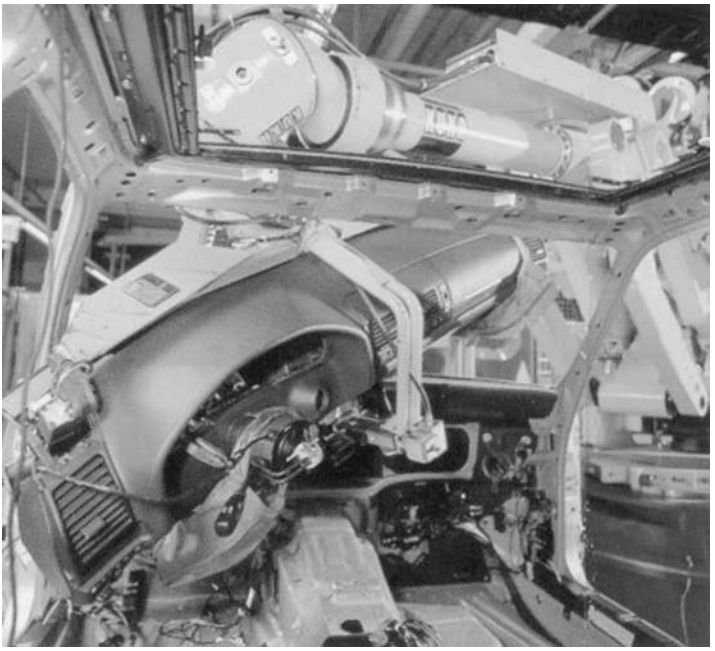

Figure 36 Assembly of Driver Control Instruments. (*Source:* KUKA Roboter GmbH)

Figure 37 Assembly of Car Door Rubber Profiles (*Source:* IPA)

Figure 38 Assembly Line for Large Steering Components. (*Source:* ATS Inc.)

In the case outlined here, the processed and partly sorted cast parts are automatically unloaded from the crates. In order to avoid the cast parts damaging each other, they are stacked in the crates on cushioned layers (see Figure 39).

After the filled crate has been delivered to the work cell, the robot first measures the four upper edges with the help of a 2D triangulation sensor that is attached to the robot. This measurement is used to calculate the exact location and height of the crate.

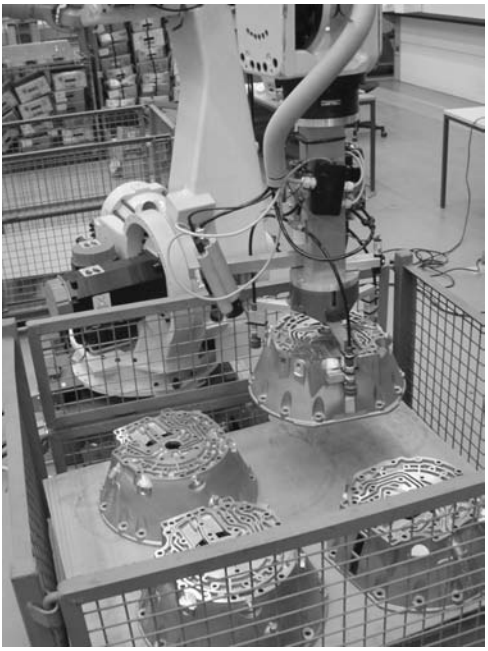

Figure 39 Robot Cell for Unloading Gearboxes from Crates. (*Source:* IPA)

The robot sensor is guided over the workpieces in the crate to determine the position of each of the workpieces. The workpiece surface that has been recognized is used to determine the three positions and orientations of the workpiece. The approach track with which the robot can grab and pick up the cast part is prepared from the workpiece position. The whole approach track is calculated in advance and reviewed for possible collisions. If the danger of a collision exists, alternative tracks are calculated and the next cast part is grabbed if necessary. In this way the system maintains a high level of operational security and has sound protection from damage.

11.4. Electronic Assembly

11.4.1. Assembly of an Overload Protector

This pallet-based assembly system produces a safety overload protection device and was designed with multiple zones (see Figure 40). The transport system is a flex-link conveyor with a dual-tooled pallet for cycle time consideration. The cycle time for the system is 1.2 sec. Tray handling and gantry robots were utilized for this application due to the high value of the component. The line features unique coil winding, wire-stripping technologies, and sophisticated DC welding for over 20 different final customer parts for the electronic assembly market.

11.4.2. Assembly of Measuring Instruments

The production of measuring instruments is often characterized by small batches, short delivery times, and short development times. Automated assembly of the measuring instrument cases enables products to be manufactured at lower costs. The cases are made of several frame parts. Each frame part is separated by a metal cord that provides screening against high-frequency radiation.

The different kinds of cases have various dimensions (six heights, three widths, and three depths). Altogether there are about 1,000 product variants with customer-specific fastening positions for the measuring instrument inserts. Therefore, the assembly line is divided into order-independent preassembly and order-specific final assembly (see Figure 41).

In the preassembly cell are automatic stations for pressing in different fastening nuts and screwing in several threaded bolts. An industrial robot handles the frame parts. After removing the frames from the supply pallets, the robot brings the frame into a mechanical centering device for fine

Figure 40 Assembly Line for Safety Overload Protection Device. (*Source:* ATS Inc.)

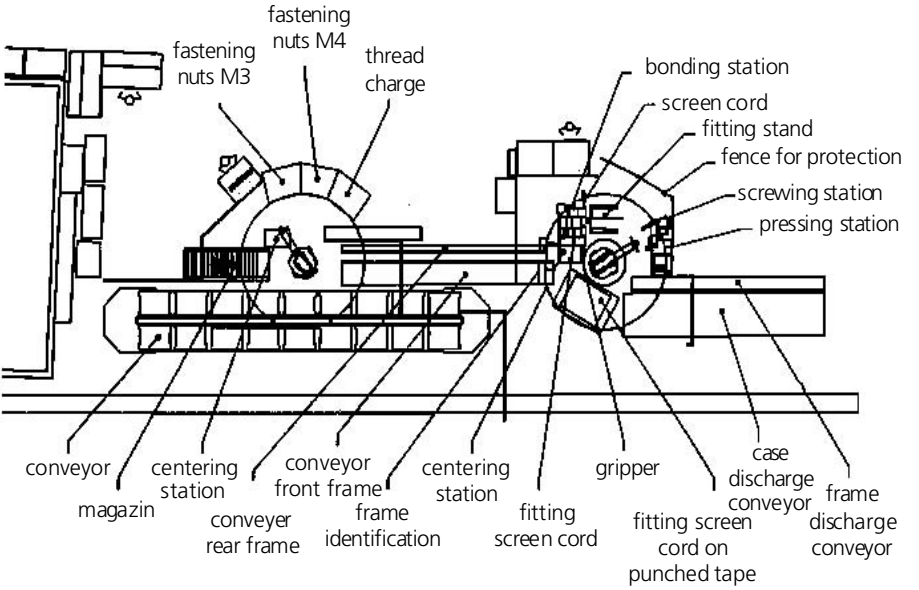

Figure 41 Layout of the Pre- and Final-Assembly Cell.

positioning and the elimination of tolerances in the pallets. In this way it is possible to achieve very exact positioning of the frame in the robot gripper.

During the pressing operation, the robot positions and fixes the frame in the press station (press force of about 3000 N). A compliance system is integrated in the gripper to eliminate tolerances in dimensions of the frame. The robot also positions and fixes the frames in the screwing station. There is a system to control the rotation angle, screwing torque, and screwing depth to reproduce a screwing depth of 0.1 mm.

After finishing preassembly, the robot places the frames on a conveyer system. The conveyer links the pre- and final-assembly cells. The final-assembly cell work steps are (see Figure 42):

- Fitting the metal cord for high-frequency screening into the frames
- Order-specific pressing of fastening elements
- Screwing together all frames to produce the finished case
- Lettering the finished case

The difficulty in assembling the metal cord is that these parts have no rigidity and can only transmit tractive forces. Two metal cords with different diameters (2.0 mm and 3.0 mm) have to be fitted into four fundamentally different running slots. To achieve the required stability of the cord in the rear-frame slot it is necessary to put in adhesive points. A cord-cutting system is integrated into the robot tool to achieve the right length of the cord (depending on the dimensions of the frames), and an adhesive dispensing system is integrated into the tool for placing the adhesive spots into the slots.

After the metal cord has been fitted into the different frames (front inside, front outside, rear, and side ledge), the fasteners for the inserts are pressed in order-specific positions into the side ledges. For this operation the robot takes the ledge with the required length out of a magazine and brings it into a press station. A guide rail defines the exact position. The fasteners are blown automatically from the feeder through a feed pipe to the press position.

The subsequent screwing of all frame components is also executed by the robot. The robot moves to the screwing position. The screws are blown automatically through the feed pipe from the feeder to the screwing tool. The rotation angle and screwing torque are monitored during the screwing operation to achieve a perfect result.

Depending on the construction of the case, it is important to have accessibility from four directions during the complete assembly process. Therefore, a clamping device that can turn the case in all

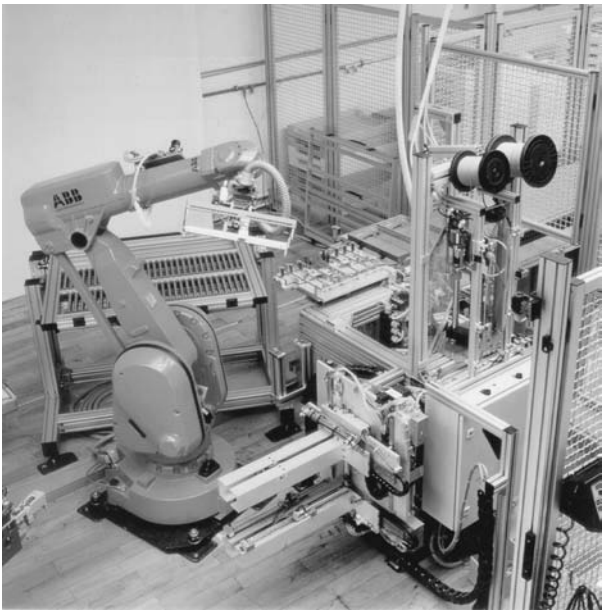

Figure 42 Final-Assembly Cell with Flexible Clamping System.

required positions is essential. The clamping device is made up of standard components that can clamp more than 25 cases with different dimensions. The robot arm has an automatic tool-changing system for changing tools quickly; each tool can be picked up within a few seconds.

Experience with the assembly cells outlined above has shown that even assembly tasks with extensive assembly steps producing less than 10,000 units per year can be automated in an efficient way.

11.4.3. Assembly of Luminaire Wiring

For the optimal economic assembly of luminaire wiring, a simultaneous development of new products and process techniques was necessary. A new method developed for the direct assembly of single leads has proved to be a great improvement over the traditional preassembly of wires and wiring sets. Single leads are no longer preassembled and placed in the end assembly. Instead, an endless lead is taken directly from the supply with the help of a newly developed fully automated system and built into the luminaire case. This greatly simplifies the logistics and material flow inside the company and reduces costs enormously.

The IDC technique has proved to be the optimal connection system for the wiring of luminaires. Time-consuming processes like wire stripping and plugging can now be replaced by a process combining pressing and cutting in the IDC connector. The introduction of this new connection technique for luminaire wiring requires modification of all component designs used in the luminaires.

Fully automatic wiring of luminaires is made possible by the integration of previously presented components into the whole system. Luminaire cases are supplied by a feeding system. The luminaire case type is selected by the vision system identifying the bar code on the luminaire case. Next, luminaire components are assembled in the luminaire case and then directed to the wiring station (Figure 43).

Before the robot starts to lay and contact the leads, a camera, integrated in the wiring tools, is positioned above the required position of the component designated for wiring. Each component is identified and its precise position is controlled by vision marks in the shape of three cylindrical cavities in the die casting of the IDC connector. Any deviation of the actual position from the target position is calculated and transmitted as compensation value to the robot's evaluation program.

Quality assurance for the processes, especially for pressing and contacting of the conductor in the IDC connector, is directly controlled during processing. When the wire is inserted into the connector, a significant and specific force gradient is shown within narrow tolerances. This measured gradient can be easily compared and evaluated immediately after pressing with the help of a reference

Figure 43 Assembly Cell for Automatic Wiring of Luminaires. (*Source:* Vossloh Schwabe GmbH)

graph. In the case of nonconformity, the luminaire is isolated, taken out of the material flow system, and directed to a manual work station for rework.

Depending on the geometry of the luminaires, it can be assumed that the application of this assembly system can reduce the share of wage costs for each luminaire by up to 65%.

11.4.4. Assembly of Fiberoptic Connectors

While communications and information technology are rapidly evolving, transmission media requirements are increasing more and more. The enormous increase in data rates, the increase in data transmission speeds, and the high level of reliability of EMI mean that copper-bounded transmission technology has reached its technical and economical limits because of its susceptibility to interference and limited transmission rates. Fiberoptic technology, by contrast, has already shown its potential and advantages in telecommunication and computer network (LAN) applications. Because manufactured units are increasing, automation of the fiberoptic connector assembly is becoming a more and more exciting field.

Fiberoptic cables are currently assembled almost completely manually. Semiautomatic devices are available on the market for the premanufacturing process. After this process is completed, the ceramic ferrule of the connector is filled with glue, then the glass fiber is introduced into the ferrule hole. This assembly sequence is executed only manually at present. However, because no measuring systems are available for this purpose, manual assembly cannot ensure that the critical joining force will not be exceeded. If this happens, the fiber will break off. The fiber will be damaged and the connector will become waste.

Figure 44 shows the construction of an ST connector and the simplex cable that is used.

An automated fiberoptic connector assembly, especially in the inserting process, is generally obstructed by following factors: glass fiber sensitivity to breaks, nonrigid cable, complex cable construction, inserting dimensions in the μm range, small backlash between fiber and ferrule (0–3 μm), varying glue viscosity, and maximal inserting forces in the mN range.

Figure 45 shows a prototype assembly cell where the above-mentioned subsystems are integrated.

11.5. Microassembly

Increasing miniaturization of mechanical components and rising demands in the precision mechanics and microtechnology industries are creating high demands on assembly automation. Today automated solutions only exist for mass series production systems (the watchmaking industry, the electronics industry). Automation of assembly tasks for small and medium-sized series is still rare. Flexible automated microassembly systems are required there due to the large number of different types and variants.

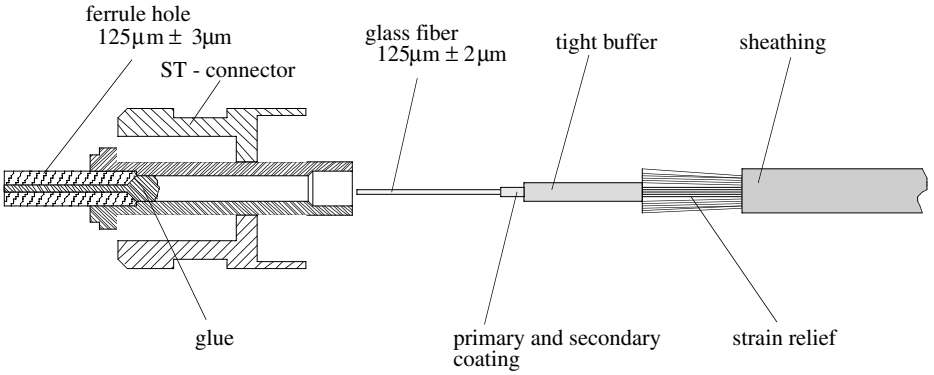

Figure 44 Construction of Connector and Cable.

The assembly of precision mechanics and technical microsystem components often requires joining work to be conducted in the micrometer range. Intelligent robot grabbing systems have been developed in order to achieve the join accuracy required. Motion-assisted systems are particularly suited for flexible offsetting of tolerances in short cycles.

Figure 46 shows an example of a oscillation-assisted joining robot tool for precision and microassembly of small planetary gears. Assisted by the adjustable oscillation in the grabber and the regulated tolerance offset, each of the gearwheels and the gearwheel housing can be process assembled very securely by means of the integrated fine positioning.

The special features of the joining tool are the joining accuracy of up to 2 μm that can be achieved, the process-integrated offsetting of orientation and position deviations (up to ± 1 mm), and the high level of adjustment as well as flexibility essential for performing the different joining tasks. The robot tool is used especially for phaseless bolt-in-hole joining tasks with accuracy requirements in the micrometer range and for the assembly of complex toothed wheel pairs.

11.6. Food Industry

The number of convenience products sold annually in recent years has increased markedly. Particularly in everyday life and in cafeterias the trend is toward meals that can be prepared more quickly and conveniently. According to the experts at *Food Consulting,* the share of convenience products in

Figure 45 Prototype Assembly Cell for Manufacturing Fiberoptic connectors.

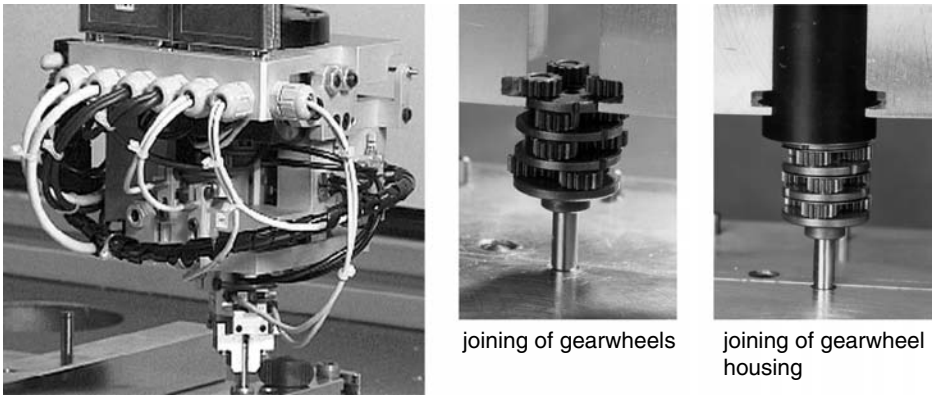

Figure 46 Oscillation-Assisted Joining Tool. (*Source:* IPA)

meat products will increase from 15% at present to above 30% in the next two years. The food industry is changing into a preparation industry and its vertical range of manufacture will increase dramatically. This will necessitate the introduction of automated manufacturing processes and thus enable the use of new automation and robot systems.

In addition to increasing productivity, automated systems allow improved levels of hygiene and thus extending the sell-by date of food products. They also allow ever-increasing consumer demands for more transparency regarding product origins to be met.

Figure 47 shows a robot in use in the food-packaging sector. At the end of a production line, the unsorted sausages that arrive on the conveyor belt are recognized by an image-processing system and automatically sorted according to the final packaging unit with the help of the robot.

11.7. Pharmaceutical and Biotechnological Industry

In the pharmaceutical industry, large sums of money are used for preclinical and clinical research. The development of a drug costs millions of dollars. Hundreds of tests have to be conducted. One of the innovative tools in the field of drug discovery is microchip technology. Microchips require less reagent volume, make analytical processes run faster because of their smaller size, and allow more sensitive detection methods to be implemented. In this way, they reduce costs, save time, and improve quality. Microchips come in two main categories: chips based on microfluidics, with components such as pumps, mixers, microinjectors, and microarray chips, which have numerous locations of samples, such as DNA samples, on their surface. Most of the interest now seems to be focused on this second category.

Figure 48 shows an arrayer for low-volume spots. With a capillary-based tip printing method, volumes in the lower pl-range can be produced. These very small drop volumes give the opportunity to use more sensitive methods of detection and produce high-density arrays. The automated arrayer is based on a gantry robot. Its three axes are driven by electronic step drives that have a positional accuracy of ± 1 μm and a speed up to 300 mm/sec. The work area is 300 $\times$ 300 mm and the total dimension is 500 $\times$ 500 mm. In order to have a controlled environment, the system is operated in a clean room.

So far, commercial available arraying systems are useful only for R&D applications and research labs. They have not achieved wide commercial availability.

CHAPTER 13
Assembly Process

K. FELDMANN
University of Erlangen-Nuremberg

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. CURRENT DEVELOPMENTS

Today's competitive environment is characterized by intensified competition resulting from market saturation and increasing demands for a customer-oriented production. Technological innovations also have an influence on the competitive environment. These facts have dramatically altered the character of manufacturing. Meeting customers' demands requires a high degree of flexibility, low-cost/low-volume manufacturing skills, and short delivery times. Production and thereby manufacturing performance thus have gained increasing significance and are conceived as a strategic weapon for achieving and maintaining competitiveness (Verter and Dincer 1992). Especially in high-tech markets, where product technology is rapidly evolving, manufacturing process innovation is becoming an increasingly critical capability for product innovation. To meet the requirements of today's markets, new paths must be trodden both in organizational methods and in manufacturing and automation technology (Feldmann and Rottbauer 1999).

1.1. General Developments in Assembly

The great significance of assembly in a company's success is due to its function- and quality-determining influence on the product at the end of the direct production chain (Figure 1). Rationalization of assembly is still technologically impeded by high product variety and the various influences resulting from the manufacturing tolerances of the parts to be joined (Tönshoff et al. 1992). As a result, considerable disturbance rates are leading to reduced availability of assembly systems and delays in assembly operations. This complicates efficient automation and leads to consideration of displacing assembly plants into lower-cost regions. Assembly is also influenced by innovative developments in the manufacturing of parts, such as surface technology or connecting technology, which can have an important influence on assembly structures. The complex reflector assembly of a car headlight, for example, can be substituted for by surface coating technology.

Due to the rapidly changing market and production conditions, the role and the design of the individual functions within the entire value-adding chain are also changing. Other factors helping to bring this about include by the influence of microelectronics on product design and manufacturing structure and global communication possibilities. Facing the customer's demands for the after-sales or service functions, for example, is becoming of increasingly important to a company's success. More and more customers would like to purchase service along with the product contract.

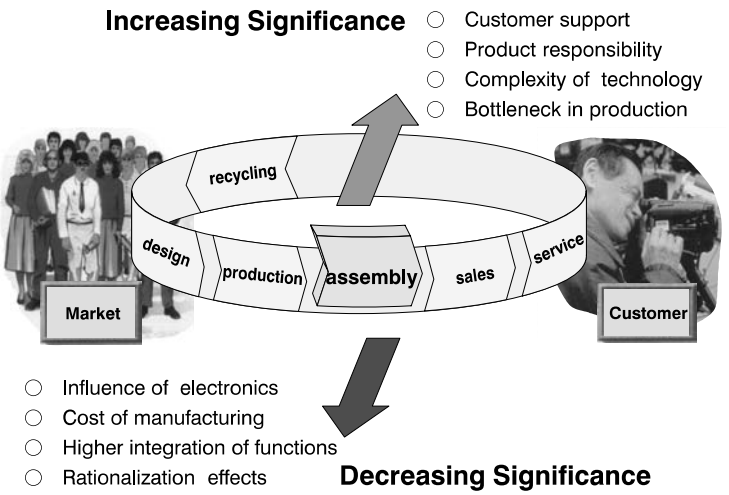

Figure 1 Significance of Assembly in the Value-Adding Chain. (From Feldmann et al. 1996)

The growing complexity of the manufacturing process in industry has its origin in the globalization of the markets, customer demands for systems instead of single products, and the introduction of new materials and technologies. Designing a product for ease of assembly using design for manufacture and assembly (DFMA) methodology leads to a reduced number of variants and parts, higher quality, shorter time-to-market, lower inventory, and few suppliers and makes a significant contribution to the reduction of complexity in assembly (Boothroyd 1994).

The influence of the different branches and product structures is more evident in the range of assembly technology than in prefabrication. This also has a lasting impact on site selection because of the required workforce potential. Therefore, the global orientation of the assembly plants should be clarified on the basis of four major product areas (Figure 2).

Car assembly can be characterized as a serial assembly with trained workers. In contrast, the machine tool industry is characterized by a high degree of specializiation and small lot sizes, requiring highly skilled workers for assembly tasks. This makes the global distribution of assembly plants difficult, especially because the close interaction of development, manufacturing, and start-up still plays an important role. In contrast, the assembly of electronic components, inspired by the technological transition to surface mount technology (SMT), has been rapidly automated in recent years. In view of the small remaining share of personnel work, labor costs do not have a major influence on site selection in this product area any longer. In contrast to car assembly, the electronics industry is characterized by a more global distribution of production sites and comparatively smaller production units. However, this simplifies the regional or global distribution of assembly plants. Product size as well as logistical costs for the global distribution of products from central assembly sites are generally lower than in the automotive industry. In the white goods industry, a relatively small ratio of product value to product size is decisive. Serving global markets under minimized logistical costs requires corresponding global positioning of distributed assembly plants.

In general, for all industries, four fundamental solutions in assembly design can be distinguished (Figure 3). Manual assembly in small batch sizes is at one end and automated serial assembly at the other. Thus, the introduction of flexible assembly systems is reinforced. Again, these flexible automated assembly systems offer two alternatives. The integration of NC axes increases the flexibility of conventional machines, whereas the introduction of robot solutions is aimed at opening up further assembly tasks for efficient automation. There have been many technological responses to the global demand for large product variety coupled with short delivery times. In this context, the concept of human-integrated production systems is gaining ground. The intention here is to allow the human operator to be a vital participant in the future computer integrated manufacturing systems. This also has an impact on the design of assembly systems.

Changes in product structure and the influence of electronics are drivers of assembly rationalization. A common approach, from car assembly up to assembly in the electronics industry, is the

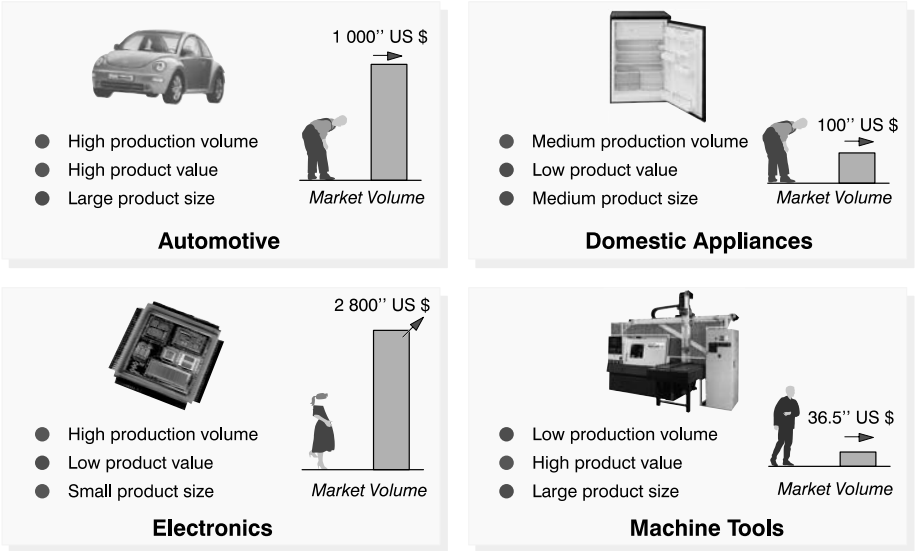

Figure 2 Major Product Areas with Different Conditions for Global Assembly.

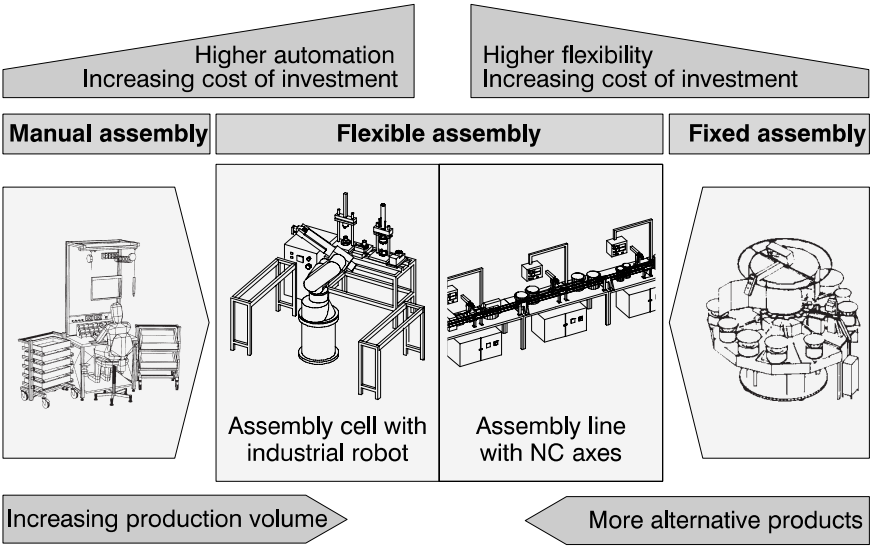

Figure 3 The Basic Technological Alternatives in Assembly. (From Feldmann et al. 1996)

stronger concentration on higher functional density in subsystems (Figure 4). In car assembly, this means preassembling complex units like doors or cockpits; in electronics, this means circuit design with few but highly integrated circuits.

The new paradigm in manufacturing is a shift from Taylorism and standardization to small-lot, flexible production with emphasis on short lead-time and responsiveness to market. Organizational decentralization in autonomous business units, called fractals (Warnecke 1993), has also encouraged the distribution of assembly plants. The reduction of production complexity as a prerequisite for a faster, more flexible, and self-organizing adaptation of business units to changing market conditions is based on a redistribution of decision making responsibilities to the local or distributed unit.

The managing of complexity in manufacturing by outsourcing is rather common in the prefabrication field, whereas the reduction of production depth and the resulting cost advantages contribute to keep assembly sites in the countries of origin. In turn, the formation of decentralized business units results in more favorable conditions for the relocation of specific assembly tasks to other regions.

1.2. Impact of Electronics on Assembly

Within the framework of assembly rationalization, electronics almost has a double effect (Figure 5). In the first step, efficient assembly solutions can be built up by electronically controlled systems with programmable controllers and sensors. In the second step, the assembly task can be completely replaced by an electronically provided function. Examples are the replacement of electromechanical fluorescent lamp starters by an electronic solution and, on a long-term basis, the replacement of technically complex letter-sorting installations by purely electronic communication via global computer networks. Not only does the replacing electromechanical solutions with electronic functional carriers reduce assembly expenditure, but electronics production can be automated more efficiently. In many cases, the functionality and thus the customer benefit can be increased by the transition to entirely electronic solutions.

The further development of semiconductor technology plays an important role in electronics production. In addition to the direct consequences for the assembly of electronic components, further miniaturization, increasing performance, and the expected decline in prices have serious effects on the assembly of electronic devices and the further development of classical engineering solutions. Within a certain range, the degree of automation in mechanical assembly can be increased only up to a certain level. In contrast, in electronics assembly, there is greater higher potential for increasing the degree of automation. This also has consequences for product design. Figure 6 shows a comparison of the degree of automation in mechanical and electronics assembly.

Today's paradigms for manufacturing require a holistic view of the value-adding chain. The disadvantages of breaking up the value-adding chain and distributing the single functions globally can be compensated for by models and tools supporting integrated process optimization. Examples of this are multimedia applications based on new developments in information technology and the

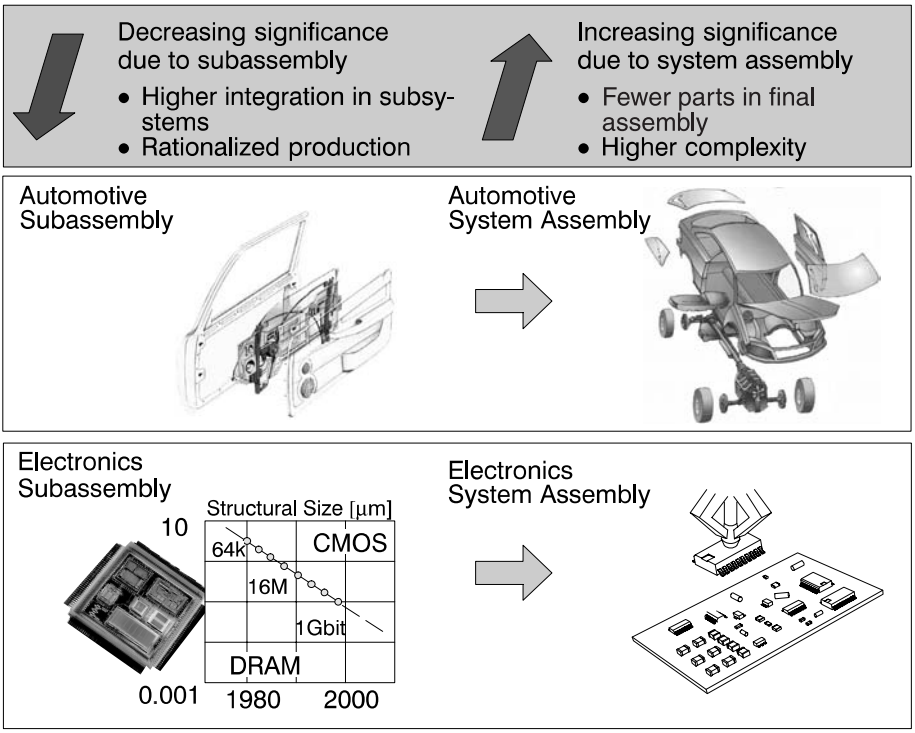

Figure 4 Trends toward New Assembly Structures. (From Feldmann et al. 1996)

concept of virtual manufacturing, which is based on simulation technology. The diffusion of systems such as electronic data interchange (EDI) and integrated service digital network (ISDN) allows a more efficient communication and information exchange (Figure 7).

Distributed and decentralized manufacturing involves the problem of locally optimized and isolated applications as well as incompatibilities of process and system. To ensure synergy potentials and stabilize the productivity of the distributed assembly plants, an intensive communication and data

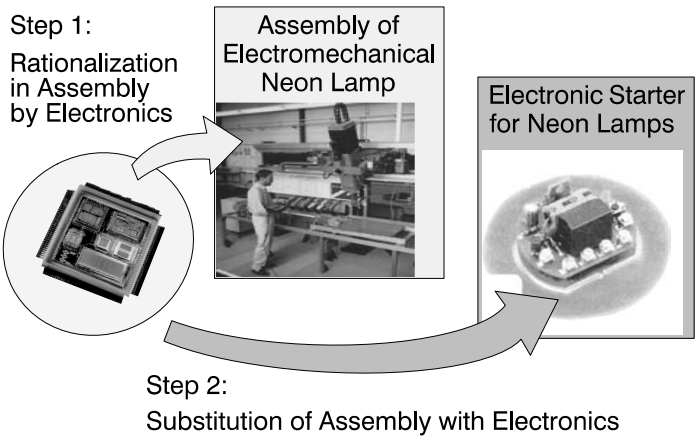

Figure 5 Impact of Electronics on Assembly Tasks. (From Feldmann et al. 1996)

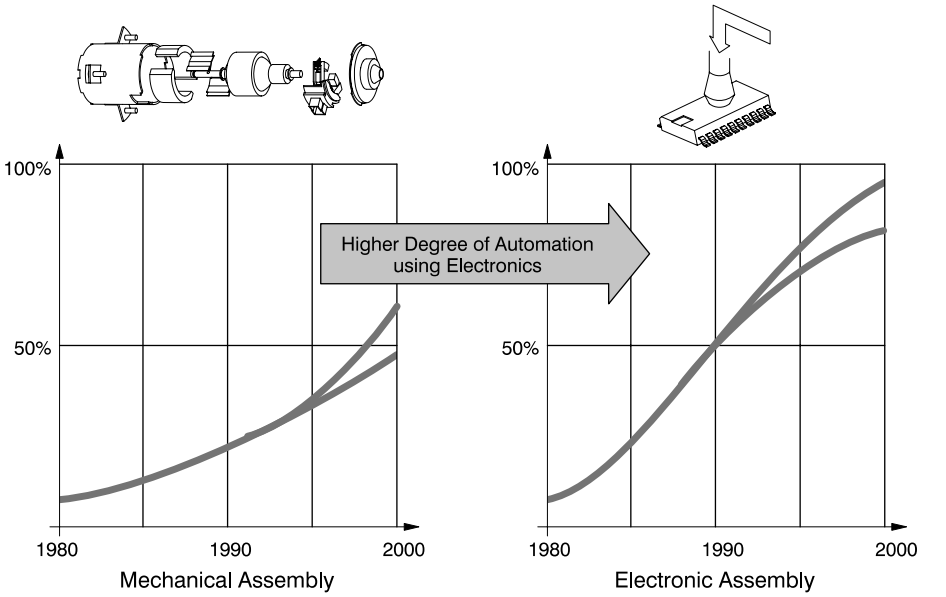

Figure 6 Comparison of the Degree of Automation in Mechanical and Electronics Assembly.

exchange within the network of business units is vital (Feldmann and Rottbauer 1999). New information technologies provide correct information and incentives required for the coordination of efficient global production networks. For instance, the diffusion of systems such as EDI and ISDN allows more efficient communication and information exchange among the productive plants linked in the same network. Furthermore, high-efficiency systems such as satellite information systems have contributed to perform operations more efficiently with regard to the critical success factors. For instance, tracking and expediting international shipments by means of preclearance operations at customs leads to a reduction in the delivery time. The coordination of a network of transplants dispersed throughout the world provides operating flexibility that adds value to the firm. From that

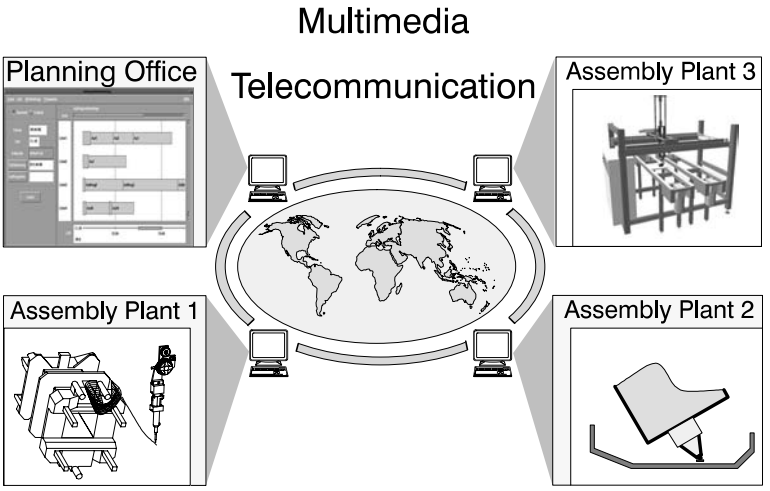

Figure 7 Global Engineering Network for Assembly Plants.

point of view, a decisive improvement in the conditions for global production networks has come about through the influence of microelectronics with the new possibilities in telecommunications.

As data definitions become more sophisticated under emerging standards such as STEP, corporate server networks can distribute a growing wealth of product and process information among different parts of the organization and its associates. Processing programs developed worldwide can be used in all production sites by means of direct computer guidance (Figure 7). The diagnosis of assembly systems is coordinated from a central control center. In this way, it becomes possible to transmit the management of a project in the global production network around the clock.

2. ASSEMBLY TECHNOLOGIES AND SYSTEMS

2.1. Basic Structures of Assembly Systems

Assembly is the sum of all processes needed to join together geometrically determined bodies. A dimensionless substance (e.g., lubricants, adhesives) can be applied in addition (VDI 1982).

In addition to joining in the manufacturing process, handling of components is the primary function of assembly. The assembly also contains secondary functions such as adjusting and inspecting as well as various special functions (see Figure 8).

Joining is defined by DIN 8593 as a part of manufacturing processes. In this case, the production of a compound consisting of several parts can be achieved by merging, pressing, pressing in, metal forming, primary shaping, filling, or by combining substances.

Handling is defined in VDI Guideline 2860/1 as the creation, defined varying, or temporary maintaining of a prescribed 3D arrangement of geometrical defined solids in a reference coordinate system. For this, procedures such as ordering, magazining, carrying on, positioning, and clamping are important. It is simple for a human being to bring parts into correct position or move them from one place to another. However, a considerably larger expenditure is necessary to automate this task. An extensive sensory mechanism often must be used.

Manufacturing of components is subject to a great number of influences. As a result, deviations cannot be avoided during or after the assembling of products. These influences must be compensated for, and thus adjusting is a process that guarantees the required operating ability of products (Spur and Stöferle 1986).

Testing and measuring are contained in the inspection functions. Testing operations are necessary in all individual steps of assembly. Testing means the fulfillment of a given limiting condition. The result of the test operation is binary (true or false, good or bad). On the other hand, specifications are determined and controlled by given reference quantities while measuring. Secondary functions are activities, such as marking or cleaning operations, that can be assigned to none of the above functions but are nevertheless necessary for the assembly process.

Assembly systems are complex technical structures consisting of a great number of individual units and integrating different technologies.

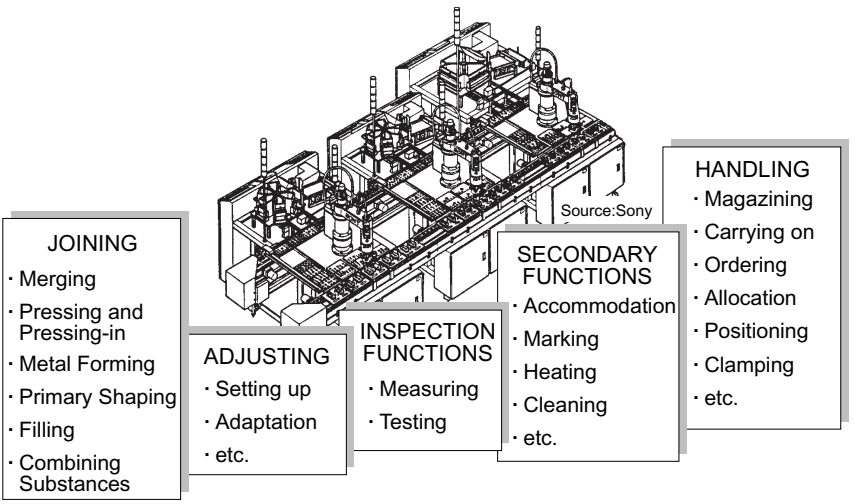

Figure 8 Functions in an Assembly System.

There are different possibilities for the spatial lineup of assembly systems. One possibility is a line structure, which is characterized by:

- Clear flow of materials
- Simple accessibility of the subsystems (e.g., for maintenance and retrofitting)
- Simple lineup of main and secondary lines
- Use mainly for mass production (the same work routine for a long time)

Alternatively, an assembly system can be arranged in a rectangular structure, which is characterized by:

- Very compact design
- High flexibility. The combination of opposing subsystems is easy to realize.
- Poor accessibility to the subsystems during maintenance and retrofitting
- Use mainly for small and middle lot sizes

In addition to different spatial lineups, other basic modifications of cell structure are possible for achieving the required efficiency (see Figure 10).

The number of work cycles that can be carried out on an assembly system depends on the size of the assembly system (number of cells) and the required productivity. The availability drops as the number of stations increases. Therefore, the distribution of work cycles onto several machines is necessary. In this case, the productivity increases with decreasing flexibility. The entire assembly system can be subdivided into different cells, which are connected by the flow of materials and information. The basic structure of a cell consists of a tabletop, a basic energy supply, the mounted handling devices, the internal conveyor system, and a safety device (protective covering, doors with electrical interlock). The individual cells should be built up modular and equipped with standardized interfaces (energy, pneumatic, and information technology). A strict module width for the spatial measurements is also useful. As a result, fast realization of the individual assembly cells, a high degree of reuse, and flexible use are guaranteed. The assembly cell itself consists of different components and units (Figure 9). The main components of an assembly cell are devices (integrated robots, modular system built of numerically controlled axes, pick-and-place devices, etc.), its mechanical construction, the design of the grippers, the actuating system, the control system, the method of programming, and the sensor technology used. Furthermore, the part supply is very important (ordered or disordered part supply; see also Section 2.3). Last but not least, the joining process (see also Section 2.2) must be adapted and optimized to meet all the necessary requirements.

The different alternatives for design of assembly systems are represented in Figure 10. The flexible cell is able to carry out all necessary assembly functions for a certain variant spectrum (three variants,

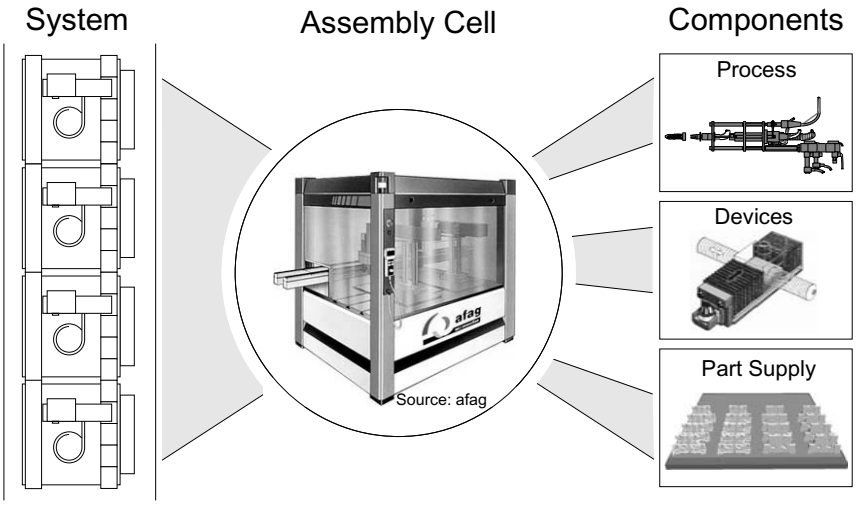

Figure 9 Structure and Components of Assembly Cells.

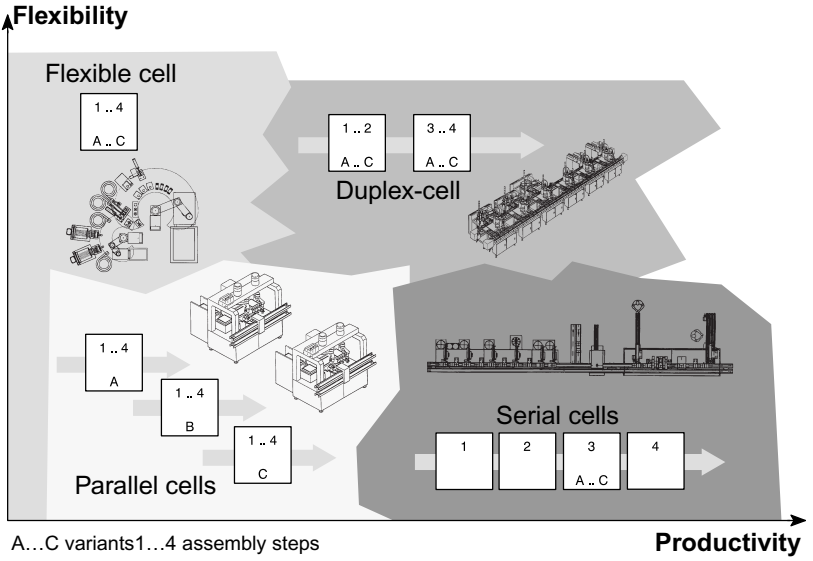

Figure 10 Alternative Cell Structures for Assembly Systems.

A, B, and C, are represented here). For this purpose, it has all the necessary main and secondary functions for the assembly process. High variant flexibility, sequential processing of the individual assembly tasks, as well as the resulting high nonproductive times, lead to the use of flexible cells, mostly for small and middle lot sizes.

If the duplex cell is used, the assembly tasks will be distributed over two handling units. These always have the full variant flexibility. With regard to function, the cells need not be completely flexible. They must be able to carry out only a part of the assembly tasks. The function size of the multiple grippers (in the case of unchangeable variation of the functions) can be increased by parallel assembly with two independent handling devices. Even shorter cycle times can be achieved than with the flexible cell.

Serial cells are flexible only with respect to the assembly of variants. However, the function size of an individual cell is highly limited. The spatial lineup of the cells is responsible for the fact that the cell with the longest cycle time determines the total cycle time of the assembly process. Considering the spatial extension of serial structures, it is obvious that the integration level of the system is smaller than that of flexible cells or duplex cells.

Parallel cells will be used if only one assembly cell is responsible for the complete assembly of a variant. Each individual cell has a high degree of functional flexibility, which unfortunately can only be used for one variant. Therefore, the potential of the resources cannot be exploited because identical assembly conditions must be used during the assembly of different variants. If the individual variants show only a small number of similar parts, which on top of that often have different gripping conditions, splitting up variants will be advantageous. As a result, a smaller variant flexibility will be necessary.

The serial structure will react extremely sensitively to fluctuation in the number of variants. At worst, restructuring or reconstruction of all cells will be required. In contrast, the rate of utilization of the system will remain almost stable if full variant flexible cells are used. Because the handling devices of parallel cells have full functional flexibility, it is not necessary to carry out an adaptation of the number of flexible systems. Due to changes in lot size, parallel cells designed for special variants will even have too much or too little capacity, which cannot be removed without adequate measures.

2.2. Joining Technologies

2.2.1. Classification and Comparison of Joining Technologies

Industrialized manufactured products predominantly consist of several parts that are usually manufactured at different times in different places. Assembly functions thus result from the demand for

joining subsystems together into a product of higher complexity with given functions. According to German standard DIN 8580, joining is defined as bringing together two or more workpieces of geometrically defined form or such workpieces with amorphous material. The selection of a suitable joining technique by the technical designer is a complex function. In DIN 8593, manufacturing methods for joining (see Figure 11) are standardized.

In addition to the demands on the properties of the product, economic criteria have to be considered (e.g., mechanical strength, optics, repair possibilities). The ability to automate processes and design products with the manufacturing process view are important points to focus on. Therefore, examples of the joining techniques in automation presented are given here.

The joining processes can be divided into various classes on the basis of several criteria:

- Constructional criteria: strength, form, and material closure connections or combinations of these possibilities
- Disassembly criteria: in removable and nonremovable connections
- Use of auxiliary joining part, e.g., screws
- Influence of temperature on the parts

Some important joining techniques and applications are presented below. Pros and cons of the joining techniques will be discussed in regard to the features of function, application, and assembly.

2.2.2. Bolting

Screwing is one of the most frequently used joining processes in assembly. Screwdriving belongs in the category of removable connections (ICS 1993). Joinings are removable if the assembly and separation process can be repeated several times without impairing the performance of the connection or modifying the components. The specific advantages of detachable connections are easy maintenance and repair, recycling, and allowing a broad spectrum of materials to be combined.

The most important component of the bolt connection is the screw as the carrier of substantial connecting functions and the link between the components. The screw's function in the product determines its geometrical shape and material. Important characteristics of a screw are the form of thread, head, shaft end, tensile strength, surface coating, tolerances, and quality of the screw lots.

Screwing can be manual, partly automated, or fully automated. The bolting tools used can be classified according to structural shape, control principle, or drive. Substantial differences occur in the drive assigned, which can be electric, pneumatic, or hydraulic (only for applying huge torques). Figure 12 shows the basic structure of a pneumatic screwdriving tool.

A basic approach is to increase the economy of automated screwing systems and reduce deadlock times. Process stabilization can be achieved by using fast control loops in process control and diagnostic support of the operators for error detection and recovery (see Figure 13) (Steber 1997). Further, position errors of the parts can be compensated automatically by adaptation of the coordinate

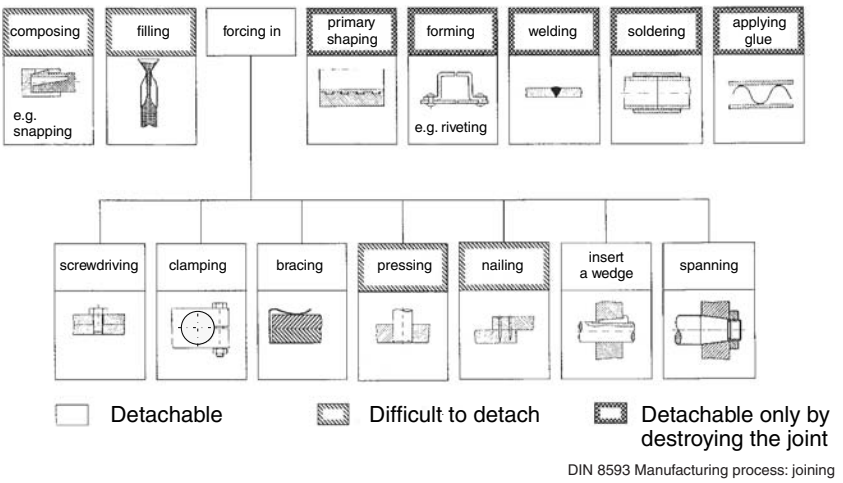

Figure 11 Survey of Joining Technologies.

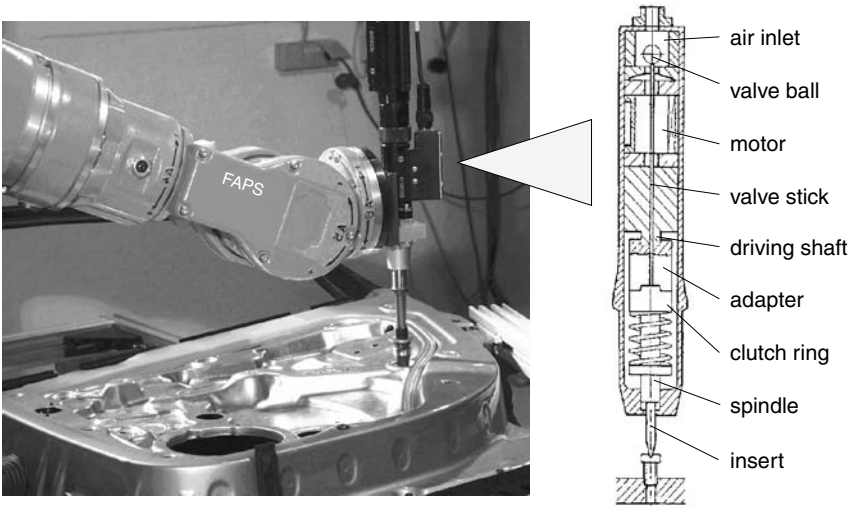

Figure 12 Structure of a Pneumatic Screwdriving System.

system in flexible handling systems, such as robots and image-processing systems. The automated screwing technique is becoming more and more important in mass or serial production. Apart from reduction unit costs, longer production times, and higher output, it offers the advantage of continuously high quality that can be documented.

2.2.3. Riveting/Clinching

Riveting is one of the classical joining processes. It is in particularly wide use in the aircraft industry. What all rivet methods have in common is that an auxiliary joining part, the rivet, must be provided. Blind rivets are often used in device assembly because accessibility from one side is sufficient.

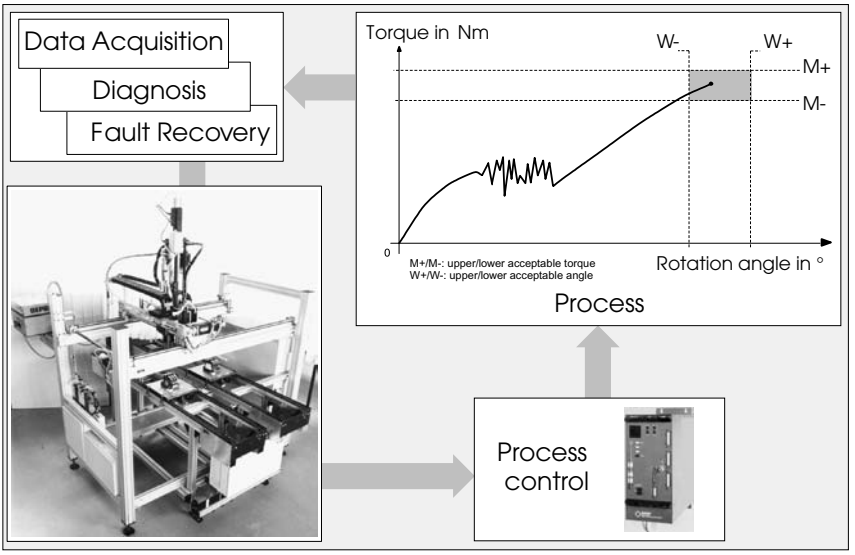

Figure 13 Optimized Process Control of a Screwdriving Machine.

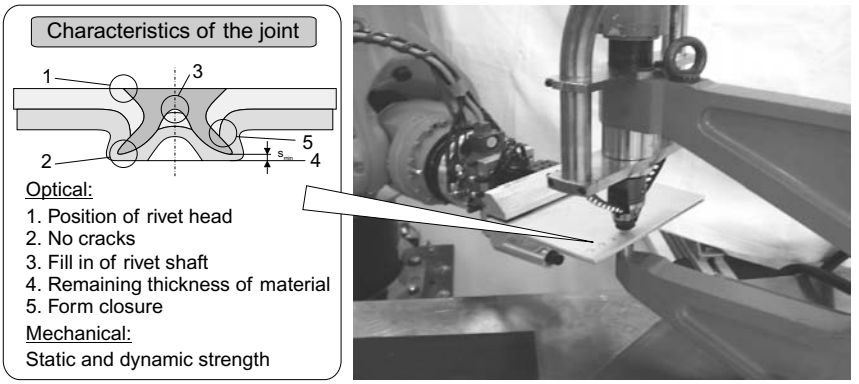

Figure 14 Characteristics of Punching Rivets.

Recently the punching rivet method has become increasingly important in the automobile industry. It is one of the joining processes with less heat influence on the material than with spot welding (Lappe 1997). The advantage of this technique is that no additional process step for punching the hole into the parts is necessary. The punching rivet itself punches the upper sheet metal, cuts through, and spreads in the lowest metal sheet. Figure 14 shows the profile of a punching rivet with typical characteristics for quality control. It is characterized by the fact that different materials, such as metal and aluminum, can be combined. The use of new lightweight design in automotive manufacturing means that materials such as aluminum, magnesium, plastics, and composites are becoming increasingly important. Audi, with the introduction of the aluminum space frame car body concept, is a pioneer in the application of punching rivets.

In clinching, the connection is realized through a specially designed press-driven set of dies, which deforms the parts at the join to provide a friction-locked connection. No auxiliary jointing part is necessary, which helps to save costs in supply and refill of jointing parts.

2.2.4. Sticking

Figure 15 shows a comparison of various destructive detachable joining technologies. The progress in plastics engineering has had positive effects on the engineering of new adhesives. Sticking is often

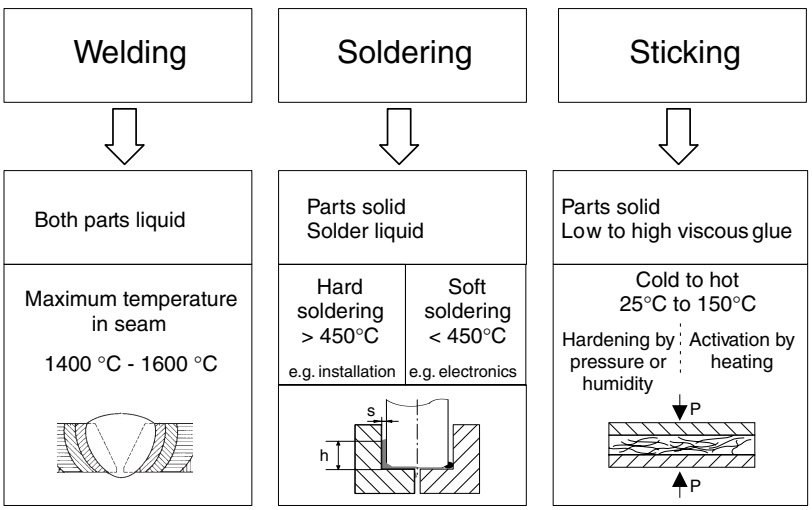

Figure 15 Comparison of Joining Technologies That Are Detachable Only by Destruction.

used in combination with other joining processes, such as spot welding and punching rivets. The connection is made by adhesion and cohesion (Spur and Stöferle 1986).

Adhesives can be divided into two groups. *Physically* hardening adhesives achieve adherence by two different mechanisms. The first is by cooling of the melted adhesive, and the second is by the evaporation of solvent or water (as the carrier) out of the adhesive. Because the adhesive does not interlace, it is less resistant to influences such as heating up, endurance stress, or interaction of solvent. *Chemically* hardening adhesives solidify themselves by a chemical reaction into a partially interlaced macromolecular substance characterized by high firmness and chemical stability. Adhesives can also be differentiated into aerobic and anaerobic adhesives.

The quality and firmness of an adhesive depends on the conditions at the part surface. The wettability and surface roughness of the parts, as well as contamination (e.g., by oil), play a substantial role. To ensure quality of sticking, therefore, often a special surface treatment of the jointing parts is necessary. This represents an additional process step, which can be automated too. Typically, car windows are automatically assembled into the car body in this way.

2.2.5. Welding

Welding methods can be subdivided into melt welding and press welding methods. In melt welding, such as arc welding, metal gas-shielded welding (e.g., MIG, MAG) or gas fusion welding, the connection is made by locally limited heating to just above the liquidus temperature of the materials. The parts that should be connected and the usually used additional welding materials flow together and solidify. In *pressure welding,* such as spot welding, the connection is realized by locally limited heating followed by pressing or hammers. Welding methods differ according to their capacity for automation. In the building of car bodies, fully automated production lines with robots are usually already in use. Fusion welding, such as gas-shielded arc welding, makes higher demands on automation. Therefore, robots are suitable, which should be also equipped with special sensors for seam tracking. Therefore, both tactile and contactless sensors (e.g., optical, capacitive, inductive) are used. With the increasing power density of diode lasers, laser beam welding with robots is becoming much studied.

2.3. Peripheral Functions

2.3.1. Handling Devices

For complex operations, industrial robots are normally used. If the handling task consists of only a simple pick-and-place operation, specially built devices with one or more linear axes are probably the better choice. These *handling devices* are classified by their degrees of freedom (DOF), which indicate the number of possible translational and rotational movements of a part. Therefore, six DOF—three translational and three rotational—are required to arrange an object in a defined way in a 3D room. Opening and closing of grippers is not counted as a degree of freedom, as this movement is used only for clamping and does not, strictly speaking, move the part.

Mechanically controlled inserting devices offer one to two DOF. They are suitable for simple handling tasks, such as inserting. Due to their strict mechanical setup, they are compact, robust, and very economical. Their kinematics allows them to reach different points with a predefined, mechanically determined motion sequence. This motion can be adapted to the different handling tasks by the use of different radial cams (control curves). Due to the sensor-less mechanical setup, it is an inherent disadvantage of the system that the precision of the movement is not very high. In an open control loop, only the end positions are detected by sensors.

If the handling task demands higher accuracy or flexibility, numerically controlled (NC) axes or industrial robots are recommended. Using two or three linear axes allows more complex and precise handling tasks to be performed than with mechanical handling devices.

Industrial robots are built in different setups. The most common are the SCARA (selective compliance assembly robot arm) robot and the six-DOF robot. The SCARA robot usually has four DOF, three translational and one rotational, whereas the z-stroke represents the actual working direction. The other axes are used for positioning. SCARA robots are often used for assembling small parts automatically with very short cycle times. Six-DOF robots are used for more complex tasks because they are more flexible in their movements so they can grip parts in any orientation.

2.3.2. Grippers

Grippers have to perform different tasks. Not only do they have to lock up the part to be handled (static force), but they also have to resist the dynamic forces resulting from the movement of the handling device. They also have to be made so that the parts cannot move within them. Additional characteristics such as low weight, fast reaction, and being fail-safe are required. There are different techniques for gripping parts. Grippers are typically classified into four groups by performing principle (Figure 17): mechanical, pneumatic, (electro-) magnetic, and other. With a market share of 66%,

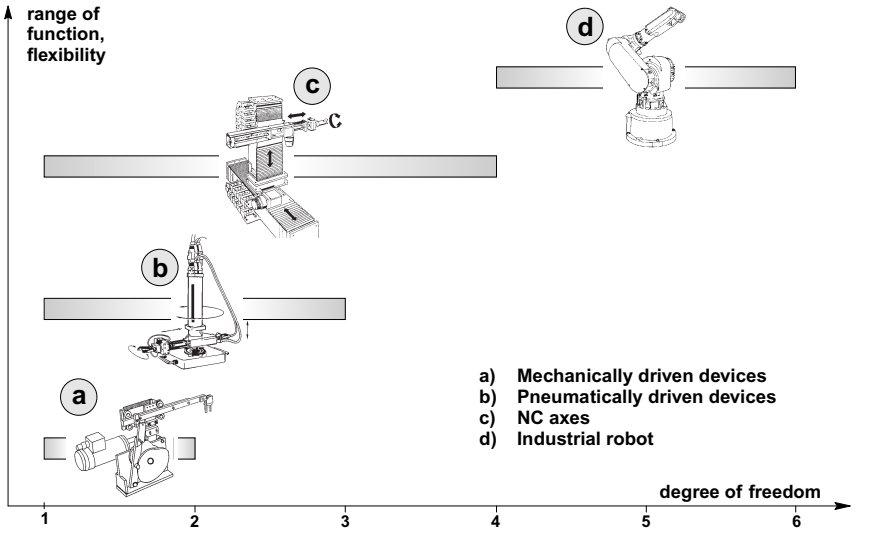

Figure 16 Degrees of Freedom of Alternative Handling Devices.

mechanical grippers are the most commonly used. Mechanical grippers can be subdivided by their kind of closing motion and their number of fingers. Three-finger-centric grippers are typically used for gripping round and spherical parts. Two-finger-parallel grippers perform the gripping movement with a parallel motion of their fingers, guaranteeing secure gripping because only forces parallel to the gripping motion occur.

Because these gripper models can cause harm to the component surface, vacuum grippers are used for handling damageable parts. Two-dimensional parts such as sheet metal parts are also handled by vacuum grippers. Using the principle of the Venturi nozzle, an air jet builds up a vacuum in the suction cup that holds the parts. When the air jet is turned off, the parts are automatically released.

Heavy parts such as shafts are lifted not by mechanical grippers but with electromagnetic grippers. However, secure handling, not exact positioning, is needed when using these grippers.

To handle small and light parts, grippers using alternative physical principles, such as electrostatic and adherent grippers, are used because they do not exert any pressure that could cause damage to the part. Fields of application include microassembly and electronics production.

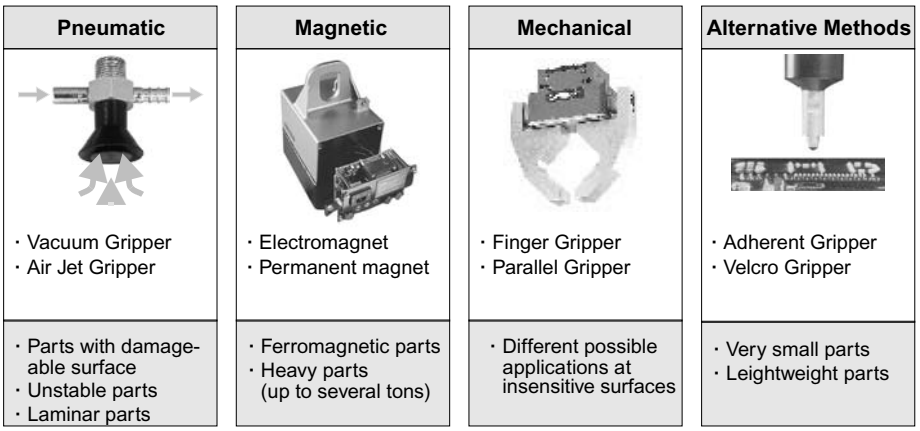

Figure 17 Different Kinds of Grippers. (Sources: Sommer, Truninger, Schunk, ipa)

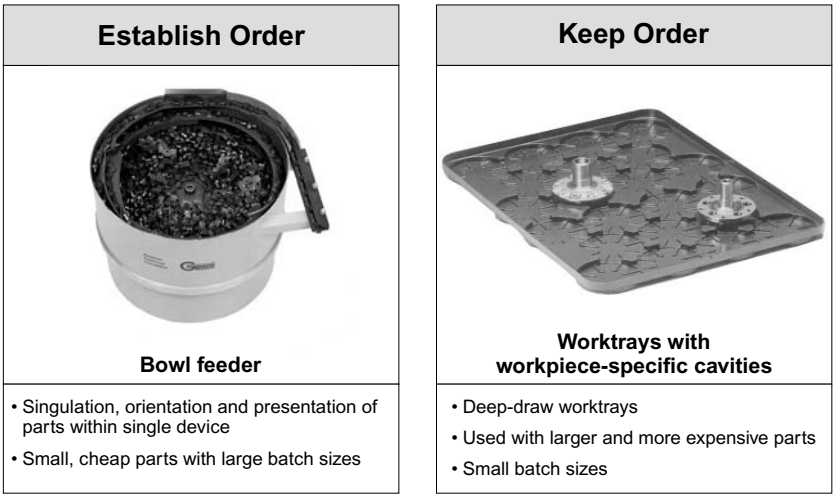

Figure 18 Establish Order-Keep Order. (Source: Bowl feeder, Grimm Zufuhrtechnik GmbH & Co.)

Security of the gripped parts and the workers is an important consideration. Toggle lever grippers, for example, ensure that the part cannot get lost even if a power failure occurs. In contrast, parts handled by vacuum grippers fall off the gripper if the air supply fails.

2.3.3. Feeding Principles

To be gripped automatically, parts have to be presented to the handling device in a defined position and orientation irrespective of the above-mentioned gripping principles. For small parts, which are assembled in high volumes, the vibratory bowl feeder is commonly used. This feeder integrates three different tasks: singulation, orientation, and presentation.

The parts are stored in the bowl feeder as bulk material in the bunker, which is connected via a slanted feeding track to the pick-up point. Using suitable vibrations generated by lamellar springs through an electric motor, the parts move serially toward the pick-up point. The movement is a result of the superposition of micro-throws and a backwards slide.

A disadvantage of the bowl feeder is that the parts may be damaged by the micro-throws and the relative movement and contact between the parts and between the single part and the surface of the bowl feeder. Additionally, this feeding principle leads to the annoyance of noise. Another disadvantage is that the bowl feeder is extremely inflexible with regard to different parts because it is strictly constructed for the use of one special part. Also, it is not yet possible to automate the process of constructing a bowl feeder. Rather, whether the bowl feeder will meet the requirements is up to the experience and skill of the person constructing it. Nevertheless, this is and will continue to be one of the most important feeding technologies for small parts.

Larger and more expensive parts, or parts that must not be damaged on their surface can be presented to the handling device palletized by using deep-draw work trays.

Generally speaking, a degree of orientation, once reached, should never be allowed to be lost again, or higher costs will result.

2.3.4. Linkage

Normally a product is not assembled and produced by only one machine. Therefore, multiple handling devices, machines, and processes have to be arranged in a special way. The different ways of doing this are shown in Figure 19. The easiest, which has been widely used since the industrial revolution, is the loose linkage. This is characterized by the use of discrete ingoing and outgoing buffers for each machine or process. It is thus possible to achieve independence for the different cycle times. Disadvantages are that very high supplies are built up and the flow time is very high. An advantage is that the production will keep running for some time even if one machine fails, because the other machines have supplies left.

The stiff linkage works the opposite way. The workpieces are transported from station to station without a buffer in between. The corresponding cycle time is equal to the process time of the slowest machine. As a consequence, if one machine is out of order, the whole production line has to be

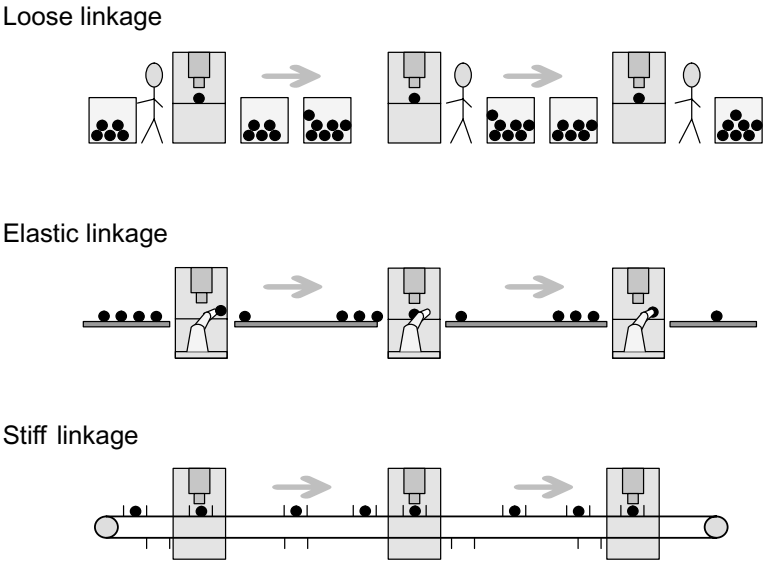

Figure 19 Different Possibilities for Linking Assembly Cells.

stopped. A well-known application of this principle can be found in automobile production, where, because there are no bypasses, the whole assembly line has to be stopped if problems occur at any working cell.

The elastic linkage can be seen as a combination of the other two. The stations are connected by different transports (belts, live roller conveyors, etc.). Because the single transports are not connected with each other, they can be used as additional buffers. The failure of one machine does not necessarily cause the whole production line to be stopped.

2.4. Manual Assembly Systems

2.4.1. Description of Manual Assembly Systems and Their Components

Manual assembly systems are often used within the area of fine mechanics and electrical engineering. They are suitable for the assembly of products with a large number of versions or products with high complexity. Human workers are located at the focal point of manual assembly systems. They execute assembly operations by using their manual dexterity, senses, and their intelligence. They are supported by many tools and devices (Lotter 1992). The choice of tools depends on the assembly problem and the specific assembly organization form. The most frequently used forms of organization are, on the one hand, assembly at one separate workstation, and, on the other, the flow assembly with chained assembly stations. Assembly at only one workstation is also an occasional form of assembly organization. The choice of the form of organization depends on the size of the product, the complexity of the product, the difficulty of assembly, and the number of units.

Workstations are used for small products or modules with limited complexity and a small number of units. High version and quantity flexibility are the most important advantages. Also, disturbances affect other workstations to only a small extent.

The components for the basic parts and the assembly parts are the substantial constituents of manual assembly systems. The assembly parts are often supplied in grab containers. The distances to be covered by the workers arms should be short and in the same direction. The intention is to shorten the cycle time and reduce the physical strain on the workers. This can be realized by arranging the grab containers in paternoster or on rotation plates. Further important criteria are glare-free lighting and adapted devices such as footrests or work chairs (Lotter and Schilling 1994).

When assembly at a workstation is impossible for technological or economical reasons, the assembly can be carried out with several chained manual assembly stations (Lotter 1992). Manual assembly systems consist of a multiplicity of components, as shown in Figure 20. The stations are chained by double-belt conveyors or transport rollers. The modules rest on carriers with adapted devices for fixing the modules. The carriers form a defined interface between the module and the

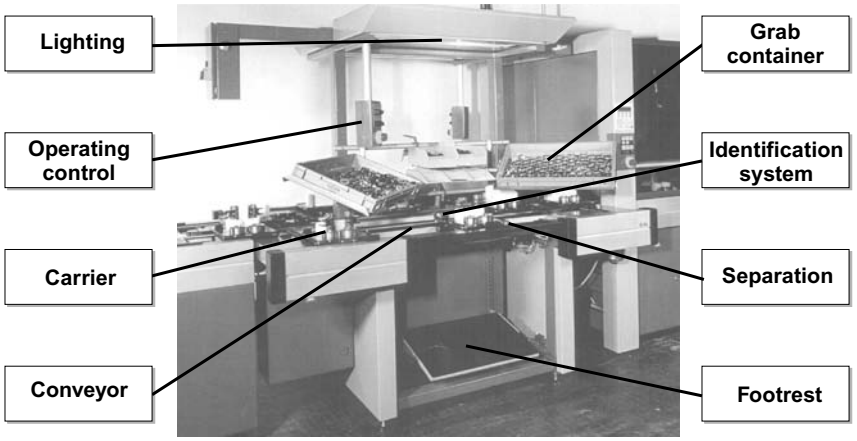

Figure 20 Components of Manual Assembly Systems. (Source: Teamtechnik)

superordinate flow of material. For identifying the different versions, the carriers can be characterized. Identification systems separate the different versions and help to transport them to the correct assembly stations.

2.4.2. Criteria for the Design of Manual Assembly Systems

There are many guidelines, tables, and computer-aided tools for the ergonomic design of workstations. The methodology of planning and realizing a manual workstation is shown in Figure 21.

The following criteria have to be considered in designing manual assembly systems.

- Design of the workstation (height of the workbench and work chair, dimensions of the footrest, etc.)
- Arrangement of the assembly parts, tools, and devices
- Physical strain on workers (forces, torque, noise)

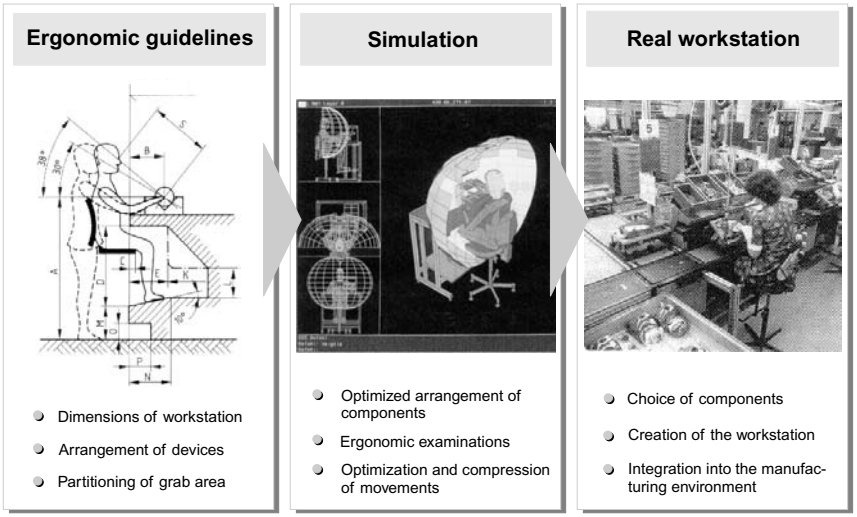

Figure 21 Ergonomic Design of Manual Workstations. (Source: Bosch)

Ergonomic design requires the adjustment of the work height, chair height, grab distance, and so on to the human dimensions. It should be possible for workers to do the work by sitting or standing (Konold and Reger 1997). To ensure that most of the possible workers work under ergonomic conditions, the human dimensions between the 5th and 95th percentiles are considered in designing manual workstations.

One of the most important criteria is the organization of the assembly sequences. The assembly operation should be easy and require little force to be exerted by the worker. Devices like a screwdriver can reduce physical strain on the worker. An optimized arrangement of the assembly parts and components can rationalize the movements. Therefore, the grab room is partitioned into four areas (Lotter 1992):

1. The grab center
2. The extended grab center
3. The one-hand area
4. The extended one-hand area

Assembly should take place in the grab center because both hands can be seen. Part supply should be in the one-hand area.

The forces and torque also have to be considered. Overstressing the worker with too great or too extended physical strain is not permitted. The maximum limit values for static and dynamic load depend on the frequency of the operation, the hold time, and the body attitude. Further correction factors are sex, age, and constitution of the worker.

Today many possible forms of computer-aided tools have been developed for optimization of devices, minimization of forces, time registration, and simplification of movements. They also enable shorter planning time, minimized planning costs, and extended possibilities for optimization of movements (Konold and Reger 1997).

2.5. Automated Assembly Systems

Automated assembly systems are used mainly for the production of series and mass-produced articles. In the field of indexing machines, a distinction is made between rotary indexing turntables and rectilinear transfer machines. The essential difference between the two systems is the spatial arrangement of the individual workstations.

Rotary indexing turntables are characterized by short transport distances. Therefore, high clock speeds are possible. The disadvantage is the restricted number of assembly stations because of the limited place. Rectilinear transfer machines can be equipped with as many assembly stations as needed. However, the realizable cycle time deteriorates through the longer transport distances between the individual stations.

Indexing machines are characterized by a rigid chain of stations. The construction design depends mostly on the complexity of the product to be mounted. The main movements (drives for transfer systems) can be effected from an electrical motor via an adapted ratchet mechanism or cam and lever gears or can be implemented pneumatically and/or hydraulically. Secondary movements (clamping

Figure 22 Rectilinear Transfer Machine with High Productivity. (Source: IMA Automation)

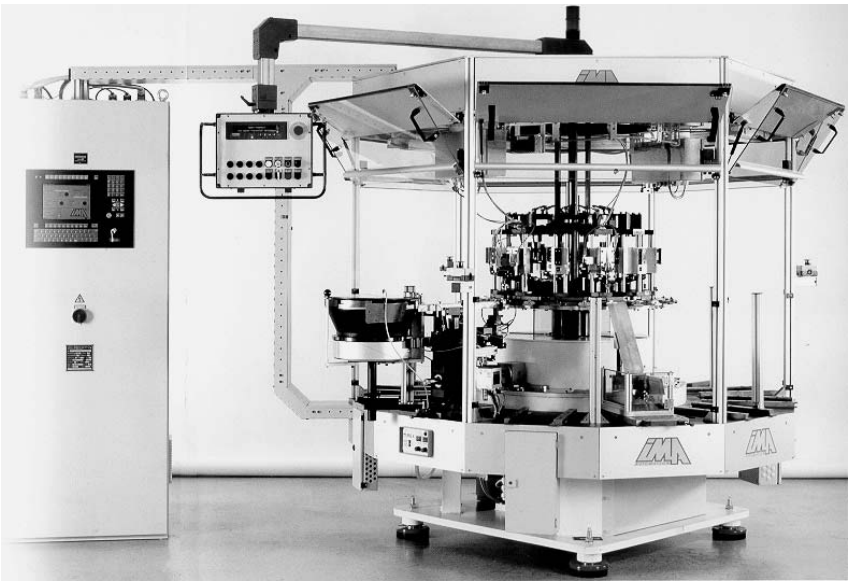

Figure 23 Rotary Indexing Turntable for an Efficient Assembly of Mass-Produced Articles. (Source: IMA Automation)

of parts, etc.) can be carried out mechanically (e.g., via cam and lever gears), electromechanically, or pneumatically. The handling and assembly stations are often driven synchronously over cam disks. If small products are assembled under optimal conditions, an output of up to 90 pieces/min will be possible. However, this presupposes a products design suitable for the automation, vertical joining direction, easy-to-handle components, processes in control, and a small number of product variants. The total availability of the assembly system is influenced by the availability of the individual feeding devices.

The number of stations needed depends on the extent of the single working cycles that have to be carried out (e.g., feeding, joining, processing, testing, adjusting). Therefore, the decision between rotary indexing and rectilinear transfer machines depends not only on the necessary number of workstations and the required space but also on the entire assembly task. On the one hand, short cycle times and high accuracy during the assembly of small products can be achieved by using typical indexing machines. On the other hand, only the assembly of mass-produced articles and small product variants is possible. Normally the reusability of the individual components is also very small. Consequently, these product-specific special-purpose machines can only be amortized heavily.

In order to balance this disadvantage, modern rotary indexing turntables are available on the market. These have higher flexibility, greater reusability, easier reequipping, and higher modularity. The product-independent components (basic unit with the drive, operating panel, protective device, control box, control system, transport unit) should be strictly separated from the product-dependent components (seat, handling and assembly modules). Defined and standardized interfaces are very useful for integrating the product-specific components into the basic system very quickly and with little effort. With modular construction, it is possible to combine the high capability of the indexing machines with economical use of the resources.

2.6. Flexible Assembly Systems

Different objectives can be pursued in order to increase the flexibility of assembly processes. One the one hand it may be necessary to handle different workpieces, on the other hand different versions of one product may have to be produced in changing amounts. Another contribution to flexibility is to use the advantages of off-line programming in order to optimize cycle time when the product manufactured is changed.

2.6.1. Assembly of Different Versions of a Product in Changing Amounts

For producing changing amounts of different versions of a product, an arrangement as shown in Figure 24, with a main assembly line to which individual modules from self-sufficient manufacturing

Figure 24 Flexible Manufacturing of Different Versions of a Product in an Assembly Line. (*Source:* Siemens)

cells are supplied, is very suitable. In order to decouple the module manufacturing from the main assembly line with respect to availability of the different modules, a storage unit is placed between module assembly and main assembly line to keep necessary numbers of presently needed versions of the modules permanently ready. Thus, even lot size 1 can be manufactured and at the same time the system remains ready for use even when one module of a module line fails. The individual manufacturing cells are connected by a uniform workpiece carrier-transport system, whereby the workpiece carriers—which are equipped with memory capacity—function as means of transport, assembly fixtures, and for product identification simultaneously. As the workpiece carriers are equipped with a mobile memory, all necessary manufacturing and test data are affiliated with the product through the whole process. Thus, the product data are preserved, even if the system controller breaks down.

2.6.2. Flexible Handling Equipment

Figure 25 shows an industrial robot with six DOF as an example of handling equipment with great flexibility of possible movement. Especially in the automobile industry, flexible robots are commonly used, and a further increase in investment in automation and process control is predicted. Robots are introduced in automobile assembly to reduce strenuous tasks for human workers, handle liquids, and precisely position complicated shapes. Typical applications include windshield-installation, battery mounting, gasoline pouring, rear seat setting, and tire mounting. Another important application where the flexibility of a robot is necessary is manufacturing automobile bodies with stop welding. In order to reach each point in the workspace with any desired orientation of the welding tongues in the tool center point, at least three main axes and three secondary axes are necessary. Because now each point of the workspace with each orientation can be reached, all kinds of workpieces can be handled and assembled.

2.6.3. CAD-CAM Process Chain

In traditional production processes such as lathing and milling, numerical control is widespread and process chains for CAD-based programming of the systems are commonly used. In contrast, winding

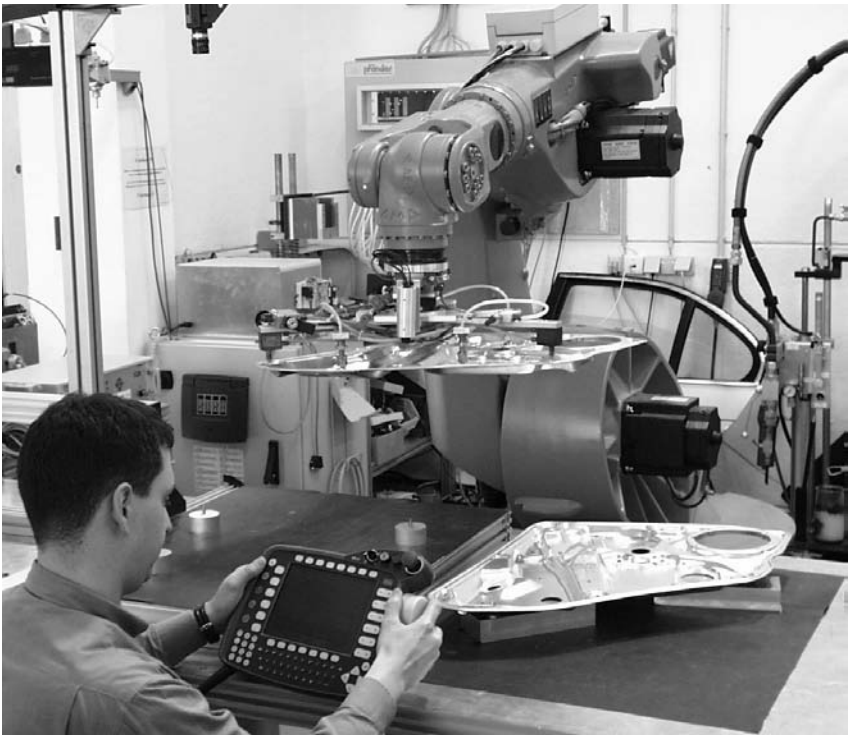

Figure 25 Most kinds of Workpieces can be assembled by an Industrial Robot Because of Its Great Flexibility of Movements.

systems are even now often programmed using the traditional teach-in method. Figure 26 shows a winding system for which a CAD-CAM process chain has been developed by the Institute for Manufacturing Automation and Production Systems in order to increase flexibility with respect to product changes. The disadvantages of on-line programming are obvious: because complex movements of the wire-guiding nozzle are necessary while the wire is fixed at the solder pins and guided from the pin to the winding space, considerable production downtimes during programming result. Furthermore collisions are always a danger when programming the machine with the traditional teach-in method. The tendency for lower production batches and shorter production cycles combined with high investment necessitates a flexible off-line programming system for assembly cells such as winding systems. Therefore a general CAD-CAM process chain has been developed. The process chain allows the CAD model of the bobbin to be created conveniently by adding or subtracting geometric primitives if necessary. Afterwards the path of the wire-guiding nozzle is planned at the CAD workstation, where the user is supported by algorithms in order to avoid collisions with the bobbin or the winding system. Simulating the wire nozzle movements at the CAD system allows visual and automated collision detection to be carried out. If a collision occurs, an automatic algorithm tries to find an alternative route. If no appropriate path can be calculated automatically, the wire nozzle movements can be edited by the user. To this point, the result of this CAD-based planning system is a data file that is independent from the winding machine used. A postprocessor translates this file into a machine-specific data file, which is necessary for the numerical control of the winding system. This fault-free NC data file can be sent from the CAD workstation to the machine control unit via network, and the manufacturing of the new product can start (Feldmann and Wolf, 1996, 1997; Wolf 1997).

2.7. Control and Diagnosis

Despite major improvements in equipment, advanced expertise on assembly processes, and computer-aided planning methods, assembly remains susceptible to failure because of the large variety of parts and shapes being assembled and their corresponding tolerances. Computer-aided diagnosis makes a substantial contribution to increasing the availability of assembly systems. Assuring fail-safe processes will minimize throughput times and enable quality targets to be achieved.

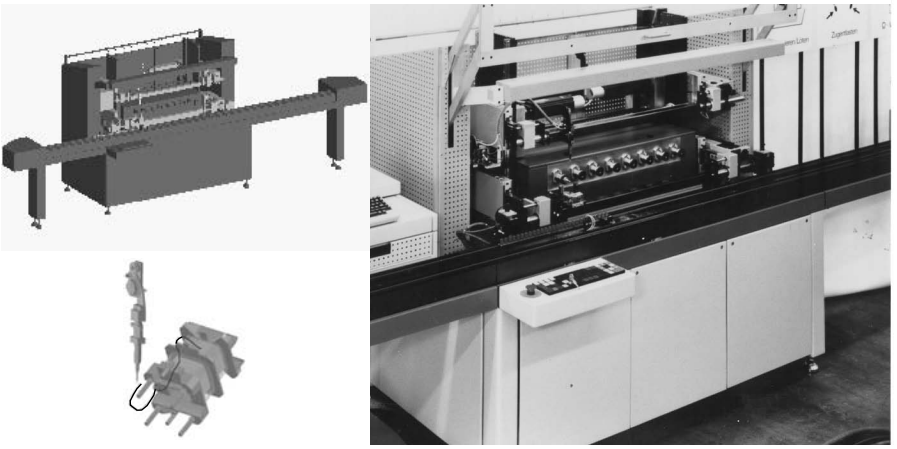

Figure 26 Flexible Automation in Winding Technology Using Off-Line Programming.

Diagnosis includes the entire process chain of failure detection, determination of the cause of failure, and proposal and execution of measures for fault recovery. Realizing and operating a high-performance diagnosis system requires comprehensive acquisition of the assembly data. For this purpose, three different sources of data entry in assembly systems can be used. First, machine data from controls can be automatically recorded. Second, for extended information, additional sensors based on various principles can be integrated into the assembly system. Third, the data can be input manually into the system by the operator.

Diagnosis systems can be divided into signal-based, model-based, and knowledge-based systems. A crucial advantage of knowledge-based systems is the simple extendability of the database, for example concerning new failures. Therefore, they are frequently used with assembly systems.

Dependent on the efficiency of the diagnosis system, different hierarchically graded control strategies are possible. In the simplest case, the diagnosis system only supplies information about the occurrence and number of a disturbance. The user must determine the cause of failure and execute

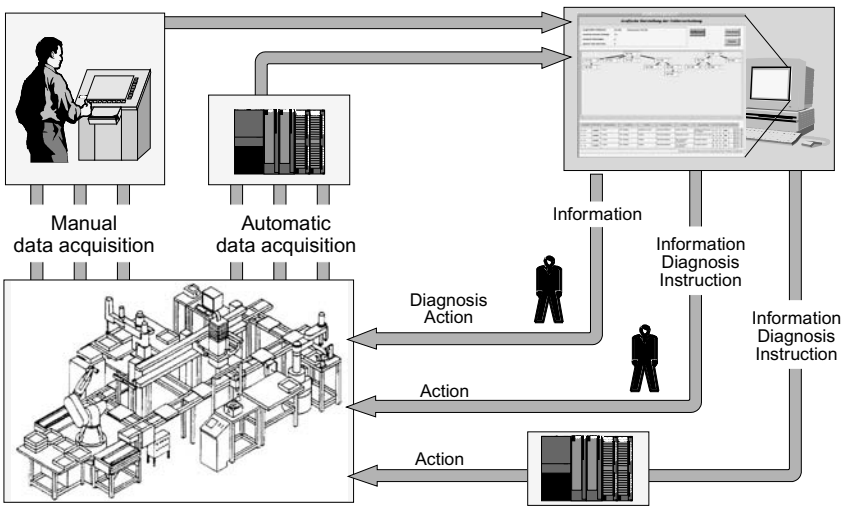

Figure 27 Computer-Aided Diagnosis with Hierarchically Graded Strategies for Fault Recovery.

the fault recovery on his own. Efficient diagnosis systems offer information to the user about the number and location of the failure. Further, appropriate diagnostic strategies are available that allow computer-aided detection of the cause of failure. The systems also suggest appropriate measures for fault recovery. In addition, diagnosis systems can independently initiate reaction strategies after the automatic determination of the cause of failure. These strategies directly affect the control of the assembly system or the assembly process. Due to the particularly high complexity of this procedure, it is applicable only to simple and frequently occurring errors.

3. ELECTRONIC PRODUCTION

3.1. Process Chain in Electronic Production

Production of electronic devices and systems has developed into a key technology that affects almost all areas of products. In the automotive sector, for example, the number of used electronic components has increased about 200,000% during the last 20 years, today accounting for more than 30% of the total value added.

The process chain of electronics production can be divided into three process steps: solder paste application, component placement, and soldering (Figure 28). Solder paste application can be realized by different technologies. The industry mainly uses stencil printing to apply the solder paste. Solder paste is pressed on the printed circuit board (PCB) by a squeegee through form openings on a metal stencil, allowing short cycle times. Several other technologies are on the market, such as single-point dispensing, which is very flexible to changes of layout of PCBs, but leads to long cycle times due to its sequential character.

In the next step the components of surface-mounted devices (SMDs) and/or through-hole devices (THDs) are placed on the PCB. Finally the PCB passes through a soldering process. Traditionally the soldering process can be classified into two groups: reflow and wave soldering. The purpose of reflow processing is to heat the assembly to specified temperatures for a definite period of time so that the solder paste melts and realizes a mechanical and electrical connection between the components and the PCB. Today three reflow methods are used in soldering: infrared (IR), convection, and condensation. A different method of molten soldering is wave or flow soldering, which brings the solder to the board. Liquid solder is then forced through a chimney into a nozzle arrangement and returned to the reservoir. For wave soldering, the SMDs must be glued to the board one step before. The quality of the electronic devices is checked at the end of the process chain by optical and electrical inspection systems (IPC 1996).

The special challenges in electronics production result from the comparatively rapid innovation of microelectronics. The continuing trend toward further integration at the component level leads to permanently decreasing structure sizes at the board level.

3.2. Electronic Components and Substrate Materials

Two main focuses can be distinguished concerning the development of electronic components. With the continuing trend toward function enhancement in electronic assembly, both miniaturization and integration are leading to new and innovative component and package forms. In the field of passive components, the variety of packages goes down to chip size 0201. This means that resistor or capacitor components with dimensions of 0.6 mm $\times$ 0.3 mm have to be processed. The advantages of

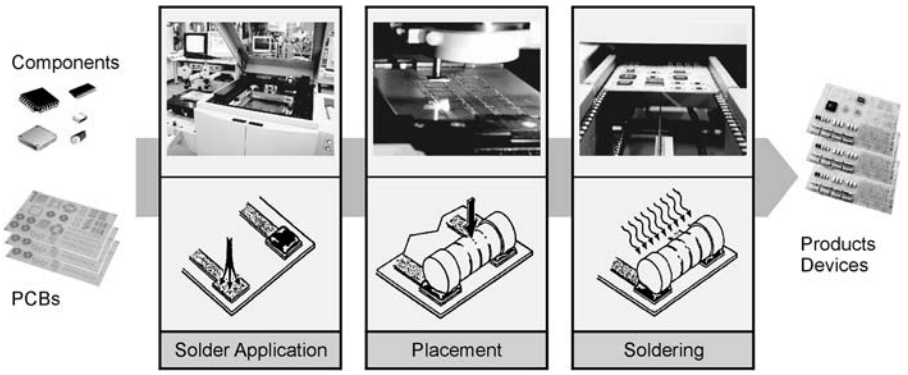

Figure 28 Process Chain in Electronics.

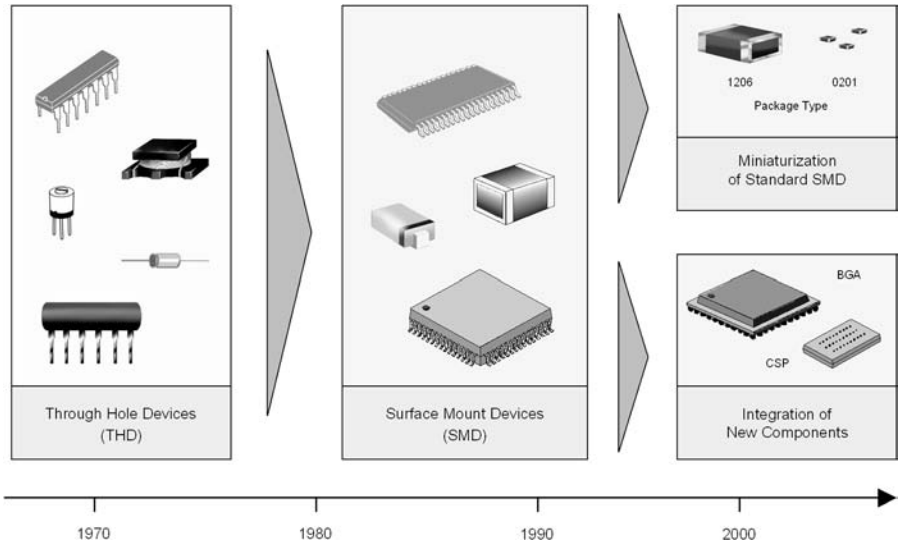

Figure 29 Component Technology: Development through the Decades.

such components are obvious: smaller components lead to smaller and more concentrated assemblies. On the other hand, processing of such miniaturized parts is often a problem for small and medium-sized companies because special and cost-intensive equipment is needed (high-precision placement units with component specific feeders, nozzles, or vision systems).

Regarding highly integrated components two basic technologies should be mentioned. First, leaded components such as quad flat pack (QFP) are used within a wide lead pitch from 1.27 mm down to 300 μm. But these packages with a high pin count and very small pitch are difficult to process because of their damageable pins and the processing of very small amounts of solder. Therefore, area array packages have been developed. Instead of leaded pins at all four sides of the package area, array packages use solder balls under the whole component body. This easily allows more connections within the same area or a smaller package within the same or even a larger pitch. Ball grid arrays (BGAs) or their miniaturized version, chip scale packages (CSPs), are among the other packages used in electronics production (Lau 1993).

Further miniaturization is enabled by direct assembly of bare dies onto circuit carriers. This kind of component is electrically connected by wire bonding. Other methods for direct chip attachment are flip chip and tape automated bonding. All three methods require special equipment for processing and inspection.

In addition to planar substrates, many new circuit carrier materials are being investigated. Besides MID (see Section 4), flexible circuit technology has proved to be a market driver in the field of PCB production. Today, flexible circuits can be found in nearly every type of electronic product, from simple entertainment electronics right up to the highly sophisticated electronic equipment found in space hardware. With growth expected to continue at 10–15% per year, this is one of the fastest-growing interconnection sectors and is now at close to $2 billion in sales worldwide.

However, up to now, most flexible circuit boards have been based on either polyester or polyimide. While polyester (PET) is cheaper and offers lower thermal resistance (in most cases reflow soldering with standard alloys is not possible), polyimide (PI) is favored where assemblies have to be wave or reflow soldered (with standard alloys). On the other side, the relative costs for polyimide are 10 times higher than for polyester. Therefore, a wide gap between these two dominant materials has existed for a long time, prohibiting broad use of flexible circuits for extremely cost-sensitive, high-reliability applications like automotive electronics. Current developments in the field of flexible-base materials as well as the development of alternative solder alloys seem to offer a potential solution for this dilemma.

3.3. Application of Interconnection Materials

The mounting of SMD components onto PCBs or flexible substrates demands a certain amount of interconnection material (solder or conductive adhesive) to form a correct joint. In contrast to wave soldering, where heat and material (molten solder) are provided simultaneously during the soldering

process, reflow soldering of SMDs necessitates the application of solder in the form of paste as the first process step in the assembly line. Also, for interconnections established by conductive adhesive, the application of interconnection material is necessary. This process is a decisive step in electronic device assembly because as failures caused here can cause difficulties during the following process steps, such as component placement and reflow soldering. In modern high-volume assembly lines, stencil printing is the predominant method for applying solder paste to the substrates. Other methods that are used industrially to a minor extent are automatic dispensing and screen printing. Each method has its specific advantages and drawbacks, depending on, for example, batch sizes or technological boundary conditions like component pitch.

The main advantage of stencil printing over screen printing occurs in applications where very small areas of paste have to be deposited. For components with pitches equal to or smaller than 0.65 mm, the stencil printing process is the only viable way for printing solder paste. Therefore, stencil printing has replaced screen printing in most cases.

Dispensing has the advantage over screen and stencil of being highly flexible. For small batches, dispensing may be an economical alternative to printing. On the other hand, dispensing is a sequential process and therefore quite slow. Additionally, paste dispensing for fine-pitch components is limited.

The principle of a stencil printer is shown in Figure 30(*a*). The major components of an automatic screen printer are squeegee blades (material stainless steel or polyurethane), the screen itself, the work nest (which holds the substrate during printing), an automatic vision system for PCB alignment, and sometimes a printing inspection system. During the printing process, solder paste is pressed by a squeegee through the apertures in a sheet of metal foil (attached in frame, stencil) onto the substrate.

Dispensing is an application of solder paste in which separate small dots of paste are deposited onto the substrate sequentially. Dispensing is a good way for applying solder paste when small batches have to be produced. The main advantages are short changeover times for new boards (due to loading only a new dispensing program) and low cost (no different screens are used). Several dispensing methods are realized in industrial dispensing systems. The two dominant principles are the time–pressure dispensing method and the rotary pump method (positive displacement). The principle of dispensing by the time–pressure method is shown in Figure 30(*b*). A certain amount of solder paste is dispensed by moving down the piston of a filled syringe by pressure air for a certain time. The paste flows from the syringe through the needle onto the PCB pad. The amount of solder can be varied by changing the dispensing time and the air pressure.

3.4. Component Placement

Traditional THD technology has nearly been replaced by SMD technology in recent years. Only SMD technology permits cost-efficient, high-volume, high-precision mounting of miniaturized and complex components. The components are picked up with a vacuum nozzle, checked, and placed in the correct position on the PCB.

3.4.1. Kinematic Concepts

Within the area of SMD technology, three different concepts have found a place in electronics production (Figure 31) (Siemens AG 1999). The starting point was the pick-and-place principle. The machine takes one component from a fixed feeder table at the pick-up position, identifies and controls the component, transports it to the placement position on the fixed PCB, and sets it down. New concepts have been developed because pick-and-place machines have not been able to keep pace with the increasing demands on placement rates accompanying higher unit quantities. The original pick-and-place principle process is now only used when high accuracy is required.

The first variant is the collect-and-place principle based on a revolver head (horizontal rotational axis) on a two-axis gantry system. Several components are collected within one placement circle and the positioning time per component is reduced. Additionally, operations such as component centering are carried out while the nozzle at the bottom (pick-up) position is collecting the next component, and the centering does not influence the placement time.

The highest placement rate per module can be obtained with the carousel principle. The most widely used version of this principle uses a movable changeover feeder table and a moving PCB. It is analogous to the revolver principle in that the testing and controlling stations are arranged around the carousel head and the cycle time primarily depends on the collecting and setting time of the components.

High-performance placement systems are available for the highest placement rates, especially for telecommunications products. These systems take advantage of several individual parallel pick-and-place systems. A placement rate of up to 140,000 components per hour can be attained.

3.4.2. Classification of Placement Systems

The classification and benchmarking of placement machines depend on different influence coefficients. In addition to accuracy and placement rate, placement rate per investment, placement rate per needed area, operation, maintenance, and flexibility have to be considered. In the future, flexible

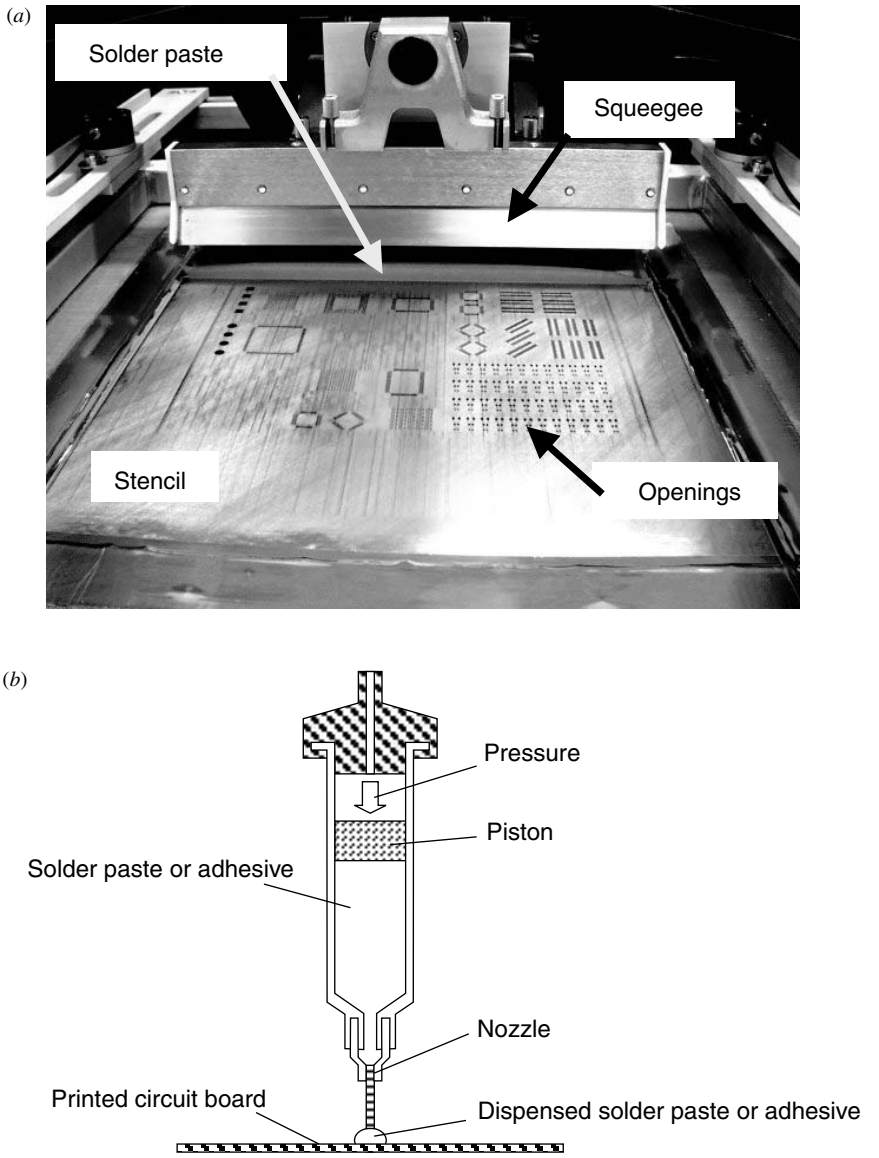

Figure 30 Alternative Principles for Application of Solder Paste. (*a*) Stencil printing. (*b*) Dispensing.

machines with changeable placement heads will be configurable to the current mounted component mix within a short time. The whole line can thus be optimized to the currently produced board in order to achieve higher throughput and reduce the placement costs.

3.4.3. Component and PCB Feeding

An important factor for the throughput and the availability of a placement machine is the component feeding. Depending on package forms, the user can choose between different types of packages (Figure 32). For packages with low or middle complexity, taped components are favored.

With the development of improved feeders, the use of components in bulk cases is becoming more important. Compared to tapes, bulk cases have reduced packaging volume (lower transport and

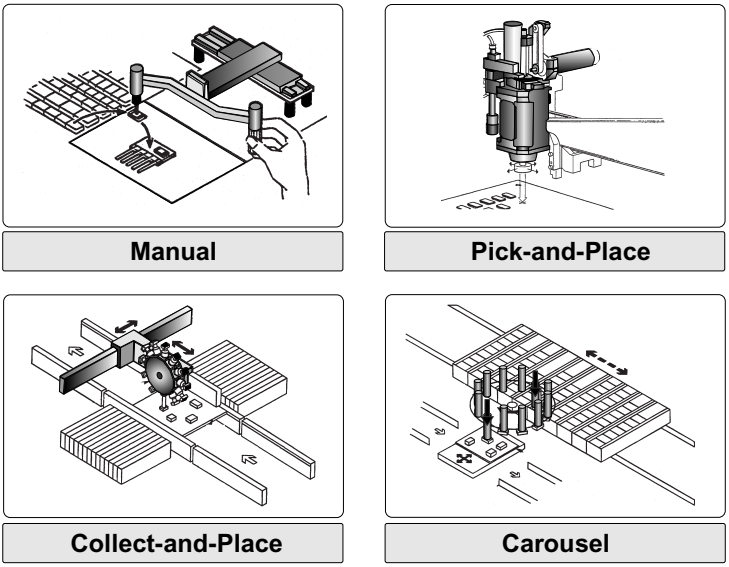

Figure 31 Alternative Concepts for Component Placement.

stock costs) and higher component capacity (less replenishing) and are changeable during the placement process. The components can be disposed with higher accuracy, and the cassette can be reused and recycled. The disadvantages of the bulk cases are that they are unsuitable for directional components and the changeover to other components takes more time and requires greater accuracy.

For feeding complex components, often in low volumes, waffle pack trays are used. Automatic exchangers, which can take up to 30 waffle packs, reduce the space requirement.

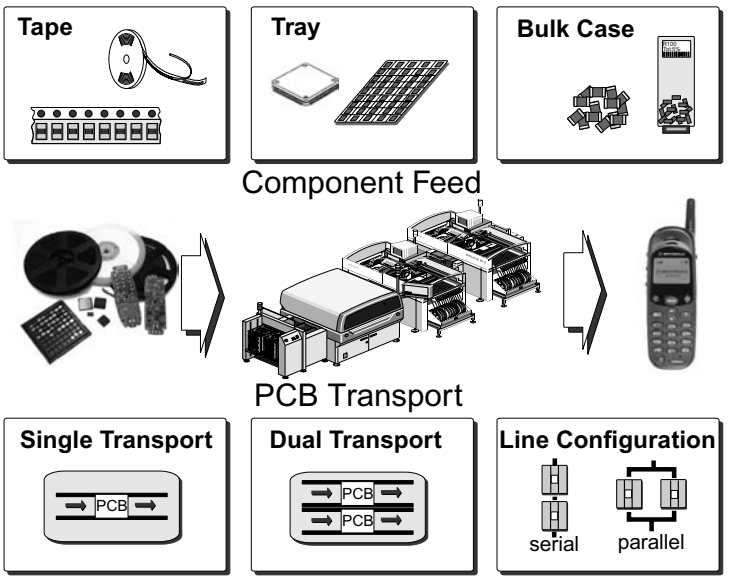

Figure 32 Component and PCB Feeding.

The trend towards more highly integrated components is reducing placement loads for PCBs. As a direct result, the nonproductive idle time (PCB transport) has a greater influence on the processing time and leads to increased placement costs. With the use of a double transport (Figure 32) in asynchronous mode, the transport time can be eliminated. During component placement onto the first PCB, the next PCB is transported into the placing area.

For the optimal placement rate to be achieved, high-performance placement machines have to assemble more than 300 components per board. To reach this optimal operating point of the machine with an acceptable cycle time, the machines are connected in parallel instead of in a serial structure. Parallel machines place the same components. Depending on the product, the placement rate can be raised up to 30%.

3.4.4. Measures to Enhance Placement Accuracy

The trend in component packaging towards miniaturization of standard components and the development of new packages for components with high pin account (fine pitch, μBGA, flip-chip) are increasing requirements for placement accuracy.

For standard components, an accuracy of 100 μm is sufficient. Complex components must be placed with an accuracy better than 50 μm. For special applications, high-precision machines are used with an accuracy of 10 μm related to a normal distribution and at a standard deviation of 4σ. This means, for example, that only 60 of 1 million components will be outside a range of ± 10 μm. Due to the necessity for using a small amount of solder paste with fine-pitch components (down to 200 μm pitch), minimal vertical bending of the component leads (about 70 μm) causes faulty solder points and requires cost-intensive manual repairs.

Each lead is optically scanned by a laser beam during the coplanarity check after the pick-up of the component (Figure 33), and the measured data are compared with a default component-specific interval. Components outside the tolerance are automatically rejected.

Given the increasing requirements for placement accuracy, mechanical centering of PCBs in the placement process will not suffice. The accuracy needed is possible only if gray-scale CCD camera systems are used to locate the position of the PCB marks (fiducials) in order to get the position of the PCB proportional to the placement head and the twist of the PCB. Additionally, local fiducials are necessary for mounting fine-pitch components. Furthermore, vision systems are used to recognize the position of each component before placement (visual component centering) and to correct the positions. Instead of CCD cameras, some placement systems are fitted with a CCD line. The component is rotated in a laser beam and the CCD line detects the resulting shadow.

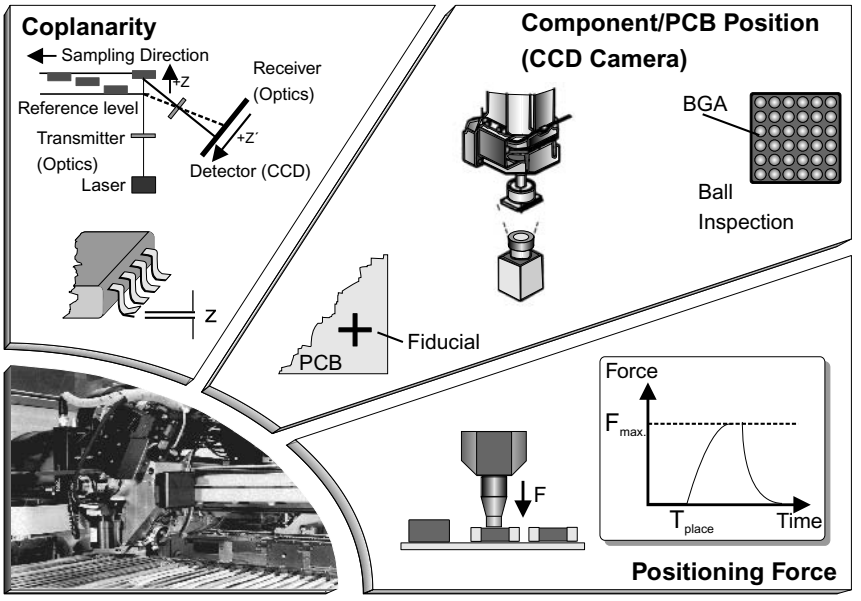

Figure 33 Measures to Enhance Placement Accuracy.

Component-specific illumination parameters are necessary for ball/bump inspection and centering of area array packages.

Direct optoelectronic scanning units are used for the positioning control of the axis to minimize positioning offsets. The glass scales have a resolution up to 1 increment per μm. The influence of the temperature drifts of, for example, the drives can be partly compensated for.

Despite the preventive measures and the high quality of the single systems in placement machines, reproducible errors caused by manufacturing, transport, or, for example, crashes of the placement head during the process must be compensated for. Several manufacturers offer different calibration tools that make inline mapping of the machines possible. Highly accurate glass components are positioned on a calibration board (also glass) with special position marks. The fiducial camera scans the position of the component proportional to the board (resolution about 2–3 μm). Extrapolating a correction value allows the placing accuracy of the machine to be improved.

Fine-pitch components must be placed within a close interval to guarantee sufficient contact with the solder paste but avoid deformations of the leads. Adapted driving profiles are necessary to reach the optimal positioning speed with accelerations up to 4 g, but the last millimeters of the placing process must be done under sensor control to take the positioning power down to a few newtons.

3.5. Interconnection Technology

In electronics production, two main principles of interconnection are used: soldering using metal-based alloys and adhesive bonding with electrically conductive adhesives (Rahn 1993).

Soldering is a process in which two metals, each having a relatively high melting point, are joined together by means of an alloy having a lower melting point. The molten solder material undergoes a chemical reaction with both base materials during the soldering process. To accomplish a proper solder connection, a certain temperature has to be achieved. Most solder connections in electronics are made with conventional mass soldering systems, in which many components are soldered simultaneously onto printed circuit boards. Two different mass soldering methods are used in today's electronics production. Wave or flow soldering is based on the principle of simultaneous supply of solder and soldering heat in one operation. The components on a PCB are moved through a wave of melted solder. In contrast, during reflow soldering process solder preforms, solid solder deposits or solder paste attached in a first operation are melted in a second step by transferred energy.

Figure 34 SMT Placement Line (Siemens Siplace).

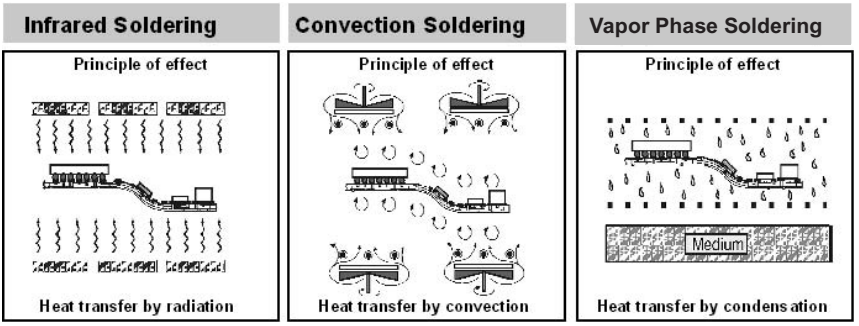

Figure 35 Reflow Soldering Methods.

Used in more than 80% of the electronic components processed worldwide, reflow soldering technology is the predominant joining technology in electronics production. Reflow soldering works satisfactorily with surface mount technology and can keep up with the constantly growing demands for productivity and quality. Current developments such as new packages or the issue of lead-free soldering, however, are creating great challenges for reflow soldering technology.

The reflow soldering methods of electronics production can be divided according to the type of energy transfer into infrared (IR), forced convection (FC), and condensation soldering. In contrast to the other versions of energy transfer, reflow soldering using radiant heating is not bound to a medium (gas, vapor), but is subject to electromagnetic waves. For IR reflow soldering, short- to long-wave infrared emitters are used as energy sources. Although heat transfer established with this method is very efficient, it is strongly influenced by the basic physical conditions. Depending on the absorptivity, reflectivity, and transmissivity of the individual surface, large temperature differences are induced

Figure 36 Soldering Profile.

across the electronic modules. The problem of uniform heat distribution is increased by intricate geometries, low thermal conductivity, and variable specific heat and mass properties of the individual components. Therefore, this soldering method leads to very inhomogeneous temperature distributions on complex boards.

The transfer of energy by means of forced air convection induces a more uniform heat distribution than in IR soldering. The heating up of the workpiece is determined by, in addition to the gas temperature, the mass of gas transferred per time unit, the material data of the gas medium, and by the geometry and thermal capacity of the respective PCB and its components.

Reflow soldering in a saturated vapor (vapor phase or condensation soldering) utilizes the latent heat of a condensing, saturated vapor, whose temperature corresponds to the process temperature, to heat the workpiece. Due to the phase change from vapor to liquid during condensation, the heat transfer is very rapid, resulting in very uniform heating that is relatively independent of different specific heat and mass properties or geometric influences. An overheating of even complex surfaces is impossible due to the nature of vapor phase heating.

Despite the optimization of these mass soldering methods, an increasing number of solder joints are incompatible with conventional soldering methods, so microsoldering (selective soldering) methods have to be used. In the last few years there has been a steady flow of requests for selective soldering. Several systems have been designed and introduced into the market. Depending on the kind of heat transfer, different systems using radiation, convection, or conduction can be distinguished. The most popular selective soldering in modern assembly lines seems to be fountain soldering, a selective process using molten solder. The process is similar to the conventional wave soldering process, with the difference that only a few joints on a PCB are soldered simultaneously.

In contrast to soldering, conductive adhesives are used for special electronic applications. Conductive adhesives simultaneously establish mechanical and electrical joints between PCBs and components by means of a particle-filled resin matrix. Whereas the polymer matrix is responsible for the mechanical interconnection, the filling particles (silver, palladium, or gold particles) provide the electrical contact between PCB and component. Therefore, in contrast to solder joints, conductive adhesive joints have a heterogeneous structure.

3.6. Quality Assurance in Electronics Production

Quality assurance has become a major task in electronics production. Due to the complex process chains and the huge variety of used materials, components, and process steps, the quality of the final product has to be assured not only by tests of the finished subassemblies but also by integrated inspection steps during processing. It is common knowledge that the solder application process causes about two thirds of process-related failures but is responsible for only about 20% of process and inspection costs (Lau 1997). This means that the first step of processing leads to a huge amount of potential failures but is not or cannot be inspected sufficiently. Therefore, a combined strategy for the assembly of complex products such as automotive electronic or communication devices is useful in electronics production (Figure 38). Both capable processes and intelligent inspection tools are needed.

Several optical inspection systems are available that measure, for example, shape and height of the applied solder paste or placement positions of components. These systems, based on image

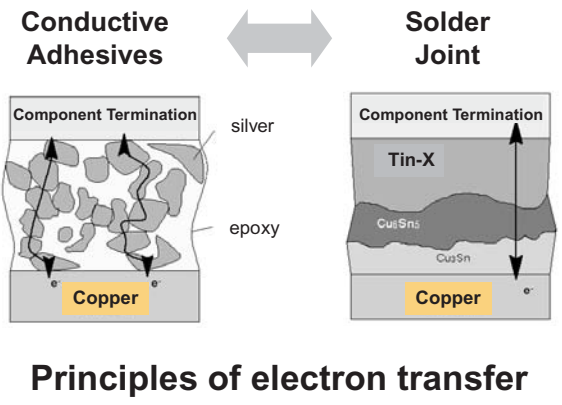

Figure 37 Comparison: Conductive Adhesive—Soldering Interconnection.

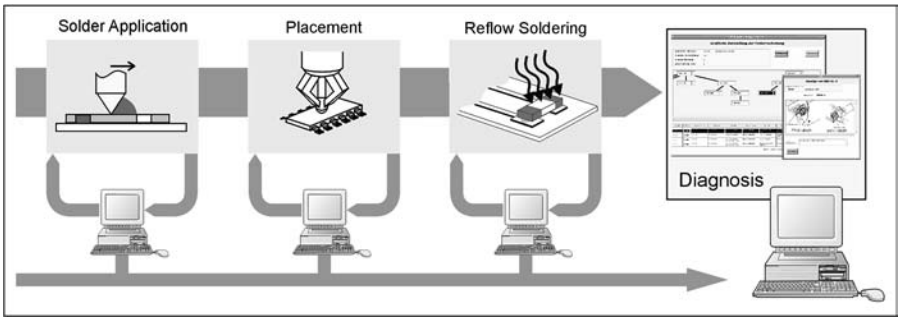

Figure 38 Basic Concept for Accompanying Quality Assurance.

processing with CCD cameras, capture 2D images for analysis. Advanced systems work with 3D images for volume analysis or with x-ray vision for visualization of hidden solder joints (as are typical for area arrays). The main problem with complex inspection strategies is inline capability and the long duration of the inspection itself. As a result, 3D inspection is used almost entirely for spot testing or in scientific labs. On the other hand, inline strategies are often combined with and linked to external systems for quality assurance. These systems are suitable for collecting, handling, and analyzing all relevant data during processing. They allow both short-term control loops within a single step and long-term coordination strategies for optimizing assembly yields. The vital advantage is the direct link between a real product and its database information.

Further tasks of quality assurance systems occur in diagnosis and quality cost analysis. Machine diagnosis is necessary to ensure and enhance machine or process capabilities. Especially, systematic errors such as constant placement offsets can only be detected and regulated by integrated diagnosis sensors. Further, telediagnosis and defect databases are possible. Both support quick and direct removal of problems with the assistance of the machine supplier, who remains distant. Another goal is to calculate process- and defect-related costs in electronics production. With an integrated quality cost-evaluation system, it should be possible to optimize not only quality, but costs as well within one evaluation step. This will finally lead to a process-accompanying system that focuses on technically and economically attractive electronics production.

4. INTEGRATION OF MECHANICAL AND ELECTRONIC FUNCTIONS

The use of thermoplastics and their selective metal plating opens a new dimension in circuit carrier design to the electronics industry: 3D molded interconnect devices (3D MIDs). MIDs are injection-molded thermoplastic parts with integrated circuit traces. They provide enormous technical and economic potential and offer remarkably improved ecological behavior in comparison to conventional printed circuit boards which they will, however, complement, not replace.

4.1. Structure of Molded Interconnect Devices

The advantages of MID technology are based on the broader freedom of shape design and environmental compatibility as well as on a high potential for rationalizing the process of manufacturing the final product. The enhanced design freedom and the integration of electrical and mechanical functions in a single injection-molded part allow a substantial miniaturization of modules to be obtained.

The rationalization potential comes from reduced part and component counts and shortened process chains. In several applications, it was possible to replace more than 10 parts of a conventional design solution with a single MID, thus reducing assembly steps and material use. Further potential lies in the increased reliability.

Additional advantages are obtainable regarding environmental compatibility and electronics waste-disposal regulations. MID technology allows the material mixture of a (conventional) combination of PCB and mechanical parts, which usually consist of a great number of materials, to be replaced by a metallized plastic part (MID). MIDs are made of thermoplastics, which can be recycled and are noncritical in disposal (Franke 1995).

The novel design and functional possibilities offered by MIDs and the rationalization potential of the respective production methods have inevitably led to a quantum leap in electronics production. The most important functions that can be integrated into an MID are depicted in Figure 39. So far, cost savings of up to 40% have been achieved by integration, depending, of course, on the specific product, lot sizes, and other boundary conditions.

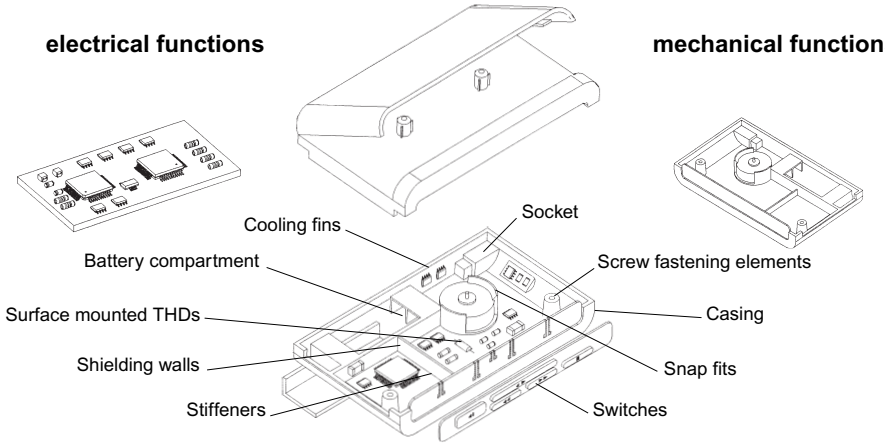

Figure 39 Advantages of MID Technology.

Key markets for MID technology are automotive electronics and telecommunication. MIDs are also suitable for use in computers, household appliances, and medical technology. The market currently shows an annual growth rate of about 25%.

Typically high geometrical and functional flexibility make MID suitable for applications in peripheral integrated electronics, such as small control units and portable devices. Past and present MID products bear this out. Standard electronics applications with high component density and multiple layers, such as motherboards in computers, will continue to be produced with conventional technologies.

MID product development shows a trend towards the implementation of MIDs in new fields of application. Examples include components in the telecommunications and computer industries, security-relevant parts in the automotive industry, and customized packages in components manufacturing (Figure 40) (Pöhlau 1999).

4.2. Materials and Structuring

The MID process chain can be divided in four main steps: circuit carrier production, metallization and structurization, component mounting, and finally joining of electronic components. A number of alternative technologies are available for each step.

Some of the production technologies are specific MID technologies, such as two-shot molding and hot embossing. Others are established processes in electronic production that have been altered and adapted to the requirements of MID. During the planning phase of a MID product it is necessary to choose a combination of the single process steps most suitable for the situation, given their respective benefits and limitations.

MIDs can be manufactured in a variety of ways, as shown in Figure 41.

Hot embossing is characterized by low investment for the embossing die or stamp and high efficiency. The layout is applied following injection molding. Because no wet chemistry is needed, hot-embossed MIDs are well suited for decorative surfaces.

The photoimaging process is perfectly suited for generating EMC screens (at the same time as the conductors) and is highly flexible as to the layer structure. The design freedom is good and few limitations exist. The use of 3D photomasks enables well-defined structures to be generated precisely where the mask contacts the MID directly (Franke 1995).

Laser imaging is highly flexible as to layer structure. It basically involves copperplating the entire workpiece surface first with a wet chemical and then with a galvanical treatment to the desired final coating thickness. Flexibility as to layout modification is very high and cost effective: all that is necessary is a rewriting of the laser-routing program.

Of all MID production processes, two-shot injection molding offers the greatest design freedom. Conductor geometries that raise major problems in the other processes, such as conductors on irregularly shaped surfaces in recesses as well as through-platings, are easily realized by means of the two-shot process. A platable and a nonplatable constituent material are injected on top of each other in two operations. In the second shot, the workpiece is supported inside the tool by the surfaces that were contoured in the first shot.

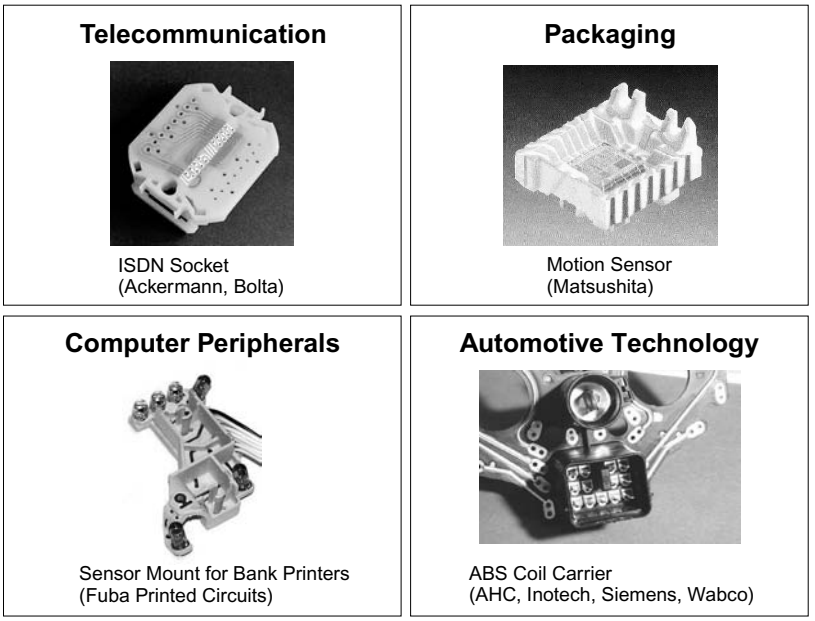

Figure 40 Application Fields for 3D MID Technology.

The capture decal (film overmolding) technique features a short process chain. It is suitable for decorative surfaces unless the surfaces are finished later on. The conductor pattern can be generated by means of screen printing or conventional PWB technology; in the latter case, through-platings are also possible. The structuring takes place separately and before the injection-molding step.

MID suppliers use various materials to which they have adapted their manufacturing processes. Basically, high-temperature and engineering thermoplastics are plated with various surface materials. The key material properties to be considered are processing and usage temperatures, required flam-

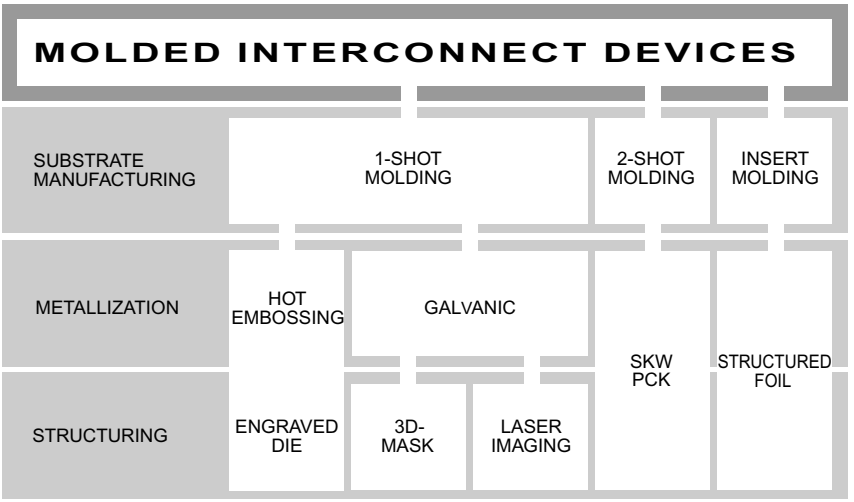

Figure 41 Manufacturing Methods for MIDs.

mability rating, mechanical and electrical properties, moldability and platability, and cost. As the price of thermoplastics generally increases with their thermal resistivity, low-temperature materials, such as ABS, PC, and PP, seem to be advantageous. These materials, however, exclude the use of conventional reflow soldering, thus necessitating an alternative joining method.

These problems can be avoided by the use of high-temperature resistance materials, such as PES, PEI, and LCP, which are also best for chemical plating.

For the completion of MID assemblies after substrate manufacturing and plating, several further steps are normally necessary.

In component placement and soldering several restrictions must be considered, as shown in Figure 42.

Conventional printing processes are less useful for applying conductive adhesives or solder paste. Dispensing of single dots in a complex geometric application is therefore necessary. Three-dimensional circuit carriers also decrease the freedom of component placement, which leads to restrictions for placement systems.

Conventional solder procedures require the use of high-temperature thermoplastics. Other plastics can be processed using low-melting-point solders, conductive adhesives, or selective soldering methods. Available assembly and interconnection technologies as well as processes for the production of the circuit carriers must be carefully considered, selected, and possibly modified to the specific MID materials.

4.3. Placement Systems for 3D PCBs

MIDs create new demands on assembly because of their complex geometric shape. The new requirements on assembly processes caused by different MID types in order to develop qualified production systems for MID assembly must be considered (Figure 43). The new task of mounting SMDs onto 3D circuit boards calls for new capabilities in dispensing and mounting systems. Both processes work sequentially and are realized with Cartesian handling systems for PCB production.

One way for SMD assembly onto MID is to use six-axis robots, which are designed as geometry-flexible handling systems for reaching each point in the workspace with every possible orientation of the tool. The available placement systems for SMD assembly onto PCBs are optimized for placement accuracy and speed. In order to work with these systems on MIDs, it is important to be able to move them during the process (Feldmann and Krimi 1998).

The first step was a systematic development of a MID placement system outgoing from an available four-axis system. This aim is realized by extending the machine by two DOF. First, an additional movement in the direction of z-axis allows high obstacles to be surmounted. Second, the MID can be inclined so that the process plane is oriented horizontally in the workspace. This concept is not suitable for MIDs with high geometrical complexity.

4.3.1. Six-Axis Robot System for SMD Assembly onto MID

Robot placement systems have till now been used primarily to place exotic THT components such as coils and plugs, whose assembly is not possible with pick-and-place machines. The application of

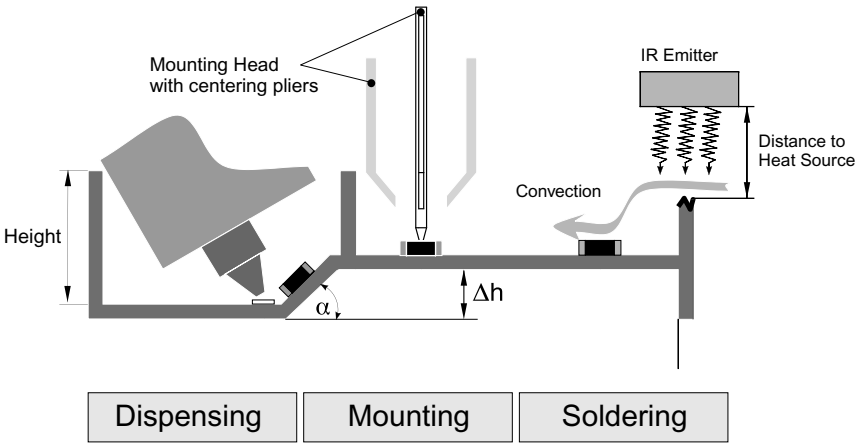

Figure 42 Definition of Design Rules for MID.

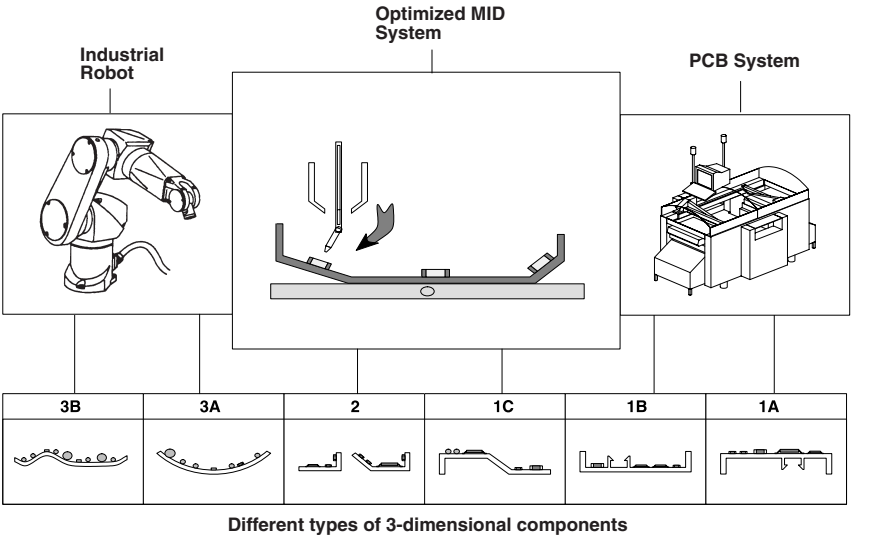

Figure 43 New Requirements for Assembly Process Caused by 3D Circuit Board.

MIDs has lead to a new task for robots in electronics assembly. Robots can be equipped with pipettes, which are built small enough to assemble SMDs with a small distance to obstacles. If the length of the free assembly perpendicular of a MID is limited, bent pipettes can be used without inclined feeders or a centering station.

Available tool-changing systems make it possible to integrate additional processes such as application of solder paste and soldering into one assembly cell. A critical point in surface-mounted technology is the necessary accuracy in centering the SMD to the pipette and the accurately placing components. This is realized by the use of two cameras, one mounted on joint five of the manipulator, pointing down toward a reference mark, and the other mounted under the stage, looking up for component registration.

The robot cell layout was designed to minimize the total distance to be covered by the robot in order to assemble onto MID. In addition, the feeder system is movable. As a result, the components can be placed at an optimized position. With this feeder moving system, the placement rate can reach 1800 components/hr (with a stationary feeder the placement rate is up to 1200 components/hr).

This geometric advantage and the flexibility of the robot system come at the expense of lower productivity and accuracy than with Cartesian systems. Therefore, Cartesian placement systems should be the basis for a specialized MID assembly system.

4.3.2. Optimized MID Placement System

The next step is to find out the possibilities for extending the detected limits of conventional SMD assembly systems. The insufficiency of Cartesian systems lies in the possible height and angle of inclination of the MID and the fact that an unlimited length of free assembly perpendicular is required. A concept has been developed to extend these limits. A module for handling the MID in the workspace of an SMD assembling system, as well as the use of a pipette with an additional axis, make 3D assembly of component onto MID possible.

For both these concepts to be realized, it is necessary to extend and work on hardware and control software of the PCB basic assembly system. These systems are realized with a widespread standard system at the FAPS Institute. Figure 45 shows the developed MID placement system with the different modules for the handling of SMD components and MID.

The way to enlarge the system kinematics of standard placement systems is to move the workpiece during the assembly process. Solutions for this problem are as follows.

First, an additional movement in the direction of the z-axis enlarges the possible height of obstacles that can be surmounted (six-axis pipette). Second, the MID can be inclined so that the process plane is oriented horizontally in the workspace (MID handling system). This allows the high accuracy and speed of a Cartesian system to be used. The tolerance chain is divided into the two parts: SMD handling system and MID moving system. Thus, it is possible to compensate for the possibly lower

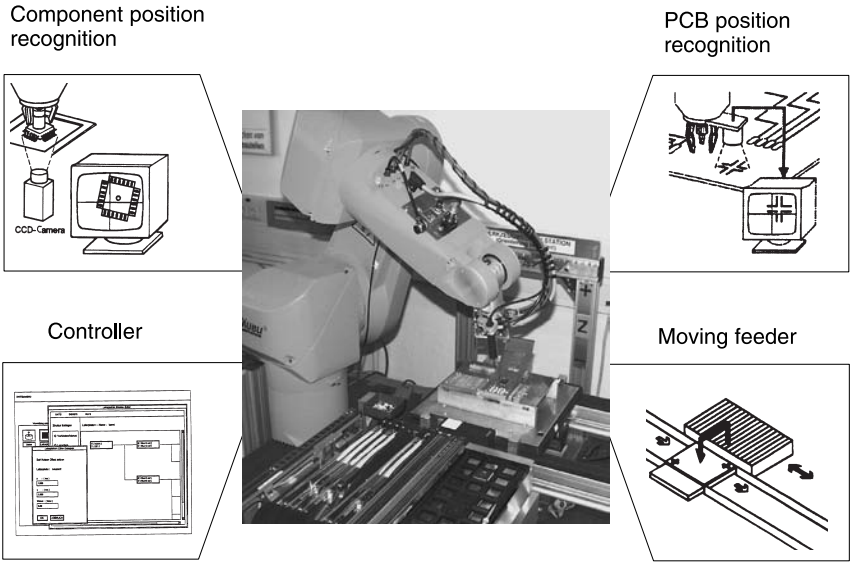

Figure 44 Flexible Robot Placement System for Assembly onto MID.

Figure 45 Prototypical Realization of MID Placement System for 3D assembly. (From Feldmann et al. 1998)

position accuracy of the MID moving system by correction of the handling system. The use of vision system is necessary here in order to detect the position of the inclined MID.

Inclination of the MID means that the process plane, which should be oriented horizontally, may be on another level than the usual. Its height must be compensated for by an additional z-axis. This means that both possibilities of enlargement of Cartesian assembly systems could be integrated into one lift-and-incline module. With this module, integrated into the Cartesian SMD assembly system, it is possible to attach SMD components onto MID circuit planes with an angle of inclination up to 70°. For this, the MID is fixed on a carrier system that can be transported on the double-belt conveyor. At the working position the carrier is locked automatically to the module, the connection to the conveyor is opened, and the MID can be inclined and lifted into the right position. It is thus possible to enlarge the capability of the Cartesian assembly system almost without reducing productivity.

4.4. Soldering Technology for 3D PCBs

Processing 3D molded interconnect devices in reflow soldering processes places stringent requirements on reflow technology due to the base materials used and the possible geometrical complexity of the circuit carriers. Most MID solutions, which are assembled with electronic components, consist of expensive high-temperature thermoplastics, such as PEI, PES, and LCP, which can resist high thermal stress during reflow soldering. However, in order for the total potential of the MID technique to be used, inexpensive technical thermoplastics like polyamide have been discussed as possible base materials, although the process window would clearly be limited regarding the tolerable maximum temperatures. As a consequence, the process parameters of the selected reflow soldering method have to be modified to reduce the thermal loading to a sufficient minimum value to avoid:

- Thermal damage to the base material
- Degradation of metallization adhesion
- Warping of the thermoplastic device

In addition, the highest solder joint quality has to be ensured for the best quality and reliability to be attained. In extensive investigations of the 3D MID soldering topic, the influence of the reflow soldering process on the points mentioned above has been examined. It can be stated that the different methods of heat transfer clearly influence the temperature distribution on the workpiece and therefore the process temperature level needed when processing complex MIDs. The example of a circuit carrier of MID type 3 (the highest level of geometrical complexity) demonstrates these facts. While during condensation or convection soldering very uniform temperature distributions, with temperature differences on the molded device of only up to a few degrees kelvin can be observed, for IR soldering, temperature differences of about 20–30°K on the surface of the 3D device can be shown by thermal measurement with an infrared scanner or attached thermocouples. Thus, particularly in the more heated upper areas of a 3D device the danger of local thermal damage to the base material exists due to the reduced distance to the infrared emitters.

If thermoplastic base materials are suspended above the usual admissible operating temperature, material damage can occur. For some hygroscopical thermoplastics (e.g., PA) the humidity stored in the material heats up, strongly expands with the transition to the vapor state, and causes a blistering on the surface of the already softened material (Gerhard 1998).

Besides thermal damage to base material caused by local overheating, the influences of thermal stress during soldering and of the soldering parameters (especially reflow peak temperature) on the geometrical shape of the molded part and the peeling strength of the metallization are important to the process quality of thermoplastic interconnection devices.

In summary, for processing 3D interconnect devices in reflow soldering processes, a minimum thermal load of the molded device has to be realized in order to eliminate unwanted thermal material damages as far as possible and achieve highest process yield. In the conflict field between solder joint quality and thermal load of the thermoplastic workpiece, fluid-based soldering methods such as convection and condensation reflow soldering represent the optimal solution. They guarantee homogeneous temperature distributions on low-temperature levels in connection with optimal soldered interconnection joints.

To reduce the thermal stress for components as well as for thermoplastic base substrates, conductive adhesives and selective soldering can be used. In working with adhesives, good interconnections with a maximum temperature of only about 100°C can be established. This temperature is necessary to harden the epoxy material. In the selective soldering technique, the heat is transferred only to places where interconnections have to be made between the component's termination and the pad on the substrate. This reduces the overall thermal stress situation for the whole 3D MID.

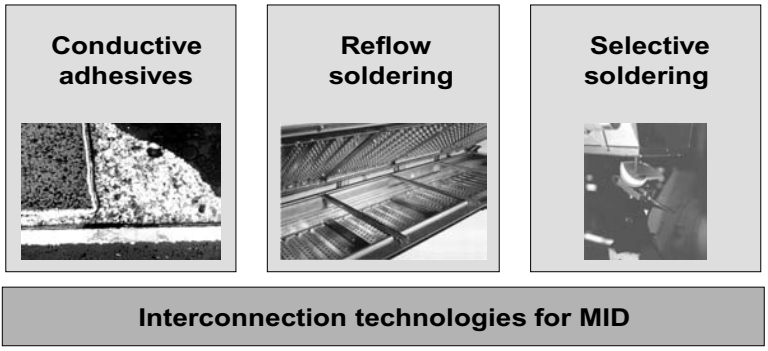

Figure 46 Interconnection Technologies for 3D MIDs.

5. DISASSEMBLY

5.1. Challenge for Disassembly

The development of disassembly strategies and technologies has formerly been based on the inversion of assembly processes. The characteristics of components and connections are like a systematic interface between both processes. In addition, assembly and disassembly can have similar requirements regarding kinematics and tools (Feldmann, et al. 1999). Nevertheless, the most obvious differences between assembly and disassembly are their goals and their position in the product's life cycle.

The objective of assembly is the joining of all components in order to assure the functionality of a product (Tritsch 1996). The goals of disassembly may be multifaceted and may have a major influence on the determination of dismantling technology. The economically and ecologically highest level of product treatment at its end of life is the reuse of whole products or components (Figure 47) because not only the material value is conserved but also the original geometry of components and parts, including its functionality. Thus, disassembly generally has to be done nondestructively in order to allow maintenance and repair of the components.

A further material loop can be closed by the disassembly and reuse of components in the production phase of a new product. In order to decrease disassembly time and costs, semidestructive dismantling technologies are applicable, such as to open a housing.

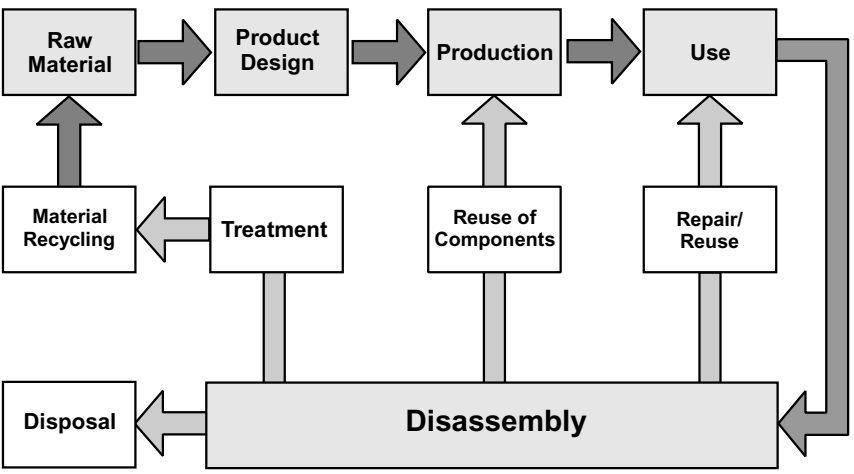

Figure 47 Role of Disassembly in the Product's Life Cycle.

In most cases, disassembly is done to remove hazardous or precious materials in order to allow ecologically sound disposal or high-quality-material recycling. All types of disassembly technology are used in order to decrease costs and increase efficiency (Feldmann et al. 1994).

In the determination of disassembly technologies, several frame conditions and motivations have to be taken into account (Figure 48). Because of rapidly increasing waste streams, the ecological problems of disposal processes, and the shortage of landfill capacities, the product's end of life has become a special focus of legislative regulation (Gungor and Gupta 1999; Moyer and Gupta 1997) that requires disassembly and recycling efforts.

Furthermore, the ecological consciousness of society (represented by the market and its respective requirements) and the shortage of resources, leading to increasing material prices and disposal costs, put pressure on the efficient dismantling of discarded products. The increasing costs and prices also provide economic reasons for dismantling because the benefits of material recycling increase as well. Finally, on the one hand, the technological boundary conditions indicate the necessity of disassembly because of increasing production and shorter life cycles. And on the other hand, the availability of innovative recycling technologies is leading to new opportunities and challenges for disassembly technology.

Due to influences in the use phase, unpredictable effects such as corrosion often affect dismantling. Also, the incalculable variety of products when they are received by the dismantling facility has a negative influence on the efficiency of disassembly. Together with the lack of information, these aspects lead to high dismantling costs because of the manpower needed (Meedt 1998).

On the other hand, some opportunities in comparison to the assembly, for example, can be exploited. Thus, with disassembly, only specific fractions have to be generated. This means that not all connections have to be released, and (semi)destructive technology is applicable for increasing efficiency.

5.2. Disassembly Processes and Tools

The advantages and disadvantages of manual and automated disassembly are compared in Figure 49. Because manual disassembly allows greater flexibility in the variety of products and types as well as the use of adequate disassembly tools, it is generally used in practice. Due to risk of injury, dirt, the knowledge needed for identification of materials, and wages to be paid, manual disassembly is not considered an optimal solution. On the other hand, problems of identification, the influence of the use phase (as mentioned above), damage to connections, and particularly the broad range of products, prevent the effective use of automated disassembly processes (Feldmann et al. 1994). Thus, for most disassembly problems partial automated systems are the best solution.

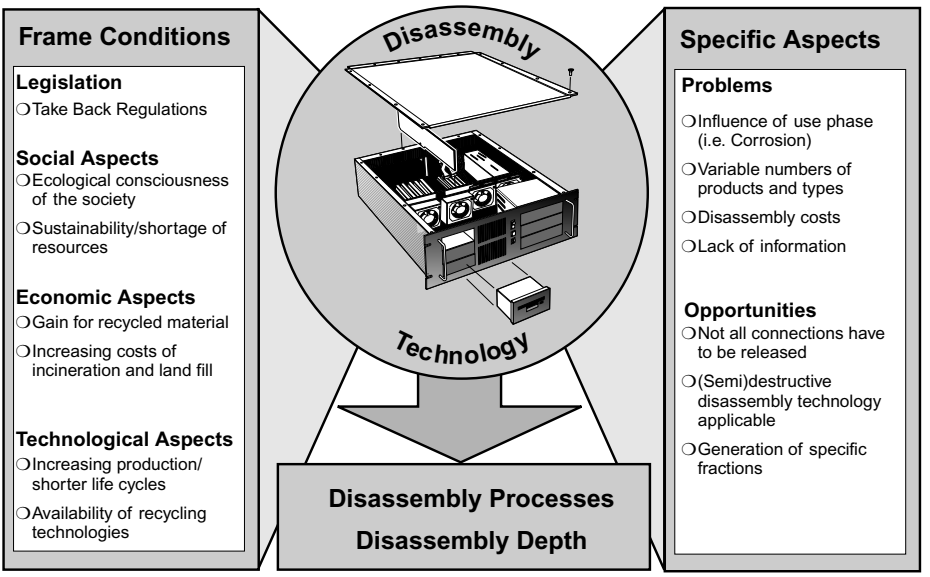

Figure 48 Frame Conditions and Specific Aspects of Disassembly.

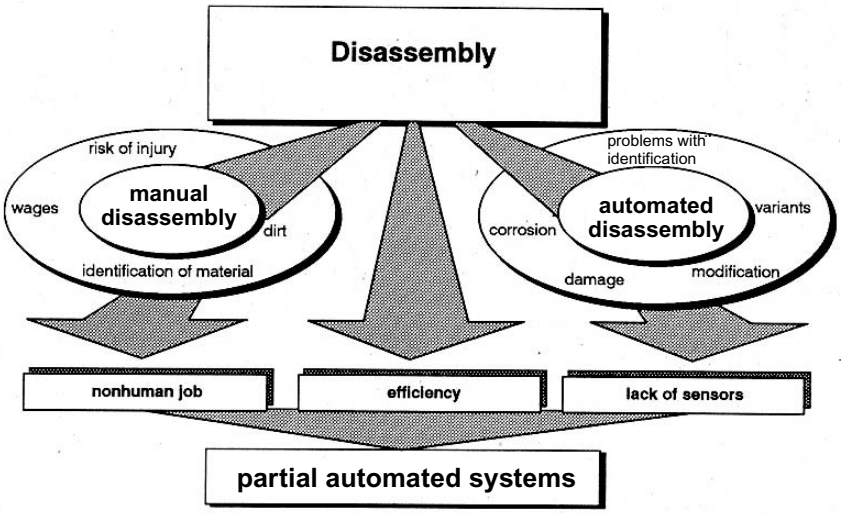

Figure 49 Features of Manual and Automated Disassembly Systems.

Along with the combination of manual and automated disassembly, other aspects, such as logistics, flow of information, and techniques for fractioning, storing, and processing residuals, have to be optimized for efficient dismantling.

In addition to the planning of the optimal disassembly strategy, the major area for improvement in the disassembly of existing products is in increasing the efficiency of disassembly processes. Highly flexible and efficient tools especially designed for disassembly are needed.

The function of tools is based on different types of disassembly: (1) destructive processes in order to bring about the destruction of components or joining; (2) destructive processes in order to generate working points for further destructive or nondestructive processes; (3) nondestructive processes such as the inversion of assembly processes (Feldmann et al. 1999).

Figure 50 shows an example of a flexible unscrewing tool developed at the Technical University of Berlin that generates working points in a destructive way. This tool consists of an impact mass that is speeded up in a first step by tangent pneumatic nozzles until a certain angular velocity is reached (Seliger and Wagner 1996).

In a second step, the rotating impact mass is accelerated towards a conical clutch and transmits the linear and rotational impulse to the end effector. Using W-shaped wedges of the end effector, a new acting surface is generated on the head of the screw, avoiding any reaction force for the worker.

Furthermore, the rotational impulse overcomes the breakaway torque and the linear impulse reduces pre-tension in order to ease loosening. The loosened screw is now unscrewed by a pneumatic drive and the impact mass is pushed to the starting position (Seliger and Wagner 1996). In case a screw cannot be released due to influences in the use phase (e.g., corrosion or dirt), the end effector can be used as a hollow drill with wide edges in order to remove the screw head.

A major problem in dismantling is in opening housings quickly and efficiently in order to yield optimal accessibility to hazardous or worthy materials. Especially with regard to small products, the effort in dismantling with conventional tools is very often too high compared to the achieved benefit. To solve this problem, a flexible tool, the splitting tool (Figure 51), has been developed (Feldmann et al. 1999).

The splitting tool has specific levers and joints that divide the entry strength or impulse (e.g., by a hammer or pneumatic hammer) into two orthogonal forces or impulses.

Through the first force component with the same direction as the original impact, the splitting elements are brought into action with the separating line of the housing in order to generate acting surfaces. The strength component set normally to the entry impact is used simultaneously as separation force. This way, screws are pulled out and snap fits are broken.

Thus, in general the housing parts are partially destroyed and torn apart without damaging the components inside. Using specially designed tools for disassembly allows unintentional destruction of other components, which is often an effect of dismantling with conventional tools such as hammers and crowbars, to be avoided.

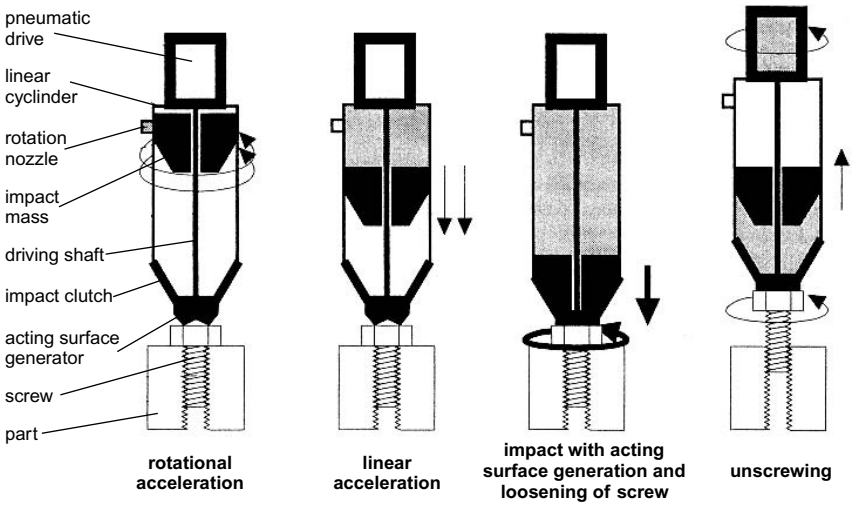

Figure 50 Example of a Flexible Unscrewing Tool. (From Seliger and Wagner 1996)

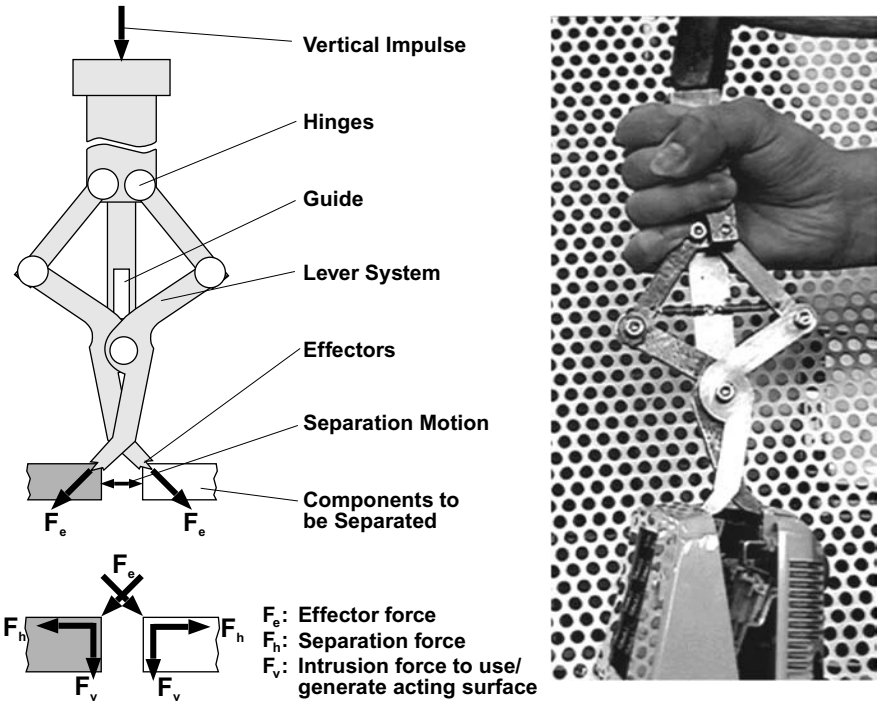

Figure 51 Example of a Flexible Splitting Tool.

The examples given show the basic requirements for disassembly tools: flexibility concerning products and variants, flexibility concerning different processes, and failure-tolerant systems.

5.3. Applications

Conventional tools such as mechanized screwdivers, forceps, and hammers are still the dismantling tools generally used. The use of tools, the choice of disassembly technology, and the determination of the disassembly strategy depend to a large degree on the knowledge and experience of the dismantler because detailed disassembly plans or instructions are usually not available for a product. This often leads to a more or less accidental disassembly result, where the optimum between disassembly effort and disposal costs/recycling gains is not met. Many approaches have been proposed for increasing the efficiency of disassembly by determinating an optimal dismantling strategy (Feldmann et al. 1999; Hesselbach and Herrmann 1999; Gungor and Gupta 1999).

Depending on the actual gains for material recycling and reusable components, the costs of disposal, and legislative regulations, products are divided into several fractions (Figure 52). First, reusable components (e.g., motors) and hazardous materials (e.g., batteries, capacitors) are removed. Out of the remaining product, in general the fractions ferrous and nonferrous metals and large plastic parts are dismantled so they can be recycled directly after the eventual cleaning and milling processes.

Removed metal–plastic mixes can be recycled after the separation in mass-flow procedures (e.g., shredding). Special components such as ray tubes are also removed in order to send them to further treatment. The remainder must be treated and/or disposed of.

As mentioned in Section 5.2, the economic margin of dismantling is very tight and the logistic boundary conditions—for example, regarding the sporadic number of similar units and the broad variety of product types—are rather unfavorable for automation. Depending on the flexibility of automated disassembly installations, three strategies can be used.

Some standardized products (e.g., videotapes, ray tubes of computer monitors) can be collected in large numbers so that automated disassembly cells especially designed for these products can work economically.

Greater flexibility from using PC-based control devices and specially designed disassembly tools, as well as the integration of the flexibility of human beings allow the automated dismantling of a certain range of discarded products in any sequence. Figure 53 shows an example of a hybrid disassembly cell that was realized on a laboratory scale. One of the integrated robots, used for unscrewing actions, is equipped with a flexible unscrewing tool that can release various types of screws. The second robot, using a special multifunctional disassembly and gripping device, is able to split components, cut cables, and remove parts without changing the device.

Another strategy for automated disassembly is the enhancement of flexibility using sensors that detect automatically connection locations and types. By an evaluation of the sensor data, the re-

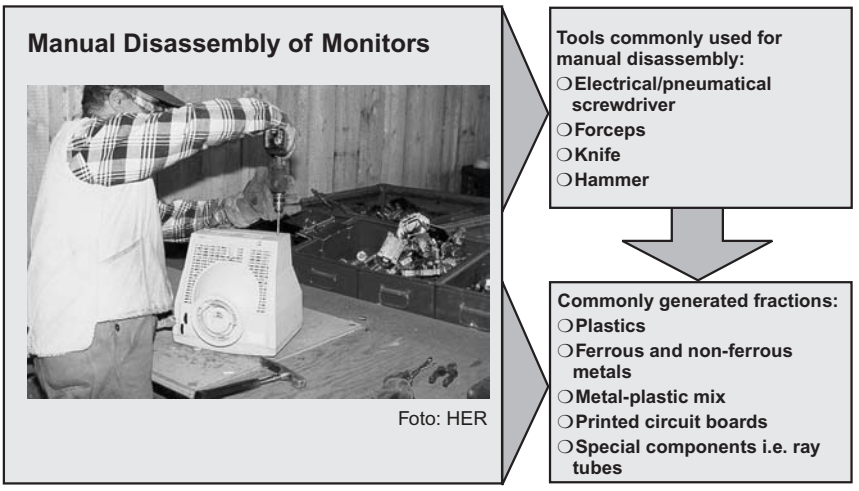

Figure 52 Manual Disassembly of Monitors.

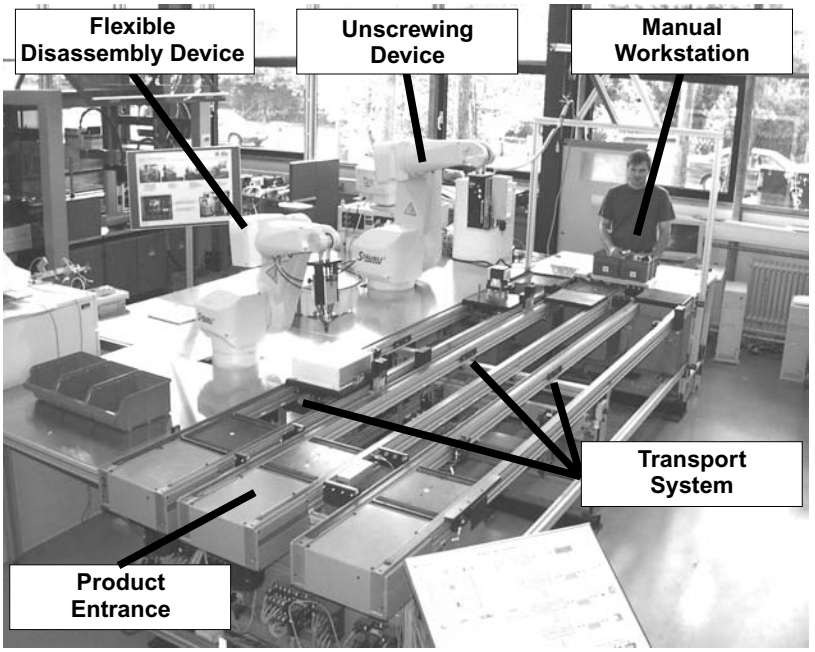

Figure 53 Layout of a Hybrid Disassembly Cell.

spective tools are determined and controlled (Weigl 1997). This strategy in general leads to high investments that have to be compensated for by disassembly efficiency.

5.4. Entire Framework for Assembly and Disassembly

Mostly in regard to maintenance and reuse of components, but also in regard to optimal disassembly planning, an integrated assembly and disassembly approach should be considered—just with the design of a product (DFG 1999). Five stages of integration can be distinguished (Figure 54).

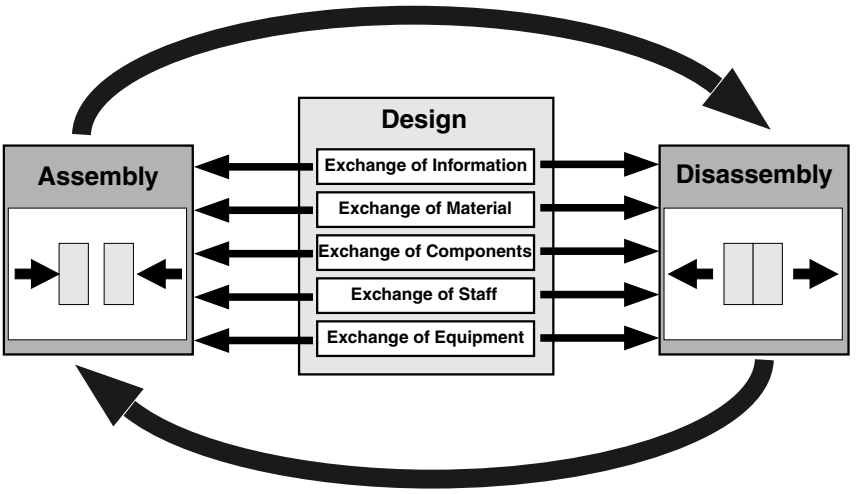

Figure 54 Stages of the Integration of Assembly and Disassembly.

1. Information is exchanged between assembly and disassembly. Data on, for example, connection locations and types ease substantially the disassembly of discarded products.
2. Recycled material, such as auxiliary materials, can be delivered from disassembly plants to the production plants.
3. The reuse and reassembly of components, which first requires disassembly, is already practiced with many products. Nevertheless, the integrated consideration of both assembly and disassembly is important for efficiency.
4. The exchange of staff requires the proximity of assembly and disassembly facilities. At this stage, the knowledge and experience of the workers can be used for both processes and thus provide major benefits in efficiency.
5. The highest stage of integration is the use of a device for both assembly and disassembly. Examples are repairing devices for printed circuit boards.

The possible level of integration is determined mainly by the design of a product. Thus, an overall approach that looks at all phases of the product's life cycle is required.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

Manufacturing process planning is an important step in the product-realization process. It can be defined as ''the function within a manufacturing facility that establishes which processes and parameters are to be used (as well as those machines capable of performing these processes) to convert a part from its initial form to a final form predetermined (usually by a design engineer) in an engineering drawing'' (Chang et al. 1998, p. 515). Alternatively, it can be defined as the act of preparing detailed work instructions to produce a part. The result of process planning is a process plan. A process plan is a document used by the schedulers to schedule the production and by the machinist /NC part programmers to control/program the machine tools. Figure 1 shows a process plan for a part. The process plan is sometimes called an operation sheet or a route sheet. Depending on where they are used, some process plans are more detailed than others. As a rule, the more automated a manufacturing shop is, the more detailed the process plan has to be.

To differentiate the assembly planning for an assembled product, process planning focuses the planning on the production of a single part. In this chapter, when a product is mentioned, it refers to a discrete part as the final product. One important step in process planning is process selection, which is the selection of appropriate manufacturing processes for producing a part. When none of the existing processes can produce the part, a process may have to be designed for this purpose. Process design can also be interpreted as determining the parameters of a process for the manufacture of a part. In this case, process design is the detailing of the selected processes. Thus, process planning and process design are used for the same purpose—determining the methods of how to produce a part.

In this chapter, process planning and design are discussed. Techniques employed for process planning and process design are also introduced. Due to the vast number of manufacturing processes, it would be impossible to cover them all in this chapter. Only machining processes are focused upon here. However, early in the chapter, casting, forming, and welding examples are used to illustrate alternative production methods.

1.1. The Product-Realization Process

Manufacturing is an activity for producing a part from raw material. In discrete product manufacturing, the objective is to change the material geometry and properties. A sequence of manufacturing processes is used to create the desired shape. The product-realization process begins with product design. From the requirements, an engineering design specification is prepared. Through the design process (the details of which are omitted here), a design model is prepared. Traditionally, the design model is an engineering drawing (drafting) either prepared manually or on a CAD system. Since the

Figure 1 Process-Plan.

1990s, solid model for engineering design has gained popularity for representing design models. A design model must contain the complete geometry of the designed part, the dimensions and tolerances, the surface finish, the material, and the finished material properties. The design model is a document, or contract, between the designer and the manufacturing facility. The finished product is checked against the design model. Only when all the specifications on the design model are satisfied is the product accepted.

There are several steps in the product-realization process (Figure 2): design, process planning, manufacturing, and inspection. Process planning is a function linking the design and the manufacturing activities. The objective of manufacturing is to produce the product at an acceptable quality (instead of the best quality), in a desired time frame (not necessarily the shortest time), and at the lowest cost (lowest cost is always desirable). Because manufacturing follows the process plan, the quality of the process plan is critical to the success of manufacturing and thus product realization. In the following section, the more detailed steps of product realization are discussed.

1.2. From Design to Process Planning to Production

Before a product is materialized, it has to be designed and manufactured. Following are the major steps in this product realization process.

1.2.1. Selection of Materials

Materials are selected based on the functionalities of the part being made. Most parts are made from a single material. Material selection may not be the first step in design. However, it is an important decision to be made. Often, several materials all satisfy the functional requirements of the part. For example, one may choose steel, aluminum, of composite material for the part. Although the physical, mechanical, and electrical properties all satisfy the design requirements, the material and processing costs might be very different. The material cost is easily estimated (Table 1), but estimating the processing cost is more involved. For example, steel-part manufacturing is very different from composite-part manufacturing. Totally different machines and material-handling methods are needed. A good designer will take manufacturing issues into consideration. Design for manufacturing should begin with the proper selection of materials for manufacturing. In some cases, due to the material property, the geometry of the part will need to be changed.

1.2.2. Geometry Creation

The shape of a product can be determined by functional or aesthetic considerations. Individual parts in an assembly must fit together to form the assembly. They use the geometric shape to carry out a specific function. For example, an angle bracket is used for mounting a machine, a hole is used to

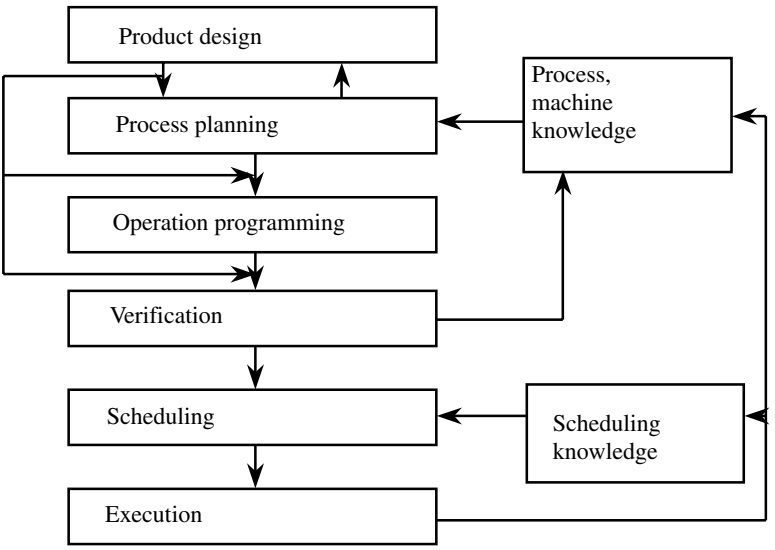

Figure 2 Product-Realization Process.

TABLE 1 Approximate Cost of Raw Materials as a Function of their Condition, Shape, and Size

Material	Cost ($)	Material	Cost ($)

fit an axle, and a T-slot is used to hold a bolt. The designer must create the appropriate geometry for the part in order to satisfy the functional requirements. The ultimate objective of the designer is to create a functionally sound geometry. However, if this becomes a single-minded mission, the designed part may not be economically competitive in the marketplace. Cost must also be considered.

Manufacturing processes are employed to shape the material into the designed geometry. A large number of unrelated geometries will require many different processes and/or tools to create. The use of standard geometry can save money by limiting the number of machines and tools needed. For example, a standard-size hole means fewer drill bits are needed. Design for manufacturing also means imposing manufacturing constraints in designing the part geometry and dimension.

The designed geometry is modeled on a CAD system, either a drawing or a solid model (see Figure 3). More and more designs are modeled using 3D solid modelers, which not only provide excellent visualization of the part and assembly but also support the downstream applications, such as functional analysis, manufacturing planning, and part programming. The key is to capture the entire design geometry and design intents in the same model.

1.2.3. Function Analyses

Because the designed part must satisfy certain functional requirements, it is necessary to verify the suitability of the design before it is finalized. Engineering analyses such as kinematic analysis and heat transfer are carried out from the design. Finite element methods can be used, often directly from a design model. The more critical a product or part is, the more detailed an analysis needs to be conducted.

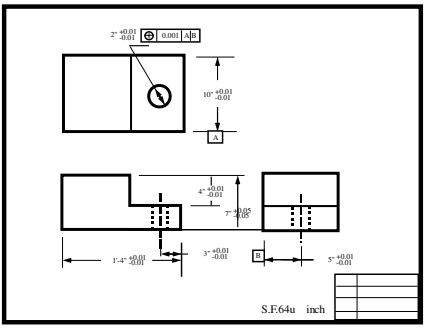
1.2.4. Design Evaluation

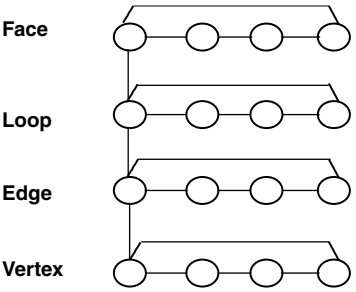
The task of design evaluation is to separate several design alternatives for the final selection of the design. Cost analysis, functionality comparison, and reliability analysis are all considerations. Based on the predefined criteria, an alternative is selected. At this point the design is ready for production.

1.2.5. Process Planning

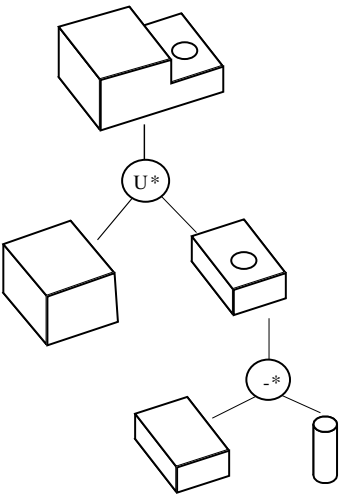
Production begins with an assembly/part design, production quantity, and due date. However, before a production order can be executed, one must decide which machines, tools, and fixtures to use as well as how much time each production step will take. Production planning and scheduling are based on this information. As noted earlier, process planning is used to come up with this information. How to produce a part depends on many factors. Which process to use depends on the geometry and the material of the part. Production quality and urgency (due date) also play important roles. A very different production method will definitely be appropriate for producing a handful of parts than for a million of the same part. In the first case, machining may be used as much as possible. However, in the second case, some kind of casting or forming process will be preferable.

When the due date is very close, existing processes and machines must be used. The processes may not be optimal for the part, but the part can be produced in time to meet the due date. The cost





B-REP MODEL



CSG MODEL

Figure 3 Design Representations.

will be high—one pays for urgent orders. On the other hand, when there is plenty of lead time, one should try to optimize the process. When the production quantity justifies the cost, it might be necessary to design new processes or machines for the part. One good example is the use of a transfer line for engine block production. Machines (stations) in a transfer line are specially designed (or configured) for a part (e.g., an engine block). Production is optimized. Lower cost and higher quality can be expected. Table 2 shows the recommended production systems for different production quantities and production lead times.

1.2.6. Production Planning and Scheduling

After process planning is complete, production is ready to begin. Production planning and scheduling are important functions in operating the manufacturing facility. Because multiple products or parts are being produced in the same manufacturing facility, the resource allocation must be done appropriately in order to maximize the production output. When a transfer line or production line (assembly line) is the choice, the line is balanced (equal numbers of tasks are allocated to each machine station)

TABLE 2 Recommended Production Methods

	Long Lead Time	Medium Lead Time	Short Lead Time
Mass production	Transfer-line	Product line	Job shop
Medium batch	Manufacturing cell Job shop	Job shop Manufacturing cell	Job shop
Small volume	Job shop	Job shop	Job shop

and designed. After a line is installed, the operation of the line is simple. Upon the workpiece being launched at one end of the line, the product is built sequentially through the line. However, in a shop environment, production scheduling is much more complex. For each planning horizon (day or week), what each machine should process and in which sequence must be decided. Predefined objectives such as short processing time, maximum throughput, and so on are achieved through proper scheduling. Scheduling uses information provided by the process plan. A poorly prepared process plan guarantees poor results in production.

1.2.7. Consideration of Production Quantity in Process Planning

As noted above, production quantity affects the manufacturing processes selected for a part. If the production quantity is not considered in process planning, the result may be an expensive part or a prolonged production delay. Large quantities make more specialized tools and machines feasible. Small-quantity production must use general-purpose machines. Although the total quantity may be high, in order not to build up inventory and incur high inventory cost, parts are usually manufactured in small batches of 50 parts or less. Therefore, production batch size is also a factor to be considered. There is decision making loop. The process plan is the input to production planning; production planning determines the most economical batch size; batch size, in turn, changes the process plan. A decision can be made iteratively.

2. PROCESS PLANNING

As noted above, process planning is a function that prepares the detailed work instructions for a part. The input to process planning is the design model and the outputs include processes, machines, tools, fixtures, and process sequence. In this section, the process planning steps are discussed. Please note that these steps are not strictly sequential. In general, they follow the order in which they are introduced. However, the planning process is an iterative process. For example, geometry analysis is the first step. Without knowing the geometry of the part, one cannot begin the planning process. However, when one selects processes or tools, geometric reasoning is needed to refine the understanding of the geometry. Another example is the iterative nature of setup planning and process selection. The result of one affects the other, and vice versa.

2.1. Geometry Analysis

The first step in process planning is geometry analysis. Because the selection of manufacturing processes is geometry related, the machining geometries on the part, called manufacturing features, need to be extracted. An experienced process planner can quickly and correctly identify all the pertinent manufacturing features on the part and relate them to the manufacturing processes. For example, the manufacturing features of holes, slots, steps, grooves, chamfers, and pockets are related to drilling, boring, reaming, and milling processes. The process planner also needs to note the access directions for each feature. Also called approach directions, these are the unobscured directions in which the feature can be approached by a tool. When features are related to other features, such as containment, intersection, and related in a pattern, these relationships must be captured. Feature relations are critical in deciding operation (process) sequence. Figure 4 shows a few features and their approach directions. The pocket at the center and steps around the center protrusion are approachable from the top. The hole may be approached from the top or from the bottom.

In computer-aided process planning, the geometry analysis (or geometric reasoning) is done by computer algorithms. The design model in the form of a solid model is analyzed. Based on the local geometry and topology, regions are extracted as features. To be significant to manufacturing, these features must be manufacturing features (Figure 5). Again, manufacturing features are geometric entities that can be created by a single manufacturing process or tool. Like manual geometry analysis, geometric reasoning must find feature access directions (approach directions) and feature relations. Due to the vague definitions of features, the large number of features, and the complexity in feature matching (matching a feature template with the geometric entities on the solid model), geometric reasoning is a very difficult problem to solve. This is one of the reasons why a practical, fully automatic process planner is still not available. However, a trained human planner can do geometry analysis relatively easily. More details on geometric reasoning can be found in Chang (1990).

2.2. Stock Selection

Manufacturing is a shape-transformation process. Beginning with a stock material, a sequence of manufacturing processes is applied to transform the stock into the final shape. When the transformation is done using machining, minimizing the volume of materials removed is desirable. Less material removal means less time spent in machining and less tool wear. The stock shape should be as close to the finished part geometry as possible. However, in addition to the minimum material removal rule, one also has to consider the difficulty of work holding. The stock material must be

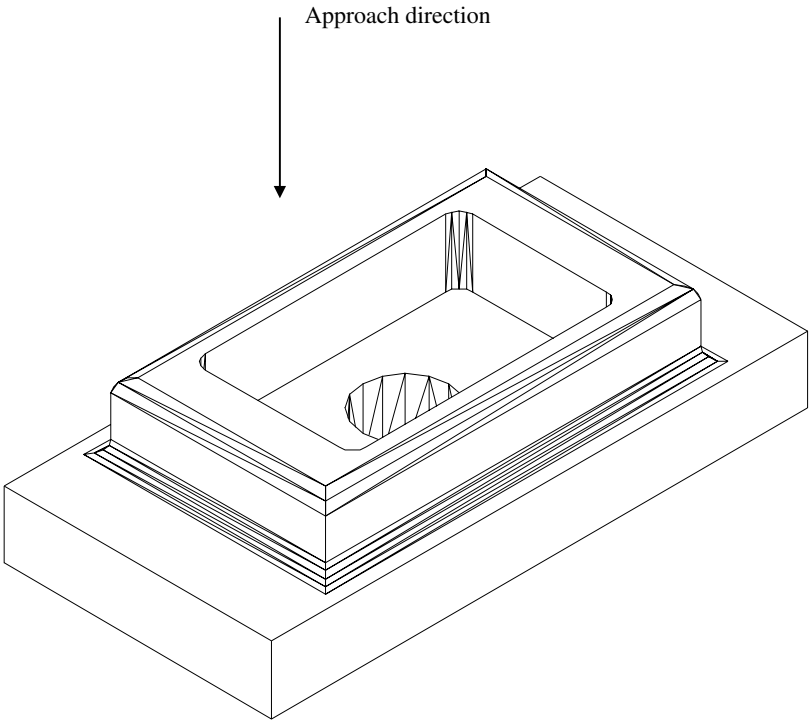


Figure 4 Protrusion, Pocket, and Hole.

clamped or chucked on the machine tool before cutting can be performed. This fixturing consideration has practical importance. However, raw materials can be purchased only in limited shapes and dimensions. For example, steel is supplied in sheets of different thickness, length, and width, strips, wires, bars, and so on. The general shape has to be determined, and then stock preparation (cutting) has to be done to produce the stock. This is also true for the forming processes.

After the stock material is selected, one can compare the stock with the finished part and decide the volume of material to be removed for each process. In automated process planning, often the difference between the stock and the part, called the delta volume, is calculated. Geometric reasoning is performed on the delta volume. Without first selecting the stock, one cannot be certain exactly how to proceed with the manufacturing processes.

In some cases, especially for mass production, minimizing metal removal means preparing a casting as the stock material. Machining is used to improve critical or hard-to-cast surfaces. In this case, the casting has to be designed based on the part. Using casting as the stock minimizes the machining yet requires a high initial investment (casting design, mold making, etc.).

2.3. Gross Process Determination

Process planning can be separated into two stages: gross planning and detailed planning. Often only detailed planning is discussed in the process planning literature. Actually, the gross planning is even more critical than the detailed planning. Gross planning is used to determine the general approach to produce a part. For example, the same part geometry may be created through casting, machining, 3D fabrication, or welding of sheet metal. Only when a general approach is determined may one proceed with the detailed planning.

2.3.1. Casting, Machining, and Joining

One of the first decisions a process planner needs to make is whether to cast the part or machine it. Rough casting, such as sand casting, requires a good amount of machining. However, precision casting, such as die casting and investment casting, can produce almost net shape part (finished part). The decision is based on both economics and material properties; this issue will be addressed below.

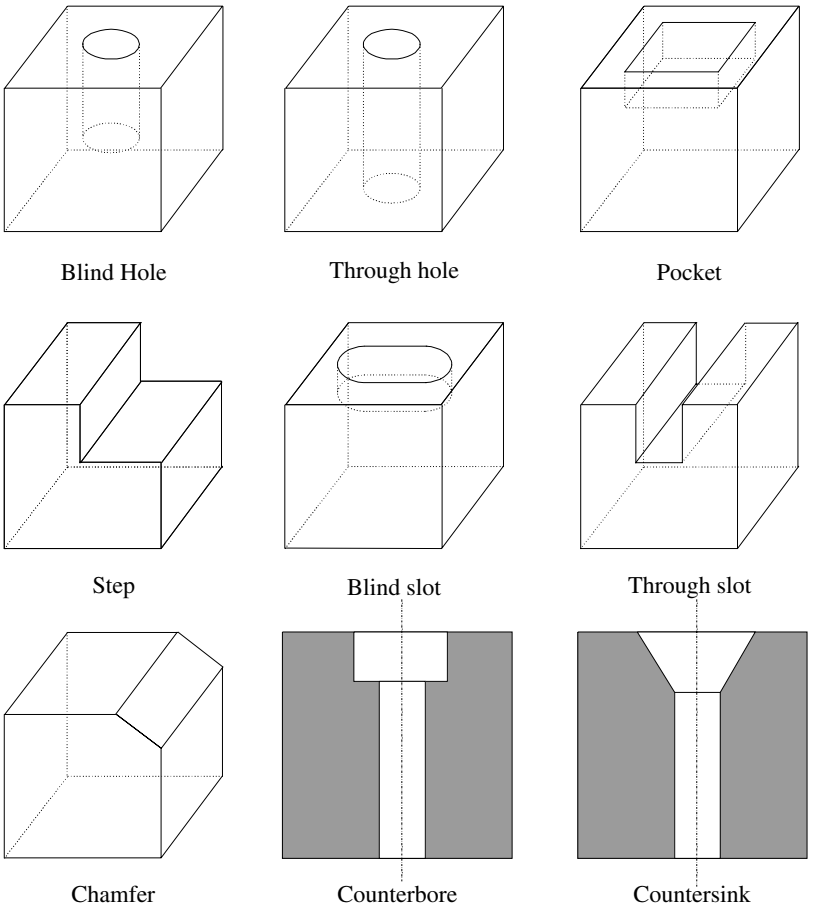

Figure 5 Some manufacturing Features.

In the initial evaluation, the technical feasibility and relative costs are taken into consideration. Process capabilities and relative cost for each casting and machining process are used in the evaluation. Based on the geometry to be created, material used, and production volume, one can propose several alternative processes. The process capability includes shape capabilities and accuracy. Casting processes, such as die casting and investment casting, can create intricate geometry with relative high precision (0.01 in.). However, sand casting is much worse. For tighter dimensional control, secondary machining is a must.

Certain parts can be built using the welding process as well. This is especially true for structural parts. Large structural parts such as ship hulls are always built using welding. Medium-sized structural parts such as airplane structure parts may be joined together from machined parts. Sectional structures for jet fighters are always machined from a solid piece of metal in order to obtain the maximum strength. For small structures, all manufacturing methods are possible. When there are several alternatives, an initial selection needs to be made.

2.3.2. Product Strength, Cost, etc.

Parts made using different stocks and processes exhibit different strength. As mentioned above, sectional structures for jet fighters are always machined from a solid piece of alloy steel. The raw material is homogeneous and rolled into the shape in the steel mill. It has high strength and consistent properties. When casting is used to form a part, a certain number of defects can be expected. The cooling and thus solidification of the material are not uniform. The surface area always solidifies first and at a much higher rate than the interior. A hard shell forms around the part. Depending on the

complexity of the part, the type of mold used (sand, metal, etc.) and the mold design, voids, hot tear, cold shut, or other problems can happen. The part is not as strong as those produced using machining. In the case of welded parts, the welded join may not be as strong as the rest of the part.

As for the manufacturing cost, there is an even greater difference. For machining, the initial cost is low but the incremental cost is higher. The opposite is true for casting. Figure 6 shows the comparison. The initial cost for casting includes the cost of designing and building the mold and is relatively high. The slope of the incremental cost is the casting cost per piece. For machining, the initial cost is relatively much lower. On a manually controlled machine, only tools and fixtures need to be purchased. When a CNC machine is used, the programming cost has to be added to the fixed cost. However, the machining cost per piece will be lowered.

There are always alternative ways to make a part. Unless the way is specified by the designer, a good process planner always considers all possible alternatives and evaluate them. This evaluation need not always be carried out formally and precisely. Using past experience and with rough estimates, one can quickly eliminate most alternatives. The most promising alternatives have to be explored further before they are accepted or discarded.

2.4. Setup and Fixture Planning and Design

Let us assume that machining is the best alternative for the production of a part. Using the result of geometry analysis, we can group machining features based on their feasible approach directions. Most machining processes require the workpiece be positioned so that the tool orientation matches with the feature approach direction. For example, the part in Figure 7 consists of four holes. All holes have the same approach direction. Therefore, it is best to set up the workpiece with the holes aligned with the machine spindle. The position of the workpiece is called the setup position. When there are multiple approach directions, multiple setups may be needed to finish the machining operations.

A fixture is used to hold the workpiece at the desired setup position. For simple workpieces, a vise is sufficient to do the job. However, for more complex workpieces, locators and clamps are needed to position and clamp the workpiece on the machine table. After each setup the workpiece geometry is transformed (Figure 8). The finished part is obtained after the last setup is done. After a fixture is designed or configured (using modular figures), tool interference has to be checked. Obviously, fixture elements should not interfere with the tool motion. If the current fixture does interfere with the tool, either a new fixture needs to be designed or the machining feature that causes interference will not be cut during this setup. Again, this illustrates the iterative nature of process planning steps.

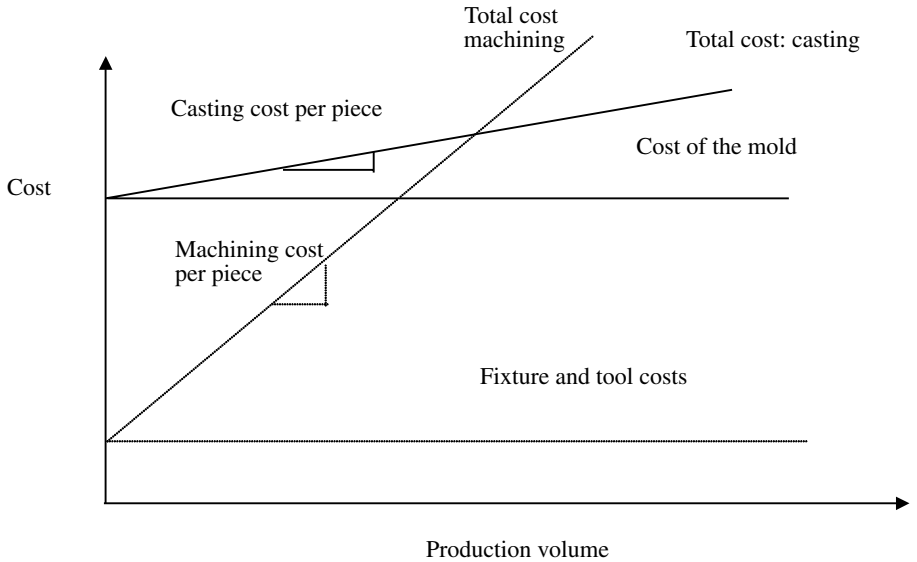

Figure 6 Costs vs. Production Volumes for Different Production Methods.

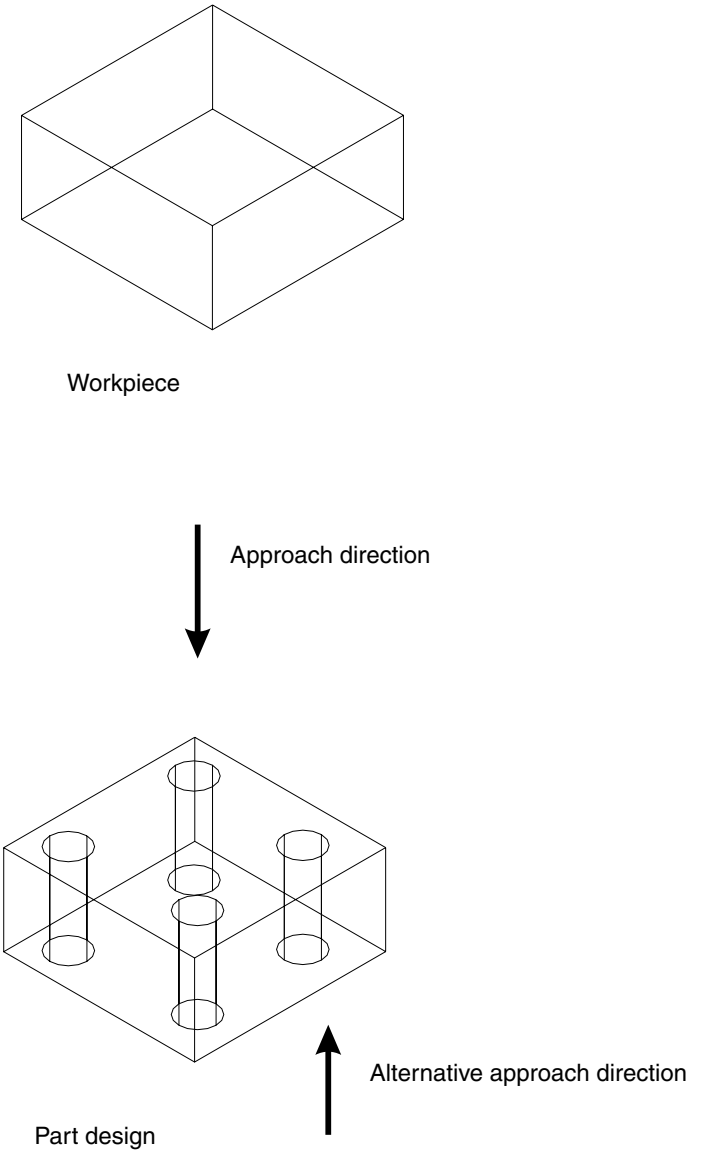

Figure 7 Workpiece and Features on a Part.

2.5. Process Selection

Process is defined as a specific type of manufacturing operation. Manufacturing processes can be classified as casting, forming, material-removal, and joining processes. Under casting are sand casting, investment casting, die casting, vacuum casting, centrifugal casting, inject molding, and so on. Forming includes rolling, forging, extrusion, drawing, powder metallurgy, thermoforming, spinning, and so on. Material removal includes milling, turning, drilling, broaching, sawing, filing, grinding, electrochemical machining (ECM), electrical-discharge machining (EDM), laser-beam machining, water-jet machining, ultrasonic machining, and so on. Joining processes include arc welding, electron-beam welding, ultrasonic welding, soldering, brazing, and so on. In this chapter only material-removal processes examples are used.

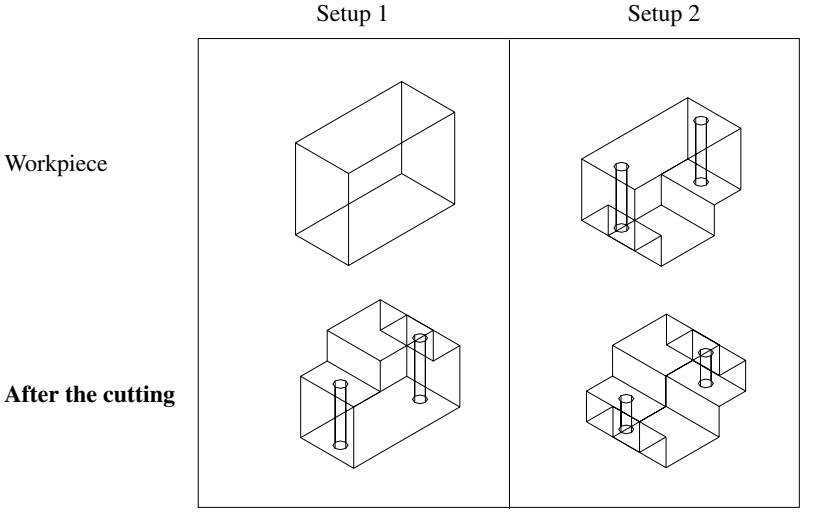

Figure 8 Setup of a Part.

Each process has its own geometric and technological capabilities. Geometric capability means the shapes a process can create and the geometric constraints it might have. For example, the drilling process usually creates round holes and due to the drill nose cone the hole bottom has the cone shape. Technological capability includes tolerances (both dimensional and geometrical), surface finish, and surface integrity. Processes are selected based on the machining features in a setup. In the previous example (Figure 7), a setup consists of four holes. The hole geometry matches the drilling process capability. Therefore, drilling is selected for the holes. In this example, the drilling sequence has no effect on the final product or the manufacturing cost. However, in many other cases the process sequence does matter. For example, in Figure 9 there are four holes and a step. It makes more sense to mill the steps before drilling the holes than the other way around. When the two left-hand holes are drilled first, much of the drilling is done in vain. The milling process will remove the top half of the holes drilled. The process sequence is determined based on the relationship between features and the technological constraints of the processes. A good process planner takes all these into consideration when selecting the processes.

2.6. Process Detailing

Process detailing involves filling the details for the process selected. It includes determining the tool for the process, tool parameters (total length, diameter, cutting length, etc.), and process parameters (speed, feed, depth of cut, etc.).

2.6.1. Tool Selection

In order to carry out the process selected for a feature, a cutting tool is needed. Many different cutting tools can be used for the same process. In drilling, for example, there are different types of drill bites, such as twist drill, spade drill, and gun drill. Each drill also comes with different diameters, cutting length, total length, nose angle, and tool material. For drilling the holes in the example (Figure 9), two different drill lengths with the same diameter are needed. Of course, the longer drill can be used to drill shorter holes, too. However, if the diameters are slightly different, separate drills need to be specified.

Figure 10 shows different kinds of drills and turn tools. The selection of a tool depends on the feature geometry and geometric constraints. In considering milling, there are even more tool parameters to consider. In addition to tool diameter, cutting depth, there are also such factors as number of cutting teeth, insert material, and rake angle. For end mills, there are also bottom-cutting and non-bottom-cutting types. Faced with this vast amount of choices, one must often rely on past experience and, for unfamiliar tools, handbooks.

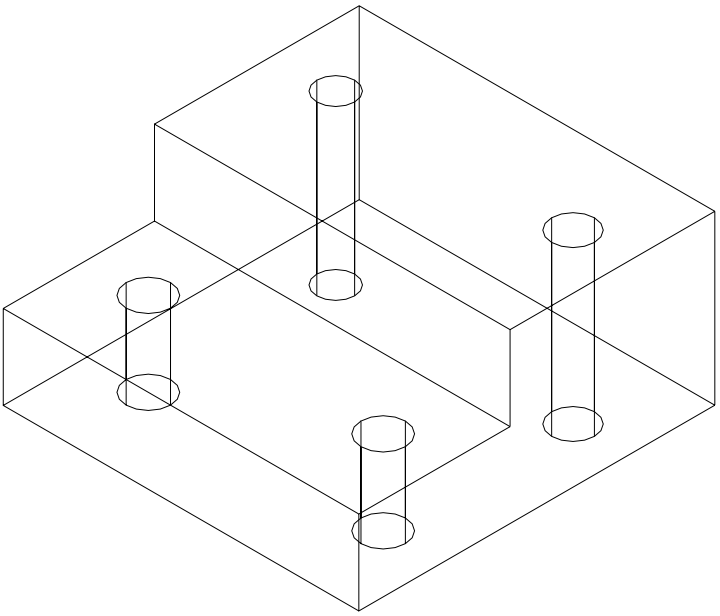

Figure 9 Sample Part with Holes and Step.

2.6.2. Process Parameters Determination

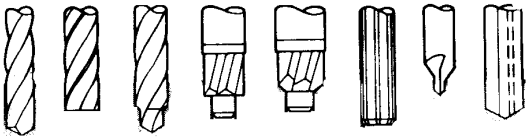
Process parameters include speed, feed, and depth of cut. They are critical to the cutting process. Higher parameter values generate higher material-removal rate, but they also reduce the tool life. High feed also means rougher surface finish. In drilling and turning, feed is measured as how much the tool advances for each rotation of the tool. In milling, it is the individual tooth advancement for each tool rotation. In turning, for example, smaller feed means closely spaced tool paths on the part surface. The finish will be better in this case. Higher feed separates the tool paths and in the worst case creates uncut spacing between two passes. Types of process, the tool and workpiece materials, and hardness of the workpiece material affect process parameters. The parameter values are determined through cutting experiments. They can be found in the tool vendor's data sheets and in the *Machining Data Handbook* (Metcut 1980). These data are usually based on the constant tool life value, often 60 minutes of cutting time. When the required surface finish is high, one must modify the recommended parameters from the handbook. For new materials not included in any of the cutting parameter handbooks, one must conduct one's own cutting experiments.

2.6.3. Process Optimization

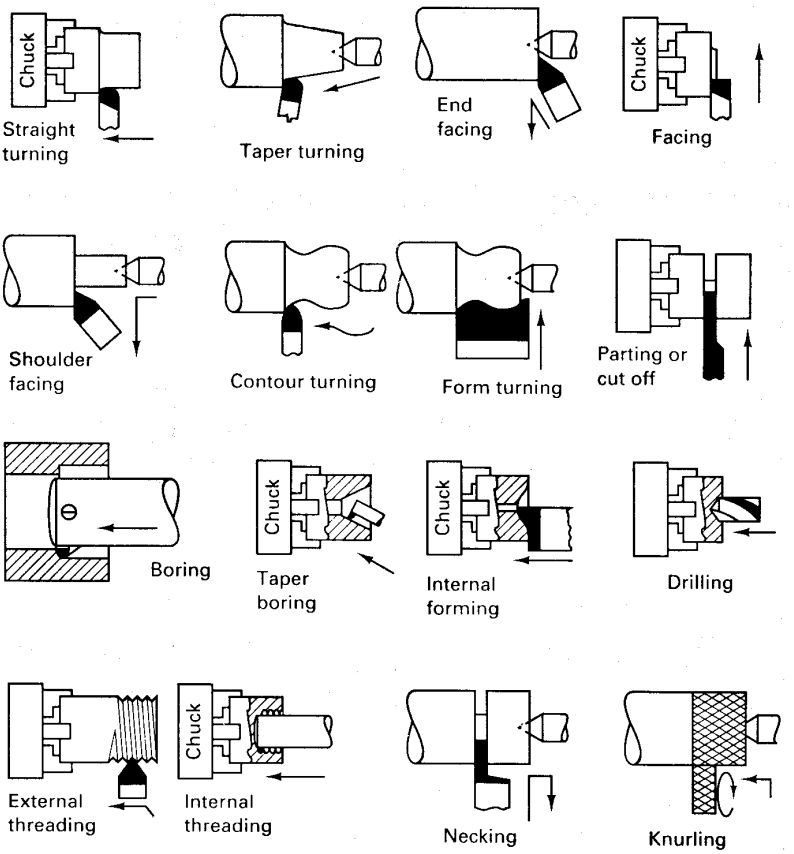
It is always desirable to optimize the production. While global optimization is almost impossible to achieve, optimization on the process level is worth trying. The total production time is the sum of the cutting time, the material handling time, and the tool-change time. Shorter cutting time means faster speed and feed and thus shorter tool life. With a shorter tool life, the tool needs to be changed more frequently and the total time is thus increased. Because there is a trade-off between cutting time and tool life, one may find the optimal cutting parameters for minimum production time or cost. The techniques of process optimization are based on an objective function (time, cost, or another criterion) and a set of constraints (power, cutting force, surface finish, etc). The process-optimization models will be discussed later in the chapter. Finding optimal cutting parameters is fairly complex and requires precise data on both tool life model and machining model. Except in mass production, process optimization is generally not considered.

2.7. Plan Analysis and Evaluation

In on an old study conducted in industry, when several process planners were given the same part design, they all came up with quite different process plans. When adopted for the product, each



Drills



Turn tools

Figure 10 Different Cutting Tools.

process plan resulted in different costs and part quality. If multiple process plans can be prepared for the same part, each plan must be analyzed and the best selected based on some preset criteria. If only one plan is prepared, it must be evaluated to ensure that the final result is acceptable. The final result here means the product quality.

2.7.1. Machining Time and Cost Estimation

Machining time can be calculated based on the cutting parameters and the feature geometry and dimension. It is used to estimate the production time and cost. It is also used in scheduling for determining the machine time. For turning and drilling, machining time can be calculated by the following formula:

$$T_m = \frac{L}{V_f}$$

$$V_f = fn$$

$$n = \frac{V}{\pi D}$$

where T_m = machining time, min
L = length of cut, in.
V_f = feed rate, ipm
f = feed, ipr (in. per revolution)
n = tool rpm
D = tool diameter, in.

For complex features, it is harder to estimate the length of the tool path. A rough estimation may be used. The material-removal rate (MRR) of the tool is calculated. The machining time is therefore the feature volume divided by the MRR. MRR for turning and drilling is:

$$\text{MRR} = V_f A$$

where A = the cross-sectional area of the cutting

For hole drilling,

$$A = \frac{\pi D^2}{4}$$

For turning,

$$A = 2\pi r^2 a_p$$

where r = cutting radius
a_p = the depth of cut

Machining cost can be calculated by the machining time times a machine and operator overhead rate.

2.7.2. Estimated Product Quality

The commonly considered technological capabilities of a process include tolerances and surface finish. Surface finish is determined by the process and process parameters. It is affected not by the order in which processes are applied but only by the last process operated upon the feature. However, tolerances are results of a sequence of processes. Operation sequences will affect the final tolerance. Using a simple 2D part, Figure 10 shows the result of different process sequences. The arrow lines are dimension and tolerance lines. The drawing shows that the designer had specified dimensions and tolerances between features *AB*, *BC*, and *CD*. Notice that in this case features are vertical surfaces. If one uses feature *A* as the setup reference for machine *B*, *B* for *C*, and *C* for *D*, the produce part tolerance will be the same as the process tolerance. However, it would be tedious to do it this way. One may use *A* as the reference for cutting *B*, *C*, and *D*. In this case, tolerance on *AB* is the result of the process that cut *B* (from *A* to *B*). However, the tolerance on *BC* is the result of processes that cut feature *B* (from *A* to *B*) and feature *C* (from *A* to *C*). The finished tolerance on *BC* is twice the process tolerance and twice that of *AB*. The same can be said for *CD*. If we choose *D* as the reference, of course, the tolerance on *CD* is smaller than that for *AB* and *BC*. So we may conclude that process sequence does affect the quality of the part produced. The question is whether the current process sequence satisfies the designed tolerance requirements. Often this question is answered with the tolerance charting method. Tolerance charting will be introduced in the next section.

3. TOOLS FOR PROCESS PLANNING

Process-planning steps were introduced in the previous section. This section discusses the tools used to carry out these steps. Manual process planning, which relies on human experience, will not be discussed. The tools discussed in this section are those used in computer-aided process-planning systems. They are used to assist the human planner in developing process plans. Most of these tools have been used in practical process-planning systems. Methodologies or algorithms used only in advanced research will not be introduced here.

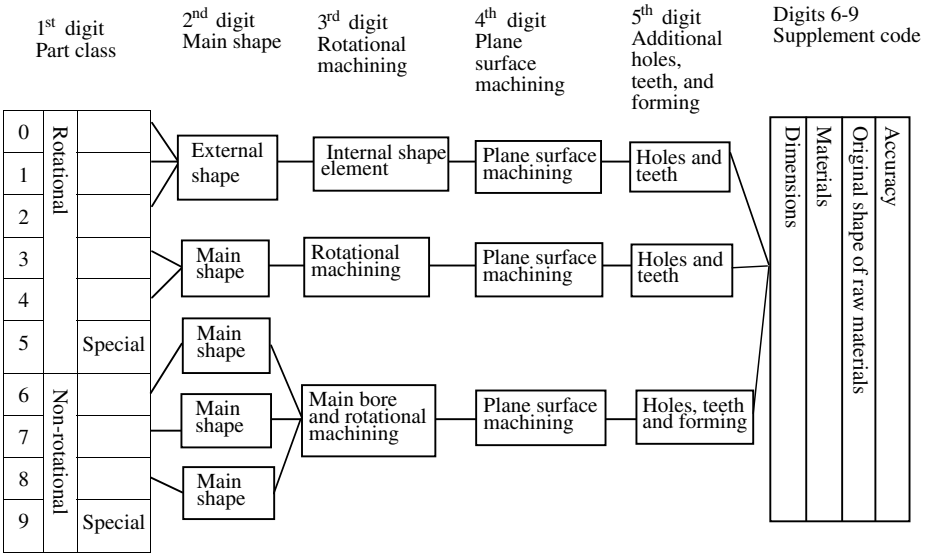


Figure 11 Opitz Code.

3.1. Group Technology

Group technology is a methodology of using the similarity among parts to simplify the production. The key is to identify the similarity. In a machine shop, the thousands of different parts produced may share a small number of geometric characteristics. Parts of similar shape may be produced on the same set of machine tools. The material-handling requirements may also be the same. Manufacturing cells can be designed to produce similar parts. This simplifies the material handling, reduces the complexity of scheduling, and increases the slope of the learning curve. A complex problem can be decomposed into smaller and simpler problems. This set of similar parts is called a part family. Identifying part families is an important step in applying group technology to different manufacturing problems. Group technology has been used in manufacturing system design, scheduling, product retrieval, fixture design, and process planning.

3.1.1. How GT Is Used in Process Planning

As mentioned in the introduction, similar parts can be produced on the same set of machine tools. Most likely they will follow the same process sequence. Therefore, if one collects all the existing process plans used in the shop and groups them based on the part family, one will find that the process plans for the family members are similar. Summarizing the process plans for the family allows a standard process plan to be defined. All parts in the family may share this standard process plan. When a new part is to be planned, one can find the part family of this part, based on the geometric characteristics. The standard process plan for the family is then modified for this new part. Using group technology for manufacturing is like using a library to find references for writing a paper. Without the library database, locating appropriate references will be much more difficult and thus so will the writing.

3.1.2. Coding and Classification

Group technology is based on the concept of similarity among parts. Classification or taxonomy is used for this purpose. The dictionary definition of taxonomy is ''orderly classification of plants and animals according to their presumed natural relationships.'' Here, taxonomy is used to classify parts in manufacturing. There are many methods of part classification. To name just a few: visual observation, manual sorting of the parts, sorting photographs of the parts, and sorting engineering drawings. Because keeping the physical parts or drawing in the sorted order is tedious or sometimes impossible, it is necessary to create a convenient representation, called a coding system.

A coding system uses a few digits or alphanumeric codes to represent a group (family) of similar parts. The classification system is embedded into the coding system. For example, one can easily see that parts can be classified as rotational and nonrotational. A crude coding system can have ''0''

representing any rotational parts and "1" representing any nonrotational parts. Rotational parts can further be classified as rods, cylinders, and disks, based on the length-to-diameter ratio. The code can be refined to have "0" represent rod, "1" cylinder, "2" disk, and "3" nonrotational parts. Further, the external and internal shapes of the part can be classified as smooth, step, screw thread, and so on. Additional digits may be used to represent the external and internal shapes. Each digit refines the classification or adds additional characteristics.

There are many public domain and proprietary coding systems. Opitz (Opitz 1970), Dclass (Allen 1994), MICLASS (OIR 1983), KK3 (Chang et al. 1998) are but a few popular ones. Opitz code (Figure 12), developed by Professor Opitz of Aachen University in the 1960s, uses five digits to represent the geometry of the part and four supplemental digits to represent part dimension, material, raw material shape, and accuracy. If only the geometry is of concern, the supplemental digits need not be coded. Extensive code tables and illustrations are given to guide the user in coding parts. Given a five-digit code, one can have a rough idea of the shape of the part. The code can also be used for searching the part database to find similar parts. Other coding systems may be more detailed or cover a different part domain, but they all serve the same purpose.

3.1.3. Family Formation

To take advantage of the similarity among parts, one must group parts into families. If the geometry is used in defining the part family, the coding and classification system discussed in the previous subsection can be used. Such families are called design families because they are design geometry based. However, often one would like to form part families based on the production methods used. In this case, the part family is called a production family. Because the manufacturing methods are geometry related, members of a production family share many similar feature geometries as well.

Families may be formed using the visual observation method, as mentioned above, or using the sorting approach. In forming design families the coding system can be used as well. Parts with the same codes always belong to the same family. To enlarge the family, several codes may be included in the same family. The determination as which codes should be included is based purely on the applications considered.

To form a production family, one has to consider the manufacturing method. The first well-known production family formation method was called production flow analysis (Burbidge 1975). First, production flows, or process sequences, for all parts are collected. An incidence matrix with columns representing each part and rows representing each process, machine, or operation code (a certain process performed on a machine) is prepared based on the production flows. By sorting the rows and columns of the matrix, one may move the entries along the diagonal of the matrix (see Figure 13). In the matrix, one may conclude that parts 8, 5, 7, 2 belong to one family and 4, 1, 3, 6, 9, 10 belong to another family. Family one needs processes P1, P5, P6, and P3. Family two needs processes P3, P2, and P4. This approach can be tedious and requires human judgment on separating families. As can be seen, P3 is needed for both families. It is not uncommon to have overlapping entries.

Over the years, many mathematics-based sorting methods, called clustering analysis, have been developed. For more details see Kusiak (1990) and Chang et al. (1998).

3.1.4. Composite Component Concept

Given a family of parts, one can identify several features. When one takes all the features and merges them into an imaginary part, this imaginary part, called a *composite component,* is a superset containing the features of the family members. The composite component concept was developed before World War II in Russia, where it was used to design flexible fixtures for a part family. By adjustment of the fixture, it can accommodate all the parts belonging to a family. This concept can also be used in design. For example, parametric design uses a parameterized design model for a narrowly defined

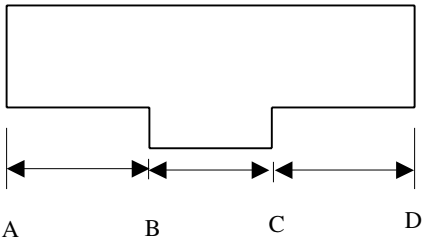

Figure 12 Tolerances.

Parts

Processes	8	5	7	2	4	1	3	6	9	10
P1	1	1	1	1						
P5	1	1	1	1						
P6		1	1	1						
P3				1	1	1	1	1	1	
P2					1	1	1	1	1	1
P4					1	1	1	1	1	1

Figure 13 Production Flow Matrix.

family. One is the model for spur gears. Assigning parameters, such as pitch, number of teeth, outer diameter, pressure angle, teeth face width, hub diameter and length, hole diameter, and keyway and set screw, allows a drawing of the gear to be generated.

The same concept can be applied to process planning. When a process model (processes, tools, and cutting parameters) is developed for each of the features belonging to the composite component, a process plan can be generated using the parameters specified by the user. This concept has been used in developing several experimental and commercial process planners, such as CPPP (Dunn and Mann 1978). Because the same set of parameter data can be used to generate a process plan or a design drawing, CAD/CAM integration can be done. The limitation of this approach is that the family members must have very similar geometry. Not only do features have to be shared, but the relative position of features on family members have to be maintained. Otherwise, not only can the drawing not be done correctly, but the process plan generated will not be usable. The composite component concept is a tool for part families with minor differences among family members.

3.2. Process Mapping

Why a process can generate certain shapes depends on the geometry generation process of the tool. For example, a drill bit has two cutting edges (lips) (Figure 14). The drilling process requires the drill bit to rotate along its axis, then move the cutting edges downward. The rotating cutting edge creates a cone. Sweeping down the cone will remove a cylindrical volume of materials. Thus, the holes created always have a cone-shaped bottom. The turn tool has a single cutting edge. A layer of the material on a rotating workpiece is shaved off by the cutting edge. This layer is actually a tube-like volume. Therefore, the turn tool can reduce the diameter of a rotational workpiece.

A human process planner can use his or her experience and imagination to envision the shape a process/tool can create. However, in trying to automate process planning, it is essential to define the geometric capabilities of manufacturing processes explicitly. During process planning, for a given feature an inverse search is conducted to find the candidate process(es) for the feature. The relationship between features and processes is defined in a mapping between the two. In an automated process planning system, rules or algorithms are written based on this mapping.

3.2.1. Process for Features Mapping

The geometric capability of a process is summarized in Table 3. As can be seen, milling can create many different features (Volume Capabilities column). Drilling, reaming, and boring primarily create holes. Turning can create different axial symmetric parts. Other processes are also listed in the table.

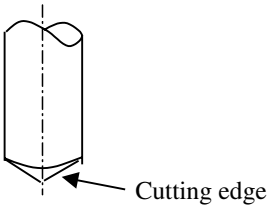

Figure 14 Drill Bit.

TABLE 3 Geometric Capabilities

Process	Subprocess	Cutters	Volume Capabilities
Milling	Face milling	Plain	flat bootom volume
		Inserted-tooth	
	Peripheral milling	Plain	flat bottom volume
		Slitting Saw	slot
		Form	formed volume
		Inserted-tooth	
		Staggered-tooth	
		Angle	
		T-slot cutter	T-slot
		Woodruff keyseat cutter	Internal groove
	End milling	Plain	pocket, slot, flat
		Shell end	
		Hollow end	
		Ball end	sculptured surface, flat
Drilling		Twist drill	round hole
		Spade drill	round hole
		Deep-hole drill	deep round hole
		Gun drill	deep round hole
		Trepanning cutter	large round hole
		Center drill	shallow round hole
		Combination drill	multiple diameter round hole
		Countersink	countersink hole
		Counterbore	counterbore hole
Reaming		Shell reamer	thin wall of round hole

One can easily find the entries for each process and determine the geometric capabilities of the process. Process planning is an inverse mapping. Given a feature, a process planner tries to find all processes that can create that feature.

The table alone is not sufficient. To select the correct process based on the geometry, one needs to look into the geometric constraints as well. Figure 15 provides a small sample of process constraints based on geometry. For example, on the upper-right corner is the ''large hole through a small slot'' constraint. One should not try to drill such a hole after the slot has been cut. The drill center will be in the air and not cutting any material. It will tend to slip and thus produce an inaccurate hole.

3.2.2. Relative-Cost Table for Manufacturing Processes

When conducting a feature-to-process mapping, one may find several candidate processes for the feature. Which process to choose also depends on the cost of the process. The process cost equation consists of a few terms: the tool and machine costs, the material removal rate, and the energy consumption. The relative cost of a process is the cost of removing a unit volume of material. Since the machining time is the inverse of the material removal rate (for a given machining volume), the cost is:

$$C = \frac{\text{tool and machine rates} + \text{energy cost}}{\text{MRR}}$$

where tool and machine rates are overhead cost of using the tool and the machine and energy cost is the energy cost per unit time.

Processes such as drilling, milling, and turning have higher material-removal rates and thus can finish a job faster at a lower cost. Finishing processes such as grinding, boring, and polishing have very low material-removal rates, and also consume more energy for the same amount of material removed. The relative cost is higher. Table 4 gives the price of machine costs, which are one of the factors in the relative cost equation. The energy consumption, for example, for cutting cast iron is 0.5–1.2 hp $\cdot$ min/in^3. When grinding is used, the energy consumption is 4.5–22 hp $\cdot$ min/in^3. Nontraditional processes such as a laser process consume much more energy.

3.3. Process Capability Analysis

Table 5 shows the technological capabilities of 13 processes. Because each shop may use machines and tools of different precision, the data are for reference only. Please note that all dimensions and tolerances are in inches and all surface finish values are in microinches. The process capability values can be used to decide whether a process can satisfy the design specifications of a feature. They can also be used to determine the need of a secondary process (finishing process). For example, a flat surface has a specified surface finish of 20 μin. Using Table 3, we chose flat end mill to cut the surface. From Table 5, we find that finish cut of end mill can create a surface finish of 50 μin. This is definitely not sufficient. Yet finish grinding can create a surface finish of 2 μin. Therefore, finish grinding will be used for finishing and milling for roughing. Milling is chosen for roughing because grinding has a very low material-removal rate. It is not economical to remove all the feature volume using grinding.

Process capability is shop specific. Each shop needs its own process capability database of its own before process planning can be done automatically. Collecting and analyzing capability data can be tedious. Some of these data can be collected through inspection, such as from the control charts. Others require experiments on the machines. Most of the processes that remove material quickly, such as milling, drilling, and turning, create poorer surface finish and accuracy.

3.4. Cost Model

Another extremely important factor is process economics. We are always interested in finding the most economical solution. Often it means the survival of the company. Process economics means the cost efficiency of the processes. For mass production, a very detailed economic analysis is necessary before a specific processing method can be selected. However, for the usual small to medium batch production, it is not practical to conduct a very detailed study. The savings cannot justify the amount of effort spent. Some rough estimation or just common sense should be used to select a better process. Whenever there are more than two candidate processes, both technologically suitable for the task, it is time to compare their relative costs. A process cost model can be stated as:

$$C = \text{labor cost} + \text{machine overhead} + \text{tool change cost} + \text{tool cost}$$

$$C = C_m(T_m + T_h) + (C_t + C_m t_t)\frac{T_m}{T_l}$$

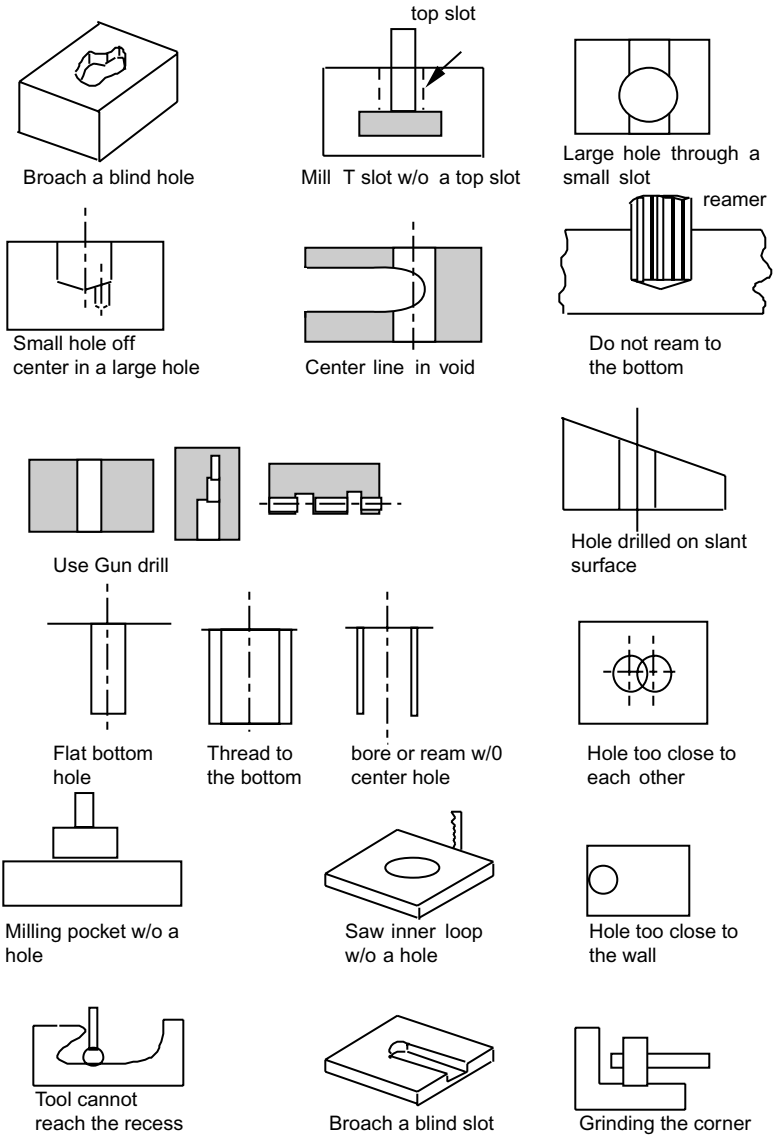

Figure 15 Process Constraints.

where C = total cost for the operation ($)
C_m = operator rate and machine overhead ($/hr)
C_t = cost of tool ($)
T_m = processing time (hr)
T_h = material-handling time, if any (hr)
T_t = tool change time (hr)
T_l = tool life (hr)

In the equation, T_m/T_l is the number of tool changes for the operation. It is determined by the tool life and the processing time. Processing time can be calculated by the necessary tool travel

TABLE 4 Cost of Machinery

Type of Machinery	Price range ($000)
Broaching	10–300

divided by the feed speed. For example, for drilling an x-in. deep hole using a feed speed of a ipm, $T_m = x/a/60$.

The tool life equation can be expressed as (for milling):

$$T_l = \frac{C}{V^{\alpha} f^{\beta} a_p{}^{\gamma}}$$

where C = a constant determined by the tool geometry, tool material, and workpiece material
V = the cutting speed, fpm
f = the feed, ipr
a_p = the depth of cut, in.
$^{\alpha}, ^{\beta}, ^{\gamma}$ = coefficients

Unfortunately, several difficulties prohibit us from using this model to predict the operation cost. First, the cutter path is not known at the process-selection time. Generating a cutter path for each possible process to be machined would be very time consuming. The second problem is the availability of coefficients for each combination of tool-material type and workpiece-material type. There is little published data for tool life equations. Most of the tool life and machinability data are published in terms of recommended feed and speed. With these two major problems, this approach will probably not work for real-world problems. A quick and dirty way must be found to estimate the cost.

Since we are dealing with the machining of a single feature, it is reasonable to assume that the material-handling time is negligible. The chance of changing a tool during the operation is also minimal. Also, the feed and speed recommended by the *Machining Data Handbook* (Metcut 1980) usually make the tool life to be about 60 minutes. Since the recommended feed and speed are what are used in most machining operations, it is reasonable to assume that T_l = 1 hr. Therefore, the cost function can be simplified to:

$$C = \frac{(C_m + C_t)T_m}{60}$$

The machining time can be estimated by the material removal rate (MRR) and the volume (V) to be removed (current feature volume):

$$T_m = \frac{V}{\text{MRR} \cdot 60}$$

Therefore, the cost function can be rewritten as:

$$C = \frac{(C_m + C_t)V}{\text{MRR} \cdot 60}$$

The maximum material-removal rate data can be estimated using some simple equations (Chang 1990). First the tool size, feed, and speed need to be found. The volume to be removed can be estimated much more easily than the length of cutter path. Cost data can also be obtained from the accounting department. With these data the processing cost can be calculated. This cost information can be used to select the most economical process to use for machining a volumetric feature. Because in the processing cost function two variables, C_t and MRR, are related to the process, other capabilities of interest are tool cost and material–removal rate. These capabilities should be used for selecting economical machining processes.

Example. The hole to be drilled is 3 in. deep. The machine and operator rate is \$40/hr. The tool cost is \$10 each. What is the production cost of the hole?

$$V = \frac{\pi\, 1^2}{4}\, 3 = 2.356 \text{ in.}^3$$

$$C = (40 + 10)\, \frac{2.356}{6.93 \cdot 60} = \$0.283$$

The above model does not consider the fixed cost of tooling. The tool cost used in the model is the incremental tool cost. If special tools are needed, a fixed cost may be incurred. In that case, the fixed cost must be evenly distributed to the entire batch of parts made.

3.5. Tolerance Charting

Tolerance charting is a method for checking the proper in-process dimensions and tolerances from a process plan. It is used to verify whether the process sequence will yield the designed dimensions and tolerances. In most of the literature, *process* is replaced by *operation*. In this section we will use the term *process*. Tolerance charting begins with a part drawing and the process plan. On the process plan are processes and machines. Consequences of processes in terms of resultant dimensions and tolerances are marked on the chart. The processes that were used to produce the dimension and the tolerance are labeled for trace. This is done step by step following the sequence of processes. Finally, the specified dimensions and tolerances are compared to the resultant dimensions and tolerances. If any of the dimensions and tolerances are not satisfied, one can trace back to the sources. Then either a different process/machine is used to reduce the process tolerance or the process sequence is changed.

Figure 16 illustrates how a simplified tolerance chart works. The example part is a cylindrical part to be turned. The calculation section of the chart is omitted. On the top of the chart is the design. Note that the tolerance chart can handle one dimension at a time. The drawing is 2D and features are vertical lines (representing surfaces). The solid line shows the boundary of a cylinder with greater diameter at the center. The dashed line shows the stock boundary that encloses the part boundary. The designer has specified dimensions and tolerances between three feature sets. The dimension values are omitted in this example. The next section is the dimension and tolerance section. The thick horizontal lines show where the dimension and tolerance are specified. For example, the overall dimension is 3 and tolerance is 0.01. The following section is the process plan section. Four cuts are shown in the process plan. The first two cuts (10 and 12) use the left-hand side of the stock as the reference. They create two surfaces: surface C and surface D (at the same time the diameters are turned). The next two cuts (20 and 22) create the dimensions between BD and AD. Dimension AB is the result of cuts 20 and 22. Therefore, the tolerance for AB equals the sum of process tolerances for 20 and 22. In this case both are the same. To achieve the designed tolerance of 0.01, the process

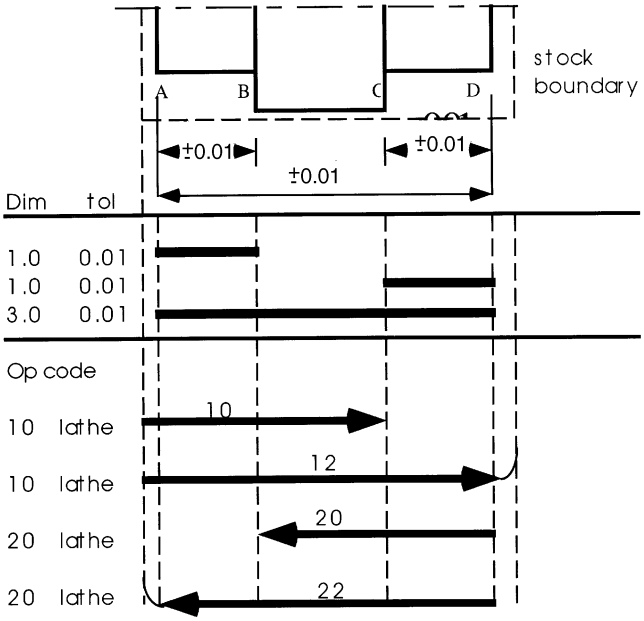

Figure 16 Tolerance Chart.

tolerance must be less than or equal to $0.01/2 = 0.005$. The same can be found for *CD*, which is the result of processes 10 and 12. However, *AD* is the result of only one cut and thus the tolerance is better.

More details on this subject can be found in Curtis (1988).

4. COMPUTER-AIDED PROCESS PLANNING

Process planning has traditionally been experience based and performed manually. A problem facing modern industry is the lack of a skilled labor force to produce machined parts as in the past. Manual process planning also has other problems. Variability among the planners' judgment and experience can lead to differences in the perception of what constitutes the optimal or best method of production. This manifests itself in the fact that most industries have several different process plans for the same part, which leads to inconsistent plans and an additional amount of paperwork. To alleviate this problem, a computer-aided approach can be taken. Development in computer-aided process planning attempts to free the process planner from the planning process. Computer-aided process planning can eliminate many of the decisions required during planning. It has the following advantages:

- It reduces the demand on the skilled planner.
- It reduces the process-planning time.
- It reduces both process-planning and manufacturing cost.
- It creates consistent plans.
- It produces accurate plans.
- It increases productivity.

The benefits of computer-aided process planning systems have been documented in several industries. Such systems can reduce planning time from days to hours and result in large cost savings.

The idea of using computers in the process planning activity was discussed by Niebel (1965). Other early investigations on the feasibility of automated process planning can be found in Scheck (1966) and Berra and Barash (1968). Many industries also started research efforts in this direction in the late 1960s and early 1970s. Early attempts to automate process planning consisted primarily of building computer-assisted systems for report generation, storage, and retrieval of plans. A database system with a standard form editor is what many early systems encompassed. Formatting of plans

was performed automatically by the system. Process planners simply filled in the details. The storage and retrieval of plans are based on part number, part name, or project ID. When used effectively, these systems can save up to 40% of a process planner's time. A typical example can be found in Lockheed's CAP system (1981). An example of a modern version is Pro/Process for Manufacturing (launched in 1996 and since discontinued). Such a system can by no means perform the process-planning tasks; rather, it helps reduce the clerical work required of the process planner.

The typical organization of using a process-planning system is shown in Figure 17. A human planner interprets an engineering drawing and translates it into the input data format for a process-planning system. Either interactively or automatically, a process plan is produced. The plan is then used by production planners for scheduling of production and used by industrial engineers to lay out the manufacturing cell and calculate production cost and time. A part programmer follows the instructions on the process plan and the engineering drawing to prepare NC (numerical control) part programs. The same organization applies to all kinds of process planning systems.

Perhaps the best-known automated process planning system is the CAM-I automated process planning system (CAPP) (Link 1976). (CAM-I stands for ComputerAided Manufacturing International, a nonprofit industrial research organization.) In CAPP, previously prepared process plans are stored in a database. When a new component is planned, a process plan for a similar component is retrieved and subsequently modified by a process planner to satisfy special requirements. The tech-

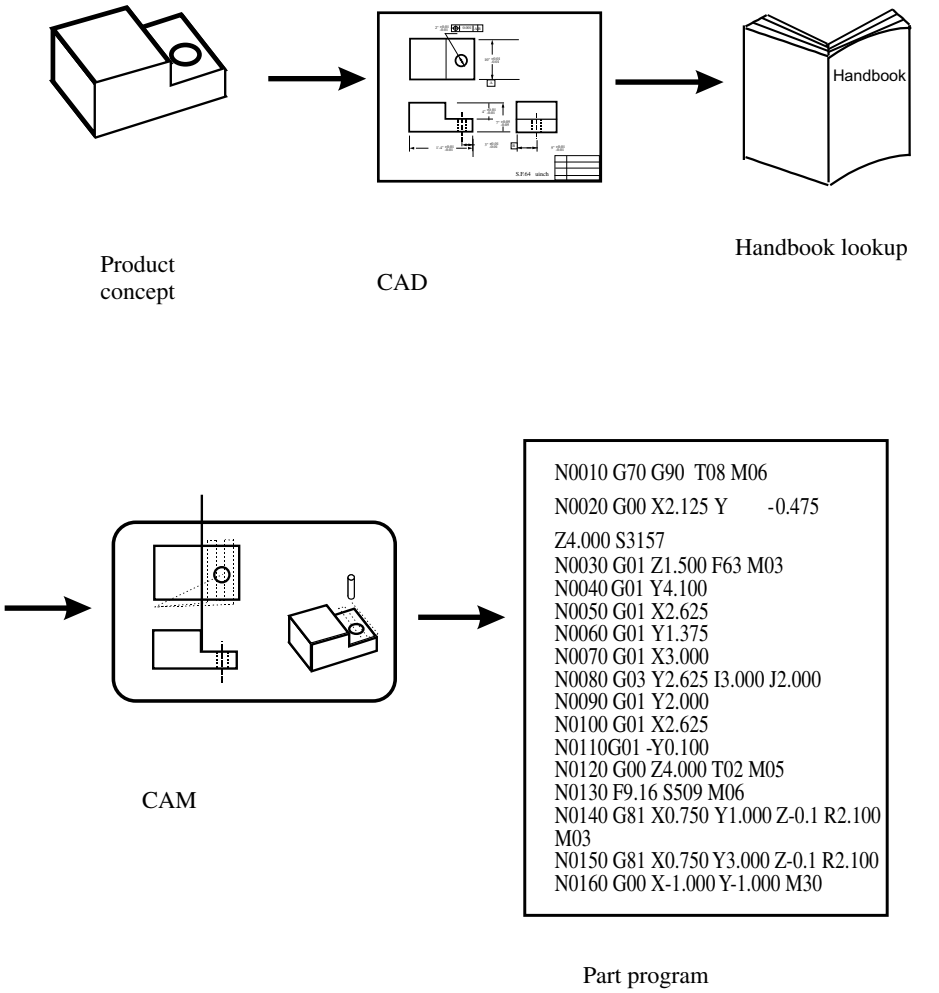

Figure 17 From Design to Part Program.

nique involved is called group technology (GT)-based variant planning (Burbidge 1975). Variant planning will be discussed in more detail in the next section.

Figure 18 represents the structure of a complete computer-aided process-planning system. Although no existing turnkey system integrates all of the functions shown in the figure (or even a goodly portion of them), it illustrates the functional dependencies of a complete process-planning system. It also helps to illustrate some of the constraints imposed on a process-planning system (e.g., available machines, tooling, and jigs).

In Figure 18, the modules are not necessarily arranged based on importance or decision sequence. The system monitor controls the execution sequence of the individual modules. Each module may require execution several times in order to obtain an optimum process plan. Iterations are required to reach feasibility as well as good economic balance.

The input to the system will most probably be a 3D model from a CAD database. The model contains not only the shape and dimensioning information, but also the tolerances and special features. The process plan can be routed directly to the production-planning system and production-control system. Time estimates and resource requirements can be sent to the production-planning system for scheduling. The part program, cutter location (CL) file, and material-handling control program can also be sent to the control system.

Process planning is the critical bridge between design and manufacturing. Design information can be translated into manufacturing language only through process planning. Today, both automated design (CAD) and manufacturing (CAM) have been implemented. Integrating, or bridging, these functions requires automated process planning as the key component.

There are two basic approaches to computer-aided process planning: variant and generative. The variant approach is used by the computer to retrieve plans for similar components using table look-up procedures. The process planner then edits the plan to create a variant to suit the specific requirements of the component being planned. Creation and modification of standard plans are the process planner's responsibility. The generative approach is based on generating a plan for each component without referring to existing plans. Generative systems are systems that perform many of the functions in a generative manner. The remaining functions are performed with the use of humans in the planning loop.

4.1. Variant Approach

The variant approach to process planning was the first approach used to computerize planning techniques. It is based on the idea that similar parts will have similar process plans. The computer can

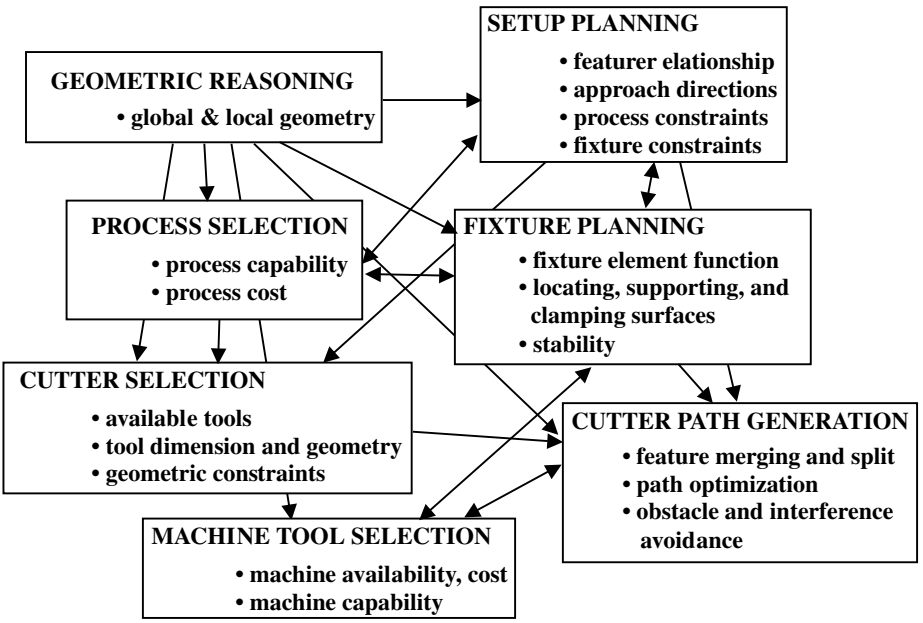

Figure 18 Process-Planning Functions.

be used as a tool to assist in the identification of similar plans, retrieving them and editing the plans to suit the requirements for specific parts.

A variant process planning system includes the following functions:

- Family formation
- Standard plan preparation
- Plan editing
- Databases

In order to implement such a concept, GT-based part coding and classification are used as a foundation. Individual parts are coded based upon several characteristics and attributes. Part families are created of ''like'' parts having sufficiently common attributes to group them into a family. This family formation is determined by analyzing the codes of the part spectrum. A ''standard'' plan consisting of a process plan to manufacture the entire family is created and stored for each part family. The development of a variant process-planning system has two stages: the preparatory stage and the production stage.

During the preparatory stage, existing components are coded, classified, and later grouped into families (Figure 19). The part family formation can be performed in several ways. Families can be formed based on geometric shapes or process similarities. Several methods can be used to form these groupings. A simple approach would be to compare the similarity of the part's code with other part codes. Since similar parts will have similar code characteristics, a logic that compares part of the code or the entire code can be used to determine similarity between parts.

Families can often be described by a set of family matrices. Each family has a binary matrix with a column for each digit in the code and a row for each value a code digit can have. A nonzero entry in the matrix indicates that the particular digit can have the value of that row. For example, entry (3,2) equals one implies that a code x3xxx can be a member of the family. Since the processes of all family members are similar, a standard plan can be assigned to the family.

The standard plan is structured and stored in a coded manner using operation codes (OP codes). An operation code represents a series of operations on one machine/workstation. For example, an OP code DRL10 may represent the sequence center drill, change drill, drill hole, change to reamer, and ream hole. A series of OP codes constitutes the representation of the standard process plan.

Before the system can be of any use, coding, classification, family formation, and standard plan preparation must be completed. The effectiveness and performance of the variant process-planning system depends to a very large extent on the effort put forth at this stage. The preparatory stage is a very time-consuming process.

The production stage occurs when the system is ready for production. New components can be planned in this stage. An incoming component is first coded. The code is then sent to a part family search routine to find the family to which it belongs. Because the standard plan is indexed by the family number, the standard plan can be easily retrieved from the database. Because the standard

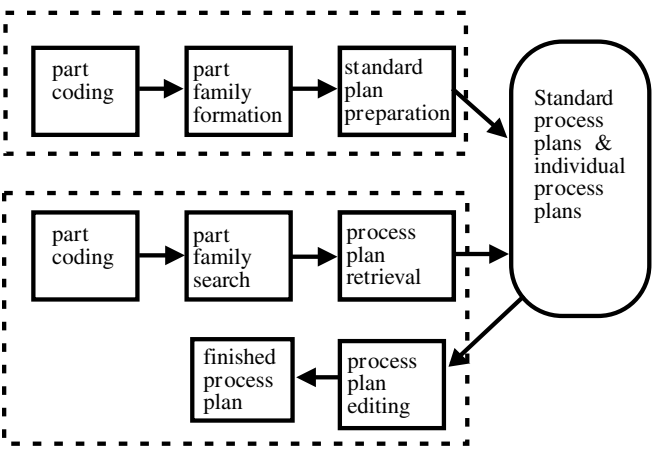

Figure 19 Variant Process Planning.

plan is designed for the entire family rather than for a specific component, editing the plan is unavoidable.

Variant process-planning systems are relatively easy to build. However, several problems are associated with them:

- The components to be planned are limited to similar components previously planned.
- Experienced process planners are still required to modify the standard plan for the specific component.
- Details of the plan cannot be generated.
- Variant planning cannot be used in an entirely automated manufacturing system, without additional process planning.

Despite these problems, the variant approach is still an effective method, especially when the primary objective is to improve the current practice of process planning. In most batch manufacturing industries, where similar components are produced repetitively, a variant system can improve the planning efficiency dramatically. Some other advantages of variant process planning are:

- Once a standard plan has been written, a variety of components can be planned.
- Comparatively simple programming and installation (compared with generative systems) is required to implement a planning system.
- The system is understandable and the planner has control of the final plan.
- It is easy to learn and easy to use.

The variant approach is the most popular approach in industry today. Most working systems are of this type, such as CAPP of CAM-I (Link 1976) and Multiplan of OIR (OIR 1983).

4.2. Generative Approach

Generative process planning is the second type of computer-aided process planning. It can be concisely defined as a system that automatically synthesizes a process plan for a new component. The generative approach envisions the creation of a process plan from information available in a manufacturing database without human intervention. Upon receiving the design model, the system is able to generate the required operations and operation sequence for the component.

A generative process-planning system consists of the following important functions:

- Design representation
- Feature recognition
- Knowledge representation
- System structures

Knowledge of manufacturing has to be captured and encoded into computer programs. A process planner's decision-making process can be imitated by applying decision logic. Other planning functions, such as machine selection, tool selection, and process optimization, can also be automated using generative planning techniques.

A generative process-planning system contains three main components:

- Part description
- Manufacturing databases
- Decision-making logic and algorithms

The definition of generative process planning used in industry today is somewhat relaxed. Thus, systems that contain some decision-making capability in process selection are called generative systems. Some of the so-called generative systems use a decision tree to retrieve a standard plan. Generative process planning is regarded as more advanced than variant process planning. Ideally, a generative process-planning system is a turnkey system with all the decision logic built in. Since this is still far from being realized, generative systems currently developed provide a wide range of capabilities and can at best be described as only semigenerative.

The generative process-planning approach has the following advantages:

- It generates consistent process plans rapidly.
- New components can be planned as easily as existing components.

- It has potential for integrating with an automated manufacturing facility to provide detailed control information.

Successful implementation of this approach requires the following key developments:

- The logic of process planning must be identified and captured.
- The part to be produced must be clearly and precisely defined in a computer-compatible format.
- The captured logic of process planning and the part-description data must be incorporated into a unified manufacturing database.

4.2.1. Part-Description Methods for Generative Process-Planning Systems

Part description forms a major part of the information needed for process planning. The way in which the part description is input into the process-planning system has a direct effect on the degree of automation that can be achieved. Since the aim is to automate the system, the part description should be in a computer-readable format. Traditionally, engineering drawings have been used to convey part descriptions and communicate between design and manufacturing. Understanding the engineering drawing was a task suited for well-trained human beings and initially not suitable for direct input for process planning. The requirements of the part-description methods include:

- Geometrical information
- Part shape
- Design features
- Technological information
- Tolerances
- Surface quality (surface finish, surface integrity)
- Special manufacturing notes
- Feature information
- Manufacturing features (e.g., slots, holes, pockets)

Before the representation method is decided, the following factors have to be determined:

- Data format required
- Ease of use for planning
- Interface with other functions, such as part programming and design
- Easy recognition of manufacturing features
- Easy extraction of planning information from the representation

Some of the representations used in a generative process-planning system include: GT code, line drawing, special language, symbolic representation, solid model, CSG, B-Rep, feature-based model. Extract and decompose features from a geometric model.

- Syntactic pattern recognition
- State transition diagram and automata
- Decomposition
- Logic
- Graph matching
- Face growing

5. COMPUTER-AIDED PROCESS PLANNING SYSTEMS SELECTION CRITERIA

Selecting a process-planning system for a company is not an easy task. Each machine shop has its own unique characteristics. Decision tables have been developed for selecting computer-aided process-planning systems. For example, Steudel and Tollers (1985) present a decision table for selecting CAPP solutions (the tables are also reprinted in Chang et al. [1991, chap. 13]). This approach assumes that certain decision rules can be written for each selection decision. However, often such rules are not available. Another approach is to compare the characteristics of the competing systems based on weights. Table 6 shows a comparison table for two process-planning systems. In the table are 12 major categories, most of which are divided into several subcategories. Weights can be assigned

TABLE 6 System Comparison Table

	Weight	Systems	
		System 1	System 2
1. Input data			
1.1. CAD file format		1	4
2. Workpiece understanding	**3**		
2.1. Shape analysis		0	5
2.2. Material analysis		1	1
2.3. Specification analysis		1	1
2.4. Tolerance analysis		2	3
Average		1	3
3. Process selection	**2**		
3.1. Feature hierarchy		3	5
3.2. Tolerance analysis		0	5
3.3. Process capability model		0	5
3.4. Specification analysis		0	2
3.5. Cost analysis		0	1
3.6. Capacity analysis		0	2
Average		**1**	**3**
4. Machine tool management	**2**		
4.1. Machine tool selection		0	5
4.2. Machine capability model		0	5
4.3. Maintenance planning		0	0
4.4. Environmental analysis		0	0
4.5. Flow analysis		0	0
4.6. Life-cycle analysis		0	0
4.7. Supplier development		0	0
4.8. Control specification		0	0
4.9. Facility planning		0	0
Average		**0**	**5**
5. Quality management	**2**		
5.1. Process-control planning		0	0
5.2. Gage planning		1	0
5.3. Scrap and rework management		0	0
5.4. Quality assurance		0	0
Average		**1**	**0**
6. Process design	**3**		
6.1. Tool selection		1	5
6.2. Fixture design		1	4
6.3. Gage design		1	0
6.4. Tool path generation		2	5
6.5. Operation sequencing		1	5
6.6. Process parameters		1	5
6.7. Feature accessibility		0	5
6.8. Tolerance analysis		0	4
Average	**1**	**4**	
7. Evaluation and validation	**3**		
7.1. Target cost		0	5
7.2. Tool path verification		5	4
7.3. Workpiece quality		0	0
7.4. Process reliability		0	0
7.5. Production times		1	5
Average		**2**	**3**
8. Document generation	**3**		
8.1. Tool/gage orders		2	4
8.2. Equipment orders		0	5
8.3. Operation sheets		2	4
8.4. Process routing		2	4
8.5. Part programs		5	5
8.6. Setup drawings		3	5
Average		**2**	**5**
9. Machine domain	**3**	**4**	**5**
10. Part domain	**3**	**4**	**4**
11. Platform	**1**	**5**	**3**
12. Technical support	**3**	**5**	**4**
Total		**65**	**101**

to either each major category or subcategory. The total weights may be used to determine the final selection. The comparison is not limited to the pair comparison as it is in the example; more systems can be added to the table.

The meanings of the categories in Table 6 are defined below:

- Input data: The process-planning system must interface with the existing CAD design system. The system can either read the native CAD data or can input through an data-exchange format such as IGES or STEP.
  - CAD file format: the design data file acceptable, e.g., Pro/E, CADDS, CATIA, IGES, STEP.
- Workpiece understanding:
  - Shape analysis: feature recognition; converting design data into manufacturing feature data.
  - Material analysis: identification of raw material shape, sizes, type (cast, bar, etc.), and weight.
  - Specification analysis: extracting other manufacturing specifications from the design (e.g., paint, hardness, surface treatment).
  - Tolerance analysis: extracting tolerance data from the design.
- Process selection:
  - Feature hierarchy: process selection based on hierarchically arranged manufacturing features.
  - Tolerance analysis: process selection based on the tolerance capabilities of processes vs. the design specifications.
  - Process capability model: a computer model that captures the capability of a process. Process models are used in process selection. They may be customized.
  - Specification analysis: understanding other manufacturing specifications and using them as the basis for selecting processes.
  - Cost analysis: estimating and analyzing manufacturing cost and using it as the basis for selecting processes.
  - Capacity analysis: machine selection with the consideration of the throughput of each machine.
- Machine tool management:
  - Machine tool selection: selecting appropriate machine tools for the job.
  - Machine capability model: a computer model that captures the process capability of a machine tool.
  - Maintenance planning: maintenance schedule for machine tools.
  - Environmental analysis: assessment of environmental requirements (temperature, pressure, humidity) necessary to achieve quality targets.
  - Flow analysis: production flow analysis (i.e., throughput).
  - Life-cycle analysis: the economic analysis, from cradle to grave, of asset costs to derive metrics like ROA.
  - Supplier development: identifying supplier for the machine tool.
  - Control specification: managing NC controller specifications for postprocessors.
  - Facility planning: integration with the facility planning functions.
- Quality management
  - Process control planning: generating control charts for process control.
  - Gage planning: CMM programming, gage calibration, certification planning.
  - Scrap and rework management: planning for management of the disposition of parts for scrap and rework
  - Quality assurance: generating quality assurance plan for certification. Process plans may be used for this purpose.
- Process design
  - Tool selection: selecting tools to be used for the machining of a part.
  - Fixture design: designing the fixture necessary for the workpiece holding under a given setup.
  - Gage design: designing the gage for inspecting the workpiece.
  - Tool path generation: generating the NC tool path for the part.
  - Operation sequencing: sequencing the NC tool path for the part
  - Process parameters: selecting process parameters, e.g., feed and speed, for each tool/cut.
  - Feature accessibility: analyzing the tool accessibility of each feature to be machined.

TABLE 7 Summary of System Functionalities

	System	
	System 1	System 2
1. Input data		
1.1. CAD file format	IGES	PDES, DXF
2. Workpiece understanding		
2.1. Shape analysis	N/A	Feature recognition
2.2. Material analysis	limited	limited
2.3. Specification analysis	Manual	Manual
2.4. Tolerance analysis	Manual	Manual input
3. Process selection		
3.1. Feature hierarchy	Pro/E	Yes
3.2. Tolerance analysis	Manual	Rules
3.3. Process capability model	N/A	Method hierarchy/DB
3.4. Specification analysis	Manual	limited
3.5. Cost analysis	N/A	implicit
3.6. Capacity analysis	N/A	implicit
4. Machine tool management		
4.1. Machine tool selection	Manual	Automatic
4.2. Machine capability model	N/A	Method hierarchy/DB
4.3. Maintenance planning	N/A	N/A
4.4. Environmental analysis	N/A	N/A
4.5. Flow analysis	N/A	N/A
4.6. Life-cycle analysis	N/A	N/A
4.7. Supplier development	N/A	N/A
4.8. Control specification	N/A	N/A
4.9. Facility planning	N/A	N/A
5. Quality management		
5.1. Process control planning	N/A	N/A
5.2. Gage planning	CMM/interactive	N/A
5.3. Scrap and Rework Management	N/A	N/A
5.4. Quality assurance	N/A	N/A
6. Process design		
6.1. Tool selection	Manual	Automatic
6.2. Fixture design	Manual	Automatic
6.3. Gage design	Manual	N/A
6.4. Tool path generation	Interactive	Automatic
6.5. Operation sequencing	Manual	Automatic
6.6. Process parameters	User-supplied DB	User-supplied RDB
6.7. Feature accessibility	N/A	Yes
6.8. Tolerance analysis	N/A	Yes
7. Evaluation and validation		
7.1. Target cost	N/A	Yes
7.2. Tool path verification	Pro/NC-Check	Yes
7.3. Workpiece quality	N/A	N/A
7.4. Process reliability	N/A	N/A
7.5. Production times	N/A	Yes
8. Document generation		
8.1. Tool/gage orders	User-defined template	Tool list
8.2. Equipment orders	N/A	Machine list
8.3. Operation sheets	User-defined template	Yes
8.4. Process routing	User-defined template	Yes
8.5. Part programs	Pro/E	APT
8.6. Setup drawings	Manual	Yes
9. Machine domain	Mill, lathe, etc.	Machining center
10. Part domain	Prismatic, turned	Prismatic 2 1/2D, turned
11. Platform	Workstations and PCs	SGI/HP, PC
12. Technical support	Local	Headquarters

  - Tolerance analysis: comparing the tolerance specification against the tolerance capabilities of the selected tools and machine tools; stacking up tolerance based on the setup and machine accuracy and setup error.
- Evaluation and validation:
  - Target cost: estimating the manufacturing cost of that part.
  - Tool path verification: graphically simulating the tool motion to ensure that the tool path has no collision with the fixture and the machine and produces correct part geometry.
  - Workpiece quality: confirming that quality indices are met.
  - Process reliability: reliability indexes for the processes selected for the part.
  - Production times: estimating the time it takes to produce the part.
- Document generation:
  - Tool/gage orders: job orders for tools and gages needed.
  - Equipment orders: job orders for equipment used.
  - Operation sheets: detailed description of each operation and operation parameters including gaging detail/instructions.
  - Process routing: process routing sheet. Lists operation sequence and processes.
  - Part programs: NC part program and part program format, e.g., RS 274, CL, BCL, APT source, COMPACT II source, postprocessed N-G code.
  - Setup drawings: drawings of the workpiece with fixture for each setup.
- Machine domain: machine tools that can be modeled and planned by the system.
- Part domain: types of part that can be planned by the system (e.g., turned, prismatic, casting).
- Platform: computer platform on which the software can be used.
- Technical support: technical support provided by the vendor.
- Total: total composite score based on the criteria above.

A composite score may not be sufficient for making the final decision. It is necessary to record the specifications in each subcategory. Table 7 illustrates such a table for the same comparison as in Figure 6. With these two tables, an appropriate computer-aided process planning system can be selected.

6. CONCLUSIONS

In this chapter, we have provided a general overview of manufacturing process planning and design. We have also discussed the tools used in process planning. As mentioned earlier in the chapter, automated process planning is especially important for small batch production. At a time when competition is keen and product changeover rapid, shortening the production lead time and production cost are critical to the survival of modern manufacturing industry. Process planning plays an important role in the product-realization process. In order to achieve the goals stated above, it is essential to put more focus on this planning function.

Process planning is a function that requires much human judgment. Over the past three decades, much effort has been put into automating process planning. Although progress has been made on geometric modeling and reasoning, knowledge-based systems, and computational geometry for tool-path generation, no robust integrated process-planning system has been developed. Developing an automated process-planning system is still a challenge to be fulfilled. In the meantime, many of these technologies have been integrated into CAD/CAM systems. They provide human planners with powerful tools to use in developing process plans. We can expect an increasing amount of planning automation be made available to manufacturing engineers. This chapter provides a general background to this important topic. Additional readings are included for those interested in a more in-depth investigation of the subject.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

Joseph Harrington introduced the concept of computer integrated manufacturing (CIM) in 1979 (Harrington 1979). Not until about 1984 did the potential benefits the concept promised begin to be appreciated. Since 1984, thousands of articles have been published on the subject. Thanks to the contributions of researchers and practitioners from industries, CIM has become a very challenging and fruitful research area. Researchers from different disciplines have contributed their own perspectives on CIM. They have used their knowledge to solve different problems in industry practice and contributed to the development of CIM methodologies and theories.

2. CIM DEFINITIONS AND CONCEPTS

2.1. Manufacturing Environment

From the name ''computer integrated manufacturing,'' it can be seen that the application area of CIM is manufacturing. Manufacturing companies today face intense market competition, and are experiencing major changes with respect to resources, markets, manufacturing processes, and product strategies. Manufacturing companies must respond to the rapidly changing market and the new technologies being implemented by their competitors. Furthermore, manufacturing, which has been treated as an outcast by corporate planning and strategy, must become directly involved in these critical long-range decisions. Manufacturing can indeed be a formidable competitive weapon, but only if we plan for it and provide the necessary tools and technologies (Buffa 1984).

Besides the traditional competitive requirements of low cost and high quality, competitive pressure for today's manufacturing companies means more complex products, shorter product life cycles, shorter delivery time, more customized products, and fewer skilled workers. The importance of these elements varies among industries and even among companies in the same industry, depending on each company's strategy.

Today's products are becoming much more complex and difficult to design and manufacture. One example is the automobile, which is becoming more complex, with computer-controlled ignition, braking, and maintenance systems. To avoid long design times for the more complex products, companies should develop tools and use new technologies, such as concurrent engineering, and at the same time improve their design and manufacturing processes.

Higher quality is the basic demand of customers, who want their money's worth for the products they buy. This applies to both consumers and industrial customers. Improved quality can be achieved

through better design and better quality control in the manufacturing operation. Besides demanding higher quality, customers are not satisfied with the basic products with no options. There is a competitive advantage in having a broad product line with many versions, or a few basic models that can be customized. A brand new concept in manufacturing is to involve users in the product design. With the aid of design tools or a modeling box, the company allows the users to design the products in their own favor.

In the past, once a product was designed, it had a long life over which to recover its development costs. Today many products, especially high-technology products, have a relatively short life cycle. This change has two implications. First, companies must design products and get them to the market faster. Second, a shorter product life provides less time over which to recover the development costs. Companies should therefore use new technologies to reduce both time and cost in product design. Concurrent engineering is one method for improving product design efficiency and reducing product costs. Another new paradigm is represented by agile manufacturing, in which the cost and risks of new product development are distributed to partners and benefits are shared among the partners. This requires changes to or reengineering of traditional organization structures.

Several demographic trends are seriously affecting manufacturing employment. The education level and expectations of people are changing. Fewer new workers are interested in manufacturing jobs, especially the unskilled and semiskilled ones. The lack of new employees for the skilled jobs that are essential for a factory is even more critical. On the other hand, many people may not have sufficient education to be qualified for these jobs (Bray 1988).

To win in the global market, manufacturing companies should improve their competitive ability. Key elements include creative new products, higher quality, better service, greater agility, and low environmental pollution. Creative new products are of vital importance to companies in the current "knowledge economy."

Figure 1 presents a market change graph. From this figure, it can be seen that the numbers for lot size and repetitive order are decreasing, product life cycle is shortening, and product variety is increasing rapidly.

End users or customers always need new products with advancements in function, operation, and energy consumption. The company can receive greater benefits through new products. A manufacturing company without new products has little chance of surviving in the future market. Better services are needed by any kind of company. However, for manufacturing companies, better service means delivering products fast, making products easy to use, and satisfying customer needs with low prices and rapid response to customer maintenance requests.

2.2. Features of a General Manufacturing System

The manufacturing company is a complex, dynamic, and stochastic entity consisting of a number of semi-independent subsystems interacting and intercommunicating in an attempt to make the overall system function profitably. The complexity comes from the heterogeneous environment (both hardware and software), huge quantity of data, and the uncertain external environment. The complex structure of the system and the complex relationships between the interacting semi-autonomous subsystems are also factors making the system more complicated.

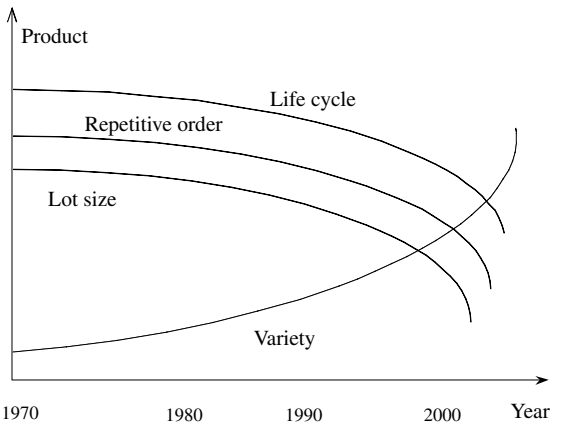

Figure 1 Market Change.

A simple model of a manufacturing system can be a black box that takes as input materials, energy, and information and gives as output products. The internal details of the manufacturing system depend on the particular industry involved, but the key feature common to all manufacturing organizations is that the system processes both materials and information. General manufacturing systems can be decomposed into seven levels of decision hierarchies (Rogers et al. 1992) (Figure 2). Decisions at the upper levels are made at less frequent intervals (but have implications for longer periods into the future) and are made on the basis of more abstract (and slower to change) information on the state of the system. Decisions at the lower levels are made more frequently using much more detailed information on the state of the system.

Three kinds of decisions should be made for any manufacturing company: (1) what kinds of products to make, (2) what resources will be needed to make the products, and (3) how to control the manufacturing systems. These decisions cannot be made separately. If the company wishes to make a decision at a certain level, such as at the business level, it should also get access to the information at other levels. In the whole process of decision making, the core concept is integration. This is the fundamental requirement for the research and development of computer integrated manufacturing.

2.3. CIM Definitions

There are many definitions for CIM, emphasizing different aspects of it as a philosophy, a strategic tool, a process, an organizational structure, a network of computer systems, or a stepwise integration of subsystems. These different definitions have been proposed by researchers working in different areas at different times from different viewpoints. Since the concept of CIM was put forward in 1973, it has been enriched by the contributions of many researchers and practitioners. One earlier definition of CIM is ''the concept of a totally automated factory in which all manufacturing processes are integrated and controlled by a CAD/CAM system. CIM enables production planners and schedules, shopfloor foremen, and accountants to use the same database as product designers and engineers'' (Kochan and Cowan 1986). This definition does not put much emphasis on the role of information.

Another definition is given by Digital Equipment Corporation (DEC): ''CIM is the application of computer science technology to the enterprise of manufacturing in order to provide the right information to the right place at the right time, which enables the achievement of its product, process and business goals'' (Ayres 1991). This definition points out the importance of information in manufacturing enterprise, but unfortunately it does not give much emphasis to the very important concept of integration.

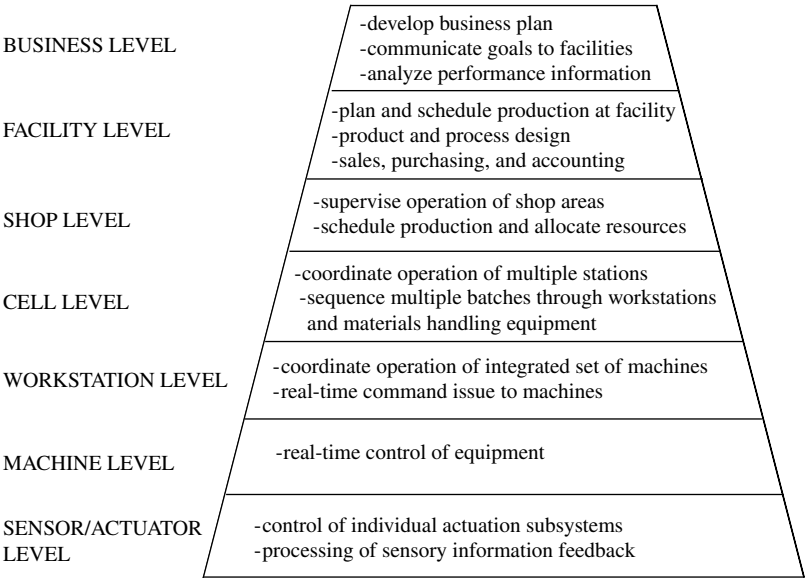

Figure 2 A Seven-Level Manufacturing Hierarchy. (From Rogers et al. 1992)

Other definitions have pointed out that CIM is a philosophy in operating a manufacturing company. For example: "CIM is an operating philosophy aiming at greater efficiency across the whole cycle of product design, manufacturing, and marketing, thereby improving quality, productivity, and competitiveness" (Greenwood 1989).

To stress the importance of integration, the Computer and Automation Systems Association of the Society of Manufacturing Engineers gives the following definition: "CIM is the integration of the total manufacturing enterprise through the use of integrated systems and data communications coupled with new managerial philosophies that improve organizational and personnel efficiency" (Singh 1996).

CIM does not mean replacing people with machines or computers so as to create a totally automatic business and manufacturing processes. It is not necessary to build a fully automatic factory in order to implement a CIM system. It is especially unwise to put a huge investment into purchasing highly automation-flexible manufacturing systems to improve manufacturing standards if the bottleneck in the company's competitiveness is not in this area. In the current situation, the design standards for creative and customized products are more important than production ability in winning the market competition.

The importance of human factors should be emphasized. Humans play a very important role in CIM design, implementation, and operation. Although computer applications and artificial intelligence technologies have made much progress, even in the future, computers will not replace people. To stress the importance of the role of humans, the idea of human-centered CIM has been proposed.

Two views of CIM can be drawn from these definitions: the system view and the information view. The system view looks at all the activities of a company. The different functions and activities cannot be analyzed and improved separately. The company can operate in an efficient and profitable way only if these different functions and activities are running in an integrated and coordinated environment and are optimized in a global system range. The SME CIM wheel (Figure 3) provides a clear portrayal of relationships among all parts of an enterprise. It illustrates a three-layered integration structure of an enterprise.

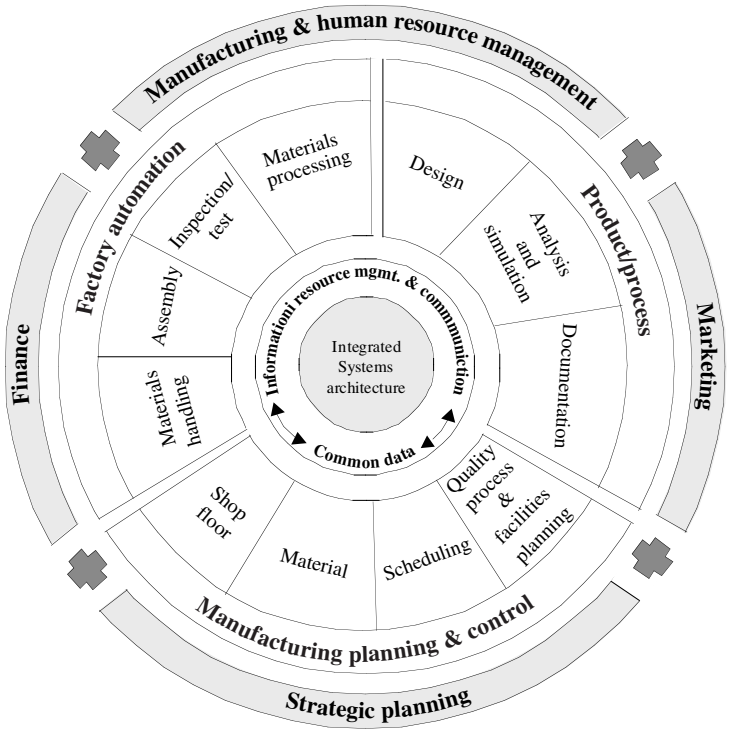

Figure 3 The SME CIM Wheel. (From *Systems Approach to Computer-Integrated Design and Manufacturing,* by N. Singh, copyright 1996 by John Wiley and Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

The outer layer represents general management and human resources management. The middle layer has three process segments: product and process definition, manufacturing planning and control, and factory automation. These segments represent all the activities in the design and manufacturing phases of a product life cycle, from concept to assembly. The center of the wheel represents the third layer, which includes information resources management and the common database.

The other view of CIM is the information view. As stated in the definition given by Digital Equipment Corporation, the objective of CIM implementation is to enable the right information to be sent to the right person at the right time. The information system plays a vital role in the operation of CIM. Although many kinds of activities are involved in managing a manufacturing company, each activity has a different function in business management and production control. The associated function unit for the information system of CIM normally can be classified into three kinds of tasks: information collection, information processing, and information transfer.

Information collection is the basic function of an information system. The information collected forms the basis of decision making at different levels from business management to device control. There are many methods of information collection, depending on the information sources and technologies used. Device sensors may provide data regarding device status; barcode scanners may provide data about the production status of online products; and form scanners and database table view interfaces may provide data about order, raw material purchasing, and user requirements. Some data may also come from e-mail systems. The data collected can be stored in different data formats and different repositories.

Information processing is closely related to the business functions of a company. Business functions range from strategy planning, process planning, product design, warehouse management, and material supply to production management and control. The upper-stream process data are processed by algorithms or human intervention and the instructions produced are used for the downstream process. In data processing, different decisions will be made. The decisions can be used to optimize the production processes or satisfy user requirements such as delivery time and quality requirements.

Information transfer between different function units has three main functions: data output from application software in a certain data format to a certain kind of data repository; data format transformation, and data transfer from one application to another application within the same computer or in a network environment.

2.4. Integration: The Core of CIM

The core of CIM is usually seen to be integration. In our opinion, computer technology is the basis of CIM, manufacturing is the aim, and integration is the key technology. Why should integration be considered the core of CIM? This can be seen from different aspects. The system view of CIM was described above. *System* means the whole company, including people, business, and technology. In order to form a coordinated system, these elements must be integrated. Material flow, information flow, and capital flow must also be integrated. Although those aims seem clear, the technology for realizing this integration is far from mature.

CIMOSA (Esprit Consortium AMICE 1993) identifies enterprise integration as an ongoing process. Enterprises will evolve over time according to both internal needs and external challenges and opportunities. The level of integration should remain a managerial decision and should be open to change over a period of time. Hence, one may find a set of tightly coupled systems in one part of a CIM enterprise and in another a set of loosely coupled systems according to choices made by the enterprise. The implementation of multivendor systems in terms of both hardware and software and easy reconfiguration requires the provision of standard interfaces. To solve the many problems of the industry, integration has to proceed on more than one operational aspect. The AMICE (European Computer Integrated Manufacturing Architecture) project identifies three levels of integration covering physical systems, application and business integration (see Figure 4).

Business integration is concerned with the integration of those functions that manage, control, and monitor business processes. It provides supervisory control of the operational processes and coordinates the day-to-day execution of activities at the application level.

Application integration is concerned with the control and integration of applications. Integration at this level means providing a sufficient information technology infrastructure to permit the system wide access to all relevant information regardless of where the data reside.

Physical system integration is concerned with the interconnection of manufacturing automation and data-processing facilities to permit interchange of information between the so-called islands of automation (intersystem communications). The interconnection of physical systems was the first integration requirement to be recognized and fulfilled.

Even when business integration has been achieved at a given time, business opportunities, new technologies, and modified legislation will make integration a vision rather than an achievable goal. However, this vision will drive the management of the required changes in the enterprise operation.

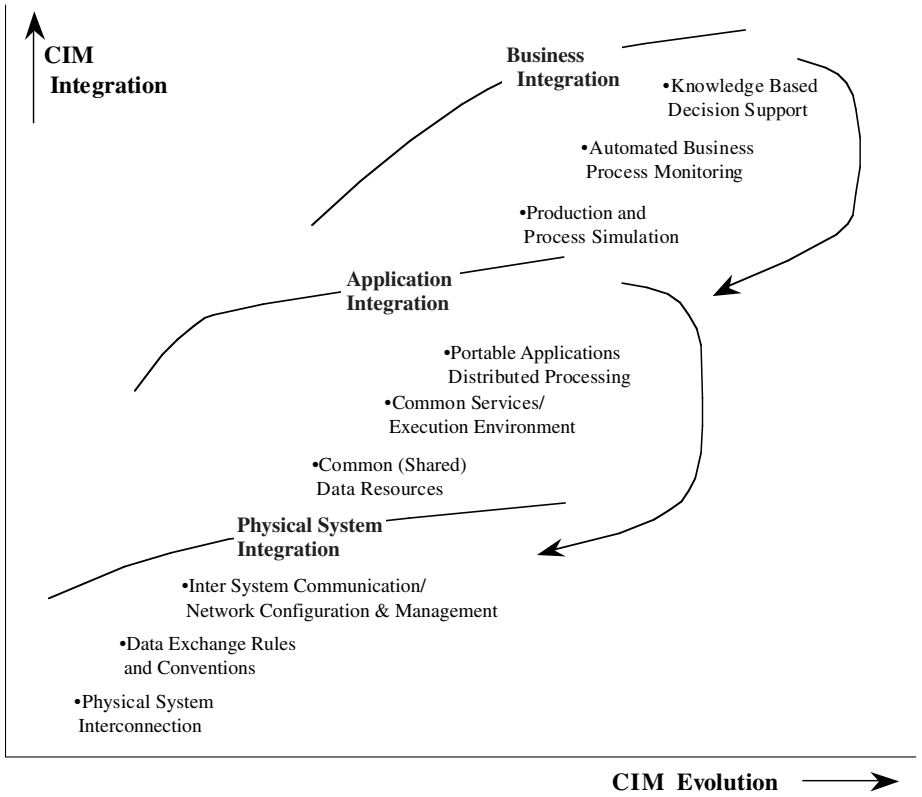

Figure 4 Three Levels of Integration. (From Esprit Consortium AMICE 1993. Reprinted by permission of Springer-Verlag.)

The classification of integration can also be given in another method, which is different from that given by CIMOSA. Regarding integration objectives and methods, integration can be classified as information integration, process integration, and enterprise-wide integration.

Information integration enables data to be shared between different applications. Transparent data access and data consistency maintenance under heterogeneous computing environments is the aim of information integration. Information integration needs the support of communication systems, data-representation standards, and data-transfer interfaces. Communication systems provide a data transfer mechanism and channel between applications located at different computer nodes. Data-representation standards serve as common structures for data used by different applications. Data-transfer interfaces are used to transfer data from one application to another. They fulfill two kinds of functions: data format transfer (from application-specified data structure to common structure and vice versa) and data transfer from application to interface module and vice versa. The traditional information-integration methods include database data integration, file integration, and compound data integration. The most efficient support tool for information integration is the integration platform (Fan and Wu 1997).

Process integration is concerned with the collaboration between different applications in order to fulfill business functions, such as product design and process control. The need to implement process integration arises from companies' pursuit of shorter product design time, higher product quality, shorter delivery time, and high business process efficiency. Business process reengineering (BPR) (Jacobson 1995) and concurrent engineering (CE) (Prasad 1996) have promoted the research and application of process integration. Business process modeling, business process simulation, and business process execution are three important research topics related to process integration.

A number of methods can be used in modeling business processes: CIMOSA business process modeling, IDEF3 (Mayer et al. 1992), Petri nets (Zhou 1995), event driven process chain (Keller 1995), and workflow (Georgakopoulos et al. 1995). The modeling objective is to define the activities within a business process and the relationships between these activities. The activity is a basic func-

tion unit within a business process. The control and data flow between these activities form the business process, which fulfils the business task of a company. Optimizing the flow path and shortening the flow time can help the company increase its working efficiency and reduce cost.

The third type of integration is called enterprise-wide integration. With the advent of agile manufacturing, virtual organization is ever more important than before. In agile manufacturing mode, a number of companies collaborate in a virtual company to gain new opportunities in the market. Enterprise-wide integration is required to enhance the exchange of information between the companies. The success of virtual organizations is predicated on the empowerment of people within the enterprise with the aid of computer technology including communication networks, database management systems, and groupware. These allow team members in the virtual organization to make more effective and faster group decisions. Such interaction lays the foundation for enterprise-wide integration, encompassing various plants and offices of an enterprise, possibly located in different cities, as well as customers and suppliers worldwide. Therefore, enterprise-wide integration is much broader than factory automation integration. It is the integration of people, technology, and the business processes throughout the enterprise.

Enterprise-wide integration is required to ensure that all the technical and administrative units can work in unison. This requires a great deal of information about a large number of activities, from product conception through manufacturing, customer delivery, and in-field support. All these lifecycle steps require a large volume of data. The transformation process from one stage to another yields volumes of new data. Furthermore, many of these design, manufacturing, distribution, and service activities responsible for generating and using volumes of data are scattered across a wide spectrum of physical locations. The information is generated by a diverse set of highly specialized software tools on heterogeneous computing hardware systems. Often, incompatible storage media with divergent data structures and formats are used for data storage. This is due to the peculiarities of the tools and systems that generate data without any regard to the needs of the tools or systems that will eventually use the data.

The main idea of enterprise-wide integration is the integration of all the processes necessary for meeting the enterprise goals. Three major tools for integration that are required for overcoming the local and structural peculiarities of an enterprise's data processing applications are network communications, database management systems, and groupware. A number of methods for enterprise-wide integration have been proposed; supply chain management, global manufacturing, and a virtual information system supporting dynamic collaboration of companies. The Web and CORBA (Otte et al. 1996) technologies are playing important roles in the realization of enterprise-wide integration.

3. CIMS STRUCTURE AND FUNCTIONS

3.1. CIMS Structure

The components of CIMS include both hardware and software. The hardware includes computer hardware, network, manufacturing devices, and peripherals. The software includes operating systems, communication software, database management systems, manufacturing planning and control software, management information software, design software, office automation software, and decision support software. These different hardware and software systems have different functions and work together to fulfill the company's business goals. To make it easier to understand, CIMS is normally decomposed into a number of subsystems interacting with each other. Unfortunately, no unique and standard decomposition method exists. Every company can define a method according to its specific situation and requirements. One decomposition method is shown in Figure 5.

From Figure 5, it can be seen that CIMS consists of four functional subsystems and two support subsystems. The four functional subsystems are management information, CAD/CAPP/CAM, manufacturing automation, and computer-aided quality management. These functional subsystems cover the business processes of a company. The two support subsystems are computer network and database management. They are the basis that allows the functional subsystems to fulfill their tasks. The arcs denote the interfaces between different subsystems. Through these interfaces, shared data are exchanged between different subsystems.

3.2. Components of CIMS

This section briefly describes the components of CIMS.

3.2.1. Management Information System

Management information system (MIS) plays an important role in the company's information system. It manages business processes and information based on market strategy, sales predictions, business decisions, order processing, material supply, finance management, inventory management, human resource management, company production plan, and so on. The aims of MIS are to shorten delivery time, reduce cost, and help the company to make rapid decision to react to market change.

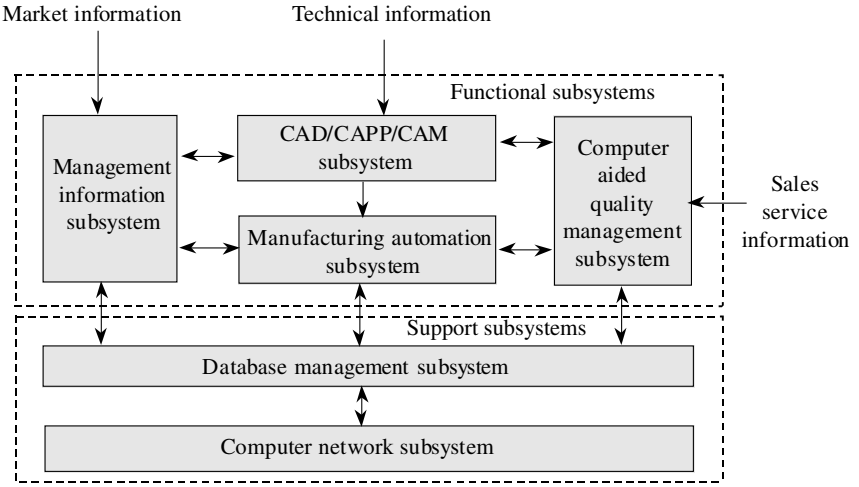

Figure 5 Decomposition of CIMS.

Currently, Enterprise Resource Planning (ERP) software is normally used as the key application software in MIS. Many commercial ERP software products are on the market, such as SAP R/3, developed by SAP, and BaanERP, developed by Baan.

3.2.1.1. Basic Concept of ERP In balancing manufacturing, distribution, financial, and other business functions to optimize company productivity, ERP systems are considered to be the backbone of corporate infrastructure. The ERP concept is derived from and extends the functions of MRPII (Manufacturing Resources Planning) system (Wright 1992). Besides the traditional functions of MRPII in manufacturing management, material supply management, production planning, finance, and sales management, ERP introduces new functions, such as transportation management, supply chain management, corporate strategy planning, workflow management, and electronic data exchange, into the system. The ERP system thus provides more flexibility and ability to the company in business process reengineering, integration with customers, and integration with material suppliers as well as product dispatchers.

3.2.1.2. Manufacturing Resource Planning The basis of MRPII is MRP (material requirements planning), which dates back to the 1940s. MRPII uses computer-enhanced materials ordering and inventory control methods. It enhances speed and accuracy in issuing raw materials to factory workstations. It is clear that linking materials with production demand schedules could optimize the flow of the product as it is being constructed in the factory. This could be done in such a manner that material queue times could be minimized (e.g., have the material show up only when needed), and the amount of material needed throughout the factory at any one time could be reduced ultimately. This is an optimization technique that allocates identified sets of materials (sometimes called kits) to specific jobs as they go through the manufacturing process.

Because it is possible for a computer to keep track of large numbers of kits, it is reserves or mortgages materials for specific jobs in time-order sequences. Linking these sequences with a production plan based on customer need dates allows management to release and track orders through the shop accurately. Prior to releasing orders by means of the kitting process based on the production schedule, it was necessary to obtain supplies. The supplies are based on a gross basis depending on the number of orders expected to be shipped to customers over the selected time period and by having the gross amount of inventory on hand at the start of the period to support production. Obviously, the kit will result in fewer extra materials on hand at any point in the production period. This results in large reductions in raw material and work in process and hence in lower operation costs.

Figure 6 gives a flow diagram of an MRPII system (Waldner 1992).

3.2.1.3. Just-in-Time Another method that has received much attention for production planning and control is just-in-time theory. In contrast to MRPII, which is ''push'' oriented, the JIT philosophy of management is ''pull'' oriented—that is, it calls for something to be manufactured only when there is a firm order for it. JIT is a productivity enhancer based on the simple proposition that all waste in the manufacturing process must be eliminated.

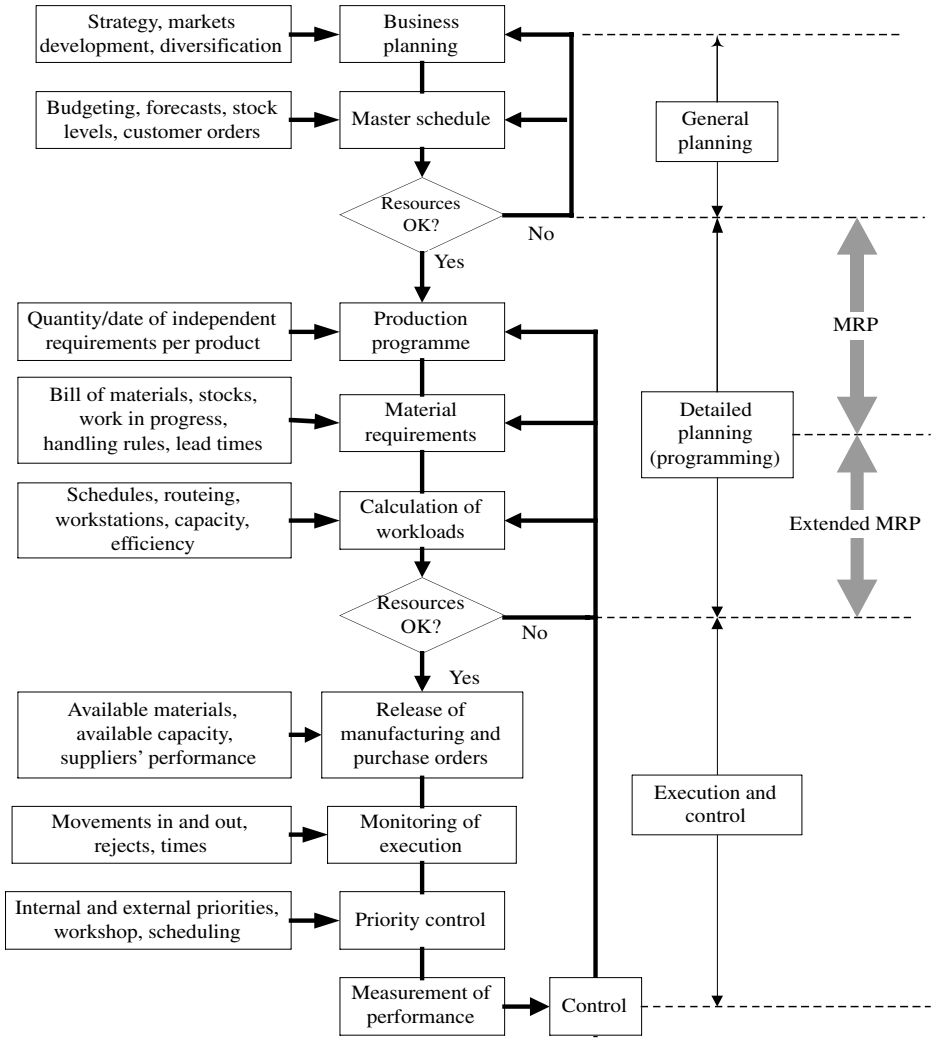

Figure 6 Flow Diagram of MRPII System. (From J. B. Waldner, *Principles of Computer-Integrated Manufacturing,* copyright 1992 John Wiley & Sons Limited. Reproduced by permission)

JIT theory states that wastes can only begin to be eliminated if the push production control system is replaced with a pull production control system. Inventory levels contain a very large volume of waste. Therefore, a way must be found to minimize inventory levels. If this is done without the analytical capability of the computer, it would be logical to conceive a system that would not let material move or be used until it is necessary. This is what Toyota did. They instituted a backward scheduling technique that started with the desired ship date. They had to know when the product needed to be at final assembly and before that when it needed to be at the subassembly levels and so forth, back through component part manufacturing. Ultimately, this means determining precisely when the raw materials should show up at the receiving dock. This in itself is not unusual or unique.

Although JIT proposes ways to reduce a great deal of waste, it cannot be implemented without the help of CIM and MRPII systems. For example, the means for producing products only at the rate at which the customer wants them can best be realized using the feedback control system production schedule of MRPII. By using the MRPII system, we can monitor the progress of all workstations carrying out the dictates of the strategic plan and thus speed up or slow down the preceding operation to optimize the usage of materials and labor. Koenig (1990) explains in detail the relationship of JIT with the MRPII and CIM systems.

Because JIT and MRPII have their advantages as well as limitations in applications, the combination of JIT and MRPII systems in the common framework of CIM may produce excellent results in production scheduling and control.

3.2.2. CAD/CAPP/CAM System

CAD/CAPP/CAM stands for computer-aided design/computer-aided process planning/computer-aided manufacturing. The system is sometimes called the design automation system, meaning that CAD/CAPP/CAM is used to promote the design automation standard and provide the means to design high-quality products faster.

3.2.2.1. Computer-Aided Design CAD is a process that uses computers to assist in the creation, modification, analysis, or optimization of a product design. It involves the integration of computers into design activities by providing a close coupling between the designer and the computer. Typical design activities involving a CAD system are preliminary design, drafting, modeling, and simulation. Such activities may be viewed as CAD application modules interfaced into a controlled network operation under the supervision of a computer.

A CAD system consists of three basic components: hardware, which includes computer and input–output devices, application software, and the operating system software (Figure 7). The operating system software acts as the interface between the hardware and the application software system.

The CAD system function can be grouped into three categories: geometric modeling, engineering analysis, and automated drafting.

Geometric modeling constructs the graphic images of a part using basic geometric elements such as points, lines, and circles under the support of CAD software. Wire frame is one of the first geometric modeling methods. It uses points, curves, and other basic elements to define objects. Then the surface modeling, solid modeling, and parametric modeling methods are presented in the area of geometric modeling area. Saxena and Irani (1994) present a detailed discussion of the development of geometric modeling methods.

Engineering design completes the analysis and evaluation of product design. A number of computer-based techniques are used to calculate the product's operational, functional, and manufacturing parameters, including finite-element analysis, heat-transfer analysis, static and dynamic analysis, motion analysis, and tolerance analysis. Finite-element analysis is the most important method. It divides an object into a number of small building blocks, called finite elements. Finite-element analysis will fulfill the task of carrying out the functional performance analysis of an object. Various methods and packages have been developed to analyze static and dynamic performance of the product design. The objectives and methods can be found in any comprehensive book discussion of CAD techniques. After the analysis, the product design will be optimized according to the analysis results.

The last function of the CAD system is automated drafting. The automated drafting function includes 2D and 3D product design drafting, converting a 3D entity model into a 2D representation.

3.2.2.2. Computer-Aided Process Planning CAPP is responsible for detailed plans for the production of a part or an assembly. It acts as a bridge between design and manufacturing by translating design specifications into manufacturing process details. This operation includes a sequence of steps to be executed according to the instructions in each step and is consistent with the controls indicated in the instructions. Closely related to the process-planning function are the functions that determine the cutting conditions and set the time standards. The foundation of CAPP is group technology (GT),

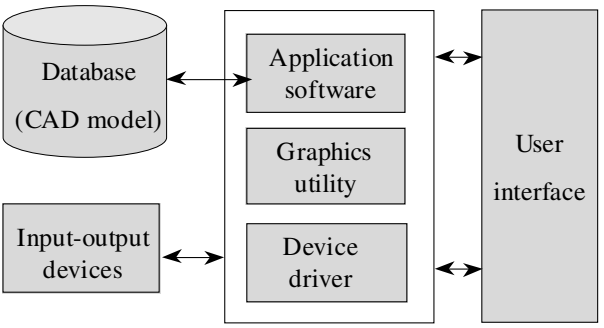

Figure 7 Basic Components of CAD.

which is the means of coding parts on the basis of similarities in their design and manufacturing attributes. A well-developed CAPP system can reduce clerical work in manufacturing engineering and provide assistance in production.

One of the first tasks of the CAPP system is to complete the selection of the raw workpiece. According to the functional requirements of the designed part, it determines the attributes of the raw workpiece, such as shape, size (dimension and weight), and materials. Other jobs for the CAPP system are determining manufacturing operations and their sequences, selecting machine tools, and selecting tools, fixtures, and inspection equipment. Determination of manufacturing conditions and manufacturing times are also part of the work of CAPP. These conditions will be used in optimizing manufacturing cost.

The CAPP system consists of computer programs that allow planning personnel interactively to create, store, edit, and print fabrication and assembly planning instructions. Such a system offers the potential for reducing the routine clerical work of manufacturing engineers. Figure 8 presents the classification of various CAPP systems.

3.2.2.3. Computer-Aided Manufacturing In this section, *computer-aided manufacturing* (CAM) refers to a very restricted area that does not include general production control functions. The production control functions will be introduced in the manufacturing automation subsystem (MAS) section. Here, CAM includes preparing data for MAS, including producing NC code for NC machines, generating tool position, planning tool motion route, and simulating tool movement. Automatic NC code generation is very important for increasing work efficiency. Before the NC code for NC machine centers can be generated, a number of parameters regarding machine tool specification, performance, computer numerical control system behavior, and coding format should be determined first. The manufacturing method and operations will be selected according to these parameters, geometric dimensions, solid forms, and designed part specifications. The CAM system will calculate the tool position data. Then the data regarding the part dimension, the tool motion track, cutting parameters, and numerical control instructions are generated in a program file. This file, called the NC program, is used by the machine tool to process part automatically.

3.2.2.4. CAD/CAPP/CAM Integration Besides the utilization of CAD, CAPP, and CAM technology alone, the integration of CAD, CAPP, and CAM is an important way to enhance the company's product design standards. Three methods can be used in the integration of CAD/CAPP/CAM: exchange product data through specific defined data format; exchange product data through standard data format, such as STEP, IGES, and DXF; and define a unified product data model to exchange product information.

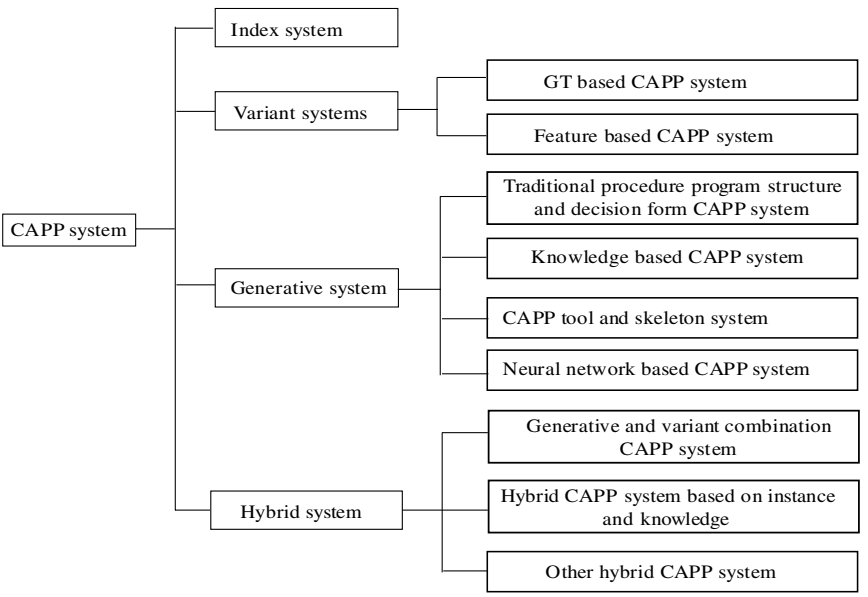

Figure 8 Classification of CAPP System.

Figure 9 is a STEP-based CAD/CAPP/CAM integration system developed at the State CIMS Engineering Research Center of China (located at Tsinghua University, Beijing). It was developed as a part of the CIMS application integration platform (Fan and Wu 1997) for manufacturing enterprises. This system focuses on part-level CAD/CAPP/CAM integration. XPRESS language and the STEP development tool ST-developer are used to define and develop the integration interfaces. Different kinds of CAD, CAPP, and CAM systems can be integrated using the interfaces provided.

3.2.3. Manufacturing Automation System

Manufacturing automation system is a value-added system. The material flow and information flow come together in MAS. For a discrete manufacturing company, MAS consists of a number of manufacturing machines, transportation systems, high-bay stores, control devices, and computers, as well as MAS software. The whole system is controlled and monitored by the MAS software system. For the process industry, MAS consists of a number of devices controlled by DCS, the monitor system, and the control software system. The objectives of MAS are to increase productivity, reduce cost, reduce work-in-progress, improve product quality, and reduce production time.

MAS can be described from three different aspects: structural description, function description, and process description. *Structural description* defines the hardware and the software system associated with the production processes. *Function description* defines the MAS using a number of functions that combine to finish the task of transforming raw material into products. The input–output mapping presented by every function is associated with a production activity of the MAS. *Process description* defines the MAS using a series of processes covering every activity in the manufacturing process.

In the research field of MAS, a very important topic is the study of control methods for manufacturing devices, from NC machines to automatic guided vehicles. But the focus of this chapter is on studying MAS from the CIM system point of view. We will describe the shop-floor control and management system functions and components below.

The shop-floor control and management system is a computer software system that is used to manage and control the operations of MAS. It is generally composed of several modules as shown in Figure 10. It receives a production plan from the MRPII (ERP) system weekly. It optimizes the sequence of jobs using production planning and scheduling algorithms, assigns jobs to specific devices and manufacturing groups, controls the operation of the material-handling system, and monitors the operations of the manufacturing process.

Task planning decomposes the order plan from MRPII system into daily tasks. It assigns job to specific work groups and a set of machines according to needed operations. Group technology and optimization technology are used to smooth the production process, better utilize the resources, reduce production setup time, and balance the load for manufacturing devices. Hence, good task planning is the basis for improving productivity and reducing cost of production.

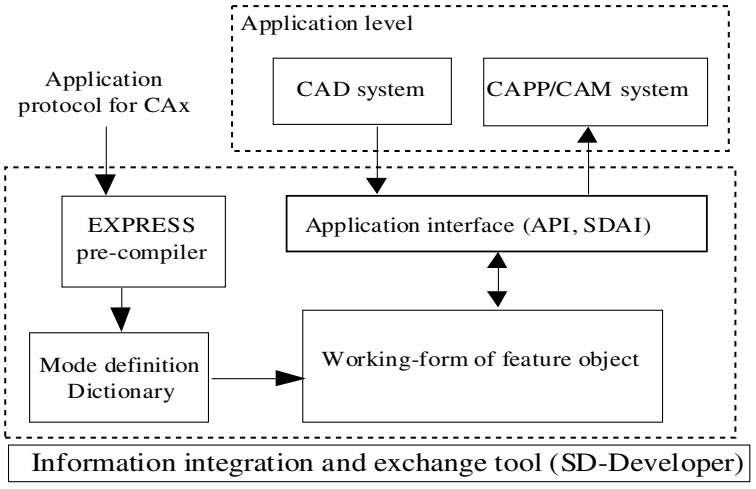

Figure 9 CAD/CAPP/CAM Integration System Structure.

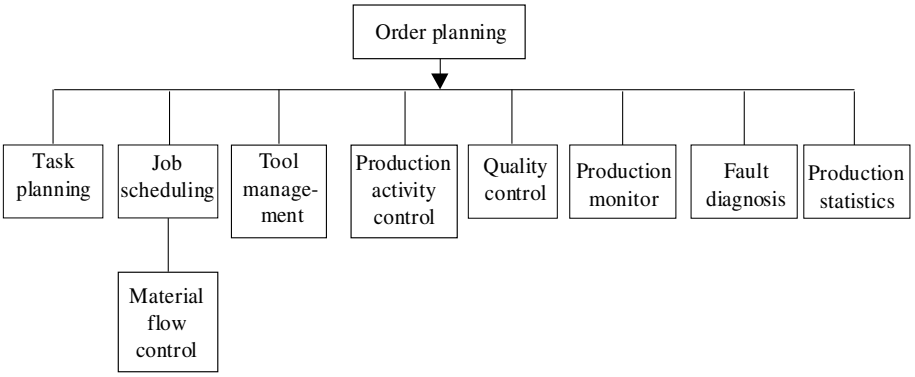

Figure 10 Function Modules of Shop-Floor Control and Management System.

Job scheduling is used to determine the entry time and sequence for different production jobs. It consists of three main functions: static scheduling, dynamic scheduling, and real-time resource scheduling. Material-flow control is one of the tasks for real-time resource scheduling. Static scheduling is a off-line scheduling method. It determines operation sequences before the production starts. The aim of static scheduling is to reduce the makespan (the time duration between when the first task enters the system and when the last task leaves the system). Operations research is an important method for generating static scheduling. Because errors and uncertainties may be caused by machine breakdown, task priorities change and dynamic scheduling is needed for rescheduling the operation sequences and production routes. It is the best method for increasing the flexibility of production system. Heuristic rules are normally used in generating dynamic scheduling. Job scheduling aims to optimize the operation of production system and increase the system flexibility.

Production activity control is used to control the operations of tasks, material flow, and manufacturing resources. Real-time data collecting, processing, and decision making are important tasks of production activity control, which aims to regulate and smooth the production processes even when errors and disturbances occur.

Tool management is also a very important task for the shop-floor control and management system. In a manufacturing system, a large number of tools are needed and the supply of necessary tools on time is vital for improving productivity. Tool quality is important to product quality. The parameters of every tool should be maintained in a correct and real-time fashion because these parameters will be used by machine centers in controlling manufacturing processes.

Quality control, production monitoring, fault diagnosis, and production statistics are important supplementary functions for the shop-floor control and management system to be operated efficiently and effectively.

3.2.4. Computer-Aided Quality-Management System

Since the 1970s, quality has become an extremely important factor for a company to win market competition. Customers always want higher product quality for their investment. The computer-aided quality-management system of CIMS is a system used to guarantee the product quality. It covers a wide range, from product design to material supply to production quality control. The International Standards Organization (ISO) has established a series of quality assurance standards, such as ISOs 9000, 9001, 9002, 9003, and 9004. The computer-aided quality-management system has also been called the integrated quality system.

The computer-aided quality system consists of four components: quality planning, inspection and quality data collection, quality assessment and control, and integrated quality management.

The quality-planning system consists of two kinds of functions: computer-aided product-quality planning and inspection-plan generating. According to the historical quality situation and production-technology status, computer-aided product-quality planning first determines the quality aims and assigns responsibility and resources to every step. Then it determines the associated procedure, method, instruction file, and quality-inspection method and generates a quality handbook. Computer-aided inspection planning determines inspection procedures and standards according to the quality aims, product model, and inspection devices. It also generates automatic inspection programs for automatic inspection devices, such as a 3D measuring machine.

Guided by the quality plan, the computer-aided quality inspection and quality data collection receive quality data during different phases. The phases include purchased-material and part-quality inspection, part-production-quality data collection, and final-assembly quality inspection. The methods and techniques used in quality inspection and data collection are discussed in special books on quality control (Taguchi et al. 1990).

Quality assessment and control fulfills the tasks of manufacturing process quality assessment and control and supply part and supplier quality assessment and control. Integrated quality management includes the functions of quality cost analysis and control, inspection device management, quality index statistics and analysis, quality decision making, tool and fixture management, quality personnel management, and feedback information storage on quality problems, and quality problems backtrack into manufacturing steps.

Quality cost plays an important role in a company's operation. The quality cost analysis needs to determine the cost bearer and the most important cost constituent part to generate a quality cost plan and calculate real cost. It also optimizes the cost in the effort to solve quality problems. Figure 11 presents a quality cost analysis flowchart.

3.2.5. Computer Network and Database Management Systems

Computer network and database management systems are supporting systems for CIMS. The computer network consists of a number of computers (called nodes in the network) and network devices, as well as network software. It is used to connect different computers together to enable the communication of data between different computers. The computer network can be classified as a local area network (LAN) or a wide area network (WAN). *LAN* normally means a restricted area network, such as in a building, factory, or campus. *WAN* means a much wider area network, across a city or internationally. Network technology is developing rapidly. The Internet concept has changed manu-

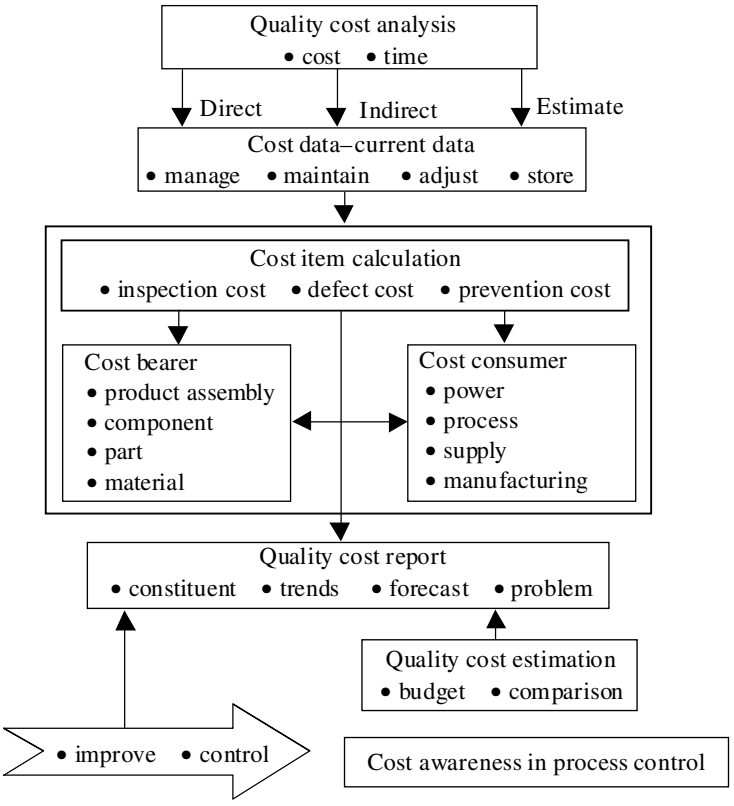

Figure 11 Quality Cost Analysis Flowchart.

facturing companies' operation method greatly. Global manufacturing, agile manufacturing, and network-based manufacturing paradigms have seen rapid development. A computer network is the infrastructure for these new manufacturing paradigms to be realized in a cost-effective way.

The database management system provides basic support for the data storage and information sharing of manufacturing companies. Currently, relational database management systems are the principal databases used. Information integration of a company is concerned with integration data sources in different locations and with different kinds of database management systems. The heterogeneous properties of computer operating systems and database management systems are the major difficulties in information integration. Advanced software techniques have been developed to cope with the heterogeneity problem. Techniques include CORBA, as well as OLE/DCOM, developed by Microsoft, and the Java language, developed by Sun.

Hundreds of books discussing computer network and database techniques can be found in almost any bookstore.

4. FLEXIBLE MANUFACTURING SYSTEMS

Flexible Manufacturing Systems (FMS) is a manufacturing system with a high degree of flexibility. It was developed due to the need to increase productivity, improve product quality, and reduce cost for product production under the constraints of various uncertainties or disturbances both internal and external to the manufacturing system.

4.1. Flexibility and Components of FMS

4.1.1. Flexibility of Manufacturing System

A number of papers have studied different aspects of FMS. Gupta and Goyal (1989) provide a comprehensive review of the literature on flexibility. Flexibility can be defined as a collection of properties of a manufacturing system that supports changes in production activities or capabilities (Carter 1986).

In a manufacturing system, various types of flexibility are needed to fulfill different requirements. The types most discussed are machine flexibility, routing flexibility, process flexibility, product flexibility, production flexibility, and expansion flexibility. Machine flexibility is the capability of a machine to perform a variety of operations on a variety of part types and sizes. Machine flexibility can reduce the changeover frequency, setup time, and tool-changing time, hence reducing the lead time and making small-lot-size production more economic. Machine flexibility is the basis for routing and process flexibility.

Routing flexibility provides the chance for a part to be manufactured or assembled along alternative routes. Routing flexibility is required to manage shop-floor uncertainties caused by such problems as machine breakdown, tool error, and controller failure. It can also be used to tackle the problems caused by external events such as change of product mix or product due date and emergency product introduction. These changes alter machine workloads and cause bottlenecks. The use of alternative routing helps to solve these problems and finally increase productivity.

Process flexibility, also called mix flexibility, is the ability to absorb changes in the product mix by performing similar operations or producing similar produces or parts on multipurpose, adaptable CNC machining centers.

Product flexibility, also known as mix-change flexibility, is the ability to change over to a new set of products economically and quickly in response to markets or engineering changes or even to operate on a market-to-order basis. In the current global market, high product flexibility is a very important factor for a company to compete.

Expansion flexibility is the ability to change a manufacturing system with a view to accommodating a changed product envelope. It has become more important in the current agile manufacturing era. Improving expansion flexibility can significantly reduce system expansion or change cost, shorten system reconfiguration time, and hence shorten the delivery time for new products.

4.1.2. FMS Definition and Components

An FMS is an automated, mid-volume, mid-variety, central computer-controlled manufacturing system. It can be used to produce a variety of products with virtually no time lost for changeover from one product to the next. Sometimes FMS can be defined as "a set of machines in which parts are automatically transported under computer control from one machine to another for processing" (Jha 1991).

A more formal definition of FMS is that it consists of a group of programmable production machines integrated with automated material-handling equipment and under the direction of a central controller to produce a variety of parts at nonuniform production rates, batch sizes, and quantities (Jha 1991).

From this definition, it can be seen that an FMS is composed of automated machines, material-handling systems, and control systems. In general, the components of an FMS can be classified as follows:

1. *Automated manufacturing devices* include machining centers with automatic tool interchange ability, measuring machines, and machines for washing parts. They can perform multiple functions according to the NC instructions and thus fulfill the parts-fabrication task with great flexibility. In an FMS, the number of automated machining centers is normally greater than or at least equal to two.
2. *Automated material-handling systems* include load/unload stations, high-bay storage, buffers, robots, and material-transfer devices. The material-transfer devices can be automatic guided vehicles, transfer lines, robots, or a combination of these devices. Automated material-handling systems are used to prepare, store, and transfer materials (raw materials, unfinished parts, and finished parts) between different machining centers, load/unload stations, buffers, and high-bay storage.
3. *Automated tool systems* are composed of tool setup devices, central tool storage, tool-management systems, and tool-transfer systems. All are used to prepare tools for the machining centers as well as transfer tools between machining centers and the central tool storage.
4. *Computer control systems* are composed of computers and control software. The control software fulfills the functions of task planning, job scheduling, job monitoring, and machine controlling of the FMS.

Figure 12 shows the FMS layout at the State CIMS Engineering Research Center (CIMS-ERC) of China. (HMC stands for horizontal machining center and VMC stands for vertical machining center.)

Another example of FMS is shown in Figure 13, from Kingdream. This system produces oil well drill bits, mining bits, hammer drills, high-pressure drills, and so on.

4.2. General FMS Considerations

Although FMS was originally developed for metal-cutting applications, its principles are more widely applicable. It now covers a wide spectrum of manufacturing activities, such as machining, sheet metal working, welding, fabricating, and assembly.

The research areas involved in the design, implementation, and operation of an FMS are very broad. Much research has been conducted and extensive results obtained. In this section, we present the research topics, problems to be solved, and methods that can be used in solving the problems.

4.2.1. FMS Design

FMS is a capital investment-intensive and complex system. For the best economic benefits, an FMS should be carefully designed. The design decisions to be made regarding FMS implementation cover

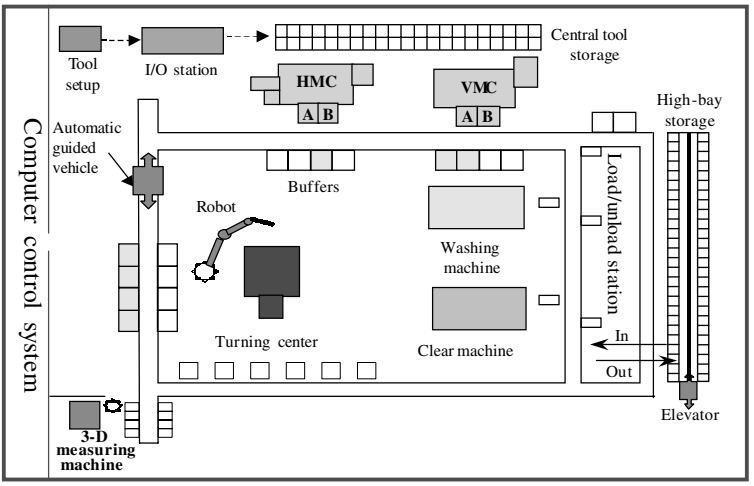

Figure 12 FMS Layout at State CIMS-ERC of China.

Figure 13 FMS for Oil Well Drill Production.

system configuration and layout, manufacturing devices, material-handling systems, central tool storage, buffers, and high-bay storage.

Before these decisions can be made, the part types to be made, the processes needed to make them, and the possible numbers of processing parts (workload) should first be determined. Based on these basic requirements, the number of machines and their abilities, tools, buffers, and storage system can be roughly determined. A rough system layout and material-handling system can be designed. The designed FMS can be simulated using an FMS simulation tool to test its ability to fulfill the requirements.

The design of an FMS is a system approach. Besides the above-mentioned basic requirements for part manufacturing, many other factors should be considered in designing an FMS. An economic assessment should always be done for every FMS plan obtained. System reliability, productivity, and performance evaluation should also be done for every FMS plan. The design of FMS is an iterative process that requires many experts from different disciplines to work together. Many alternative plans are compared and modified before an optimized plan is decided upon.

Talavage and Hannam (1988) summarize the work of other researchers in FMS design methodology and present a five-step approach to FMS design:

1. Development of goals
2. Establishment of criteria on which goal achievement can be judged
3. Development of alternative candidate solutions
4. Ranking of alternatives by applying the criteria to the alternate solutions
5. Iteration of the above four steps to obtain a deeper analysis of alternate solutions and to converge on an acceptable solution

Other considerations regarding FMS design can be found in Tetzlaff (1990).

4.2.2. FMS Planning, Scheduling, and Control

Planning, scheduling, and control are important and difficult problems in FMS operations. A good planning and scheduling system will improve FMS operation efficiency and yield economic benefits. Extensive research and development of FMS planning and scheduling has been done. The general optimization indexes are:

1. Maximizing the productivity at certain period of time
2. Minimizing the makespan for a group of parts
3. Minimizing the cost for parts manufacturing
4. Maximizing the utility of key manufacturing devices
5. Minimizing the work in progress
6. Minimizing the production time for certain parts
7. Satisfying the due dates of parts

Figure 14 presents a function model for FMS planning, scheduling, and resource management.

The resource management and real-time control functions of FMS are closely related to the dynamic scheduling system. The resource-management system should be activated by a dynamic scheduling system to allocate resources to production process to achieve real-time control for FMS. The resources to be controlled involve tools, automatic guided vehicles, pallets and fixtures, NC files, and human resources.

4.2.2.1. Planning Planning seeks to find the best production plan for the parts entered into the FMS. Its aim is to make an optimized shift production plan according to the shop-order and part-due dates. The FMS planning system receives the shop-order plan in the weekly time scale from the MRPII system. According to the product due dates, it analyzes the shop order and generates a daily or shift production plan. Group technology is used for grouping parts into families of parts. The capacity requirement is calculated for every shift plan generated. Capacity balance and adjustment work should be carried out if the required capacity is higher than that provided by machines.

After feasibility analysis, capacity balancing, and optimization, a shift plan is generated. The shift plan gives detailed information for the following questions:

1. What kind of parts will be machined?
2. In what sequence will the parts enter the FMS?
3. What operations are needed to process the parts? What is the operation sequence?
4. What are the start time and complete time for processed parts?
5. What materials are needed? In what time?
6. What kinds of tool are needed?

4.2.2.2. Static Scheduling Static scheduling is the refinement of the shift production plan. It seeks to optimize machine utility and reduce system setup time. Three functions are performed by a static scheduling system: part grouping, workload allocating and balancing, and part static sequencing. Because all these functions are performed before production starts, static scheduling is also called off-line sequencing.

A number of factors affecting production sequence should be taken into account for static scheduling, such as the part process property, FMS structure, and optimization index. The part process property determines what kind of production method should be used. Flow-shop, flexible-flow-line, and job-shop are three major strategies for producing parts. Different methods can be used to generate static scheduling for the different production strategies.

The second factor affecting static scheduling is FMS structure. The main structural properties are whether a central tool system, a fixture system, or bottleneck devices are present. The third factor is the optimization index chosen. The general optimization index is a combination of several optimization indexes, that is, the FMS static scheduling is a multiobjective optimization process.

The following parameters have an important effect on implementing optimal static scheduling.

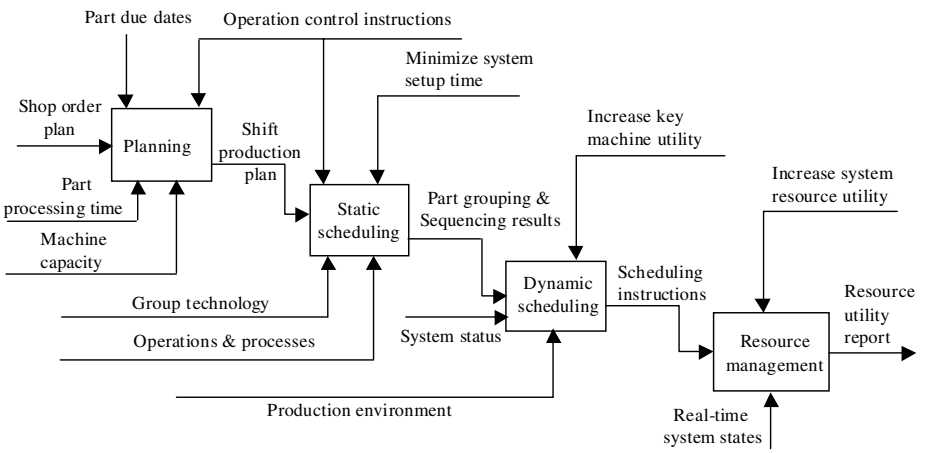

Figure 14 Function Model of FMS Planning and Scheduling.

1. *Time distribution,* such as time distributions for part arrival, tool setup, part fixture, part transfer, machine failure, and delivery time
2. *Shop conditions,* such as device type, transfer system, storage method, shop layout, and device condition
3. *Shop control conventions,* such as priority rule, operation method, hybrid processing route, task decomposition, performance-evaluation method, and workload
4. *Alternate processing route,* such as alternate processing device, alternate processing routing, and alternate processing sequence

A great deal of literature about static scheduling algorithms and systems can be found in the academic journals on FMS, operations research, and manufacturing technology and IEEE magazines on systems, robotics, and automatic control.

4.2.2.3. Dynamic Scheduling Dynamic scheduling is used to control the operations of FMS according to the real-time status of the AFMS. It is a real-time (online) system that focuses on solving uncertainty problems such as device failures, bottlenecks on certain machines, workload unbalance, and resource-allocation conflict. These problems are not anticipated by off-line static scheduling. They can only be solved using real-time dynamic scheduling or rescheduling.

Three strategies can be used to complete the rescheduling functions. The first is periodical scheduling. A certain time interval must be set as a production cycle. A periodical scheduling system calculates a period operation sequence before the next period starts. The sequence is the job list execution instructions followed by the FMS. The second strategy is continuous scheduling, which monitors the FMS and executes scheduling whenever an event (such as the arrival of a new part or a machine completing the production of a part) occurs and the system states has been changed. Since the calculation of work content is effective for rescheduling FMS operations for every event (so as to get optimal scheduling at every point), the third strategy, hybrid scheduling, is frequently used. The hybrid strategy combines periodical and continuous scheduling so that only when an unexpected event occurs is the continuous scheduling algorithm used. Otherwise, periodical scheduling is executed at certain intervals.

For a dynamic manufacturing environment with possible disturbances both internal and external to the FMS, dynamic scheduling seeks to optimize the sequencing for the queue before the device is manufactured. Because the dynamic scheduling of an FMS is an NP-hard problem, it is impossible to find the optimal solution in a short time, especially for continuous scheduling with a very high speed requirement. Normally a suboptimal solution is used in real-time FMS operations. A number of heuristic rules are frequently used for finding the suboptimal solutions in dynamic scheduling. The heuristic rules that are frequently used are:

1. *RANDOM:* assigns a random priority to every part entering the queue and selects a part with smallest priority to be processed
2. *FIFO* (*LIFO*)*:* first-in-first-out (last-in-first-out)
3. *SPT* (*LPT*)*:* selects the part that has the smallest (largest) current operation processing time to be processed
4. *FOPNR* (*MOPNR*)*:* selects the part that has the fewest (most) remaining operations to be processed
5. *LWKR* (*MWKR*)*:* selects the part that has the smallest (largest) remaining processing time to be processed
6. *DDATE:* selects the part that has the earliest due date to be processed
7. *SLACK:* selects the part that has the smallest slack time (due date minus remaining processing time) to be processed

In most cases, several rules will be used in a dynamic scheduling system to reach the satisfied sequencing solution. Besides rule-based scheduling, simulation-based and knowledge-based scheduling systems are also widely used.

4.2.3. FMS Modeling and Simulation

Modeling and simulation are important topics for both design and operation of FMS. FMS modeling is the basis for simulation, analysis, planning, and scheduling. Because FMS is a typical discrete event dynamic system (DEDS), a number of methods for DEDS modeling and analysis can be used to model an FMS, such as Petri nets, network of queues (Agrawal 1985), and activity cycle diagram (Carrie 1988). This section briefly introduces Petri nets, their application in FMS modeling, and the FMS simulation method.

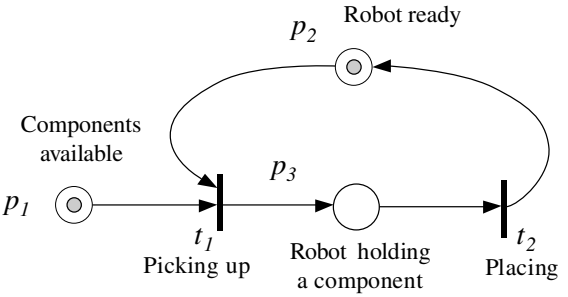

Figure 15 A Simple Petri Net Example. (From M. C. Zhou, Ed., *Petri Nets in Flexible and Agile Automation,* Figure 1, copyright 1995, with kind permission from Kluwer Academic Publishers)

4.2.3.1. Petri Nets and Their Application in FMS Modeling A Petri net (PN) may be identified as a particular kind of bipartite directed graphs populated by three types of objects. These objects are places, transitions, and directed arcs connecting places to transitions and transitions to places. Pictorially, places are depicted by circles, transitions by bars or boxes. A place is an input place to a transition if a directed arc exists connecting this place to the transition. A place is an output place of a transition if a directed arc exists connecting the transition to the place. Figure 15 represents a simple PN. Where places p_1 and p_2 are input places to transition t_1, place p_3 is the output place of t_1.

Formally, a PN can be defined as a five-tuple PN = (P, T, I, O, m_0), where

1. $P = \{p_1, p_2, \ldots, p_n\}$ is a finite set of places
2. $T = \{t_1, t_2, \ldots, t_m\}$ is a finite set of transitions, $P \cup T \neq \phi$, $P \cap T = \phi$.
3. $I:(P \times T) \vdash\!\!\rightarrow N$ is an input function that defines directed arcs from places to transitions, where N is a set of nonnegative integers.
4. $O:(P \times T) \vdash\!\!\rightarrow N$ is an output function that defines directed arcs from transitions to places.
5. $m_0:P \vdash\!\!\rightarrow N$ is the initial marking.

The state of the modeled system is represented by the tokens (small dots within the places) in every place. For example, in Figure 15, a small dot in place p_1 means components available. The change of the states represents the system evolution. State changing is brought by firing a transition. The result of firing a transition is that for every place connected with the transition, after the firing of the transition, a token will be removed from its input place and a token will be added to its output place. In the example of Figure 15, the firing of transition t_1 will cause the tokens in places p_1, p_2 to disappear and a token to be added to place p_3.

Due to the advantages of its formal theory background, natural link with DEDS, and mature simulation tool, PN is well suited to FMS modeling. Figure 16 shows a two-machine production line to demonstrate the modeling of FMS using PN.

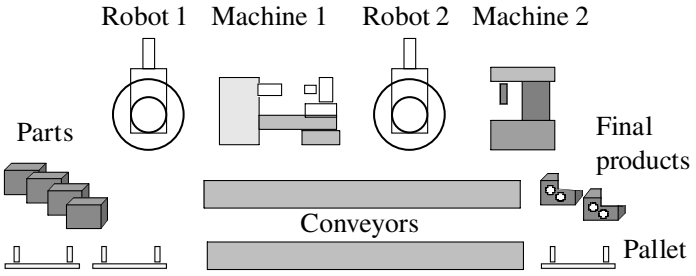

Figure 16 A Two-Machine Production Line.

The production line consists of two machines (M1 and M2), two robots (R1 and R2), and two conveyors. Each machine is serviced by a dedicated robot that performs the load/unload task. One conveyor is used to transport workpieces, a maximum two at one time. The other conveyor is used to transport empty pallets. Three pallets are available in the system. Each workpiece is machined on M1 and then on M2. The machining time is 10 time units on M1 and 16 time units on M2. The load and unload tasks takes 1 time unit.

As with modeling general FMS or other systems, the modeling of this system using PN takes several steps:

1. Major activities are identified. In this example, they are R1 loading, M1 processing, R1 unloading, R2 loading, M2 processing, and R2 unloading. The resources are raw materials with pallets, conveyors, M1, M2, R1, R2.
2. The relationships between the four major activities form a sequential order.
3. A partial PN model is defined to describe the four major activities and their relations as shown in Figure 17(*a*), where four transitions are used to represent four short operations, i.e., R1 loading, R1 unloading, R2 loading, and R2 unloading. Two places are used to represent two long operations, i.e., M1 and M2 processing.
4. Through a stepwise process, gradually adding resources, constraints, and links to the partial PN model will finally form the refined model as shown in Figure 17(*b*).
5. The model is checked to see whether it satisfies the specification. The PN simulation tool can also be used in this phase to check the model. If some problems are found, the model will be modified.

4.2.3.2. FMS Simulation Simulation is a useful computer technology in FMS modeling, design, and operation. Simulation modeling allows real-world objects to be described in FMS, such as moving of workpieces from one place to another. There are three approaches to simulation modeling for FMS. The first is network or graphical models, where some objects (such as machines) may be represented by graphical symbols placed in the same physical relationship to each other as the corresponding machines are in the real world. The graphical aspects of this kind of models are relatively easy to specify, and once completed they also provide a communication vehicle for the system design that can be readily understood by a variety of people. SLAM (Pritsker 1984) and SIMAN (Pegden 1982) are two widely used network modeling tools for FMS.

The second approach to FMS modeling is data-driven simulation. The model consists of only (or mainly) numerical data, usually representing, for example, a simple count of machines in a system or a table of operation times for each process on the route of a given part type. The nature of these data is such that, if they were collected in the factory information system, it would only be necessary to access them and place them in proper format in order to run a simulation of the corresponding

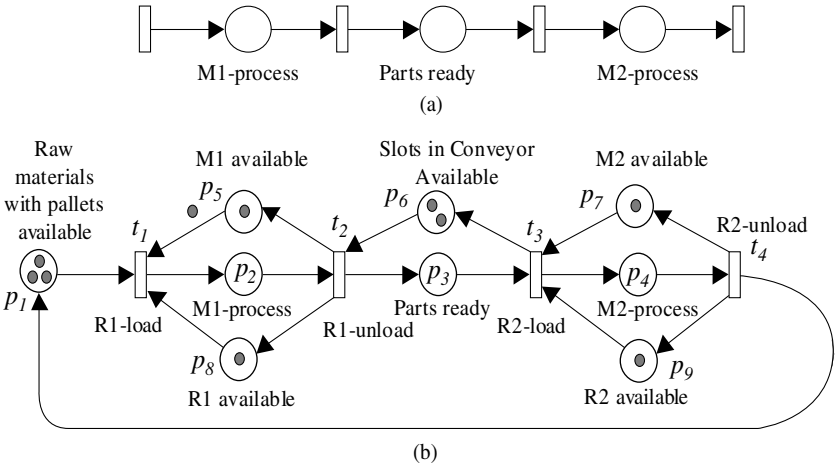

Figure 17 Petri Net Model for the Two-Machine Production Line. (From M. C. Zhou, Ed., *Petri Nets in Flexible and Agile Automation,* Figure 8, with kind permission of Kluwer Academic Publishers)

real-world system. This concept is quite close to automated simulation. It has the ultimate ease of use. The first such program for FMS was developed at Purdue, the general computerized manufacturing system (GCMS) simulator (Talavage and Lenz 1977).

The third approach for FMS modeling uses a base programming language, such as SIMULA and SIMSCRIPT, which provides more model-specific constructs that can be used to build a simulation model. This approach thus has a much stronger modeling capability. Unfortunately, it is not widely used. One reason may be that few people know it well enough to use it.

Another method for DEDS simulation, called activity cycle diagram (ACD), can also be used in FMS simulation. This is a diagram used in defining the logic of a simulation model. It is equivalent to a flowchart in a general-purpose computer program. The ACD shows the cycle for every entity in the model. Conventions for drawing ACDs are as follows:

1. Each type of entity has an activity cycle.
2. The cycle consists of activities and queues.
3. Activities and queues alternate in the cycle.
4. The cycle is closed.
5. Activities are depicted by rectangles and queues by circles or ellipses

Figure 18 presents an ACD for a machine shop. Jobs are arriving from the outside environment. Jobs are waiting in a queue for the machine. As soon as the machine is available, a job goes to the machine for processing. Once processing is over, the job again joins a queue waiting to be dispatched.

Because ACDs give a better understanding of the FMS to be simulated, they are widely used for FMS simulation.

4.3. Benefits and Limitations of FMS

FMS offers manufacturers more than just a flexible manufacturing system. It offers a concept for improving productivity in mid-variety, mid-volume production situations, an entire strategy for changing company operations ranging from internal purchasing and ordering procedures to distribution and marketing. The benefits of FMS can be summarized as follows:

1. Improved manufacturing system flexibility
2. Improved product quality, increased equipment utility
3. Reduced equipment cost, work-in-progress, labor cost, and floor space
4. Shortened lead times and improved market response speed
5. Financial benefits from the above

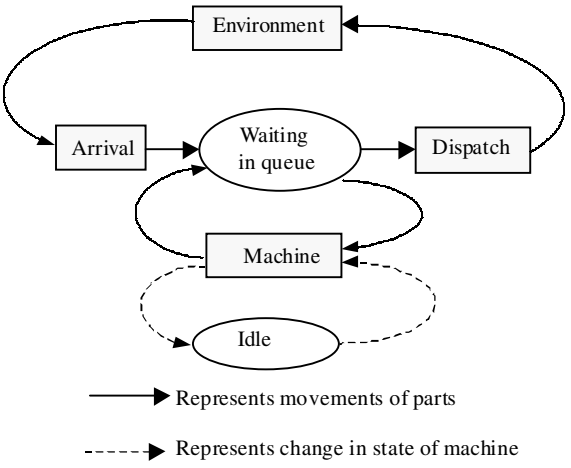

Figure 18 Activity Cycle Diagram. (From A. Carrie, *Simulation of Manufacturing Systems,* copyright 1988 John Wiley & Sons Ltd. Reproduced with permission)

Talavage and Hannam (1988) contains a chapter discussing the economic justification for FMS.

The difficulties with FMS should also be given attention. First, FMS is expensive, normally requiring large capital resources. Even if a company is able to afford the investment, FMS may not be financially beneficial if the company does not have much product variety and volume. Second, the design, implementation, and operation of FMS is a quite complex process. Money may be lost if any of the work in the process is not well done. Third, the rapidly changing market may compel the company to change its product. This change may have a negative impact on the production system, causing the large investment in FMS not to be returned before it is abandoned.

5. CIM ARCHITECTURE AND ENTERPRISE MODELING

An enterprise is a complicated social, economic, and physical system. The implementation of CIMS in an enterprise is an even more complicated feat of system engineering. To implement CIMS successfully, engineers with an excellent analytical and technological background and abundant experience are needed, as well as the guidance of advanced CIM system architecture and implementation methodology and powerful support tools. CIM system architecture studies the components and their relationship to CIM to provide the basis and guidelines for the design and implementation of CIMS in a company. A good system architecture can not only act as a basis for describing the system components but also provide a good way to communicate among users, designers, and other parties. A number of CIM system architectures are available, such as the SME wheel structure (Figure 3), CIM open system architecture (CIMOSA), the Purdue enterprise reference architecture (PERA) (Williams 1992), the architecture for information system (ARIS) (Scheer 1992), and GRAI (graphs with results and activities interrelated) integrated methodology (GIM) (Doumeingts et al. 1992).

With the development of CIM reference architecture, a number of enterprise modeling methods have been put forward to describe the enterprise. Because the enterprise is a very complex system, it is difficult to describe it using a simple and unified model. A typical method used by almost all enterprise modeling methods is to describe the enterprise using several view models. Each view defines one aspect from a specific point of view, and then the integration method between the different view models is defined. The general view models now used in describing enterprise are function view, information view, organization view, resource view, and process view. Other views are also presented by researchers are control view, defined in ARIS, decision view, defined in GRAI/GIM, and economic view, proposed by Chen et al. (1994).

5.1. Views of the Enterprise Model

As discussed above, the enterprise model consists of several interrelated view models. Each view describes a specific aspect of the enterprise and has its own modeling method. This section gives a brief description of the aims of each view and the method currently used in building the view model.

5.1.1. Process View

The process view model takes a major role in defining, establishing, analyzing, and extracting the business processes of a company. It fulfills the requirements of transforming the business process, the manufacturing process, and the product-development process into a process view model. The process model is the basis for business process simulation, optimization, and reengineering.

5.1.1.1. Modeling Method for Process View Process view modeling focuses mainly on how to organize internal activities into a proper business process according to the enterprise goals and system restrictions. Traditional function-decomposing-oriented modeling methods such as SADT and IDEF0, which set up the process based on activities (functions), can be used in business process modeling.

The business description languages WFMC (Workflow Management Coalition 1994), IDEF3, and CIMOSA are process-oriented modeling methods. Another modeling method uses object-oriented technology, in which a business process can be comprehended as a set of coordinated request/service operations between a group of objects. Jacobson (1995) presents a method for using object-oriented technology, the use case method, to reengineer the business process. Object-oriented methods offer intrinsic benefits: they can improve systemic extendibility and adaptability greatly, their services based on object-operated mode can assign systemic responsibility easily, existing business processes can be reused easily, and distribution and autonomy properties can be described easily.

The main objective of the process view modeling method is to provide a set of modeling languages that can depict the business process completely and effectively. To depict a business process, it should be able to depict the consequent structure of processes, such as sequence, embranchment, join, condition, and circle, to establish a formal description of the business process. Generally accepted modeling languages today are IDEF3, CIMOSA business process description language, and WFMC workflow description language.

Some business process description methods originating in the concepts and models of traditional project-management tools, such as the PERT chart and other kinds of network chart, are generally

adopted in practical application systems because they can be easily extended from existing project management tool software. If the business process is relatively complex, such as existing concurrent or collision activities, some superformal descriptions, such as Petri net, should be used.

Figure 19 is a workflow model of a machine tool-handle manufacturing process. The process model is designed using the CIMFlow tool (Luo and Fan 1999). In Figure 19(*a*), the main sequential process is described and the icon stands for a subprocess activity. Figure 19(*b*) is the decomposition of the subprocess activity Rough Machining in Figure 19(*a*). After Turning activity is executed, two conditional arcs are defined that split the activity route into two branches. The activity Checking is a decision-making task that is in charge of the product quality or the progress of the whole process.

5.1.2. Function View

The function view is used to describe the functions and their relationships in a company. These functions fulfill the objectives of the company, such as sales, order planning, product design, part manufacturing, and human resource management. The efficient and effective operation of these functions contributes to the company's success in competing in the market.

5.1.2.1. Modeling Method for Function View Function view modeling normally uses the top-down structural decomposition method. The function tree is the simplest modeling method, but it lacks the links between different functions, especially the data flow and control flow between different functions, so it is generally used to depict simple function relationships. In order to reflect data and control flow relationships between different functions, SADT and IDEF0 (Colquhoun and Baines 1991) methods are used to model function view. The IDEF0 formalism is based on SADT, developed by Ross (Ross 1985).

The IDEF0 model has two basic elements: activity and arrow. Figure 20 gives the basic graphic symbol used in the IDEF0 method. IDEF0 supports hierarchical modeling so that every activity can be further decomposed into a network of activities. In order to organize the whole model clearly, it is advised that the number of the child activities decomposed from the parent activity be less than 7 and greater than 2. Figure 21 gives a demonstration IDEF0 model (A0 model) of the control shop floor operation function.

In the CIMOSA model, the overall enterprise functions are represented as an event-driven network of domain processes (DPs). An individual domain process is represented as a network of activities. The domain process is composed of a set of business processes (BPs) and enterprise activities (EAs). The BP is composed of a set of EAs or other BPs. An EA is composed of a set of functional operations (FOs). The BP has a behavior property that defines the evolution of the enterprise states over time in reaction to enterprise event generation or conditions external or internal to the enterprise. It is defined by means of a set of rules called procedure rules. The structure property of BP describes the functional decomposition of the enterprise functions of enterprise. This can be achieved by means of a pair of pointers attached to each enterprise function. EA has an activity behavior that defines

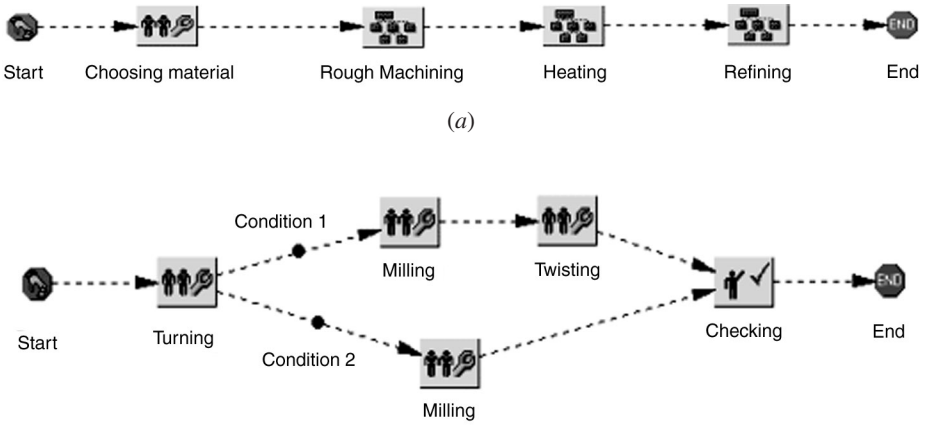

Figure 19 Process Model for Tool-Handle Manufacturing.

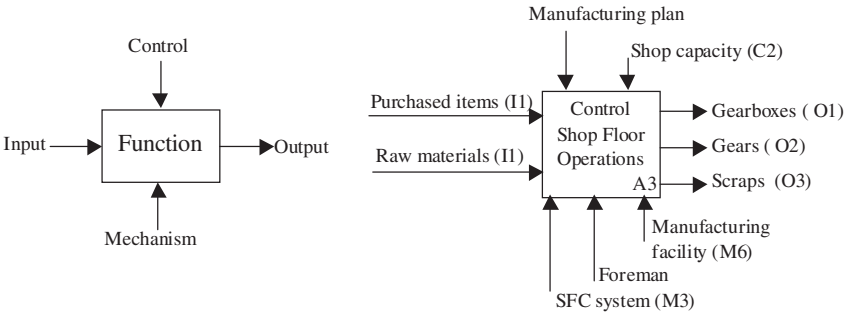

Figure 20 General Symbol and a Practical Model of IDEF0. (From Vernadat 1996. Reprinted with kind permission of Kluwer Academic Publishers.)

the internal behavior (or flow of control) of enterprise activities. It specifies how to perform the functionality of an EA in terms of an algorithm making use of FO.

It can be seen that the process view and the function view are closely related to the CIMOSA modeling method. Hence, any tool that supports the CIMOSA modeling methodology should be process oriented and include function decomposition.

5.1.3. Information View

The information view organizes the information necessary to support the enterprise function and process using an information model. Data for a company are an important resource, so it is necessary to provide a method to describe or model the data, such as data structures, repository types, and locations, especially the relationships among different data. It is very important for the company to maintain the data resource consistently, eliminate possible data redundancy, and finally enable data integration.

The information view modeling method provides different models for different phases of a company's information system, from requirement analysis to design specification to implementation. The most commonly used model to express data today is the relational data model, which is the basis

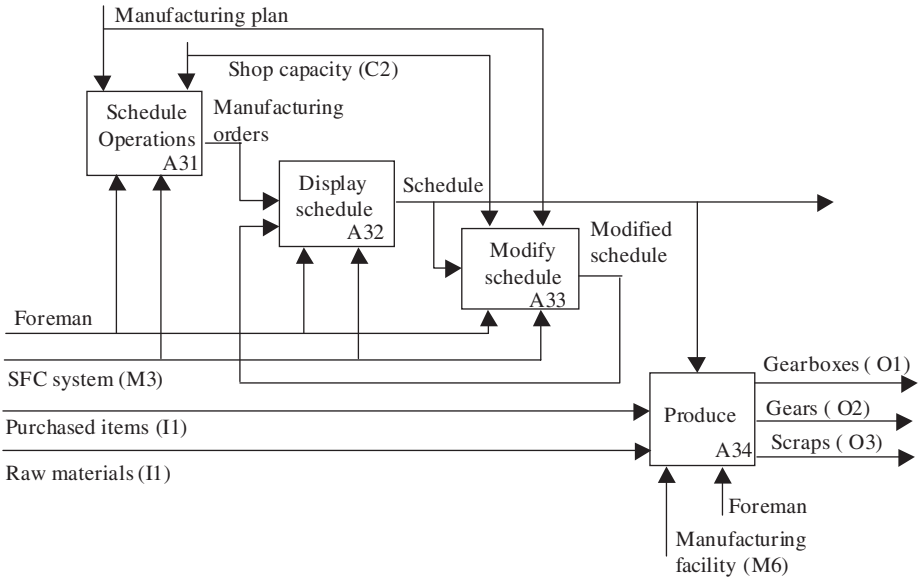

Figure 21 IDEF0 Model of the Control Shop-Floor Operation Function. (From Vernadat 1996. Reprinted with kind permission of Kluwer Academic Publishers.)

for the relational database management system. The currently used IDEF1X method is an extension of the entity-relationship model proposed by Chen (1976). Three phases of the modeling process, a conceptual model, a logical model, and a physical model, are used in designing and implementing an information system. Vernadat (1996) gives a good introduction to information modeling in the context of enterprise modeling.

5.1.4. Organization View

The organization view is used to define and represent the organization model of a company. The defined model includes the organization tree, team, faculty, role, and authority. It also creates an organization matrix. In the organization view, the relationships between different organization entities are defined. It provides support for execution of the company's functions and processes.

The hierarchical relationship between the organization units forms the organization tree, which describes the static organization structure. The team describes the dynamic structure of the company. It is formed according to the requirements of business processes. Personnel and organization units are the constituents of the team.

Figure 22 shows the organization view structure. The basic elements of the organization view are organization unit, team, and personnel.

The attributes of the organization unit include organization unit name, position, description, role list, leader, and the organization's associated activities and resources. The leader and subordinate relationships between different units are also defined in the organization unit. In defining a team, the attributes needed are team name, description, project or process ID, associated personnel, and resources.

5.1.5. Resource View

The resource view is similar to the organization view. It describes resources used by the processes to fulfill the company's business functions. Three main objects are defined in the resource view model: resource type object, resource pool object, and resource entity object. Resource type object describes the company's resource according to the resource classification. The resource type object inherits the attributes from its parent object. A resource classification tree is created to describe the company's resource. The resource pool object describes resources in a certain area. All the resources located at this area form a resource pool. Resource entity object defines the atomic resources. An atomic resource is some kind of resource that cannot be decomposed further—that is, the smallest resource entity.

Figure 23 gives the resource classification tree structure. In this tree, the parent node resource consists of all its child node resources. It depicts the static structure of the company's resources.

The resource–activity matrix (Table 1) defines the relationships between resources and process activities. Every cross ($\times$) means that the resource is used by this activity. The resource–activity matrix presents the dynamic structure of the resources.

5.2. Enterprise Modeling Methods

As pointed out in the previous section, there are many enterprise modeling methods. Here we only give a brief introduction to the CIMOSA, ARIS, and GIM methods.

5.2.1. CIMOSA

CIMOSA supports all phases of a CIM system life cycle, from requirements specification, through system design, implementation, operation and maintenance, even to a system migration towards a

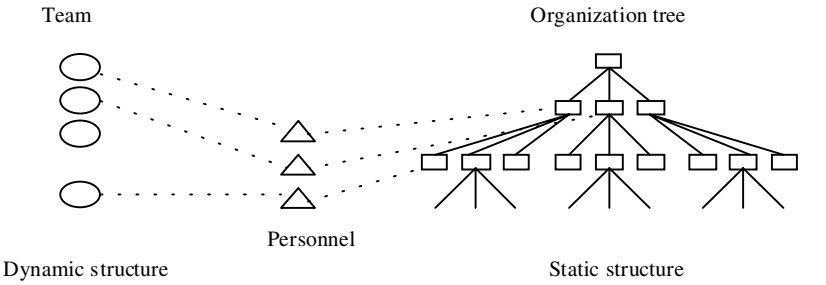

Figure 22 Organization View Structure.

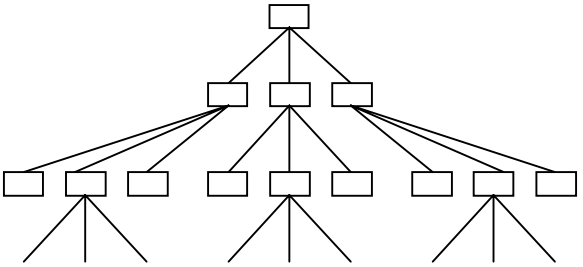

Figure 23 Resource Classification Tree Structure.

CIMOSA solution. CIMOSA provides modeling, analysis, and design concepts in a set of languages and methodologies adapted to enterprise users at different levels and according to different users' viewpoints.

The CIMOSA reference architecture, developed by the AMICE consortium within the European ESPRIT project, is a set of semiformal structures and semantics that is intended to be used as a modeling language environment for any business enterprise. The basic constructs and fundamental control structures of the architecture are collected in volumes called Formal Reference Base II (FRB) and Formal Reference Base III. FRB consists of two parts: the modeling framework and the integrating infrastructure (IIS).

The CIMOSA modeling framework, known as the CIMOSA cube, is shown in Figure 24. The modeling framework provides a reference architecture and a particular architecture. It contains three modeling levels (requirements definition, design specification, implementation description) and four views (function, information, resource, organization). The CIMOSA reference architecture (two left slices of the CIMOSA cube) provides a set of generic building blocks, partial models, and user guidelines for each of the three modeling levels. The particular architecture (right slice of the CIMOSA cube) is the part of the framework that is provided for the modeling of a particular enterprise, that is, it exhibits a given CIM solution.

Generic building blocks or basic constructs are modeling elements with which the requirements and solutions for a particular enterprise can be described. Partial models, which are partially instantiated CIMOSA solutions applicable to one or more industrial sectors, are also provided in the reference architecture. The user can customize partial models to a part of the model of his or her particular enterprise. The CIMOSA modeling framework ensures that partial models from different sources can be used to build a model of one particular enterprise.

The CIMOSA integrating infrastructure (IIS) provides services to integrate all specific application processes of the enterprise into one cooperating system. IIS consists of the following services:

- *Information services:* administering all information required by the various application processes
- *Business process services:* scheduling the provision of resources and dispatching the execution of enterprise activities
- *Presentation services:* representing the various types of manufacturing resources to the business process services in a homogeneous fashion
- *Communication service:* being responsible for system-wide homogeneous and reliable data communication

CIMOSA model creation processes, namely instantiation, derivation and generation, define how generic building blocks and partial models are used to create particular enterprise models.

TABLE 1 Resource-activity Matrix

	Activity 1	Activity 2	–	Activity *n*
Resource 1	×			
Resource 2	×	×		
–			×	
Resource m		×		×

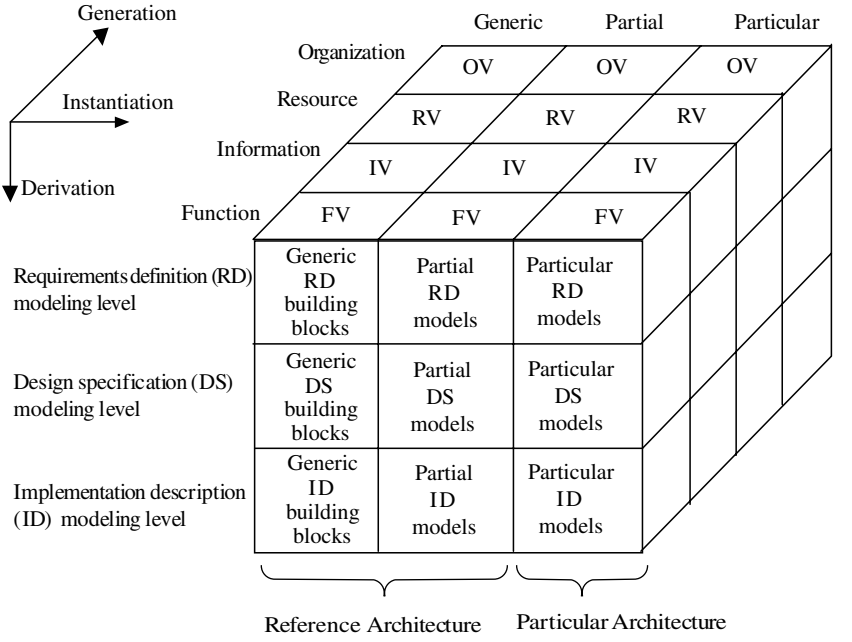

Figure 24 CIMOSA Modeling Framework. (From Esprit Consortium AMICE 1993. Reprinted by permission of Springer-Verlag.)

The instantiation process is a design principle that suggests: (1) going from a generic type to particular type (types are refined into subtypes down to particular instances); and (2) reusing previous solutions (i.e., using particular models or previously defined models) as much as possible. This process applies to all four views. It advocates going from left to right of the CIMOSA cube.

The derivation process is a design principle that forces analysis to adopt a structured approach to system design and implementation, from requirements specification through design specification and finally to full implementation description. This process also applies to all four views. It advocates going from the top to the bottom of the CIMOSA cube.

The generation process is a design principle that encourages users to think about the entire enterprise in terms of function, information, resource, and organization views, in that order. However, the complete definition of the four views at all modeling levels usually requires going back and forth on this axis of the CIMOSA cube.

5.2.2. ARIS

The ARIS (architecture of integrated information systems) approach, proposed by Scheer in 1990, describes an information system for supporting the business process. The ARIS architecture consists of the data view, function view, organization view, and control view. The data view, function view, and organization view are constructed by extracting the information from the process chain model in a relatively independent way. The relationships between the components are recorded in the control view, which is the essential and distinguishable component of ARIS. Information technology components such as computer and database are described in the resource view. But the life-cycle model replaces the resource view as the independent descriptive object. The life-cycle model of ARIS is divided into three levels. The requirement definition level describes the business application using the formalized language. The design specification level transfers the conceptual environment of requirement definition to the data process. Finally, the implement description level establishes the physical link to the information technology. The ARIS architecture is shown in Figure 25.

The ARIS approach is supported by a set of standard software, such as the application systems ARIS Easy Design, ARIS toolset, and ARIS for R/3, which greatly help the implementation of ARIS.

5.2.3. GIM

GIM (GRAI integrated methodology) is rooted in the GRAI conceptual model shown in Figure 26. In this method, an enterprise is modeled by four systems: a physical system, an operating system, an information system, and a decision system.

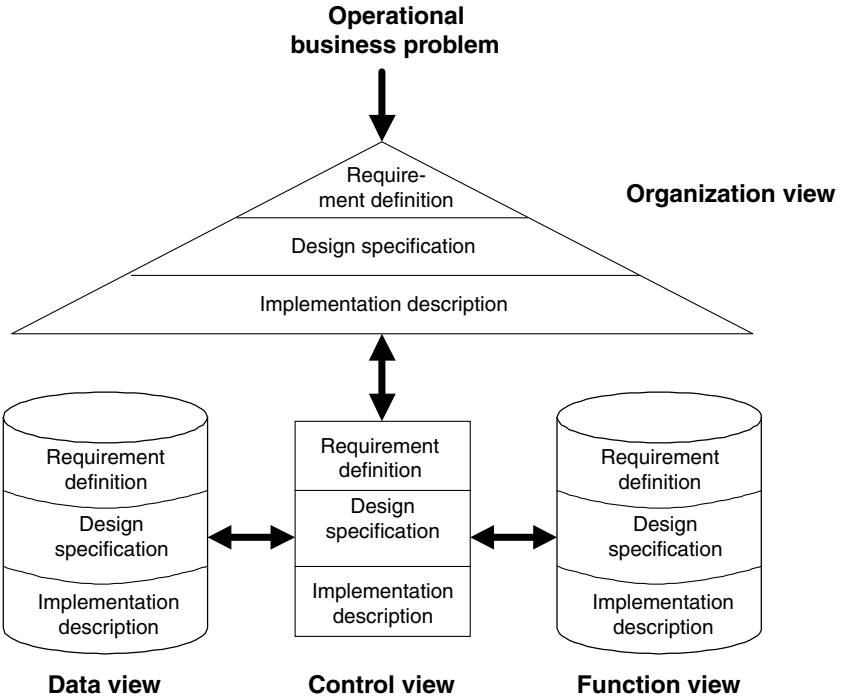

Figure 25 ARIS Architecture. (From Scheer 1992 by permission of Springer-Verlag New York, Inc.)

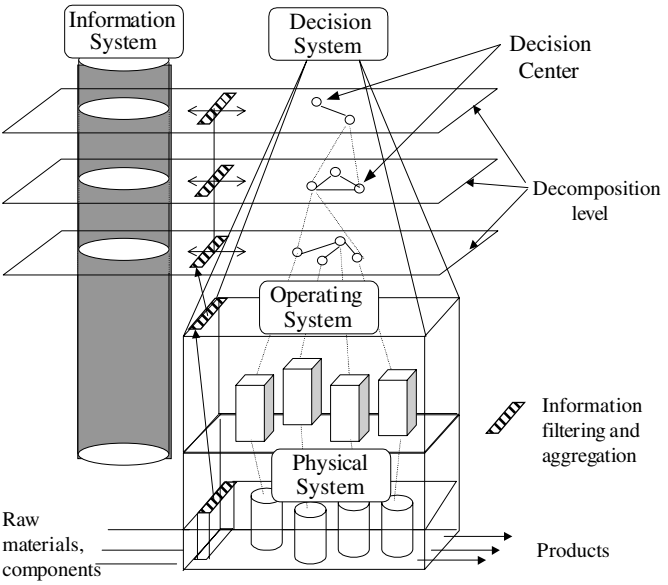

Figure 26 The GRAI Conceptual Model. (From Vernadat 1996)

The GRAI method makes use of two basic modeling tools: the GRAI grid and the GRAI net. The GRAI grid is used to perform a top-down analysis of the domain of the enterprise to be analyzed. It is made of a 2D matrix in which columns represent functions and lines represent decision levels. The decision level is defined by a horizon H and a period P. Long-term planning horizons are at the top and short-term levels are at the bottom of the grid. Each cell in the matrix defines a decision center. The grid is then used to analyze relationships among decision centers in terms of flows of information and flows of decisions.

GRAI nets are used to further analyze decision centers in terms of their activities, resources, and input–output objects. With this method, a bottom-up analysis of the manufacturing systems studied can be made to validate the top-down analysis. In practice, several paths in both ways are necessary to converge to a final model accepted by all concerned business.

GRAI and GIM are supported by a structured methodology. The goal is to provide specifications for building a new manufacturing system in terms of organization, information technology, and manufacturing technology viewpoints. The methodology includes four phases: initialization, analysis, design, and implementation.

6. CIM IMPLEMENTATION

CIM implementation is a very important but also very complex process. It requires the participation of many people with different disciplines. Benefits can be gained from successful implementation, but loss of investment can be caused by inadequate implementation. Therefore, much attention should be paid to CIM implementation.

6.1. General Steps for CIM Implementation

The general life-cycle model discussed in CIM architecture and modeling methodology is the overall theoretical background for CIM implementation. In a practical application, due to the complexity of CIM implementation, several phases are generally followed in order to derive the best effect and economic benefits from CIM implementation. The phases are feasibility study, overall system design, detailed system design, implementation, operation, and maintenance. Each phase has its own goals and can be divided into several steps.

6.1.1. Feasibility Study

The major tasks of the feasibility study are to understand the strategic objectives, figure out the internal and external environment, define the overall goals and major functions of a CIM system, and analyze the feasibility of CIM implementation from technical, economical, and social factors. The aim of this phase is to produce a feasibility study report that will include, besides the above, an investment plan, a development plan, and a cost–benefit analysis. An organization adjustment proposal should also be suggested. A supervisory committee will evaluate the feasibility study report. When it is approved, it will lay the foundation for following up the phases of CIM implementation. Figure 27 presents the working steps for the feasibility study.

6.1.2. Overall System Design

Based on the results of the feasibility study, the overall system design phase further details the objectives and plans regarding proposed CIM system implementation. The tasks of overall system design are to define the CIM system requirements, set up the system function and information model, put forward an overall system design plan, design the system architecture, draft the implementation plan, present the investment plan, carry out the cost–benefit analysis, and finally form the overall system design report. The key technologies and their problem-solving methods should also been given in the overall system design report. Data coding is important work to be done in the overall system design phase.

In order to keep the whole CIM system integrated, in the functional and logical model design, the overall system design follows the top-down decomposition principle. The top level and general functions should be first considered, then decomposed to low-level and detailed operations.

The general procedures and contents of overall system design are as follows:

1. *System requirement analysis:* determines the system requirements of function, performance, information, resource, and organization. This phase's work focuses on the managerial and tactical point of view.
2. *System architecture design:* determines the overall system architecture of the CIM system.
3. *System function and technical performance design:* determines the functions needed to meet the system requirements and system performance.
4. *Information model design:* determines the logical data model of the information system.

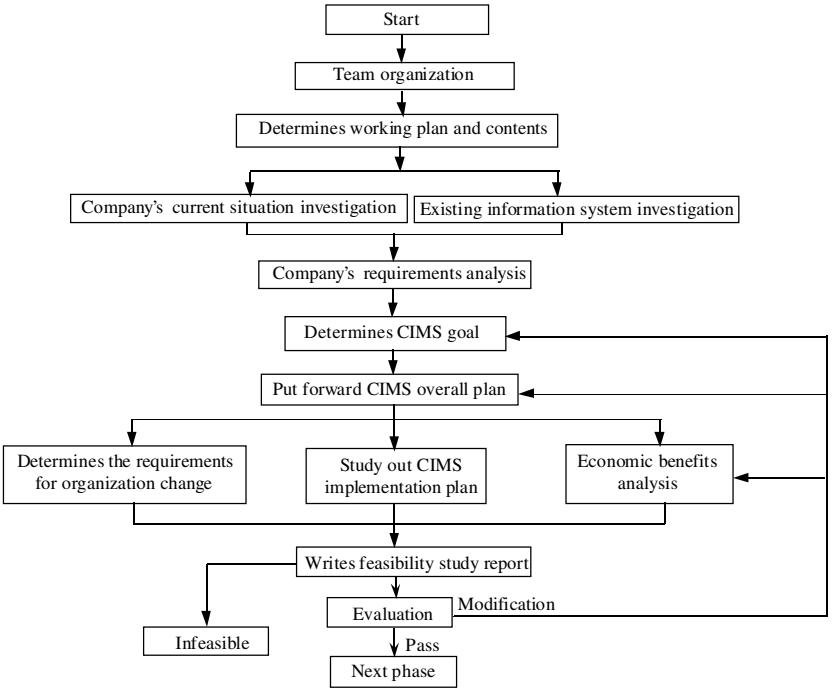

Figure 27 Steps of Feasibility Study.

5. *Internal and external interface design:* determines these interfaces for the purpose of system integration, including the functional interfaces between different subsystems and data interfaces between different applications.
6. *Key technology:* lists all key technologies that have important influence on CIM system implementation, gives their solution methods;
7. *System configuration specification:* determines the hardware and software configurations.
8. *Implementation schedule definition:* defines the implementation schedule for the CIM system in the network plan or other forms.
9. *CIM system organization definition:* defines the suitable organization structure for the CIM environment.
10. *Budget making and cost–benefit analysis.*
11. *Overall system design report generation.*

6.1.3. Detailed System Design

The detailed system design phase solves the problem of system specification definition, the associated hardware and software configuration assignment, the functional and data interface definition, the implementation plan and making of steps, the forming of the associated implementation team, and the assignment of responsibility and setting of benchmarks.

In this phase, an important goal is to define the interfaces between different subsystems. The shared data physical model for the CIM system needs to be specified. The number, type, and configuration of hardware systems should be defined. The detailed software products that should meet the requirements defined in overall system design should also be specified. The network scheduling for the implementation plan should be generated and evaluated. A leadership group is formed that will manage the entire CIM implementation. A number of implementation teams with personnel from different disciplines and different business sectors are formed. Each implementation team will be engaged in the implementation of a specific part of the CIM system.

After the detailed system design phase is finished, the CIM system is ready to go into practical implementation.

6.1.4. Implementation and Operation

The implementation phase follows a bottom-up approach. Subsystems are implemented in order according to the implementation scheduling. When the subsystem implementation is finished, integration interfaces between the subsystems are developed and several higher-level subsystems are formed through integration of some low-level subsystems. Finally, the whole CIM system is implemented through an integration.

After the system is built and tested, it becomes an experimental operation, which will last for three to six months. During that period, errors that occur in the operation are recorded and system modifications are carried out. The CIM system is turned to practical use. In the implementation and operation phase, the following steps are generally followed:

1. *Building computer supporting environment:* including computer network, computer room, network and database server, UPS, air conditioner, and fire-proof system
2. *Building manufacturing environment:* including whole system layout setup, installation of new manufacturing devices, and old manufacturing configuration
3. *Application system development:* including new commercial software installment, new application system development, old software system modification
4. *Subsystem integration:* including interface development, subsystem integration, and system operation test
5. *CIM system integration:* including integration and testing of whole CIM system
6. *Software documentation:* including user manual writing, operation rule definition, setting up of system security and data backup strategies
7. *Organization adjustment:* including business process operation mode, organization structure, and operation responsibility adjustment
8. *Training:* including personal training at different levels, from top managers to machine operators
9. *System operations and maintenance:* including daily operations of CIM system, recording of errors occurring in the operation, application system modification, and recording of new requirements for future development

6.2. Integration Platform Technology

6.2.1. Requirements for Integration Platform

The complexity of manufacturing systems and the lack of effective integration mechanisms are the main difficulties for CIMS implementation. Problems include lack of openness and flexibility, inconvenient and inefficient interaction between applications, difficulty in integrating a legacy information system, the long time required for CIMS implementation, and the inconsistency of user interfaces.

To meet the requirements enumerated above, the integration platform (IP) concept has been proposed. IP is a complete set of support tools for rapid application system development and application integration in order to reduce the complexity of CIMS implementation and improve integration efficiency. By providing common services for application interaction and data access, IP fills the gaps between the different kinds of hardware platforms, operating systems, and data storage mechanisms. It also provides a unified integration interface that enables quick and efficient integration of different applications in various computing environments.

6.2.2. The Evolution of Integration Platform Technology

IP has evolved through a number of stages. It was initially considered an application programming support platform that provided a common set of services for application integration through API. A typical structure of the early IPs is the system enabler/application enabler architecture proposed by IBM, shown in Figure 28. Under such a structure, the IP provides a common, low-level set of services for the communication and data transfer (the system enabler) and also provides application domain specific enabling services (the application enabler) for the development of application systems. Thus, the application developer need not start from coding with the operating system primitive services. One disadvantage of the early IP products was that they only provided support for one or a limited number of hardware and operating system and the problem of heterogeneous and distributed computation was not addressed. Also, the released products often covered a specific domain in the enterprises, such as the shop-floor control. These early IPs focused mainly on support for the development of application software, and their support for application integration was rather weak.

Since the 1990s, IP has developed for use in a heterogeneous and distributed environment. An example is shown in Figure 29, where the architecture is divided into several layers, the communication layer, the information management service layer, and the function service layer, providing

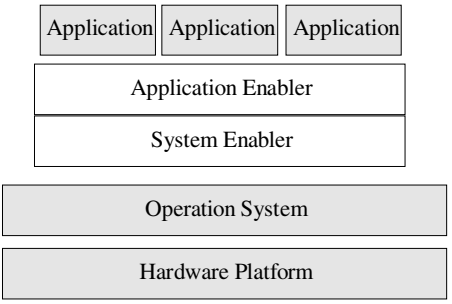

Figure 28 IBM System Enabler/Application Enabler.

commonly used system-level services. These services form the middleware layer of IP. The higher layers of IP are classified as general-purpose API, domain-specific API, and application development integration tools. The integration supporting area is extended from a specific domain to the whole enterprise, including management, planning, and manufacturing execution.

6.2.3. MACIP System Architecture

MACIP (CIMS Application Integration Platform for Manufacturing Enterprises) is a Chinese national high-technology R&D key technology research project. The MACIP project is designed to develop a research prototype of an application platform oriented to the new IP technology described above.

The MACIP system architecture is presented in Figure 30. It is a client–server structured, object-oriented platform with a high degree of flexibility. MACIP consists of two layers, the system enabling level and the application enabling level. The system enabling level is composed of two functions, the communication system and the global information system (GIS). The primary function of these components is to allow for the integration of applications in a heterogeneous and distributed computing environment. The communication system provides a set of services that allow transparent communication between applications. The global information system allows applications to have a common means for accessing data sources in a variety of databases and file systems. These functions are implemented in the form of application independent API (AI API). Application independence means that these functions are not designed for specific applications but are general services for communication, data access, and file management. Hence, the system enabling level provides the basic integration mechanisms for information and application integration.

The application enabling level, which utilizes the functions contained within the system enabling level, is composed of three domain sub-integration platforms (SIPs): MIS SIP, CAD/CAM/CAPP SIP, and shop-floor control SIP. Each SIP is designed according to the requirements of a domain application and provides functions for applications in the form of Application Dependent API (AD API). The AD API functions are designed specifically to enable the quick and easy development of

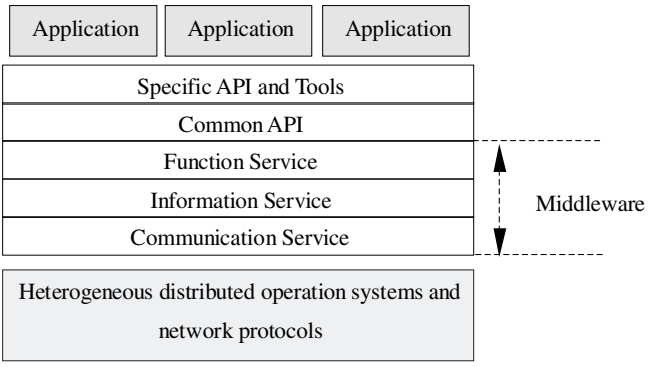

Figure 29 A Multilayer IP Structure.

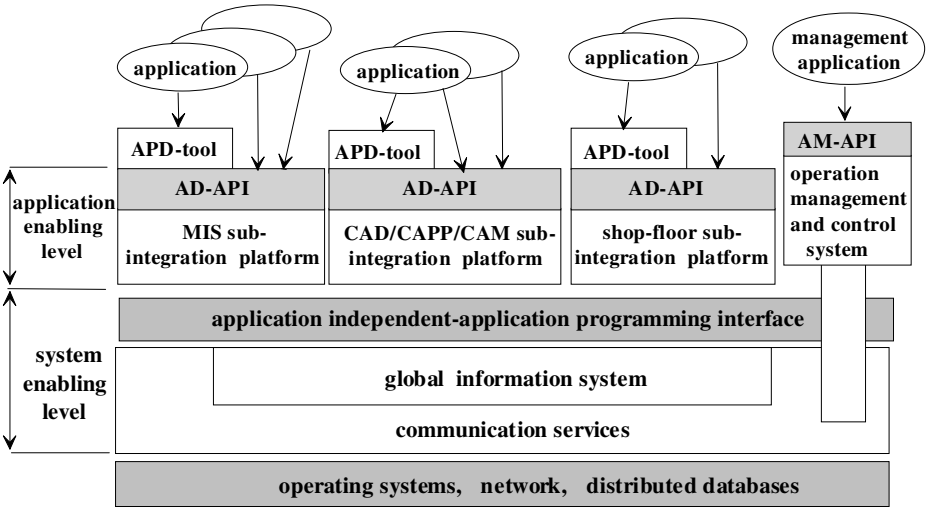

Figure 30 System Architecture of MACIP.

domain specific applications. These functions enable the complete integration of the application. Application development tools (APD tools) are developed using the AD-API. Users can also develop applications using the functions provided by AD-API. Existing applications are integrated by modifying the data exchange interface using AD-API functions. An Internet interface is also included in the application enabling level interfaces and provides access to MACIP through appropriate Internet technologies.

An operation management system was also designed that uses AI API functions to provide an application management API (AM API) for the users. Users use AM API to develop management applications that manage the IP resources and coordinate the operation of different applications.

The development of MACIP was finished in early 1999. It has since been used in several companies to support the rapid implementation of CIMS.

7. CIMS IN PROCESS INDUSTRY

7.1. Introduction

Process industry, by which we refer to continuous or semicontinuous production industry processes, principally includes the petroleum industry, the electric power industry, the metallurgical industry, the chemical industry, the paper industry, the ceramic industry, the glass industry, and the pharmaceutical industry. Process industry is a kind of highly complicated industrial system that not only includes biochemical, physical, and chemical reactions but also transmission or transition of matter and energy. Most process industries are subject to the interlocked relations of enterprise decision making, business marketing, schedule planning, material supplying, repertory transportation, and product R&D, in addition to the characteristics of continuity in wide scope, uncertainty, high nonlinearity, and strong coupling. All these factors are responsible for the unusual difficulty of comprehensive management, scheduling, optimization, and control in process industry enterprises. Therefore, these problems cannot be solved relying on either control and optimization theory, which are based on accurate mathematical models and exact analytical mathematical methods, or automation techniques alone (Ashayberi and Selen 1996). The CIMS technique is one possible solution to complex, comprehensive automation of process industry.

7.1.1. Definitions

- *Process industry:* Those industries in which the values of raw materials are increased by means of mixing and separating, molding, or chemical reaction. Production can be continuous or batch process. The characteristics of process industry must be considered when CIMS is applied to those industries.

- *Architecture structure:* The models that reflect these characteristics of production and business in process industry. The models represent all aspects of CIMS in the multiview and multilayer approach.
- *Models:* The structural representations of object concepts. Models include rules, data, and formal logical methods that are used to depict states, behaviors, and the interactive and inferential relations of objects or events.
- *Reference model:* The model definition for the architecture structure.
- *Modeling method:* According to the architecture descriptions, designers obtain the descriptions of all the states in an enterprise by abstracting the business function, business data, and business period.
- *Information integration:* Information integration activities in the production process or enterprise or even group can be described as a process of obtaining, handling, and processing information so that accurate information can be sent punctually and in the right form to the right people to enable them to make correct decisions.

7.1.2. Key Technologies

Because CIMS in process industry is in the developmental stage, some key technologies still need to be developed further:

1. *Total technology:*
   - Architecture structure and reference model of CIMS in process industry
   - Business reengineering model and managerial modes of enterprise
   - Control modes of Material and cost streams
   - Modeling methods for CIMS in process industry
   - Structural design methods for CIMS in process industry
   - Design specifications for CIMS in process industry
2. *Integration technologies:*
   - Information integration in enterprise and between enterprises
   - Integration of relation database and real-time database systems
   - Core data model, data booting, data compression, and data mining
   - Integration and Utilization of development tools and applications
   - Information integration-based Internet, data navigation, and browser technology
3. *Network technologies:*
   - Architecture structure of computer network system
   - Openess, reliability, safety, expandability, monitoring and management of networks
   - Speed, collisions resolution, concurrency control of networks
4. *Supervisor control technologies:*
   - Distributed intelligent decision-making support system-based intelligent agent
   - Optimization model establishment of large-scale systems
   - Description and analysis of hybrid system
   - Multimode grouping modeling and production operation optimization
   - Advanced process-control strategy and intelligent coordination control
   - Production safety monitoring, fault diagnosis and isolation, failure forecast
   - ''Soft'' measurement, intelligent data synthesis and coordination

7.2. Reference Architecture of CIMS in Process Industry

CIMS in process industry involves complex systematic engineering. Since its inception, advanced management theories, such as BPR (business process reengineering), CE (concurrent engineering), and TQM (total quality management), have been introduced. Using these theories, managers could reorganize departments that overlapped in function so as to facilitate the development of the enterprise. The realization of CIMS in these enterprises must build a clear reference architecture that can depict all functions in various phases and levels. Under the guidance of the reference architecture, the designers can simulate all potential solutions in an appropriate workbench and determine the total integration solution. The reference architecture of CIMS in process industry can refer to the frame of CIMS-OSA and PERA. The CIMS-OSA frame has many definitions and modeling approaches, in which the concepts are very clear. The PERA frame is very suitable for the definition of every phase in the CIMS life cycle, which considers every human factor that will affect the enterprise integration.

7.2.1. Architecture Structure Model

The architecture structure model of CIMS in process industry has four phases (Aguiar and Weston 1995): the strategic planning, requirement analysis, and definition phase; the conceptual designs phase; the detailed design and implementation phase; and the operation and maintenance phase, as shown in Figure 31. They reflected all the aspects of building process of CIMS. The strategic planning and requirement definition phase relates to senior management. The models in this phase manipulate information with reference to enterprise models and external factors to assess the enterprise's behavior, objective, and strategy in multiview and multidomain so as to support decision making. The conceptual design phase is the domain of system analysis. According to the scope defined in the previous phase, the models in this phase give a detailed description of a system in formalized system modeling technology. A solution will be found that satisfies the demands for performance and includes what and how to integrate. In general, the solution is expressed in the form of functions. Detailed design and implementation will be carried out in the system design phase. In this phase, the physical solutions should be specified, which include all subsystems and components. The models given in this phase are the most detailed. The models in the operation and maintenance phase embody the characteristics of the system in operation. These models, which define all active entities and their interaction, encapsulate many activities in enterprise operation.

The reference models depicted in Figure 31 consist of run-time models, resource models, integration models, system models, and business models, which correspond to the descriptions of the AS-IS system and the TO-BE system in the process of designing CIMS in process industry. Their relationships are abstracted step by step from down to up, opposite to the process of building CIMS.

- *Run-time models* encapsulate the information related to system operation, such as dynamic math models of production, input–output models, and order management models.
- *Resource models* contain the information related to relationships between the resource and the satisfaction of demands. In these models, the resource information that designers will add for some special functions is still included.

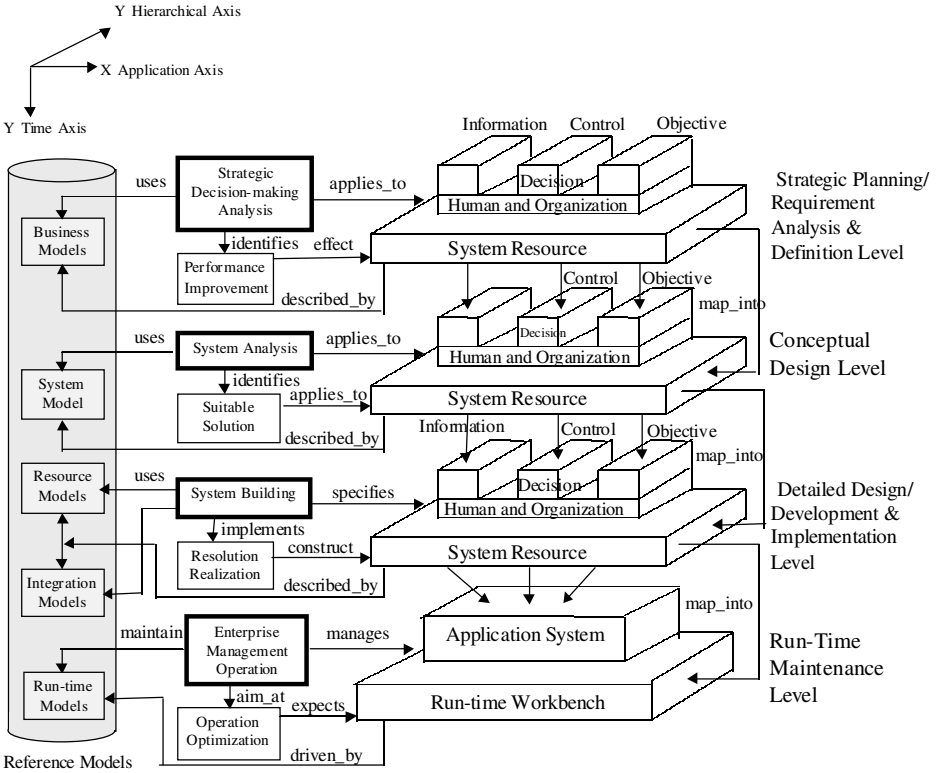

Figure 31 Architecture Structure Model. (From Aguiar and Weston 1995)

- *Integration models* present the way in which various component elements of the AS-IS system and the TO-BE system could be integrated to complete an integrated system.
- *System models* capture the structure and knowledge of the department in related domains that are currently organized or should be organized to improve the performance of the system. They encapsulate the experiences of system analysts and the descriptions of the prototype.
- *Business models* collectively contain the business knowledge required to accomplish strategic analysis and requirement definition, including business rules and the accumulated experience from analyzing enterprise performance.

With these reference models, CIMS in process industry could be built from up to down. Each phase is dynamic in nature and can be related to each other phase. That is, the implementation in every phase can be modified to adapt to changes in environment and demands.

7.2.2. Hierarchical Structure Model

The hierarchical structure model is a structured description of CIMS engineering. It is an aggregation of models and their relationships in the whole CIMS of an enterprise. It is the foundation of the design and realization of CIMS. A hierarchical structure model used in CIMS in process industry is shown in Figure 32. It has five levels and two supporting systems. The five levels are the direct control system, the supervisory control system, the production scheduling system, the management information system, and the enterprise decision making system. The two supporting systems are the database system and the computer network system.

The main function of the hierarchical structure model is:

- *Direct control system level:* This is the lowest level of automated system in the production process, including the distributed control system used in production devices and the fundamental automated equipment used offsite. The parameters of the production process are measured and controlled by the automated system. They also receive instruction from the supervisory control system level and accomplish the process operation and control.
- *Supervisory control system level:* The system in this level fulfills supervisory control of main production links in the whole production process. According to the instructions from the sched-

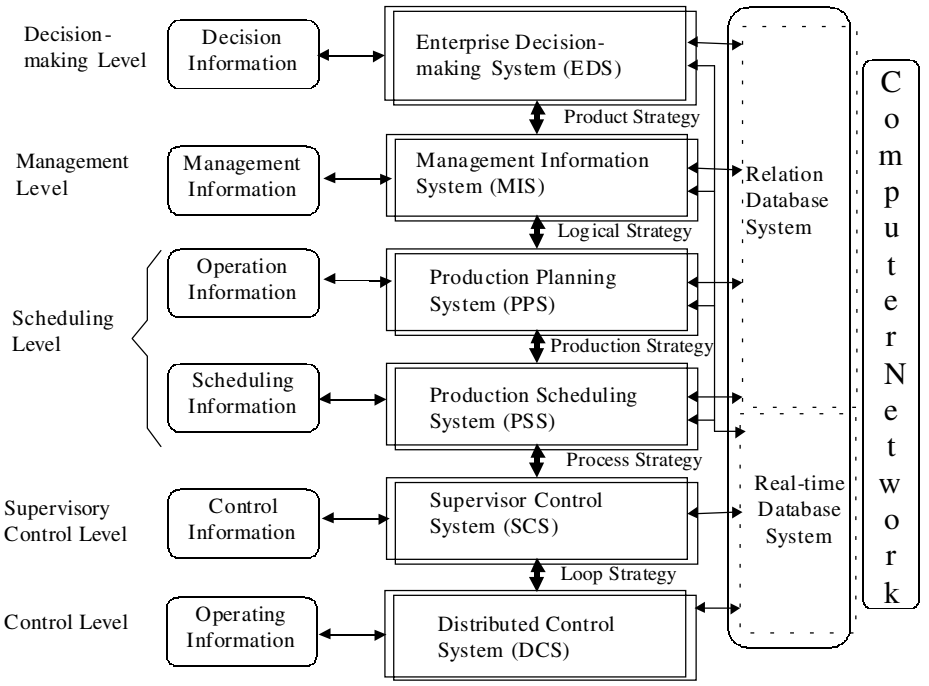

Figure 32 Hierarchical Structure Model.

uling system level, it formulates process tactics and conducts the actions at the direct control system level, including operation optimization, advanced control, fault diagnosis, and process simulation.

- *Production scheduling system level:* At this level, the production load is determined and the production planning is decomposed into five days rolling work planning for every month, according to the information from the decision-making system and the material-stream and energy-stream data. By optimizing scheduling, allocating energy, and coordinating operations in every workshop, the production becomes balanced, stable and highly efficient.
- *Management information system level:* The system at this level accomplishes the MIS function for the whole enterprise and carries out integrated management of production and business information. According to the instructions from the decision-making system, it makes logical decisions. It is in charge of day-to-day management, including business management and production management.
- *Enterprise decision-making system level:* The system at this level comes up with decisions supporting enterprise business, product strategy, long-term objectives, and developing planning and determines the strategy of production and business. Within the company group, it aims at integration optimization in the whole enterprise so as to yield the maximum benefit.

7.3. Approach to Information Integration for CIMS in Process Industry

The core of CIMS in process industry is the integration and utilization of information. Information integration can be described as follows: The production process of an enterprise is a process of obtaining, processing, and handling information. CIMS should ensure that accurate information is sent punctually on in the right form to the right people to enable them to make correct decisions.

7.3.1. Production Process Information Integration

Production is the main factor to be considered in CIMS design for a process industry. Driven by the hierarchical structure model discussed in Section 7.2.2, these information models of every subsystem at all levels are built. In these models, the modeling of production process information integration is the crux of the matter. This model embodies the design guidance, centering on production in three aspects:

1. Decision → comprehensive planning → planning decomposition → scheduling → process optimization → advanced control
2. Purchase → material management → maintenance
3. Decision → comprehensive planning → planning decomposition → scheduling → product storage and shipment control

The computation of material equilibrium and heat equilibrium and the analysis/evaluation of equipment, material and energy can be done using this model so as to realize the optimized manipulations in the overall technological process.

7.3.2. Model-Driven Approach to Information Integration

Figure 33 depicts the mapping relationship of the models in the building process of CIMS in process industry. It demonstrates that the designed function related to every phase of building CIMS can be depicted from the design view using the structural and model-driven approach (Aguiar and Weston 1995).

The realization of model mapping relies on the building of software tools supporting every phase in a hierarchical way. *Model mapping* refers to the evolutionary relationships of models between the phases of building CIMS. As the enterprise hierarchy is developed downwards, the description in the models becomes more detailed. In contrast, with the increasing widening of modeling scope, the granularity of descriptions in models will be reduced so as to form more abstract models. For example, at the detailed design and implementation level, various dynamic math models should be used, and detailed IDEF0 and static math models should be used in the conceptual design phase. We can conclude that the models of various phases in the building CIMS can be evolved step by step in the model-driven approach from up to down.

In the previous analysis, the realization of the model-driven information integration method requires a workbench. This consists of a series of tools, such as modeling tools from entity to model, simulating tools supporting the simulations in various levels from higher-level strategic planning to lower-level detailed design, and assessing tools appraising the performance of solution simulation at various levels.

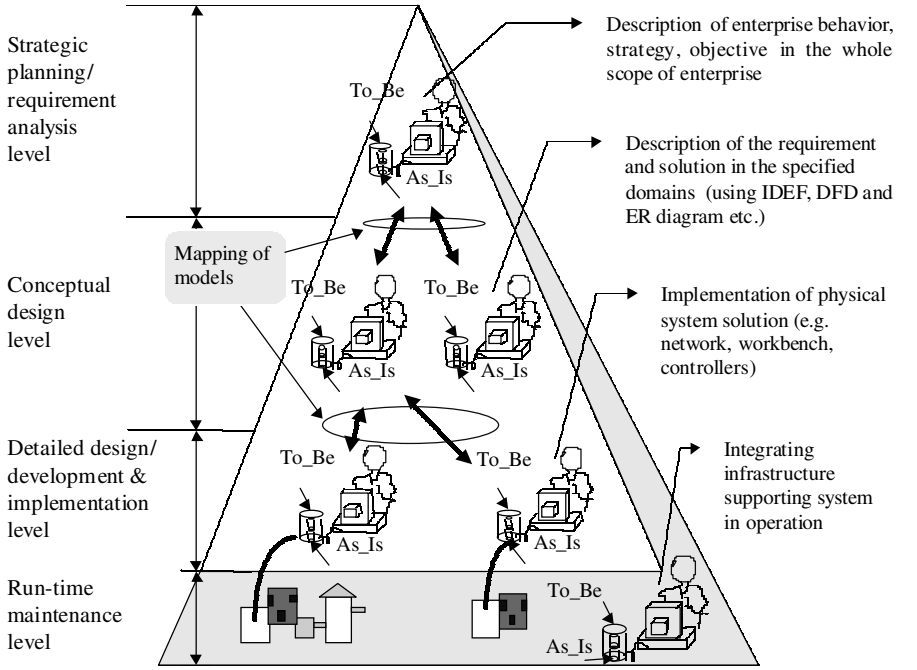

Figure 33 Integrating Map of Models Based on Model-Driven Approach. (From Aguiar and Weston 1995)

7.4. An Application Example

We will discuss an application example of CIMS in a giant refinery enterprise. The technological process of the refinery is continuous, the material stream cannot be interrupted, and strict real-time demands for production manipulation are made. The enterprise aims at the following objectives: material equilibrium, energy equilibrium, safety and high efficiency, low cost and good quality, and optimized operation of the technological process. The realization of CIMS in this type of enterprise requires the consideration not only of problems such as production management, production scheduling, operation optimization, and process control, but also of business, marketing, material supply, oil product transport and storage, development of new products, capital investment, and so on (Fujii et al. 1992). The computer integrated production system of the enterprise is constructed according to changes in crude oil supply, market requirements for products, flexibility of the production process, and different management modes. The integration of business decision making, production scheduling, workshop management, and process optimization is realized in the giant refinery.

7.4.1. Refinery Planning Process

The refinery enterprise consists of many production activities (Kemper 1997). If the blend operation day is called the original day, then the production activities on the day 90 days before that day include crude oil evaluation, making of production strategy, and crude oil purchasing. In the same way, the production activities on the day 10–30 days after the original day include stock transportation and performance adjustment of oil products. Every activity in the production process is relevant to each other activity. For example, in crude oil evaluation, the factors in the activities following the making of production strategy must be analyzed. In another example, people in the activity of crude oil evaluation need to analyze those production activities following the refinery balance in detail. Deep analysis of those activities in the refinery enterprise is the basis of design of CIMS in that enterprise. Figure 34 depicts the refinery planning process.

7.4.2. Integrated Information Architecture

By analyzing of the refinery planning process, we can construct the integration frame depicted in Figure 35.

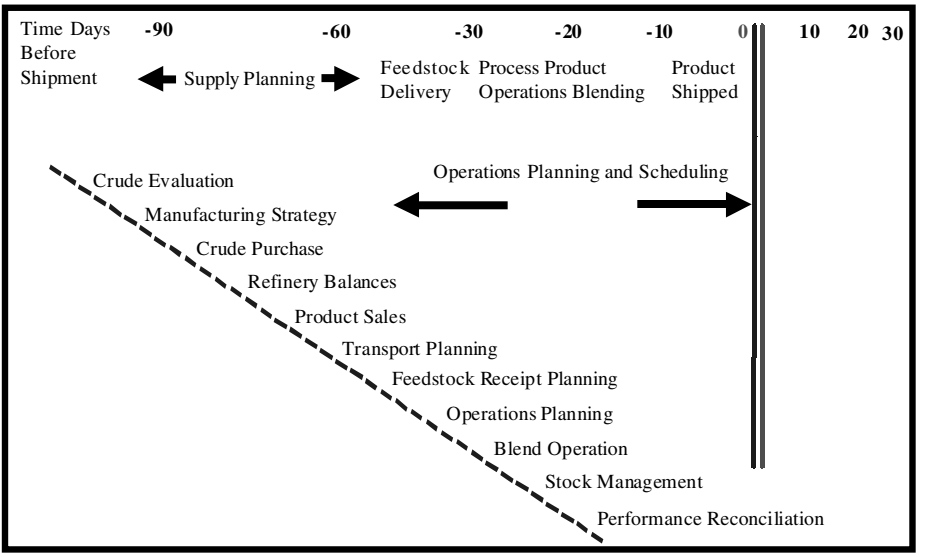

Figure 34 Refinery Planning Process.

Using the model-driven approach to the modeling of all subsystems, the information integration model in this refinery enterprise could be built as shown in Figure 36 (Mo and Xiao 1999). The model includes the business decision-making level, the planning and scheduling level and the process supervisory control level. Their integration is supported by two database systems.

The relevant information, such as market, costing, financial affairs, and production situation, is synthesized to facilitate business decisions of the enterprise, and crude oil supply and oil product sale planning are both determined at the business decision-making level.

The planning and scheduling level synthesizes management information, decomposes production planning to short-term planning and executes the daily scheduling, and gives instructions directly to process supervisory control level. In the meantime, it accomplishes the management and control of oil product storage and transport, including the management and optimized scheduling control of the harbor area and oil tank area.

The process supervisory control accomplishes process optimization, advanced control, fault diagnosis, and oil product optimized blending.

7.4.3. Advanced Computing Environment

The information integration model of the giant refinery depicted in Figure 36 is built using the model-driven method. The model is the design guidance of the realization of CIMS in the enterprise. Figure

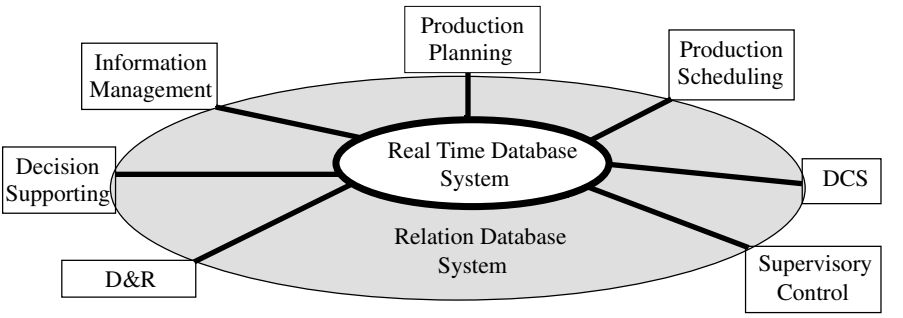

Figure 35 Integration Frame.

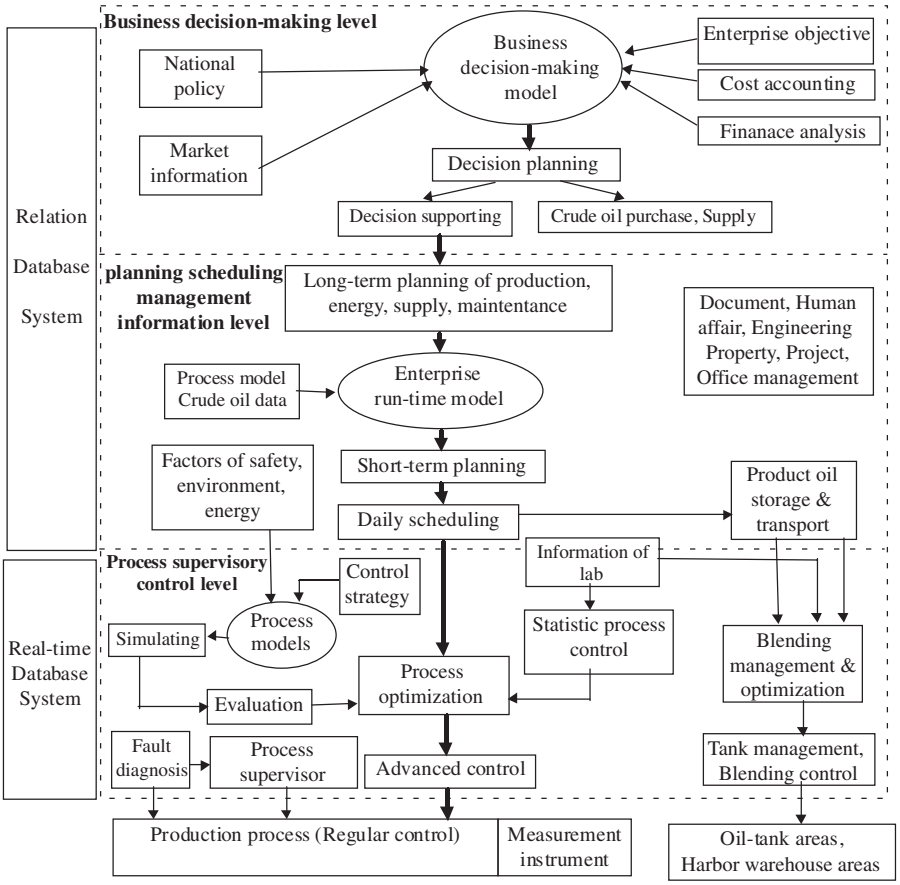

Figure 36 Information Integration Model.

37 depicts the computing environment for the realization of the information integration model, using the client–server computing mode (Kemper 1997).

7.5. Conclusions

The reference architecture of CIMS in process industry can instruct designers to optimize solutions by repeatedly optimizing and simulating so as to obtain the final physical system realization in an enterprise. Practical experience indicates that CIMS in process industry is not like selling a car. With the progressive development of technology and the changes in the external environment, CIMS in process industry needs to continue adjusting to yield the maximum economic and social benefit.

8. BENEFITS OF CIMS

Many benefits can be obtained from the successful implementation and operation of a CIM system in a manufacturing company. The benefits can be classified into three kinds: technical, management, and human resources quality.

8.1. Technical Benefits

Technical benefits obtained from implementation CIM system are:

1. *Reducing inventory and work-in-progress:* This can be accomplished through the utilization of an MRPII or ERP system. Careful and reliable material purchasing planning and production planning can to a great extent eliminate high inventory and work-in-progress level, hence reducing capital overstock and even waste through long-term material storage.

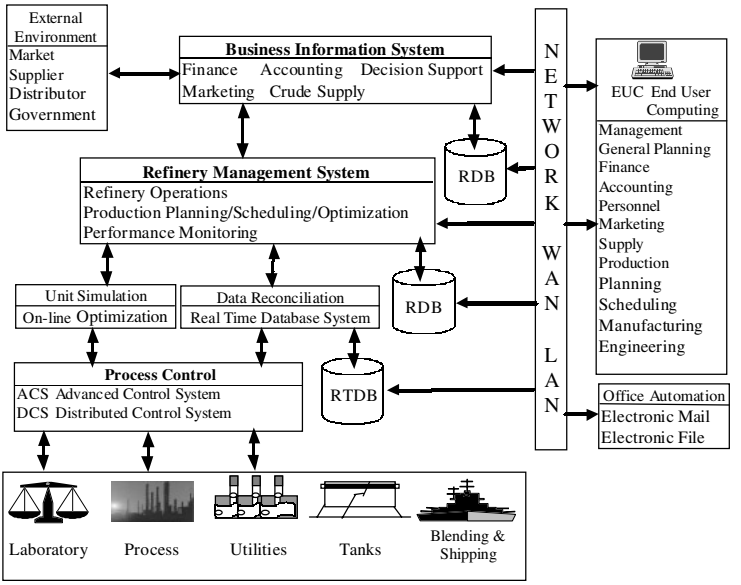

Figure 37 Advanced Computing Environment.

2. *Improving production efficiency:* Through the integration of a production system, planning system, and material supply system, the production processes can be operated in a well-organized way and hence production can be carried out with the shortest possible waiting times and machine utilization greatly increased. Through the integration of CAD, CAPP, and CAM systems, the setup time for NC machines can be reduced significantly. The improvement of production efficiency will bring economic returns from investment in the CIM system.
3. *Improving product quality:* The integration of the company's business processes, design processes, and production processes will help in improving product quality. TQM can be put into effect in the CIM integrated environment.
4. *Reducing cost:* This is the direct effect obtained from the above three benefits.
5. *Improving product design ability:* Through the integration of CAD, CAPP, and CAM systems, by using the current engineering method, the product design ability of the company can be significantly improved. New and improved products can be designed and developed in a shorter time, and the company can win the market competition with these products.

8.2. Management Benefits

The following management benefits can be obtained from the CIM sysem implementation:

1. *Standardizing processes:* The business processes, design processes, and production processes can be standardized. This can help to streamline the company's processes and reduce errors caused by uncontrolled and random operations.
2. *Optimizing processes:* The business processes, design processes, and production processes can be optimized. This can help to locate bottlenecks in the processes and cost-intensive activities and thus to provide methods to reduce the cost.
3. *Improving market response ability:* The traditional pyramid organization structure will be changed to flat structure that can greatly improve the speed of response to market change and user requirements.

8.3. Human Resource Quality

Almost all employees will be involved in the implementation of the CIM system. Through different courses of training, from CIM philosophy to computer operation, the total quality of the employees can be improved at all levels, from management staff to production operators. More importantly,

employees will get to know better the company's objectives, situation, technical standards, and manufacturing paradigm, inspiring them to devote their energy to improving the company's operation efficiency.

9. FUTURE TRENDS OF CIM

As a manufacturing paradigm, CIM concepts and practice have developed for more than 20 years. CIM is still in active development and has received much attention from researchers and companies. Some of the development trends for CIM are as follows.

9.1. Agile Manufacturing

In today's continuously, rapidly, and unforeseeably changing market environment, an effective way to keep the company competitive is to use the agile manufacturing strategy. Agile manufacturing has been called the 21st-century manufacturing enterprise strategy (Goldman and Preiss 1991; Goldman et al. 1995). By agile, we mean that the company can quickly respond to market change by quickly reengineering its business processes, reconfiguring its manufacturing systems, and innovating its products.

A number of papers discuss the characteristics of an agile manufacturing company, such as:

- Greater product customization
- Rapid introduction of new or modified products
- Increased emphasis on knowledgeable, highly trained, empowered workers
- Interactive customer relationships
- Dynamic reconfiguration of production processes
- Greater use of flexible production technologies
- Rapid prototyping
- An agile and open system information environment
- Innovative and flexible management structures
- Rapid collaboration with other companies to form a virtual company.

9.2. Green Manufacturing

The increasingly rapid deterioration of environment has caused many problems for society. During the production of products, manufacturing companies also produce pollution to the environment. Pollution produced during the manufacturing processes includes noise, waste gas, wastewater, and waste materials. Another kind of pollution is caused by waste parts at the end of the product's life, such as batteries, printed circuit boards, and plastic covers. Green manufacturing aims at developing a manufacturing paradigm and methods for reducing pollution by a manufacturing company of the environment. The green manufacturing paradigm covers the whole life cycle of a product, from requirements specification, design, manufacturing, and maintenance to final discarding. Research topics in green manufacturing include:

- *Green design* (also called *design for environment*) considers the product's impact on the environment during the design process, designing a product that causes minimal pollution. Multi-life-cycle design, which considers multiple use of most parts and recycling one-time-use parts, has received much attention.
- *Green materials* involves development of materials that can be easily recycled.
- *Green production* involves developing methods to reduce pollution during the production process.
- *Green disposal:* developing new methods to recycle the discarded products.

9.3. Virtual Manufacturing and Other Trends

By using virtual reality and high-performance simulation, virtual manufacturing focuses on building a digital model of the product and studies the dynamic and kinetic performance of the product to reduce product development cost and time.

Many development trends are affecting CIM and its related technologies. Technologies that may have a great influence on CIM include network (Web) technology, distributed object technology, intelligent agent technology, knowledge integration technology, and CSCW technology. CIM systems, using these advanced paradigms and technologies, will have a brilliant future. In the future, a manufacturing company supported by an advanced CIM system may be operated in an Internet environment (Web user interface), running on a virtual dynamic organization structure, using CSCW tools,

to design and produce products in a cooperated and integrated way. The company will fully satisfy user requirements and produce products quickly and cheaply. Materials and products will be delivered on time.

CHAPTER 16
Clean Manufacturing

JULIE ANN STUART
Purdue University

1. INTRODUCTION

Clean manufacturing focuses on planning, designing, and producing manufactured products to incur minimal environmental impacts during their lifetimes. Implementation of clean manufacturing includes reliable process control, substitution of hazardous materials with nonhazardous materials, reduction of energy consumption, repair for product life extension, and design for materials recycling. Thus, clean manufacturing may apply to materials and process analyses that reach beyond the manufacturing process to include the environmental impacts of the entire product life. Clean manufacturing requires a broad range of multidisciplinary approaches that include local, regional, national and global policies, engineering and technology advances, economics, and management perspectives.

Industrial engineers study industrial metabolism—that is, the linkages between suppliers, manufacturers, consumers, refurbishers, and recyclers. Environmental engineers, on the other hand, study environmental metabolism—that is, the linkages between entities such as biota, land, freshwater, sea water, and atmosphere (Graedel and Allenby 1995). Clean manufacturing requires the study of the interactions between industrial metabolism and environmental metabolism.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

TABLE 1 Types of Environmental Impacts

General Environmental Impacts	Environmental Hazards
Resource depletion	♦ Materials extraction, use, and disposal ♦ Loss of soil productivity ♦ Landfill exhaustion ♦ Loss of species diversity
Pollutants and wastes	♦ Groundwater quality (biological, metals, and toxic contamination, eutrophication,[a] acid deposition,[a] sedimentation) ♦ Atmospheric quality (stratospheric ozone depletion,[a] global warming,[a] toxic air pollution)
Energy consumption	♦ Energy use that results in resource depletion and/or pollutants

Adapted from Norberg-Bohm et al. 1992.
[a] This term is defined in Section 4.3, Table 6.

2. MOTIVATION

The environmental impacts of manufacturing may include resource depletion, energy consumption, air pollutants, water pollutants, and both hazardous and nonhazardous solid waste. Table 1 shows the hazards associated with general environmental impacts.

2.1. Metrics

The simplest metric for environmental impact with respect to material consumption, pollution, waste generation, or energy consumption is the quantity or inventory for a specified period of time. Microlevel inventory may be measured with respect to a geographical area or industrial facility. Sources for macrolevel inventory data for the United States are summarized in Table 2.

Metrics may also be indexed with respect to a manufacturing output, input, throughput, or batch size, as discussed in Allen and Rosselot (1997). Product-based environmental impact analysis requires activity-based inventory assessment (Stuart et al. 1998). Similar to activity-based costing (see Chapter 89), activity-based environmental inventory assessment recognizes the hierarchy of impacts and assigns them proportionately to an activity such as a product or service.

Due to the complexity of environmental impacts, the Swedish Environmental Institute and Volvo recommend consideration of the following characteristics in their environmental priority strategies (EPS) system: scope, extent of distribution, frequency and intensity, duration or permanence, significance of contribution, and remediability (Horkeby 1997; Ryding et al. 1993). Another complexity to consider is the transfer of impacts along the supply chain because materials extraction, assembly, use, reuse, recycling, and disposal may occur in different locations around the world.

2.2. Legal Requirements

Traditional command-and-control requirements that primarily targeted the manufacturing phase of the product life cycle increased significantly in the past 20 years in the United States. For example, the number of environmental laws passed in the United States increased from 7 between 1895 and 1955 to 40 between 1955 and 1995 (Allenby 1999). Similarly, the number of environmental agreements in the European Union has generally escalated from 1982 to 1995, as described in European Environmental Agency (1997). Many of the regulations in the Asia-Pacific region mirror those in the United States and Europe (Bateman 1999a,b).

TABLE 2 Example of Information Sources for Macrolevel Inventory Data for the United States

Medium	Report	Agency
Material	Toxic Release Inventory (TRI)	U.S. EPA
Pollutant	Aerometric Information Retrieval System (AIRS)	U.S. EPA
Waste	Resource Conservation and Recovery Act Biennial Report System (RCRA BRS)	U.S. EPA
Energy	Manufacturing Energy Consumption Survey	U.S. Department of Energy

Manufacturers must also follow local legislation such as mandates for permits to install or operate processes with regulated effluents. In addition to local and federal mandates where manufacturing and sales take place, manufacturers must also keep abreast of global agreements. For example, the manufacture of chlorofluorocarbon (CFC) solvents, which were used for cleaning electronic assemblies, was banned in 1995 (Andersen 1990). Environmental law is discussed in Chapter 19. Additional legal and service trends are discussed in the next section.

2.3. Responsibility Trends

This section outlines three emerging trends that directly affect the manufacturer's responsibility for environmental impacts: extended product responsibility, extended services, and environmental information reporting. The first trend calls for producers to prevent pollution associated with their products over the products' life cycles. For the second trend, rather than solely selling products, some manufacturers are expanding their business to offer service packages that include the use of their products. In the third trend, the availability and mandatory reporting requirements for environmental information for customers are increasing. These trends are discussed in the next three subsections.

2.3.1. Extended Product Responsibility

There is a trend in Europe and East Asia toward product life cycle responsibility legislation that requires manufacturers to minimize environmental impacts from materials extraction to manufacturing to distribution/packaging to repair to recycling to disposal. Essentially, extended product responsibility shifts the pollution prevention focus from production facilities to the entire product life cycle (Davis et al. 1997). For example, proposed legislation may require that manufacturers not only recycle in-plant wastes but also recycle their discarded products (Denmark Ministry of the Environment 1992; Davis 1997). The evaluation of life cycle stages and impacts are discussed further in Section 4.3.

2.3.2. Manufacturers as Service Providers

In recent years, as manufacturers have assumed the additional role of service provider, responsibility for environmental impact has shifted from the user to the manufacturer. For example, a chemical supplier may be reimbursed per total auto bodies cleaned rather than for the procurement of chemicals for auto body cleaning. Under such an arrangement, there is a financial incentive for the supplier to reduce material consumption (Johnson et al. 1997). In another example, an electronic component manufacturer may use a chemical rental program. The supplier provides chemical management from purchasing and inventory management to waste treatment and disposal (Johnson et al. 1997). Thus, chemical suppliers are gaining a broader responsibility for their products throughout their products' life cycles.

Another important service trend is the replacement of products with services. For example, telecommunications providers offer voice mail rather than selling answering machines. Another example is electronic order processing rather than paper processing. These service trends result in dematerialization, the minimization of materials consumed to accomplish goals (Herman et al. 1989).

2.3.3. Environmental Information Provided by Manufacturers

The third trend is the increasing amount of environmental information that manufacturers communicate to customers. Three general approaches for communicating environmental attributes to corporate procurement and consumers have emerged: eco-labels, self-declaration, and life cycle assessment.

Eco-labels are the simplest format for consumers but the most inflexible format for manufacturers in that they require that 100% of their standard criteria be met. Examples of eco-labels include the Energy Star label in the United States and the Blue Angel in Germany. Because over 20 different eco-labels with different criteria are in use around the world, manufacturers may need to consider multiple eco-label criteria sets (Modl 1995).

Another type of label, self-declaration, allows producers to select methods and metrics. However, comparisons among competing products or services are difficult. Self-declaration is the most flexible form for manufacturers, but its use depends on the manufacturer's environmental reputation among customers. The ECMA, a European industry association that proposes standards for information and communication systems, has proposed product-related environmental attribute standards (Granda et al. 1998).

Full life-cycle assessment, a comprehensive method to analyze the environmental attributes of the entire life cycle of a product, requires environmental engineering expertise. Life cycle assessment is described in Section 4.3.

Consumers may learn about environmental impacts from eco-labels, self-declaration, and life cycle assessment studies. Industrial engineers may learn about clean manufacturing as universities integrate industrial ecology concepts into business and engineering programs (Santi 1997; Stuart 2000). Important clean manufacturing concepts are defined in the next section.

3. HIERARCHY OF IMPORTANT CONCEPTS

To provide a framework for clean manufacturing methods, this section will define important basic concepts. Interestingly, many of the concepts, such as recycling, are defined differently by government, societal, industrial, and academic entities (Allen and Rosselot 1997). Other terms are used interchangeably; for example, *pollution prevention* is often defined as source reduction.

In Table 3, sustainable development and industrial ecology top the hierarchy in clean manufacturing. Industrial ecology is an emerging study that attempts to lessen the environmental impacts of manufacturing activities through planning and design. Industrial ecology is a systems approach to optimizing materials and energy cycles of products and processes (Graedel and Allenby 1995). Methods for clean manufacturing and industrial ecology are described in the next section.

4. METHODS

Traditional methods for clean manufacturing focus on waste or energy audits, which are summarized in Section 4.1. New methods focus on life cycle design, life cycle assessment, production planning models with environmental considerations, and environmental management systems, which are described in Sections 4.2, 4.3, 4.4, and 4.5, respectively.

4.1. Waste/Energy Audits for Waste/Energy Minimization

Waste and energy audits require a detailed inventory analysis of waste generation and energy consumption. The point of origin of each waste and the breakdown of the equipment energy consumption patterns must be determined. Audits are used to identify significant sources of waste and energy costs. Because some environmental impacts are interconnected, both individual source and system impacts must be considered. General guidelines are given for waste audits and energy audits in the next two subsections.

4.1.1. Waste Audits

Waste audits may be performed at the waste, product, or facility level. Waste-level audits simply require that each waste stream and its source be identified. Although this approach is the simplest, it ignores the implications and interactions of the waste stream as a whole. Waste audits performed at the product level are product life cycle inventory assessments, which are discussed in Section 4.3. Facility waste audits are the most common type of audit because most environmental laws require discharge reporting by facility. Estimating plant-wide emissions is discussed in Chapter 19.

Facility waste audits require process flow charts, product material information (commonly from the bill of materials), process material information (such as cutting fluids in a machine shop), and

TABLE 3 Hierarchy of Terms in Clean Manufacturing[a]

Term	Definition
Sustainable development	". . . to meet the needs of the present without compromising the ability of future generations to meet their own needs" (President's Council on Sustainable Development 1996)
Industrial ecology	"the self-conscious organization of production and consumption to reduce adverse environmental impacts of human activity" over time (Socolow 1999)
Product life-cycle assessment	assessment of environmental impacts (materials, energy, and waste) from materials extraction to manufacturing to distribution/packaging to repair to recycling to disposal for a specific product
Pollution prevention[a] or source reduction[a]	product, process, or equipment design that emits fewer pollutants to air, water, and/or land
Waste minimization[a]	in-plant activities to reduce gas, liquid or solid waste
In-process recycling[a]	the nonproduct output is treated and fed back into the process
On-site recycling[a]	waste from a process is converted on-site as a raw material for a different product
Off-site recycling[a]	waste from a process is sent off-site, where it is converted to a raw material for a different product
Waste treatment[a]	waste is treated to lessen its toxicity
Secure disposal[a]	waste is sent to a secure landfill
Direct release[a]	waste is released directly into the environment

[a]These terms are adapted/republished with permission of John Wiley & Sons, Inc. from Allen and Rosselot.

environmental information (solid, liquid, and gaseous wastes). Waste auditing guides are available from state-funded programs (e.g., Pacific Northwest Pollution Prevention Resource Center 1999). Allen and Rosselot suggest that waste audits answer the following series of questions: What waste streams are generated by the facility? in what quantity? at what frequency? by which operations? under what legal restrictions or reporting requirements? by which inputs? at what efficiency? in what mixtures? (Allen and Rosselot 1997)

Waste audits require identification of solid wastes, wastewater, direct and secondary emissions. In the United States, solid wastes may be classified as nonhazardous or hazardous according to the Resource Conservation and Recovery Act (RCRA). In general, wastewater is the most significant component of total waste load Allen and Rosselot (1997). Several methods for estimating the rates of direct (fugitive) and secondary emissions are outlined with references for further information in Allen and Rosselot (1997).

Once companies have identified their major wastes and reduced them, they can turn their focus toward prevention. Pollution-prevention checklists and worksheets are provided in U.S. EPA (1992) and Cattanach et al. (1995). Process- and operations-based strategies for identifying and preventing waste are outlined in (Chadha 1994). Case studies sponsored by the U.S. Department of Energy NICE^3 program detail success stories for cleaner manufacturing or increased energy efficiency for several major industries (see Office of Industrial Technologies, NICE^3, www.oit.doe.gov/nice3/).

4.1.2. Energy Audits

Energy audits may be performed at either the facility or equipment level. Plant-wide energy audits are most common because utility bills summarize energy usage for the facility. Facility energy audits focus on characteristics of use such as occupancy profiles, fuel sources, building size and insulation, window and door alignment, ventilation, lighting, and maintenance programs. (Facility audit forms and checklists are available on the Web from the Washington State University Cooperative Extension Energy Program, www.energy.wsu.edu/ten/energyaudit.htm.) Some industries have developed specialized audit manuals. For example, an energy audit manual for the die-casting industry developed with funds from the state of Illinois and the Department of Energy describes how to assess energy use for an entire die casting facility (Griffith 1997). In addition to industry-specific energy consumption information, the U.S. Department of Energy Industrial Assessment Centers provide eligible small- and medium-sized manufacturers with free energy audits to help them identify opportunities to save energy and reduce waste (Office of Industrial Technologies 1999). Energy management is described in Chapter 58.

At the equipment level, energy usage may be determined through engineering calculations or monitors placed on the equipment in question. Identifying equipment with significant energy consumption may lead to actions such as adding insulation or performing maintenance.

Waste and energy audits are performed to identify existing problems. In the next four subsections, new approaches are presented that focus on prevention through life cycle design, life cycle assessment, production planning models with environmental considerations, and environmental management systems.

4.2. Life-Cycle Design*

The design and implementation of manufacturing activities and products have environmental impacts over time. Thus, industrial ecology requires consideration of the materials and energy consumption as well as effluents from resource extraction, manufacturing, use, repair, recycling, and disposal. Environmental considerations for product design and process design are summarized in the next two subsections.

4.2.1. Product Design

Product design guidelines for clean manufacturing are scattered throughout the industrial, mechanical, environmental, and chemical engineering, industrial design, and industrial ecology literature with labels such as ''life-cycle design,'' ''design for environment (DFE),'' ''environmentally conscious design,'' and ''green design.'' Traditionally, product design and materials selection criteria included geometric, mechanical, physical, economic, service environment, and manufacturing considerations. Industrial ecology introduces criteria such as reducing toxicity, avoiding resource depletion, increasing recyclability, and improving product upgradeability. The product design criteria in Table 4 are categorized by component and assembly level. As design functions for complex products are increasingly distributed, it is important to recognize product level considerations so that local, component design efforts are not cancelled out. For example, if a simple repair module is inaccessible, the design efforts for easy maintenance will be lost.

*This section has been adapted and reprinted with permission from Stuart and Sommerville (1997).

TABLE 4 Product Design Guidelines

	Component-Level Guidelines	Product-Level Guidelines
Process Stage	See Table 5	
Distribution Stage	• Minimize component volume and weight to minimize packaging and energy consumption.	• Minimize product volume and weight to minimize packaging and energy consumption.
	• Minimize special storage and transport requirements that lead to extra packaging (e.g., reduce fragility, sharp edges, and unusual shapes).	• Minimize special storage and transport requirements that lead to extra packaging (e.g., reduce fragility, sharp edges, and unusual shapes).
	• Design to avoid secondary, tertiary, and additional packaging levels.	• Design to avoid secondary, tertiary, and additional packaging levels.
	• Design for bulk packaging.	• Design for bulk packaging.
Use Stage	• Design components with multiple functions.	• Design product with multiple functions.
	• Consider renewable or rechargeable energy sources.	• Consider renewable or rechargeable energy sources.
	• Minimize energy consumption during start-up, use, and standby modes.	• Minimize energy consumption during start-up, use, and standby modes.
	• Minimize hazardous material content.	• Minimize use of hazardous joining materials.
	• Minimize material content of dwindling world supply or requiring damaging extraction.	• Minimize toxicity, quantity, and number of different wastes and emissions.
Refurbishment Repair Upgrade	• Use standard components.	• Maximize ease of disassembly (access and separation).
	• Consider replaceable components.	• Minimize orientation of components.
	• Use repairable components.	• Design upgradeable modules.
	• Maximize durability/rigidity.	• Maximize durability/rigidity.
	• Consider easily replaceable logos for second market.	• Consider easily replaceable logos for second market.
	• Maximize reliability of components.	• Maximize reliability of assembly.
Reclamation/materials recycling	• Maximize use of renewable and/or recyclable materials.	• Minimize the number of different materials and different colors; minimize incompatible material combinations.
	• Avoid encapsulates, fillers, paint, sprayed metallic, coatings, labels, or adhesives that reduce recyclability.	• Use easily identifiable, separable materials; make high-value parts and materials easily accessible with standard tools.
	• Avoid hazardous materials.	• Minimize number of different components and fasteners.

Adapted and reprinted with permission from Stuart and Sommerville (1997).

Because design decisions may result in environmental burden transfers from one stage in the life cycle to another or from one medium to another, it is important to recognize life cycle environmental impacts. Therefore, Table 4 is also categorized by five life-cycle stages: process, distribution, use, refurbishment, and recycling. Note that the process design stage for clean manufacturing is detailed separately in Section 4.2.2 and in Table 5.

One of the emerging themes in Table 4 is dematerialization. Dematerialization focuses on using fewer materials to accomplish a particular task (Herman et al. 1989). For example, consumers may subscribe to periodicals and journals on the Web rather than receive printed paper copies. Clearly, miniaturization, information technology, and the World Wide Web are increasing the potential for

TABLE 5 Process Design and Material Selection Guidelines

- Minimize use of materials with extensive environmental impacts.
- Minimize toxic emissions.
- Minimize material and water consumption.
- Minimize energy consumption.
- Consider materials that allow in-process, on-site, and off-site recycling.
- Perform preventive maintenance to reduce environmental impacts over time.
- Minimize secondary processes such as coatings.
- Eliminate redundant processes.
- Minimize cleaning process requirements.
- Capture wastes for recycling, treatment, or proper disposal.

Adapted and reprinted with permission from Stuart and Sommerville (1997).

dematerialization. Evaluating the criteria in Table 4 to avoid resource depletion or to use renewable materials requires assumptions to be made regarding the uncertainties in technological improvement, material substitutability, and rates of extraction and recycling (Keoleian et al. 1997).

The design criterion to increase product life reduces the number of products discarded over time. In the mid-1970s, DEC VT100 terminals could be disassembled quickly without tools to access the processor for maintenance and upgrades (Sze 2000). In 1999, the Macintosh G4 was introduced with a latch on the side cover that provides quick access to upgrade memory and other accessories (Apple 1999). Product life extension is especially important for products with short lives and toxic materials. For example, battery manufacturers extended the life of nickel–cadmium batteries (Davis et al. 1997). An example of product toxicity reduction was the change in material composition of batteries to reduce mercury content while maintaining performance (Tillman 1991). In another example, popular athletic shoes for children were redesigned to eliminate mercury switches when the shoes were banned from landfills (*Consumer Reports* 1994). The criteria related to recyclability may apply to product material content as well as the processing materials described in the next section.

4.2.2. Process Design

The criteria for process design for clean manufacturing focus on minimizing pollution, energy consumption, water consumption, secondary processes, or redundant processes. Table 5 provides a summary of suggested guidelines for materials selection and process design.

Careful process design can reduce environmental impacts and processing costs. For example, many companies eliminated the cleaning step for printed circuit card assembly by changing to low-solids flux and controlled atmospheres. These companies eliminated the labor, equipment, materials, and waste costs as well as the processing time associated with the cleaning step (Gutierrez and Tulkoff 1994; Cala et al. 1996; Linton 1995). Another example of reducing processing material consumption is recycling coolants used in machine shops. Recycling coolant reduces coolant consumption as well as eliminates abrasive metal particles that can shorten tool life or scar product surfaces (Waurzyniak 1999).

4.3. Product Life-Cycle Assessment*

Life-cycle assessment (LCA) is a three-step design evaluation methodology composed of inventory profile, environmental impact assessment, and improvement analysis (Keoleian and Menerey 1994). The purpose of the inventory step is to examine the resources consumed and wastes generated at all stages of the product life cycle, including raw materials acquisition, manufacturing, distribution, use, repair, reclamation, and waste disposal.

Materials and energy balance equations are often used to quantify the inputs and outputs at each stage in the product life cycle. Vigon et al. (1993) defines multiple categories of data for inventory analysis, including individual process, facility-specific, industry-average, and generic data. The most desirable form of data is the first data category, data collected from the process used for a specific product. However, this data category may require extensive personnel, expertise, time, and costs.

A three-step methodology for activity-based environmental inventory allocation is useful in calculating data for the first step of life cycle assessment. First, the process flow and system boundary

*The following section is adapted and reprinted with permission from Stuart et al. (1998). Copyright MIT Press Journals.

are determined. Then the activity levels and the activity percentages of the inputs and outputs are identified. Finally, the activity percentages are used to determine the actual quantities of the inputs and outputs and assign them to the product and process design combination responsible for their generation. A detailed example of this method is given in Stuart et al. (1998). As industrial engineers assist companies in calculating the allocation of their wastes to the product responsible, they can help managers make more informed decisions about product and process design costs and environmental impacts.

Industry-average and generic data must be used with caution because processes may be run with different energy requirements and efficiencies or may exhibit nonlinear behavior (Barnthouse et al. 1998; Field and Ehrenfeld 1999). For example, different regions have different fuel-producing industries and efficiencies that will have a significant effect on the LCA if energy consumption is one of the largest impacts (Boustead 1995).

Once the inputs and outputs are determined, the second and third steps of LCA, impact analysis and improvement analysis, can be pursued (Fava et al. 1991). For impact analysis, the analyst links the inventory of a substance released to an environmental load factor such as acid deposition, which is defined in Table 6 (Potting et al. 1998). Environmental load factors are a function of characteristics such as location, medium, time, rate of release, route of exposure, natural environmental process mechanisms, persistence, mobility, accumulation, toxicity, and threshold of effect. Owens argues that because inventory factors do not have the spatial, temporal, or threshold characteristics that are inherent to the environmental load, other risk-assessment tools should be used to evaluate a local process (Owens 1997).

LCA software tools and matrices may be used to estimate environmental load factors for impact analysis (Graedel 1998; Graedel et al. 1995). Alting and Legarth (1995) review 18 LCA tools for database availability, impact assessment methodology, and complex product capability.

The results of life-cycle impact assessment (LCIA) provide relative indicators of environmental impact. Eight categories for LCIA are defined in Table 6. Details regarding how to use life cycle impact assessment categories are provided in Barnthouse et al. (1998) and Graedel and Allenby (1995).

Life cycle assessment is a comprehensive, quantitative approach to evaluate a single product. ''An extensive survey of the use of mathematical programming to address environmental impacts for air, water, and land is given in [Greenberg (1995)]. A review of applied operations research

TABLE 6 Environmental Categories for Life-Cycle Impact Assessment

Environmental Category	Description
Greenhouse effect Global warming	Lower atmospheric warming from trapped solar radiation due to an abundance of CO_2, CH_4 (methane), N_2O, H_2O, $CFCl_3$, CF_2Cl_2, and O_3 (ozone) (Graedel and Crutzen 1990)
Ozone depletion	Losses in stratospheric ozone due to $CFCl_3$ and CF_2Cl_2 (Graedel and Crutzen 1990)
Photochemical smog	Reactions in the lower troposphere caused by emissions such as NO_x gases and hydrocarbons from automotive exhaust (Theodore and Theodore 1996)
Consumption of abiotic resources	Consumption of nonliving (nonrenewable) substances
Acid deposition	Acidic precipitation that deposits HNO_3 and H_2SO_4 into soil, water, and vegetation (Graedel and Crutzen 1990)
Eutrophication	Large deposits of phosphorous and nitrogen to a body of water that leads to excessive aquatic plant growth, which reduces the water's oxygen levels and capacity to support life (Theodore and Theodore 1996; Riviere 1990)
Ecotoxity	Substances that degrade the ecosystem either directly (acute) or over time (chronic) (Barnthouse et al. 1998; Graedel and Allenby 1995)
Habitat loss	Encroachment by humans into biologically diverse areas, resulting in the displacement and extinction of wildlife
Biodiversity	Living species that constitute the complex food web (Graedel and Allenby 1995)

papers on supply chain analysis and policy analysis with respect to environmental management is in [Bloemhof-Ruwaard et al. (1995)]'' (Stuart et al. 1999). Models for production planning with environmental considerations are summarized in the next section.

4.4. Production Planning with Environmental Considerations

''Introduction of product designs and process innovation requires a company to evaluate complex cost and environmental tradeoffs. In the past, these have not included environmental costs'' (Stuart et al. 1999). In this section, production planning models are described for the entire product life cycle as well as for different stages of the product life cycle.

4.4.1. Models for Production Planning over the Product Life Cycle

Stuart et al. (1999) developed the first mixed integer linear programming model ''to select product and process alternatives while considering tradeoffs of yield, reliability, and business-focused environmental impacts. Explicit constraints for environmental impacts such as material consumption, energy consumption, and process waste generation are modeled for specified assembly and disassembly periods. The constraint sets demonstrate a new way to define the relationship between assembly activities and disassembly configurations through take-back rates. Use of the model as an industry decision tool is demonstrated with an electronics assembly case study in Stuart et al. (1997). Manufacturers may run ''what if'' scenarios for proposed legislation to test the effects on design selection and the bottom line cost impacts.'' The effects over time of pollution prevention or product life extension are analyzed from a manufacturer's and potentially lessor's perspective. Several new models explore the relationship between product and component reuse and new procurement. These models include deterministic approaches using mixed integer linear programming (Eskigun and Uzsoy 1998) and stochastic approaches using queueing theory (Heyman 1977) and periodic review inventory models (Inderfurth 1997; van der Laan and Salomon 1997). Location of remanufacturing facilities are analyzed in Jayaraman (1996); Bloemhof-Ruwaard et al. (1994, 1996); Fleischmann et al. (1997). Scheduling policies for remanufacturing are presented in Guide et al. (1997).

4.4.2. Production Planning Models for the Manufacturing and Assembly Stage

Early models focused on reducing the environmental impacts concurrent with process planning for continuous processes in the petroleum and steel industries (Russell 1973; Russell and Vaughan 1974). Recently, models with environmental considerations focus on process planning for discrete product manufacturing (Bennett and Yano 1996, 1998; Sheng and Worhach 1998).

4.4.3. Disassembly Planning Models

Based on graph theory, Meacham et al. (1999) present a fast algorithm, MAXREV, to determine the degree of disassembly for a single product. They are the first to model selection of disassembly strategies for multiple products subject to shared resource constraints. They use their MAXREV algorithm to generate maximum revenue disassembly configurations for their column generation procedure for multiple products. Other disassembly models based on graph theory approaches focus on determining economic manual disassembly sequences for a single product (Ron and Penev 1995; Penev and Ron 1996; Zhang and Kuo 1996; Johnson and Wang 1995; Lambert 1997). A process planning approach to minimize worker exposure hazards during disassembly is given in Turnquist et al. (1996). Disassembly may be economically advantageous for module and component reuse. However, for material recovery, escalating labor costs favor bulk recycling.

4.4.4. Production Planning Models for Bulk Recycling

Production planning for bulk recycling is in the early stages of development. Models include a macro-level transportation model for paper recycling (Glassey and Gupta 1974; Chvatal 1980) and a goal-programming model for recycling a single product (Hoshino et al. 1995). Sodhi and Knight (1998) develop a dynamic programming model for float–sink operations to separate materials by density. Spengler et al. (1997) present a mixed integer linear programming model to determine the manual disassembly level and recycling quantity. Stuart and Lu (2000) develop a multicommodity flow model to select the output purity by evaluating various processing and reprocessing options for bulk recycling of end-of-life products. Isaacs and Gupta (1998) use goal programming to maximize disassembler and shredder profits subject to inventory balance constraints for the automobile recycling problem. Krikke et al. (1998) propose dynamic programming for disassembly planning and an algorithm to maximize revenue from material recycling. Realff et al. (1999) use mixed integer linear programming to select sites and determine the amount of postconsumer material collected, processed, stored, shipped, and sold at various sites.

4.5. Environmental Management Systems

An environmental management system (EMS) is a management structure that addresses the long-term environmental impact of a company's products, services, and processes. An EMS framework should include the following four characteristics:

1. Environmental information collection and storage system
2. Management and employee commitment to environmental performance
3. Accounting and decision processes that recognize environmental costs and impacts
4. Commitment to continuous improvement of environmental performance

Federal U.S. EMS guidelines and information are documented in (Department of Energy 1998). International standards for EMS will be discussed in Section 4.5.3. Environmental management systems (EMS) include environmental policies, goals, and standards, which are discussed in the next three subsections.

4.5.1. Corporate Environmental Policies

Corporate environmental policies require the commitment and resources of senior management. These policies often focus on actions that can prevent, eliminate, reduce, reuse, and recycle, respectively. These policies should be incorporated into all employees' practices and performance evaluations. Communication of environmental policies and information is integral to the success of the policies. Setting viable goals from corporate environmental policies is the subject of the next section.

4.5.2. Environmental Goals and Metrics

Traditional environmental metrics often focus on compliance with legislation. Goals may concentrate on state-dependent benchmark metrics such as reducing emissions, reducing the volume or mass of solid waste, or reducing gallons of waste water to a specified level. On the other hand, goals may focus on non-state-dependent improvement metrics such as reducing the percentage of environmental treatment and disposal costs. It is also important to distinguish between local and aggregate data when developing goals.

Metrics may focus on local product or process goals or system-wide facility or company goals. An example of a local goal might be to lengthen tool life and reduce cutting fluid waste disposal costs. Sometimes local goals may translate to system goals. One machinist's use of a new oil-free, protein-based cutting fluid that eliminates misting and dermatitis problems but provides the necessary lubricity and cooling may be a candidate for a system-wide process and procurement change (Koelsch 1997). With local goals, it is important to investigate their potential positive and negative impacts if implemented throughout the system. An example of a system-wide goal might be to reduce the percentage of polymer sprues and runners discarded at a particular facility by implementing regrinding and remolding or redesigning the mold. For system goals, it is important to identify the most significant contributors through Pareto analysis and target them for improvement.

4.5.3. ISO 14000 Series Standards

ISO 14001, ''an international standard describing the basic elements of an environmental management system, calls for identification of the environmental aspects and impacts of a company's products, processes, and services [Block 1997]. Industrial engineers may develop the information systems to quantify environmental aspects such as input materials, discharges, and energy consumption [Alexander 1996]'' (Stuart et al. 1998).

5. CONCLUDING REMARKS

Clean manufacturing is an important concept to integrate into industrial engineering methodologies. Traditional waste and energy audits help companies identify cost and environmental savings opportunities. New concepts such as life cycle design, product life cycle assessment, production planning with environmental considerations, and environmental management systems help companies to prevent costly negative environmental impacts. In summary, clean manufacturing provides opportunities for increased efficiencies and cost effectiveness as well as movement towards sustainability.

CHAPTER 17

Just-in-Time, Lean Production, and Complementary Paradigms

TAKAO ENKAWA
Tokyo Institute of Technology

SHANE J. SCHVANEVELDT
Tokyo Institute of Technology/Weber State University

1. INTRODUCTION AND OVERVIEW

The just-in-time (JIT) concept was first developed and implemented over a span of many years by Toyota Motor Corporation under the appellation of the Toyota Production System (TPS). Its overarching goal is to enable production of a variety of end items in a timely and efficient manner, smoothly synchronized with the production and delivery of component materials and without reliance on the conventional stratagem of keeping extra work-in-process and finished goods inventory. By the 1970s, Toyota's just-in-time system had evolved into a remarkable source of competitive advantage, achieving higher quality and productivity and lower cost than traditional mass production systems. Indeed, the Toyota Production System was widely credited with buoying Toyota through the economic turmoil following the 1973 oil crisis. Though originally limited mostly to Toyota and its supplier network, the TPS concept spread to other Japanese manufacturers and by the early 1980s was re-

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

ceiving tremendous attention from manufacturers worldwide. Over the years, a number of labels, such as stockless production and zero inventory, have been applied to TPS-like approaches for managing production and inventory. JIT, however, has become the accepted, albeit imprecise, term.

A broader conceptualization of world-class manufacturing called ''lean production'' was realized through the landmark studies conducted by MIT's International Motor Vehicle Program. This lean production concept was created based on extensive benchmarking of automobile manufacturers' best practices worldwide—arguably, principally those of Japanese manufacturers and the Toyota Production System. From a practical standpoint, lean production may be considered as an expanded view of JIT/TPS that includes additional intraorganizational and interorganizational aspects such as the role of suppliers and information sharing in not only the manufacturing stage but also in product development and distribution.

In the remainder of this chapter, we first provide a more detailed discussion of JIT/TPS in Section 2, including its philosophy and implementation issues. In Section 3, we examine the kanban system, widely used in JIT for control of production and inventory, and present a case study of JIT/kanban implementation. Section 4 follows with an examination of JIT's relation to complementary approaches such as total quality management (TQM) and total productive maintenance (TPM), together with a case study of their joint implementation. In Section 5, we examine lean production as an extension of JIT, explore the relationship of JIT to theory of constraints (TOC), and conclude with a brief consideration of applications to service industries of JIT, TOC, and other manufacturing-based approaches.

2. THREE PILLARS OF JUST-IN-TIME AND THE TOYOTA PRODUCTION SYSTEM

In broad terms, JIT is a management philosophy that seeks manufacturing excellence with an emphasis on eliminating waste from all aspects of the production system. At its most basic level, a JIT system produces only what is used or sold, in the needed quantity and at the needed time. Accordingly, low levels of work-in-process and finished goods inventory are a prominent feature of JIT. Though it can be said that other production management approaches, such as material requirements planning (MRP), share this same overall goal, JIT differs in that it focuses on inventory reduction not only as an *end* but as a purposeful *means* to foster broader improvements in performance. Thus, JIT may be considered a dynamic system, always seeking to achieve still higher levels of performance. In contrast, conventional systems such as MRP or models such as economic order quantity (EOQ) are typically static in that they derive a solution for a given set of conditions (such as lead times or setup costs) and make no consideration for improvement of those conditions.

Another typical element of JIT is the use of a pull method of production coordination, such as the well-known kanban system. In a pull system, production is initiated only to replenish what has been actually used at the next stage of the production system (or sold to the customer). This is a reversal of the push concept, in which production is initiated in anticipation of future demand. Kanban functions as a pull system in that, as materials are used in a downstream stage of the production system, replenishment orders for component materials are relayed to the upstream stages in a progressive cascade upwards. Because actual usage of materials downstream is the only trigger for making more of something upstream, production is initiated only when needed and automatically stopped when the demand ceases. Thus, kanban may be viewed as a decentralized, self-regulating system for controlling production and material flows, even in a complex manufacturing environment with thousands of discrete parts, such as an auto assembly plant. It should be noted, however, that kanban is most appropriate for high-volume, repetitive manufacturing environments and that it is only one means for implementing JIT.

The success of JIT, as well as kanban, is contingent on meeting several prerequisites: (1) smoothing of volume and variety; (2) development of a flexible, multiskilled workforce; and (3) implementation of continuous improvement and *autonomation*. These prerequisites are discussed in the sections below. In addition, achievement of high quality levels is also essential to implement JIT. For this purpose, JIT and TQM efforts should be closely linked with each other, as will be discussed later.

Though some references for further information on JIT are provided in this chapter, no attempt is made to review the thousands of articles and books now available. For more exhaustive reviews of the early JIT literature, the reader is referred to Keller and Kazazi (1993), Golhar and Stamm (1991), and Sohal et al. (1989). Reviews of research focusing on the modeling/design of JIT and kanban systems are provided by Akturk and Erhun (1999) and Groenevelt (1993). General references on Toyota's JIT system include the first publication in 1977 by Sugimori et al., as well as Ohno (1988), Shingo (1989), Monden (1998), and Fujimoto (1999).

2.1. Smoothing of Volume and Variety

Production leveling—in other words, smoothing of volume as well as variety to achieve uniform plant loading—is imperative for JIT implementation. What would happen if the production volume

of an item were to fluctuate every day and we blindly pursued a pull policy of withdrawing the needed quantity of parts at the needed time from the preceding process? In that situation, the preceding process must always maintain an inventory and workforce sufficient to meet the highest possible quantity demanded. Consequently, its production volume will exhibit fluctuations larger than those of the downstream process. Since a typical production system involves many sequential processes, there are many stages for these fluctuations to be transmitted from final assembly backward through to the suppliers. At each stage, the fluctuation is transmitted in amplified form to the previous stage, with the result that upstream processes and suppliers may incur vast inventory and waste. This is the so-called bullwhip effect known in the field of supply chain management.

In order to prevent these undesirable effects, an effort must be made to smooth out the production quantities of each item in the final assembly schedule and then keep that schedule fixed for at least some period of time. Smoothing the production schedule minimizes variation in the quantities of parts needed and enables the preceding processes to produce each part efficiently at a constant speed per hour or per day.

Figure 1 shows a simple illustration of production leveling on a daily basis. Based on demand forecasts and firm customer orders, a three-month production schedule is created and shared with relevant suppliers. Each month the production schedule is revised on a rolling basis to reflect the latest information. The first month of the schedule is then frozen and broken down into a daily production schedule as follows.

Suppose that the monthly production schedule for final assembly indicates demand for 2400 units of product A, 1200 units of product B, and 1200 units of product C. The level daily production schedule is determined by dividing these monthly demand quantities by 20 working days per month, that is, 120 A's, 60 B's, and 60 C's per day, along with the corresponding numbers of parts. Minor adjustment of these quantities may occur on, say, a weekly basis, but alterations must be small (within $\pm 10\%$ empirically) so as to avoid introducing excess fluctuations into the system. Though suppliers use this leveled daily production schedule as a guideline for planning, the actual day-to-day production quantities are determined by actual demand from downstream stages and coordinated through the kanban system or similar approach. By initiating production only as demand occurs, kanban eliminates the possibility of waste due to excess production while absorbing minor, unavoidable fluctuations on the factory floor.

Next, the daily production schedule is smoothed for product variety through the generation of a production sequence. Rather than all A's being made in one batch, then all B's in a following batch, and so on, a mix of items should flow through the system. Because the demand for A's, B's, and C's has a ratio of 2:1:1 in this case, an appropriate mix or sequence for their production would be a cycle of A B A C repeated through the day. For determining sequences in more complex situations, refer to algorithms in Monden (1998) and Vollmann et al. (1997).

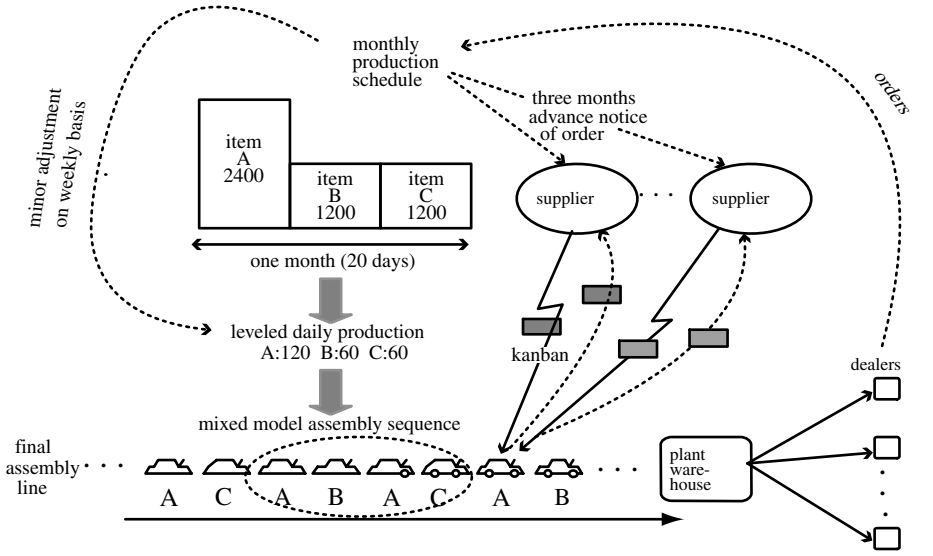

Figure 1 Smoothing Volume and Variety to Achieve One-Piece Flow Production.

Using this kind of mixed model sequencing, the line balance can be kept close to 100 percent even though the standard time or cycle time varies for each product. For example, suppose that the line's *takt* time (cycle time to meet demand) is two minutes and the respective standard times of products A, B, and C are two minutes, three minutes, and one minute for a certain process. Then the cycle time for the A B A C sequence is balanced and equal to eight minutes. The individual time differences between products in the sequence can be accommodated by utilizing a space buffer between adjacent processes.

The ultimate goal is to have a production system so responsive that products can be made in a batch size of one and scheduled according to the market's demand rate. This is also called one-piece flow production. However, to achieve one-piece flow, it is obvious that setup or changeover times must be short for all processes involved. The benchmark of reducing setup times to less than 10 minutes is well known. This is also known as single-minute exchange of dies (SMED) or rapid setup and has a number of associated techniques (e.g., Shingo 1985, 1989). Of these, the most important is to distinguish between internal setup tasks that must be performed while the machine is stopped and external setup tasks that can be done in parallel with continued operation. Once short setup times are realized, production lot size and lead time can be reduced, enabling upstream stages to work in response to the needs of the leveled final assembly schedule.

2.2. Development of Flexible, Multiskilled Workforce

Under one-piece flow production, different operations are potentially required for each succeeding item being produced. For it to be effective, workers must have the skills necessary for handling multiple operations properly. Consequently, a prerequisite for JIT is the development of multiskilled workers who can cope with the frequent changes in products and operations seen in a one-piece flow production environment.

In an automobile engine plant, for example, a multiskilled operator is typically responsible for several semiautomatic machine tools. This system is called multiprocess holding. Combining multiprocess holding together with layout approaches such as U-shaped lines enables production efficiency to be maintained even when production volume varies. To illustrate, consider a fabrication line consisting of 12 machines and 6 operators and suppose that the production quantity is decreased from 100 to 80 per day due to reduced demand. Labor productivity still can be maintained if the operations can be rearranged to be shared by 4 multiskilled operators. This makes sense only with the existence of multiskilled operators capable of handling any of the 12 machines' operations. U-shaped line layouts can facilitate flexible sharing of the operations by minimizing operator movement between the machines.

Figure 2(*a*) illustrates the type of changes seen in automobile final assembly lines. They have evolved from long straight lines into U-shaped lines and more recently have been rearranged into many short lines contrived so that each line consists of similar operations. The major purpose of this arrangement is to enable workers to learn multiple skills quickly and efficiently because they can easily learn the other operations within a line once they master one of its operations. After becoming a multioperation worker, he or she can move to another line to become a multifunction worker.

An extreme case of multiskilled workers is found in self-contained cell lines. Figure 2(*b*) illustrates a self-contained cell line at a Japanese microscope plant, where a single worker moves with his or her workstation from operation to operation. The experienced worker not only assembles and adjusts the entire product him- or herself but also takes responsibility for quality assurance and for production management issues such as scheduling. This facilitates production efficiency for high value-added, low-volume products and also provides workers with intrinsic motivation and satisfaction. At the same time, it is considered an effective means to maintain skills and technologies for a new generation of workers. The concern for preserving worker skills is also illustrated by a common industry practice regarding welding operations: by policy, many companies will automate up to 95% of weld points and reserve the remaining 5% for manual operation. Through the manual welding, skill and knowledge are preserved in the organization and can be applied, for example, to programming the robotic welders.

In today's competitive environment, development of multiskilled operators is universally viewed as a critical issue. Well-organized training programs are seen at virtually every plant in Japan, irrespective of industry. As one means for motivating workers to develop further skills, many plants list workers' names along with their acquired skills on a prominently placed bulletin board. Another important issue is for workers to acquire creative thinking and problem-solving skills and to feel themselves responsible for quality and productivity improvement. For this purpose, small group improvement activities such as QC circles and PM circles are organized. Workers receive training and develop *kaizen* capabilities through these activities. Another effective approach is the implementation of worker suggestion systems, wherein financial rewards are paid based on the value of the suggestion. Not only do these various activities and systems contribute directly to improved performance, they help indirectly to maintain quality and productivity by increasing workforce morale.

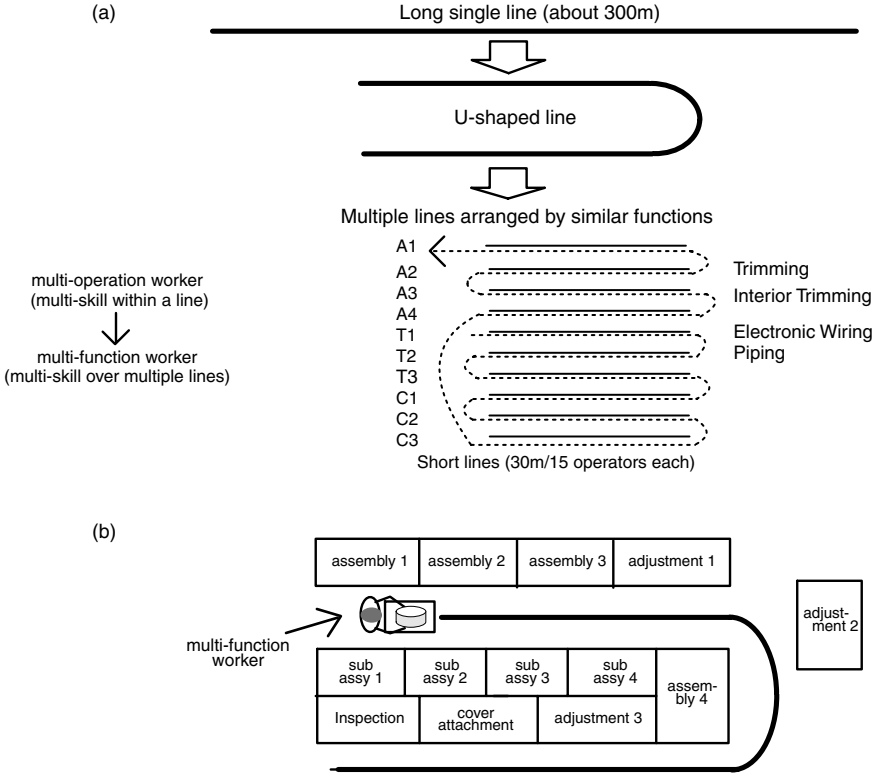

Figure 2 (*a*) Layout Types and Their Evolution in Automobile Final Assembly Lines. (*b*) Layout of Self-Contained Cell Line.

2.3. Continuous Improvement and *Autonomation*

As previously mentioned, JIT is a production system that dynamically seeks ever-higher performance levels. Elimination of waste and defects is an important goal in this regard. Indeed, to achieve true just-in-time, all parts must be defect-free, as there is no excess inventory to draw upon for replacement. To achieve defect-free production, JIT production systems emphasize continuous improvement and utilize autonomation and other related techniques for assuring quality at the source.

The original meaning of autonomation in JIT/TPS is to stop a machine automatically when abnormal conditions are detected so as not to produce defective products. This is made possible by installing automatic detection and stopping devices in machines or equipment, thus making them capable of operating autonomously. The purpose of autonomation is to keep the machine working always for added value only and to prevent it from producing defects or waste. As discussed below, the idea of autonomation is extended in two ways: *poka-yoke* (mistake-proofing) and visual control.

Whereas autonomation is the application of detection and stopping devices to the operation of equipment, poka-yoke can be considered as the application of error detection and stopping devices to the activities of workers and the worker–machine interface. It is assumed that human errors are inevitable, so rather than rely on the vigilance of workers, various poka-yoke devices, such as jigs, sensors, and cognitive aids, are built into the work process (cf. Shingo 1986; Nikkan 1989). A simple example of poka-yoke is the use of color coding. Certain colors can be designated for the position and setting of a machine, so that the presence of any other color alerts the worker to an error and the need to take action. By reducing errors and the resulting defects, poka-yoke assumes an important role in assuring quality. In terms of job safety as well, poka-yoke is an indispensable means for protecting workers and preventing accidents in work operations.

Similarly, visual control systems (cf. Nikkan 1995) may also be viewed as an extension of the autonomation concept because they utilize various devices to share information and make abnor-

malities evident at a glance. A simple example is the designation of storage positions for tools, with an outline figure drawn for each tool. Any empty spot indicates the absence of a tool as well as its type. Perhaps the best-known example of visual control systems is the *andon*, a light board or stand consisting of red, yellow, and green lamps positioned so as to be visible from anywhere in the plant. A flashing red lamp indicates that a machine or workstation is experiencing some abnormal condition such as a breakdown. A green lamp stands for normal operation, and a flashing yellow lamp may indicate a setup operation or an upcoming tool exchange. The important role of the andon board is that it communicates the working status of the plant to everyone. In conjunction with andon, a common practice at many plants is to stop a production line when the red lamp flashes at any of the workstations so that the cause may be investigated and countermeasures taken.

Inventory level itself may also be considered as an important indicator for visual control. Not only is the inventory considered to be a non-value-adding expense, but high levels of inventory provide visible indication that waste and inefficiency may be hidden within the production system. To reveal the cause of the inefficiency, the inventory level is first decreased by removing some of the kanban containers from the system. The weakest part or bottleneck of the production system is then exposed because it will be the first affected by the removal of the inventory buffer. After reinforcing the weakest point, the inventory level is reduced further to expose the next weak point in an ongoing cycle. In this approach, the number of circulating kanbans is a visible measure of inventory level, and adjusting their number is a means of inventory reduction. More generally, this idea is employed as a continuous improvement cycle for improving production and material flows.

3. KANBAN AS A DECENTRALIZED CONTROL SYSTEM FOR JUST-IN-TIME

3.1. Prerequisites and Role of Kanban System

As discussed above, continuous improvement, reduced lead times, and a multiskilled workforce are crucial in enabling a production system to respond flexibly to the environmental changes confronting manufacturers. Given these prerequisites and a production schedule that has been leveled, a kanban system can function as a self-regulating, decentralized system for controlling the flow of materials from upstream stages through final assembly.

The Japanese term *kanban* simply means card or ticket. They are typically enclosed in a protective vinyl cover and contain the following information: part number and name, process name where the kanban is to be used, number of units in the standard container and type of packing, number of kanban cards issued, preceding process outbound stockpoint number, and subsequent process inbound stockpoint number. There is a one-to-one correspondence between the cards themselves and the standard parts containers that they represent. Furthermore, the cards always circulate together with the actual material flow. Through the kanban system, workers understand their operations' procedures and standards and learn and share the information required for process control. In this way, kanban functions as an information system as well as a means of visual control.

Two kinds of kanbans are used in controlling production and material flows: withdrawal-authorizing kanbans (also called movement kanbans) and production-ordering kanbans. When taken to the preceding process, a withdrawal kanban authorizes the transfer of one standard container of a specific part from the preceding process where it was produced to the subsequent process where it is to be used. A production kanban orders the production of one standard container of a specific part from the preceding process.

Figure 3 illustrates the circulation of kanban cards and containers. Every parts container at an inbound stock point must have a withdrawal kanban attached. When even one of a container's parts is to be used at the subsequent process, the withdrawal kanban is detached from the container and taken to the outbound stock point of the preceding process together with an available empty container. At the outbound stock point of the preceding process, an already full container of the desired parts is located and its production kanban is removed, with the withdrawal kanban now attached in its place. The full container with withdrawal kanban attached is now ready to be transferred to the inbound stockpoint of the subsequent process, while the empty container is left at the preceding process for later use. In addition, the production kanban that was just removed is now placed in a collection box at the preceding process. These production kanbans are frequently collected and become work orders authorizing the production of one more full container of parts. When a new, full container is produced, the production kanban is attached to it and the container is placed in the outbound stockpoint to complete the cycle.

It can be seen that circulation of the kanbans is triggered only by actual usage of parts at the subsequent process. Only what is needed is withdrawn from the preceding process, and then only what is needed for replacement is produced. This chain of usage and production ripples back through upstream stages to the suppliers, with the kanbans functioning as a sort of decentralized, manual

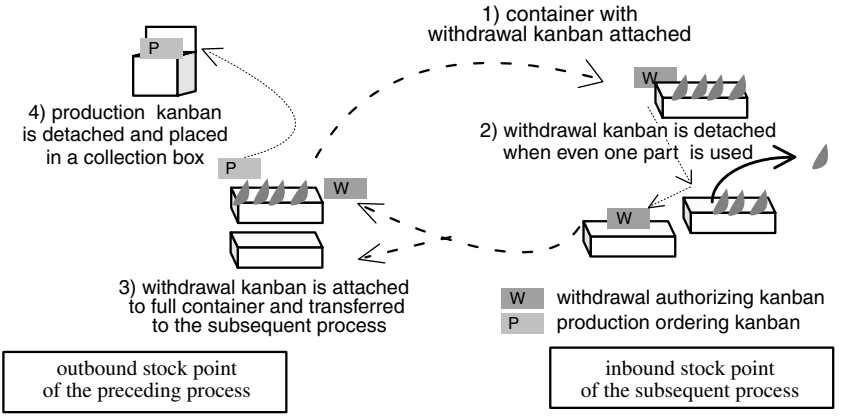

Figure 3 Flow of Kanban Cards and Containers between two Processing Areas.

coordination mechanism. Given that major fluctuations in demand have been smoothed and frozen by the leveled production schedule, the kanbans can self-regulate to maintain the needed production quantities while absorbing the inevitable minor variations in everyday operations.

3.2. Control Parameters of Kanban System

In considering kanban as a decentralized control system, the following control parameters are necessary: number of kanbans in circulation; number of units in the kanban standard container; and kanban delivery cycle *a-b-c* (where *b* is number of deliveries per *a* days and *c* indicates the delivery delay factor as an indication of replenishment lead time). For example, 1-4-2 means that every 1 day the containers are delivered 4 times and that a new production order would be delivered by the 2nd subsequent delivery (in this case, about a half-day later, given four deliveries per day).

Minimizing work-in-process inventory is a goal of JIT. In keeping with this, the number of units per standard container should be kept as small as possible, with one being the ideal. Furthermore, the number of deliveries per day (b/a) should be set as frequently as possible so as to synchronize with the *takt* time of the subsequent process, and the delivery delay factor c should be kept as short as possible. Ideally, the number of kanbans in circulation between two adjacent workstations also should be minimized. However, in consideration of practical constraints, a tentative number of kanbans may be calculated as follows:

$$\text{Number of kanbans} = \frac{\text{number of units required per day}}{\text{number of units in standard container}} \times \frac{a}{b} \times (1 + c + \text{safety stock factor})$$

This tentative number of kanbans is reconsidered monthly because the daily leveled production requirement may differ under the new monthly production schedule. In addition, the number of kanbans is sometimes further reduced by systematically removing them from circulation in the system. The resultant reduction of work-in-process inventory will stress the production system and reveal the weakest point for further improvement. Thus, the kanban system is part of the approach used in JIT to move toward the goal of stockless production and achieve continuous improvement of the production system.

3.3. Kanban's Limitations and Alternatives

As previously noted, the kanban system is particularly appropriate for high-volume, repetitive manufacturing environments. However, in comparison to the situation when the kanban system was originally created, many industries now face tremendous increases in the variety of products and parts coupled with lower volumes for each individual item. This is seen also in the automobile industry, where more than 50% of parts now have their respective kanbans circulate less than once per day (Kuroiwa 1999). Such a low frequency of circulation leads to undesirably high levels of work-in-process inventory, and the kanban system ends up functioning the same way as the classic double-bin inventory system.

Several alternatives are available when production is not repetitive and/or high volume in nature. For example, when demand is lumpy and cannot be smoothed into a level production schedule, a

push method of production coordination may be more appropriate. Karmarkar (1989), for example, discusses this situation and suggests how a hybrid production system utilizing both MRP and kanban may be used. Toyota itself has alternatives to the kanban system (Kuroiwa 1999). For low consumption parts, Toyota uses a push method called *chakko-hiki* (schedule-initiated production). In this approach, production and delivery of the necessary parts is determined in advance, based upon the vehicle final assembly schedule and an explosion of the bills-of-material, rather than through the kanban system. For large components and parts such as engines or seats, yet another system, called *junjo-hiki* (sequence-synchronized production), is used. Here the sequence of the part's production and delivery is synchronized item-by-item with the corresponding vehicle sequence of the final assembly schedule. For example, the engines are produced and delivered from the engine plant to the final assembly line in the exact order and timing needed for final assembly. In determining which of the various production coordination methods is appropriate, the most important factors for consideration are demand volume and delivery lead time. From this standpoint, it should be obvious that kanban is most suitable for parts with relatively high volume and short lead time.

Another important issue in kanban systems is the role of information technology. Kanban is a decentralized, manual system that developed without reliance on computers or other technologies. Given the powerful information technologies presently available, there is some debate over whether to implement electronic kanban systems with the use of bar codes and electronic data interchange (EDI). On the surface, these technologies provide a smart tool in terms of information handling, but it should be noted that the traditional, paper-based kanban has another important role in that workers learn process control and standards through reading the written information on the cards and physically manipulating the system. For this reason, Toyota has limited its use of electronic kanban systems to deliveries involving unavoidably long lead times, such as from distant plants. For example, when a part is consumed at the Kyushu plant, which is located more than 500 kilometers from Toyota's main plants in the Nagoya region, a withdrawal kanban in bar code form is scanned and its information is transferred through EDI to the preceding supplier or distribution center in the Nagoya region. Then a new withdrawal kanban in bar code form is issued in Nagoya for later attachment and delivery with the new parts, while the old card is disposed of in Kyushu. This is physically analogous to a one-way kanban system, though the electronic information is also utilized for many other purposes, such as physical distribution management, financial clearing systems, and so on.

3.4. Case Study of JIT/Kanban Implementation

Aisin Seiki is a Toyota group company that, in addition to manufacturing complex parts for the auto industry, also produces such items as mattresses for sale to retail and institutional customers. As noted in Imai (1997) and Spear and Bowen (1999), Aisin Seiki's Anjo plant achieved remarkable improvements through the introduction of JIT and kanban production systems. In 1986, prior to beginning JIT, the plant produced 200 styles and variations of mattresses with a daily production volume of 160 units and 30 days worth of finished-goods inventory. Production was based on monthly sales projections and scheduled on a weekly cycle. Due to unreliable forecasts and long lead times, the plant maintained high amounts of inventory yet often experienced material shortages, and suppliers had difficulty keeping up with changing orders.

Over the course of several years, the plant introduced various changes to achieve a JIT system with reduced inventories and one-piece production flow. A major change was to produce mattresses only in response to customer demand and based on the sequence in which orders were received. The production schedule cycle was reduced from one week to one day and then eventually to two hours, thereby necessitating many more setups and a reduction in setup times. The quilting machines, for example, now have 60 times as many setup changes. Kanban was introduced for the more popular models so as to produce and hold only the average number of units ordered per day. When a popular model is shipped from the plant to fill an order, its kanban card is returned to the production line as a signal to make a replacement. Lower-volume models are produced only after an order is received. When a large order is received from a hotel, its production is spread out among other orders in order to maintain a level production schedule. As a result of such changes and improvements, the plant is now able to produce a wider variety of end items in higher volumes and with shorter lead times and higher productivity. By 1997, for example, it produced 850 styles of mattresses with a daily production volume of 550 units and only 1.5 days of finished-goods inventory. At the same time, units produced per person had increased from 8 to 26, and overall productivity had increased by a factor of 2.08.

4. COMPLEMENTARY PARADIGMS OF JUST-IN-TIME

4.1. 3T's as Mutually Reinforcing Activities for Quality, Cost, Delivery Performance

Like JIT, total quality management (TQM) and total productive maintenance (TPM) are managerial models that were formulated and systematized in Japan. Each of these managerial paradigms is made

up of concepts and tools of great significance for operations management. With TPS used as the name for just-in-time, together with TQM and TPM, a new acronym ''3T's'' can be created to denote these three paradigms and their vital contribution to a firm's competitiveness in terms of quality, cost, and delivery performance (QCD) (Enkawa 1998).

From a historical perspective, it is somewhat difficult to determine when a framework of their joint implementation began to emerge. This certainly took place after the individual advents of JIT/TPS in the 1950s, TQC/TQM in the 1960s, and TPM in the 1970s. If we view these paradigms as a historical sequence, it can be asserted that pressing needs to meet new competitive requirements were the driving impetus behind each of their creations. Being the later-emerging paradigms, TQM and TPM can be considered as systematized activities to support JIT with areas of overlap as well as unique emphasis. This interrelationship is depicted in Figure 4, wherein it may be seen that the three paradigms have roles of mutual complementarity in terms of Q, C, and D.

4.2. Total Quality Management (TQM)

The primary focus of TQM is on achieving customer satisfaction through the design, manufacture, and delivery of high-quality products. This addresses JIT's requirement for strict quality assurance and elimination of defects. Though having roots in American approaches, TQM broadened and matured as a management paradigm in Japanese industry. By the 1980s, industries worldwide began emulating the Japanese model of quality management (e.g., Ishikawa 1985; Akiba et al. 1992) and have subsequently adapted and reshaped it in new directions.

With the concept of continuous improvement at its core, Japanese-style TQM seeks to boost performance throughout the organization through participation of all employees in all departments and levels. In addition to the tenet of total employee involvement, TQM incorporates the following beliefs and practices: management based on facts and data, policy deployment, use of cross-functional improvement teams, systematic application of the Plan, Do, Check, Act (PDCA) cycle, and the ability of all employees to use fundamental statistical techniques such as the seven basic quality improvement tools. One mainstay of TQM is its involvement of front-line employees in organized QC circle activities wherein the workers themselves identify and correct problems. These small-group activities are instrumental in diffusing continuous improvement capability throughout the company. Besides supporting successful JIT implementation, these activities also improve employee morale and enhance skills.

The essence of TQM can also be understood from the many maxims that have appeared to express new approaches and ways of thinking necessitated by competitive change:

- Quality is built in at the process (instead of by inspection).
- Focus on and correct the process rather than the result (emphasizing prevention).
- Emphasize system design and upstream activities.
- The next process is your customer (to emphasize customer orientation).
- Quality first—the more quality is improved, the lower cost becomes.
- Three-*gen* principle: observe the actual object (*genbutsu*) and actual situation (*genjitsu*) at the actual location (*genba*).

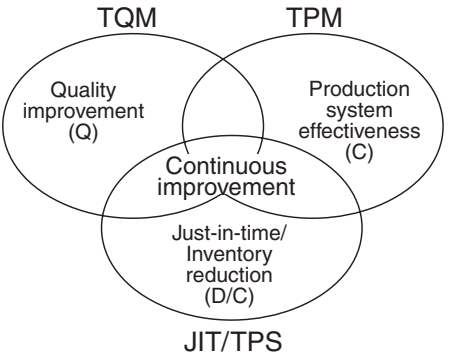

Figure 4 Mutual Overlap and Complementarity of the 3T's (JIT/TPS, TQM, TPM) with respect to quality, cost, and delivery performance (QCD).

4.3. Total Productive Maintenance (TPM)

TPM is a systematic and inclusive approach for achieving maximum utilization of a plant's capability. In particular, TPM focuses on maximization of overall equipment effectiveness, which is defined as the ratio of net value-added time to total available time (where net value-added time is total available time adjusted for time lost due to failures, setup/adjustment, cutting blade changes, start-up, minor stoppage and idling, reduced speed, and defect/rework-related losses). Many companies identify 16 or more major losses, involving not only the equipment-related losses above but also worker and production system factors. These are measured quantitatively as the discrepancy between their current state and ideal state and are often converted into monetary terms as the target of cost reduction goals. To reach these goals, TPM advocates a clearly defined, stepwise approach for eliminating the losses through systematic, plant-wide efforts.

The principal activities of TPM fall into eight areas:

1. Autonomous maintenance
2. Improvement by project team
3. Planned maintenance
4. Quality maintenance
5. Initial-phase management for development and installation of equipment/products
6. Administrative and indirect operations management
7. Education and training
8. Safety, health, and environmental management

Of these, autonomous maintenance (*jishu hozen*) is the original core of TPM and involves the transfer of diverse maintenance-related duties to the machine operators themselves. In fostering operator responsibility for maintenance, autonomous maintenance follows seven formal steps starting from initial cleaning. In addition, small-group activities called PM circles are organized by the company to carry out improvement activities and further develop operators' capabilities. Further discussion of TPM and its implementation is provided by Shirose (1996), Suzuki (1992), and Nakajima et al. (1992).

In instituting the good industrial housekeeping practices required in TPM, many companies use an approach called 5S. This term comes from five Japanese words: *seiri* (sort and clear out), *seiton* (straighten and configure), *seiso* (scrub and cleanup), *seiketsu* (maintain sanitation and cleanliness of self and workplace on an ongoing basis) and *shitsuke* (self-discipline and standardization of these practices) (cf. Imai 1997; Osada 1991). These activities roughly correspond to the initial cleaning step of TPM and involve all employees in an organization.

Like TQM, TPM has an important role in implementing JIT. Specifically, failure-free equipment is a principal factor behind the high quality and short setup times necessary in JIT. At the same time, TPM has benefited from many of JIT's approaches, including its emphasis on visual control and the promotion of education and training for multiskilled operators. As for differences between TPM and the other paradigms, it should be noted that TQM and TPM diverge in their approaches undertaken for problem solving. Whereas TQM stresses the use of empirical, data-oriented methods such as statistical quality control, TPM emphasizes the application of technological theory and principle (*genri-gensoku*). In other words, TQM relies on inductive reasoning while TPM relies on deductive reasoning. These approaches work in complementary fashion with each other because both types of reasoning are indispensable for effective problem solving.

To summarize this discussion of the three paradigms, Table 1 outlines and compares TQM, TPM, and JIT/TPS along the dimensions of focus of attention, methods, and organizational issues.

4.4. Joint Implementation of the 3T's and Case Study

Since the 1980s, the diffusion of the three paradigms from Japanese manufacturers to overseas manufacturers has progressed at an accelerated rate. As evidenced by the coinage of terms such as *3T*'s and *TPQM* (= TPM + TQM), many cases now exist of the simultaneous implementation of part or all of the three paradigms, both inside and outside of Japan. This is underscored by the results of a mail survey of members of American Manufacturing Excellence, an organization whose members are known as leaders in manufacturing practice (White et al. 1999). On average, manufacturers included in the sample had implemented 7 out of 10 listed practices relating to JIT. As a whole, these 10 practices encompass a breadth of activity virtually equivalent to the 3T's. The percentages of manufacturers implementing each practice is as follows, broken down by size of company (small firms sample size $n = 174$; large firms sample size $n = 280$): quality circles (56.3%; 70.4%); total quality control (82.2%; 91.4%); focused factory or reduction of complexities (63.2%; 76.8%); TPM

TABLE 1 A Comparison of the JIT/TPS, TQM, and TPM Paradigms

	Criteria	JIT/TPS	TQM	TPM
Focus	Scope	Materials flow	Product life cycle	Equipment life cycle
	Origin	"Supermarket-style" inventory control	Statistical quality control (SQC)	Preventive maintenance
	Direction of expanded focus	Supply chain management (from source through user)	Upstream activities (towards new product development)	Preventive approach (towards maintenance prevention/ design issues)
	Control attribute	Inventory (*muri, muda, mura*)	Quality of product and process	Losses related to equipment, workers, materials
Means	Fundamental attitude	Kaizen	Kaizen	Kaizen
	Concept/premise	Load smoothing	Market-in orientation	Utmost equipment effectiveness/zero loss
	Approach to problem solving	Deductive/"simple is best"	Inductive	Deductive
	Means for problem solving	Exposing system weaknesses through inventory reduction	Application of PDCA cycle/data emphasis	Pursuit of ideal/technological theory and principles
	Key methods	Mechanisms that activate improvement (*autonomation*, *andon*, *kanban*, etc.)	Managerial methods with emphasis on statistical thinking	PM analysis, 5S activities, basic technologies, etc.
Organizational Issues	Human resources development	Multifunctional workers	QC education appropriate to level	Basic technologies-related skills
	Vertical integration	Reliance on formal organization/staff	Policy deployment/quality audits by top management	Overlapping small-group activities
	Horizontal integration	–	Cross-functional management	Special committees/project teams
	Bottom-up involvement	–	QC circles	Autonomous maintenance
	Implementation approach	Company-specific	Company-specific	12-step implement-ation program

(51.7%; 65.7%); reduced setup time (82.8%; 90.7%); group technology (66.7%; 69.6%); uniform workload (52.3%; 59.3%); multifunction employees (86.8%; 79.3%); kanban (53.4%; 68.9%); and JIT purchasing (66.1%; 81.8%).

Some caution may be warranted, however, on the question of simultaneously implementing TQM and TPM. One reason is the financial burden arising from their simultaneous introduction. Empirically, there is said to be a delay of up to a few years for TPM, or longer for TQM, before a company can enjoy their financial effects. Another reason relates to organizational issues. Although both TQM and TPM share the same broad objectives of strengthening corporate competitiveness and developing human resources, there are significant differences in their implementation and focus, as shown in Table 1. Thus, the simultaneous introduction of both into a formal organization may be a source of confusion and hamper their success. For this reason, the overwhelming majority of companies in Japan have avoided concurrent implementation. Instead, they have adopted a phased approach wherein one of the paradigms is mastered first before undertaking the second (Miyake and Enkawa 1999; Mathis 1998). As to which of TQM and TPM should be undertaken first, there is no clear consensus in terms of conceptual grounds or actual industry trends, though TPM is seen as having quicker financial benefits.

As the originator of JIT and TPM as well as a leader in TQM, the Toyota group continues to be known for best practice of the 3T's. In Toyota's case, JIT was implemented first, followed by TQM and finally TPM, though this merely reflects the historical order of each paradigm's emergence and the evolving competitive demands that they address. In most Toyota group companies, the management planning department organizes the implementation and education of the 3T's. An exception is Toyota itself, where TQM is administered by the TQM promotion department and JIT and TPM-like activities are coordinated by the operations management consulting department.

Outside of the Toyota group, Sanden Corporation is regarded to be one of the best companies for 3T practices in Japan. As one of the world's three largest manufacturers of car air conditioners and compressors, Sanden is a supplier to most leading auto producers in the world. Beginning in 1993, Sanden introduced TPM to one of its major plants, Sanden Yattajima Manufacturing Site, in response to fierce global competition and pressures to reduce cost. Within three years, it completed the conventional 12-step TPM implementation regimen, enabling Sanden Yattajima to apply successfully in 1996 for the TPM Excellence Award, a prize recognizing outstanding achievements that is granted by the Japan Institute of Plant Maintenance (JIPM). During this same period, Sanden bolstered its quality assurance front through ISO 9001 implementation and certification. Shortly afterwards, JIT was formally introduced in 1997 under the name SPS (Sanden Production System) with the aim of reorganizing process flows and further reducing lead times and inventory. After firmly establishing TPM and JIT, Sanden was poised to complete the triad of the three paradigms through a regeneration of its TQM practices. Its primary motivation was to reinforce the quality of its management systems, as it had already achieved a level of competitiveness in product quality. Sanden's TQM success was evidenced by its receiving of the Deming Prize in 1998 from the Japanese Union of Scientists and Engineers (JUSE) in recognition of outstanding results in the practice of TQM.

5. LEAN PRODUCTION AND EXTENSIONS OF JIT

5.1. Lean Production

The term *lean production* was introduced by Krafcik (1988) and the famous book, *The Machine That Changed the World* (Womack et al. 1990). These publications present the results of a major MIT study to identify systematically best practices of Japanese and other automobile manufacturers worldwide. Lean production is "lean" in that it uses half of the various production resources (labor, manufacturing space, tool investment, engineering hours, inventory, etc.) used in the Ford-style mass production that was prevalent into the 1980s.

The essence of lean production may be summarized into four aspects: (1) lean plant; (2) lean supplier network; (3) lean product development; and (4) relationship with distributors and customers. Of these, the lean plant forms the original core and may be considered as equivalent to the JIT/TPS concept presented earlier. The remaining three aspects delineate how the lean plant interacts with and mutually influences other entities. Thus, lean production may also be considered as an extended paradigm of JIT that includes new intraorganizational and interorganizational aspects. It is interesting to note that Toyota itself was influenced by the systematic, encompassing framework of lean production as presented by the MIT study. Though Toyota's practices indeed formed the basis for the lean production model, many of those practices had evolved gradually in response to local organizational needs or involved historically separate organizational units. The lean production model consequently provided a conceptual thread for understanding its many aspects as a synergistic, integrated whole.

Lean supplier network, referring to various innovative practices in supplier relationships, can be considered as an interorganizational extension of JIT. It is well known that Toyota reorganized its

suppliers into functional tiers in the 1950s. Its aim was to provide suppliers with incentive for improvement and promote learning mechanisms among suppliers and workers alike while maintaining long-term relationships. In this system, different responsibilities are assigned to the suppliers in each tier. First-tier suppliers are responsible not only for the manufacture of components, but also for their development while interacting and sharing information with Toyota and other first-tier suppliers. In turn, each first-tier supplier forms its own second tier of suppliers. They are assigned the job of fabricating individual parts and occasionally assist in their design, within the confines of rough specifications provided by the first-tier companies. In many cases, even a third tier of suppliers may exist to manufacture parts according to given specifications.

Roughly only 30% of Toyota's parts production is done in-house, with the remainder allotted to the supplier network. This high degree of outsourcing affords Toyota flexibility in coping with change. At the same time, it underscores the criticality of a competitive supply chain. Toyota's supplier network is neither a rigid, vertical integration nor an arm's-length relationship. Furthermore, it attempts to maintain a delicate balance between cooperative information sharing and the principle of competition. For this purpose, Toyota has employed several organizational strategies.

One approach for promoting information sharing is the formation of supplier associations and the cross-holding of shares with supplier-group firms and between first-tier suppliers. Another is the two-way sharing of personnel with Toyota and between supplier-group firms.

As an approach for encouraging competition, there is ample opportunity for a supplier to move up the ladder if it exhibits very high performance in quality, cost, delivery, and engineering capability. A parts-manufacturing specialist, for example, can expand its role to include the design of parts and even integrated components. Further incentive is provided by a degree of competition between suppliers over their share of business for a given part. Contrary to common assumption, parts are not sole-sourced except for certain complex systems that require considerable investments in tools. Rather, the business is typically divided between a lead supplier and one or more secondary suppliers. Each supplier's relative share of business may grow or shrink depending on performance. By providing substantial incentives to suppliers, this flexible system has spurred a variety of improvements relating to quality, cost, and JIT delivery of parts.

Another aspect of the lean production enterprise concerns the way that new products are designed and developed. Lean product development differs from traditional approaches on four key dimensions: leadership, teamwork, communication, and simultaneous development (Womack et al. 1990). In the case of automobile development, hundreds of engineers and other staff are involved. Consequently, strong leadership is the first condition for doing a better job with less effort. Toyota adopted the *shusa* system, also known as the heavyweight project manager system (Clark and Fujimoto 1991). The *shusa* (literally the chief engineer) is the leader of a project team whose job is to plan, design, and engineer a new product as well as to ramp up production and deliver it to market. Great responsibility and power are delegated to the *shusa*. Most importantly, the *shusa* assembles a flat team with members coming from the various functional departments throughout the company, from marketing to detail engineering. Though retaining ties to their original department, the team members are now responsible on a day-to-day basis to the *shusa*.

The development process used to explore the optimum design solution has been called by names such as set-based engineering (Liker et al. 1995). It can be defined as an approach for engineers to explicitly consider and communicate sets of design alternatives at both conceptual and parametric levels within clearly defined constraints. They gradually narrow these design sets by eliminating inferior alternatives until they eventually freeze the detailed product specifications based on feasibility studies, reviews, and analysis. This broad, sweeping approach helps the design team avoid premature design specifications that might appear attractive based on narrow considerations but that would suboptimize the overall design. Furthermore, set-based engineering facilitates sharing of the product's overall image among all members involved in the project, making it possible to develop different aspects of the product simultaneously.

This simultaneous development approach is now generally known as concurrent or simultaneous engineering. It is defined as the overlapping or parallel development of what otherwise would be sequential jobs. For example, the design of a production die ordinarily is not initiated until the detail engineering is completed for the part to be produced. In concurrent engineering, however, the die design is commenced even before the part design in finalized by utilizing shared knowledge concerning the approximate dimensions of the part, its requirements, and its design process. This overlapping design process is made possible by close communication between the sequential tasks and is somewhat analogous to the exploitation of off-line or external setup in order to reduce production lead time. Concurrent engineering is also employed with outsourced components by sharing personnel and information between Toyota and its suppliers.

Through concurrent engineering and other approaches, lean product development has achieved astonishing results, requiring only one half or less of the time and human resources traditionally needed to develop a new car. Accordingly, it has become a cornerstone of time-based competition. Further means for improvement lie in the full exploitation of information technologies. In particular,

CAD, CAE, and electronic interchange of technical data facilitate the sharing of information and have further potential for supporting concurrent engineering, particularly in later development stages.

The final aspect of lean production is the relationship with distributors and customers. As it did with its supplier network, Toyota built a distribution network that incorporated the dealers into the production system. In fact, the dealer is considered the first step in the kanban system. It sends orders for presold cars to the factory for delivery to specific customers about two weeks later, thereby initiating the pull signal for production. For this to be workable, the dealer works closely with the factory to sequence orders in a way that the factory can accommodate, just as the factory works closely with its suppliers. At the same time, dealers have played another role in assessing customer needs and relaying that information to Toyota for consideration in designing new models. Dealers have done this by making house calls directly to customers and increasingly by collecting customer information in databases maintained at the dealers.

Through these innovative practices, Toyota's lean production system formed a complete supply chain from source to user. Its system integrated suppliers and distributors with manufacturing and involved them in product development. In so doing, the lean production model has provided a prototype of the business paradigms of concurrent engineering and supply chain management. For an examination of the implementation of lean production in North American companies, see Liker (1998) and Liker et al. (1999).

5.2. Theory of Constraints (TOC) and JIT

The concept and practice of *kaizen* are features common to TQM, TPM, JIT, and lean production. However, despite great effort expended for continuous improvement throughout their organizations, many Japanese companies in the 1990s faced difficulty in improving their financial bottom line, including even the leaders in JIT practice. This was largely due to Japan's prolonged economic recession, but many companies would have benefited from a more focused approach to their improvement efforts.

One such approach lies in the Theory of Constraints (TOC). Devised by Eli Goldratt (e.g., Goldratt 1990; Goldratt and Cox 1992), TOC can be viewed as an inclusive philosophy and methodology of improvement, which includes bottleneck-focused scheduling methods, performance measurement system, thinking process, and problem-solving tools. Its core idea is that every system, such as a for-profit company, must have at least one constraint. Since a constraint is a factor that limits the system from getting more of whatever it aims to achieve, a company that wants more profits must manage its constraints. See Spencer and Cox (1995) for an analysis of the history and scope of TOC and its relation to optimized production technology (OPT), as well as Umble and Srikanth (1990), Noreen et al. (1995), and Dettmer (1997) for detailed discussions of TOC's sub-areas of scheduling/logistics, performance measurement, and thinking process, respectively. A review of TOC-related journal publications is given by Rahman (1998).

Among TOC's many techniques and tools, the five-step focusing process (e.g., Goldratt and Cox 1992) is the one most closely related to JIT:

Step 1. Identify the system constraint(s).

Step 2. Decide how to exploit the system constraint(s), i.e., better utilize the constraint's existing capacity.

Step 3. Subordinate everything else to the above decision, i.e., align the rest of the system to work in support of the constraint.

Step 4. Elevate the constraint(s), i.e., improve/increase the constraint's capacity.

Step 5. If a constraint has been broken, go back to step 1. Do not allow inertia to cause a system constraint.

Of these, steps 1, 4, and 5 are practically equivalent to the continuous-improvement logic of JIT if *constraint* is considered in the narrow meaning of a production bottleneck. One could even consider these five focusing steps as JIT concepts in combination with steps 3 and 4's unique bottleneck scheduling logic.

Despite this similarity, two important differences should be noted. The first difference relates to the meaning of the term *constraint* and to understanding which goal is being constrained. In JIT, the constraint is tantamount to a production bottleneck, and the primary focus is placed on inventory level. In the case of TOC, the issue is not inventory level per se, but rather achieving the company's goal of making profit by means of increasing throughput, reducing expenses, and/or reducing inventory.

To understand TOC's approach to improving company profitability, consider the often-drawn analogy between a system and a chain, where the strength of the chain corresponds to the company's profit. To improve the strength of the chain, one must identify the weakest link and concentrate effort

on strengthening it, instead of applying effort uniformly over all the links. This analogy implies that the focus for continuous improvement must be on the area that will bring about the greatest benefit in relation to the effort extended. Furthermore, this area for improvement may lay outside the manufacturing plant because the constraint may not be a physical one but may involve managerial policies or market factors. Consequently, in such a situation, plant-wide improvement efforts in ''carpet bombing'' fashion may not lead to an improved bottom line for the company.

The second point of difference concerns the focus of improvement efforts. Whereas JIT, TQM, and TPM concentrate on *changing* the production system as the means to improve it, TOC explicitly considers options for increasing profits while making the constraint work more effectively *as it is*. This concept is embodied in steps 2 and 3 of the five-step focusing process. In particular, step 3 corresponds to the famous scheduling solution called drum-buffer-rope (DBR). As illustrated in Figure 5(*a*), DBR is easily understood using Goldratt's analogy of a Boy Scout troop. Each Scout stands for one workstation or process, while the distance the troop moves during a specific period is throughput earned and the length of the Scout troop column corresponds to work-in-process. Under the condition that we cannot eliminate statistical fluctuations and disruptions in each Scout's hiking performance, the objective is to have the Scout troop advance as much distance as possible while keeping the troop's length short.

The solution to this problem lies in having the slowest Scout (constraint) set the pace of the troop by beating a drum and tying a rope with some slack (work-in-process or time buffer) between him and the leading Scout. The rope prevents the troop length from increasing unnecessarily. At the same time, the slack in the rope allows the slowest Scout to work at his full capability without any interference from disruptions in the preceding Scouts' performance, thereby enabling the troop as a whole to advance the maximum attainable distance.

For reference, the corresponding analogy for a kanban system is shown in Figure 5(*b*). In a kanban system, all adjacent pairs of Scouts are tied together by a rope whose length represents the number of kanbans in circulation, and the pace of the drum beat must be constant, in keeping with JIT's prerequisite of leveled production. It should be noted that there is no individual Scout who corresponds to a constraint or bottleneck. Instead, once any Scout experiences difficulty walking with the given length of rope, that Scout is identified as a constraint and countermeasures are taken straightaway to increase his capability. Next, the length of rope between each pair is further shortened and another constraint is discovered to repeat the cycle of continuous improvement. In this sense, kanban should be considered as a means to expose the constraint, rather than a means to schedule it and fully exploit its existing capability.

In sum, TOC adds a beneficial and indispensable viewpoint to the 3T's in that it helps to clarify the goal of improvement and to identify where improvement should be focused so as to achieve maximum financial benefits from a global optimum standpoint. In addition, TOC complements JIT, TQM, and TPM by emphasizing that improvement should not always be the first option. Rather, quick returns are often possible from first exploiting the constraint as it is, making it work to its own utmost limit.

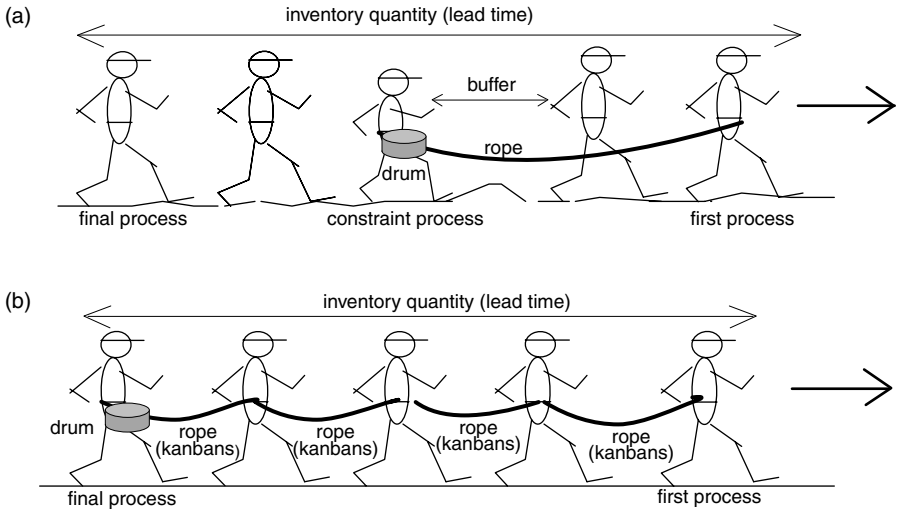

Figure 5 Analogy of Drum-Buffer-Rope in (*a*) Theory of Constraints and (*b*) Kanban System.

5.3. Applications to Service Industries

As exemplified by such terms as the *production-line approach to service* or the *service factory,* manufacturing and service industries have a history of mutually influencing each other's theory and practice. Despite their manufacturing industry origins, JIT, TQM, TPM, and TOC also have applications to service industries. The purpose of this section is briefly to identify some of these application issues and provide references for further information.

JIT and lean production concepts such as rationalization of process flows, batch size reduction, demand leveling, and multifunctional workers are quite applicable to many service environments. Duclos et al. (1995) provide a review of JIT practices in services as well as references for articles describing their implementation. For example, Mehra and Inman (1990) describe an overnight package delivery company's implementation of JIT for its business supplies, and Billesbach and Schneidemans (1989) examine the application of JIT in administrative areas. A broader discussion of the application of lean production principles to service operations is provided by Bowen and Youngdahl (1998), wherein they describe how service businesses such as Taco Bell, Southwest Airlines, and Shouldice Hospital have mastered ''lean'' service. Southwest Airlines, for example, is known for its rapid turnaround (setup) of planes between flights—about three times faster than the industry average. Service companies should not wrongly assume that production efficiency and customer responsiveness are tradeoffs, as they were in the mass production paradigm. Rather, lean production principles can be used to eliminate non-value-added activities from service processes, integrate the value chain, and increase flexibility and responsiveness.

Of various other JIT and TQM-related concepts, poka-yoke merits special attention. In many services, due to the simultaneity of a service's creation and consumption, mistakes are readily apparent to the customer and it is not possible to carry out inspection or rework. Examples of mistake-proofing in service environments range from color coding of patients' medical files to techniques for differentiating drinks with similar colors. Further discussion and examples of poka-yoke in services are provided by Schvaneveldt (1993) and Chase and Stewart (1994).

While TPM is practiced in the administrative areas of many leading manufacturers, it has received scant attention from service industries. This is understandable given the different nature of technology and equipment in most service environments. However, a precursor to TPM called 5S is very appropriate for services. As briefly described in the TPM section above, 5S is a Japanese acronym for five good housekeeping practices for organizing and cleaning the workplace. These practices involve all employees, not just designated maintenance or custodial staff, and help to establish an environment of self-responsibility and problem awareness among employees.

Finally, several aspects of TOC have application to service industries, particularly the five-step focusing process for system constraint identification and management. In addition to reviewing the emerging literature on TOC in services, Siha (1999) provides a framework for interpreting and applying TOC concepts to different service industries. An interesting case study of TOC in an engineering services firm is given in Motwani and Vogelsang (1996), which describes how the firm identified its constraint in the survey department and took measures to increase throughput. In another case (Olson 1998), a security and alarm company was unable to meet market demand. It determined that installation technicians were the bottleneck resource and consequently redesigned the alarm-installation process to allow technicians to work in teams and perform tasks in parallel. TOC has even been applied in an accounting firm (Green and Larrow 1994). After identifying the constraint to be the tax department, the firm found ways for the rest of the organization to support the work of the tax department better without increasing staff or work hours.

CHAPTER 18
Near-Net-Shape Processes

REIMUND NEUGEBAUER
Fraunhofer Institute for Machine Tools and Forming Technology

KLAUS HERFURTH
Technical University of Chemnitz

1. PROCESS CHAINS IN PART MANUFACTURING

Part manufacturing is aimed at producing components for various destinations and functionalities. These components can be either autonomous products or parts of a more complex product. Components are characterized by their geometry and material properties. They have to cope with specific quality requirements depending on the corresponding part function and the individual application. The number of required components which determines the type of manufacturing—e.g., in small and

medium series or large-lot production—depends on the part's destination. In conclusion, the type of manufacturing mainly results from a wide range of possible preconditions.

The nature of manufacturing itself is to transform in steps the different variants of the initial material that is available for manufacturing technology into the final state predefined by the component's target geometry. For this procedure, very different process stages, depending on the component itself and the manufacturing conditions, are required. These steps can be realized by various mechanical, thermal, and chemical manufacturing techniques. The process chain represents the technological sequence of the individual process steps, which guarantees adequate fabrication of the component (see Figure 1).

As a rule, to manufacture a given component, different process chains are possible, posing the question of optimizing manufacturing processes and subsequently the process chains that should be applied. The first goal is to keep the process costs to a minimum at constant or even enhanced product quality. Another goal is to improve process productivity. Environmental protection, careful use of resources, and use of reproductive materials are increasingly important considerations.

Within this context, *near-net-shape* (nns), which involves optimizing the manufacturing process and particularly shortening the process chains, describes one trend in part manufacturing development.

1.1. Near-Net-Shape Processes: Definition and Limitations

For a better understanding of the near-net-shape principle, all explanations should be based on the different characteristics of the manufacturing techniques employed for shaping within the fabrication of components. These are methods that, on the one hand, create shapes by removing material from an initial state, including cutting methods such as turning, drilling, milling, and grinding as well as some special techniques. In contrast, shaping can be realized by distributing or locating material in an intentional way. The primary shaping methods (e.g., casting, powder metallurgy), metal-forming technology, as well as similar special techniques are based on this principle.

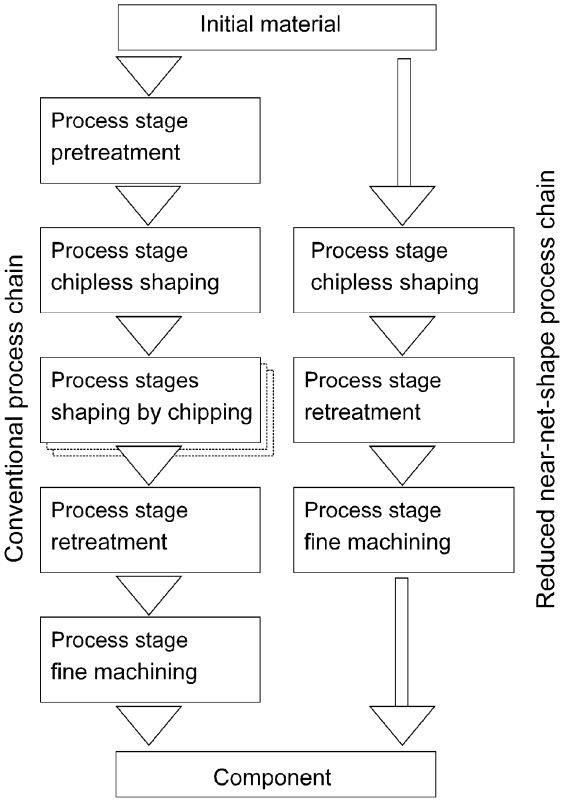

Figure 1 Process Chain Variants: Examples.

Starting with this distinction and bearing in mind the heterogeneous terminology in technical literature, we can define near-net-shape production as follows:

> Near-net-shape production is concerned with the manufacture of components, whereby shaping is realized mostly by nonchipping manufacturing techniques and finishing by cutting is reduced to a minimum. Near-net-shape manufacturing involves such objectives as reducing the number of process stages, minimizing costs, and guaranteeing enhanced product quality.

Essentially nonchipping shaping is necessary if materials such as compounds and ceramics are characterized by poor machinability.

The near-net-shape principle carried to its limits finally results in net-shape production that makes finishing by cutting totally unnecessary. In net-shape manufacturing, shaping is performed only with nonchipping techniques. The decision on the extent of residual cutting work—that is, the extent to which finishing by cutting can be reasonably diminished or even completely eliminated—depends on the associated manufacturing costs.

Thus, in some cases it may be more economical to manufacture a shape element by cutting than by metal forming. Maintaining a certain minimum value for finishing by cutting may be necessary for technical reasons as well. For example, a disturbing surface layer (skin after casting or decarburized skin caused by hot working) that results from a nonchipping shaping procedure will have to be removed by cutting.

Near-net-shape manufacturing can cover the whole component, but also only parts of it, such as functional surfaces of outstanding importance.

1.2. Goals and Benefits

To keep the manufacturing industry competitive in today's global markets, innovative products must constantly be developed. But high product quality also has to be maintained at reasonable costs. At the same time, common concerns such as protecting the environment and making careful use of resources must be kept in mind. Near-net-shape manufacturing has to cope with these considerations.

The goals of near-net-shape production are to reduce the manufacturing costs and make the manufacturing procedure related to a given product more productive. These goals can be achieved by employing highly productive nonchipping shaping techniques and minimizing the percentage of cutting manufacturing, thus generating more efficient process chains consisting of fewer process steps. Value adding is thus shifted to the shaping methods as well. For that reason, enhancement of shaping procedures involves great development potential.

An increasing variety of advanced products with new functionality and design are being developed. However, novel components characterized by higher manufacturing demands are emerging. Lightweight manufacturing, reduction of moving mass at energy-consuming assemblies or products, and the application of sophisticated multifunctional parts that save space and weight are typical manifestations. Frequently, when nonchipping shaping methods are used, geometrically complex components can be realized much better than would be possible with conventional cutting techniques perhaps used in conjunction with joining operations. With enhancing near-net-shape manufacturing as a must, the specific features of the different chipless shaping methods, such as low-waste and environmentally compatible production, increase in product quality, and better characteristics for use, can be taken advantage of.

1.3. Preconditions for Near-Net-Shape Manufacturing

As a precondition for developing near-net-shape manufacturing for and applying it to a given manufacturing task, efficient nonchipping shaping techniques that enable working accuracy commensurate with that of cutting techniques are needed. For guidelines for some achievable cutting accuracy values, see Table 1. Table 2 includes the corresponding values for nonchipping shaping techniques.

When the values in Tables 1 and 2 have been compared, a wide variety of feasible nns methods is available. At the same time, the differences that are still apparent pose a challenge to further development and improvement of nonchipping shaping methods. A trend toward still-higher accuracy and productivity of cutting techniques can also be observed. Thus, synergy effects that act mainly on the design of nns processes are emerging. The new quality of part-manufacturing development towards nns technologies is also related to the complex consequences of all those factors influencing quality and efficiency in part manufacturing. Figure 2 represents diagrammatically the principal dependencies and relationships.

From their origin, the influencing factors mentioned above can be assigned to workpiece, process, or equipment. In component design and when choosing the part material, apart from the component's function, the requirements resulting from the foreseen near-net-shape production the workpiece must fulfill must be considered. In cases where shaping has to be realized by a metal forming procedure, the material should possess sufficient formability. Profound knowledge of the theoretical and practical

fundamentals of the manufacturing technique to be employed within the process chain is also very important. This expertise is a fundamental precondition for optimizing the entire process chain as well as each technique individually with respect to the manufacturing result and working efficiency. For such optimization tasks, FE simulation of manufacturing operations and production sequences is becoming more and more important. Finally, interaction between the development of manufacturing techniques and expanding the range of application of near-net-shape technologies exists.

With regard to equipment, the chosen parameters and manufacturing constraints must be maintained in order to guarantee the required process reliability.

2. AN APPROACH TO NEAR-NET-SHAPE PHILOSOPHY: PRINCIPLE AND POSSIBILITIES

The basic idea underlying the near-net-shape philosophy is to approximate, as far as possible, an initial material to the target shape of the final product by means of innovative techniques of shaping and structure formation. As a rule, all measures are estimated by their contribution to achieving economic effects such as minimized costs and higher productivity. With respect to the production of components, the trend is to displace chipping operation stages with much more efficient casting, powder metallurgy, and bulk metal forming processes. Inspired by technological progress, the term *near-net-shape* has also been widened to include other ranges such as the fabrication of special and semifinished materials. The criteria for deciding upon the techniques to be applied for creating a special shape and structure do not have to be those known from part manufacturing. Thus, for instance, in the process chain of near-net-shape casting of semifinished materials, the percentage of casting vs. bulk metal forming is greater than in conventional fabrication of semifinished material.

2.1. Component Shaping Techniques (Selection)

2.1.1. Casting and Powder Metallurgical Techniques (Primary Shaping)

Primary shaping is the manufacturing of a solid body from an amorphous material by creating cohesion. Thus, primary shaping serves originally to give a component an initial form starting out from a material in an amorphous condition. Amorphous materials include gases, liquids, powder, fibers, chips, granulates, solutions, and melts. With respect to a product shape and follow-up processing, primary shaping can be divided into three groups:

1. Products made by primary shaping that will be further processed by forming, cutting, and joining. With respect to shape and dimensions, the final product is no longer similar to the product originally made by primary shaping. In other words, shape and dimensions are also essentially altered by means of techniques from other main groups of manufacturing processes. The manufacturing of flat products from steel, which is widely realized by casting, is one near-net-shape application. Thereby, later shaping by rolling can be kept to a minimum.
2. Products made by primary shaping whose forms and dimensions are essentially similar to those of the finished components (e.g., machine parts) or final products. The shape of these products corresponds to the product's purpose to the maximum extent. Obtaining the desired final form as well as final dimensions mostly requires only a few, as a rule chipping, operations to be carried out at functional surfaces.
3. Metal powders produced by primary shaping, whereby the powders are atomized out of the melt. From powder, sintering parts are produced as a result of powder metallurgical manufacturing.

The fabrication of moldings from metals in foundry technology (castings) and powder metallurgy (sintered parts) as well as of high-polymer materials in the plastics processing industry yields significant economic advantages, such as:

- The production of moldings is the shortest way from raw material to finished product. Forming, including all related activities, is thereby bypassed. A form almost equal to the component's final shape is achieved in only one direct operation, and masses ranging from less than 1 g to hundreds of tons can thus be handled.

- Maximum freedom for realizing shapes that cannot be achieved by any other manufacturing technique is enabled by manufacturing of moldings that are primarily shaped from the liquid state.
- Primary shaping can also be applied to materials that cannot be processed with other manufacturing techniques. An advantageous material and energy balance is ensured by the direct route from raw material to the molding or the final product.
- Components and final products of better functionality, such as moldings of reduced wall thickness, diminished allowances, fewer geometric deviations, and enhanced surface quality (near-net-shape manufacturing), can be produced to an increasing extent due to the constantly advancing primary shaping methods.
- Great savings in materials and energy can be realized with castings and sintered parts. Positive consequences for environmental protection and careful use of natural resources can be traced back to these effects.

2.1.1.1. Primary Shaping: Manufacturing Principle In general, the technological process of primary shaping methods can be divided into the following steps:

- Supply or production of the raw material as an amorphous substance
- Preparation of a material state ready for primary shaping
- Filling of a primary shaping tool with the material in a state ready for primary shaping
- Solidification of the material in the primary shaping tool, e.g., usually the casting mold
- Removal of the product of primary shaping from the primary shaping tool

For a survey of primary shaping methods, see Figure 3.

2.1.2. Bulk Metal Forming Techniques

Aiming at the production of parts described by defined geometry and dimensions, all bulk metal forming techniques are based on the plastic alteration of the form of a solid body (whose raw material is massive in contrast to sheet metal forming) whereby material cohesion is maintained. The form is altered (forming procedure) due to forces and moments applied from the outside and generating a stress condition able to deform the material—that is, to transform it into a plastic state, permanently deformable inside the region to be formed (forming zone). The form to be produced (target form) is

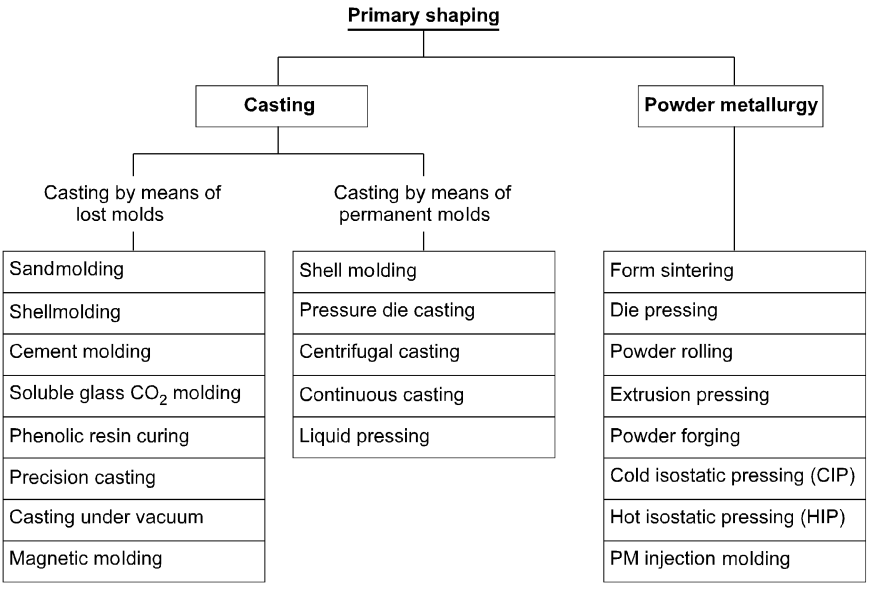

Figure 3 Survey of Primary Shaping Techniques.

mapped by the form of the tool's active surfaces and the kinematic behavior of each forming method. The requirements to be fulfilled by the material to be formed—summarized as the material formability property—result from the precondition that internal material cohesion not be destroyed during manufacturing. Formability of a material is influenced by the conditions under which the metal forming procedure is performed. Forming temperature, strain rate, and the stress condition within the forming zone are essential factors influencing formability.

A selection of essential bulk metal forming techniques to be used for realizing near-net-shape technologies in part manufacturing is given in Table 3.

All bulk metal forming techniques can be run at different temperature ranges dictated by the characteristics of each material (which in turn acts on the forming conditions), design of the process chain, and the forming result. According to their temperature ranges, cold, semihot, and hot forming processes can be distinguished.

2.1.2.1. Cold Forming In cold forming, the forming temperature is below the recrystallization temperatures of the materials to be formed. The workpiece is not preheated. In this temperature range, workpieces with close dimensional tolerances and high surface qualities can be manufactured. The cold forming process results in some work-hardening of the metal and thereby in enhanced mechanical components' properties. As a minus, the forces and energy required for cold forming as well as the tool stresses are much higher than for hot forming, and the formability of the material in cold forming is less.

2.1.2.2. Semihot Forming The warm forming temperature range starts above room temperature and ends below the recrystallization temperature from which the grain of metal materials such as steels begin to be restructured and the material solidification due to deformation degraded. For most steel materials, the semihot forming temperature ranges from 600–900°C. In comparison to hot forming, higher surface qualities and closer dimensional tolerances are obtained. The forces and energy required for semihot forming as well as the tool stresses are less than for cold forming. However, the additional thermal stress acting on the tool is a disadvantage. Consequently, in manufacturing, the requirements for exact temperature control are high.

2.1.2.3. Hot Forming In hot forming processes, the workpiece is formed at temperatures above the temperature of recrystallization of the corresponding metal. For the majority of materials, formability is higher due to higher forming temperatures. The forces and energy required for hot forming, as well as the tool stresses, are essentially lower than those for cold and semihot forming. Surfaces of poor quality due to scaling and decarburized skin (for steel materials: reduced carbon content in marginal layers near the surface) and wider tolerances at the component's functional surfaces, which in turn result in increased allowances for the necessary follow-up chipping operation, are disadvantageous. Further limitations are caused by the forming tools' grown thermal stress and the high expenditure involved in heating and reworking the part.

2.2. Special Applications

The near-net-shape technologies of part manufacturing also involve applications whose type of shaping can be assigned to none of the conventional primary shaping or forming technologies. This concerns, for instance, the thixoforming method, which involves processing metals at temperatures between the molten and partially solidified state so that the working conditions are between hot forming and casting. Depending on whether the component is shaped on a die-casting or forging press, the procedure is termed *thixocasting* or *thixoforging*. A specific globular structure of the initial material is required to transform metals into a thixotropic state. During heating to produce the thixotropic condition, the matrix phase, which becomes liquid at a lower temperature, is molten first and the metal becomes pulpy and easily formed.

Thixoforming is able to produce complex components of sophisticated form with minimum use of material and energy in only one operation.

Generic part manufacturing, represented by the rapid prototyping techniques, occupies a special position. The rapid prototyping principle is based on successive sedimentation of material (shaping layer by layer). These techniques are used not only for manufacturing of patterns but also for producing tools in a near-net-shape manner, such as for casting.

3. NEAR-NET-SHAPE MANUFACTURING EXAMPLES IN ADVANCED PROCESS CHAINS

3.1. Casting: Selected Examples

The main advantage of shaping by casting or powder metallurgy is the realization of near-net-shape production of castings and sintered parts, thereby minimizing cutting processing and drastically shortening the process chains due to fewer process stages. The process chain is dominated up to the finished part by chipless shaping.

TABLE 3 Bulk Metal Forming Techniques (Selection)

Manufacturing Technique	Process Principle	Technological Background	Obtainable Manufacturing Results
Die forging		• Forming under compressive conditions, translational tool motion • Shaping by means of tools replicating the part shape(dies) • with or even without loss of material (with flash, low flash, flashless) • Primarily hot forming, but also warm forming • Different design types depending on the forming machine (hammer, press, horizontal forging machine)	• Manifold of shapes (flat, cramped long parts with/without secondary shape elements) • Components of higher accuracy (close tolerance forging) • Components with functional surfaces ready to be installed • Surface roughness R_a = 1.6 . . . 12.5 μm and R_z = 16 . . . 400 μm
Extrusion		• Forming under compressive conditions, translational tool motion • Shaping by squeezing the material from almost closed tool installations • Varying kinematics of metal flow • Cold, semihot, hot forming	• Wide variety of forms, also due to the combination with other techniques (upsetting, pressing in) • Very close manufacturing tolerances can be kept • Components with functional surfaces ready to be installed (e.g., gearings) • Surface roughness R_a = 0.8 . . . 12.5 μm and R_z = 6.3 . . . 100 μm

TABLE 3 (*Continued*)

Manufacturing Technique	Process Principle	Technological Background	Obtainable Manufacturing Results
Orbital pressing		• Incremental forming under compressive conditions • One die moves on rolling contact in a tumbling manner, the other is fixed • Varying tumbling motion such as circular, helical, linear orientation • Shaping: one workpiece face is moving on rolling contact + translationally, another face is moving translationally • Semihot and cold forming	• Flat parts, wide variety of forms, high accuracy and most complicated contours on the face with only translational shaping • Manufacturing tolerances in the range from 0.05–0.2 mm can be maintained • Components with functional surfaces ready to be installed (e.g., gearings)
Axial die rolling		• Incremental forming under compressive conditions • Two rotating dies (both driven in the same direction or one driven, the other following) with crossing rotary axes • Shaping: one workpiece face moves on rolling contact + translationally, another workpiece face translationally • Primarily hot forming	• Flat rotationally symmetrical parts (ring- and disk-shaped) • Obtainable accuracies and surface qualities commensurate with die forging
Swaging		• Incremental forming under compressive conditions, tool moved in translational direction • Shaping by two or more tools bound to path in conjunction with the workpiece motion (rotation + translation or rotation, only) • Cold and hot forming	• Bar- and rod-shaped parts with straight or shouldered outer and inner contours, different profiles • Precision parts ready to be installed as a result of cold forming

1: workpiece; 2: upper tool/die; 3: lower tool; 4: bottom die; 5: plasticizing jaw.

Development in shaping by casting is focused on two directions. First, the components become increasingly closer to the finished parts. Second, many single parts are aggregated to one casting (integral casting). Both directions of development are realized in all variants of casting technology. However, in precision casting, casting by low pressure, and pressure die casting, the material and energy savings to be achieved are especially pronounced.

For evaluation, the manufacturing examples in Figures 4 and 5 were considered starting from melting up to a commensurable part state.

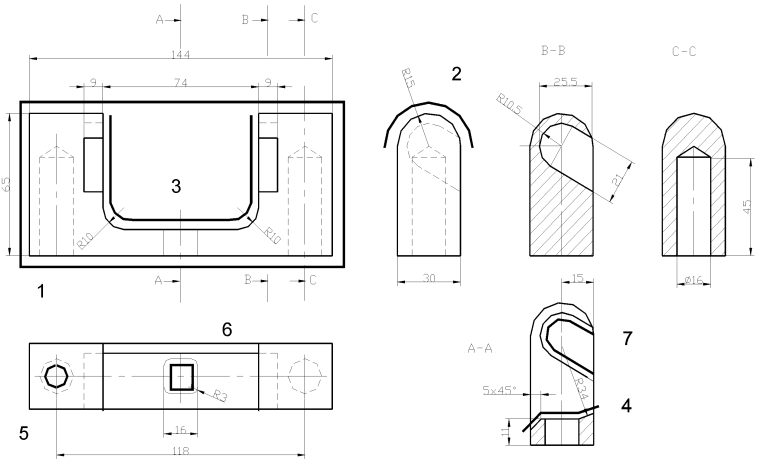
Figure 4 shows a technical drawing of a flat part that had previously been produced by cutting starting from a bar, that is now made as a casting (malleable cast iron) using the sand-molding principle. In cutting from the semifinished material, material is utilized at only 25.5%. As a result of shaping by casting, utilization of material was increased to 40%. The effects of shaping by casting become evident in the energy balance (primary energy). For cutting the flat part from the solid, 49.362 GJ/t parts are required. For shaping by casting, 17.462 GJ/t parts are required. Consequently, 64.6% of the energy can be saved. Compared to cutting of semifinished steel material, for part manufacturing about a third as much primary energy is required.

The doorway structure of the Airbus passenger door (PAX door: height about 2100 mm; width about 1200 mm) is illustrated in Figure 5.

In conventional manufacturing of the doorway structure as practiced until now, apart from the standard parts such as rivets, rings, and pegs, 64 milling parts were cut from semifinished aluminum materials with very low utilization of material. Afterwards, those parts were joined by about 500 rivets.

As an alternative technological variant, it is proposed that the doorway structure be made of three cast segments (die casting—low pressure). Assuming almost the same mass, in production from semifinished materials, the ratio of chips amounted to about 63 kg, whereas in casting, it can be reduced to about 0.7 kg. Thus, in casting, the chip ratio amounts to only 1% in comparison to the present manufacturing strategy. In the method starting from the semifinished material, about 175 kg of materials have to be molten, however, in shaping by casting, this value is about 78 kg—that is, 44.6%.

As a result of the energy balance (primary energy), about 34,483 MJ are required for manufacturing the doorway structure from the semifinished material. However, in shaping by casting, 15,002



Designation of shape elements:

6 Square profile (drilling into the solid, broaching)
7 Pocket element (milling)

Figure 4 Example: Flat Part.

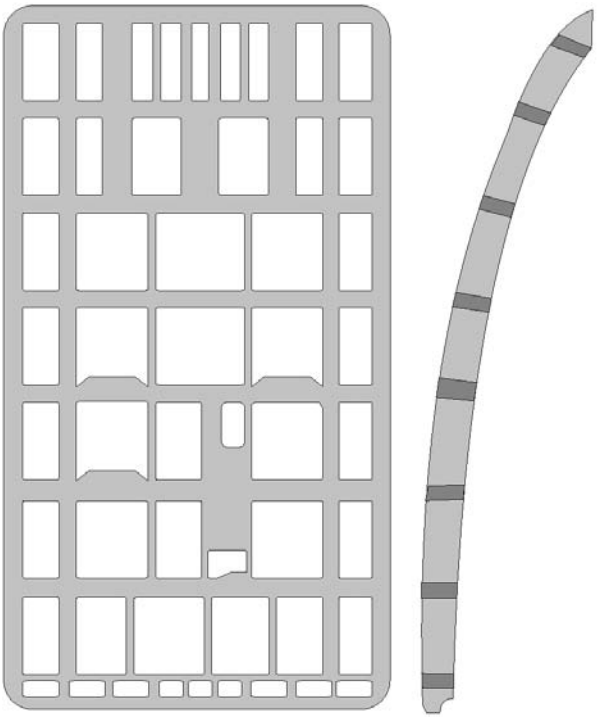

Figure 5 Example: Airbus Doorway.

MJ are needed—that is about 46%. The result of having drastically diminished the cutting volume due to nns casting can be clearly proven in the energy balance: in the variant starting from the semifinished material, 173 MJ were consumed for cutting; in casting, less than 2 MJ.

Today, the Airbus door constructions that have, in contrast to the studies mentioned above, cast as one part only are tried out. In this variant, 64 parts are aggregated to one casting (integral casting).

Figure 6 illustrates a welding-constructed tool holder consisting of seven steel parts (on the left), for which one consisting of two precision castings has been substituted (steel casting, GS-42CrMo4, on the right). Comprehensive cutting and joining operations can be saved through substitution by investment casting. In the variant where the nns design is based on precision casting, only a little cutting rework is required.

3.2. Powder Metallurgy: Manufacturing Examples

3.2.1. Hot Isostatic Pressing (HIP)

Since the 1950s, hot isostatic pressing technology has been developing rapidly in the field of powder metallurgy. Assuming appropriate powders are used, precision parts of minimum allowances can be produced. Applications provide solutions especially in cases of maraging steels, wear steels with high carbon content, titanium and superalloys, and ceramic materials.

As usual in this process, after the production of the appropriate powder, powder is enclosed in an envelope under an almost complete vacuum or inert gas atmosphere. Within this envelope, the powder is compacted under high pressure and temperature (hot isostatic pressing or compaction, see Figure 7). Almost isotropic structural properties are achieved by identical pressure acting from all sides. Thereby, the pressing temperature is partially far below the usual sintering temperature, which results in a fine-grained structure apart from the almost 100% density.

HIP technology can be applied to

- Postcompaction of (tungsten) carbide
- Postcompaction of ceramics

Figure 6 Tool Holder for a CNC Machine Tool (with Hinge).

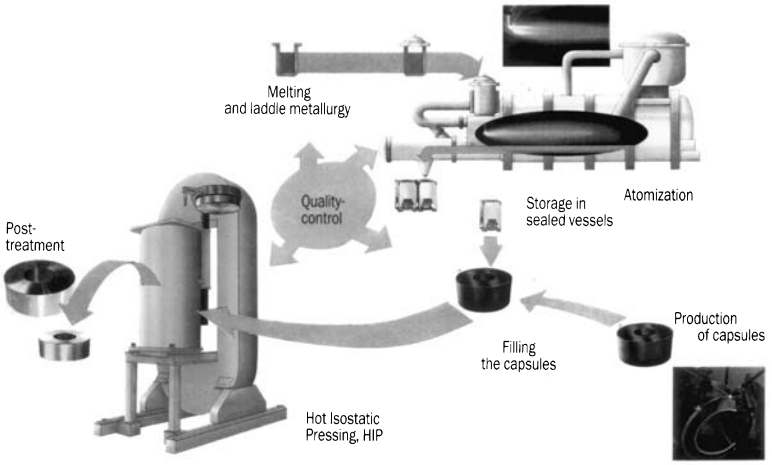

Figure 7 Hot Isostatic Pressing (HIP): Process Flow. (From firm prospectus, courtesy ABB, Västeräs, Sweden, 1989)

Metal powder parts Ceramic part Casting

Figure 8 Workpieces Made Using HIP Technology. (From firm prospectus, courtesy ABB, Västeräs, Sweden, 1989)

- Powder compaction
- Postcuring of casting structures
- Reuse and heat treatment of gas turbine blades
- Diffusion welding
- Manufacturing of billets from powders of difficult-to-form metals for further processing

Workpieces made using the HIP process are shown in Figure 8. These parts are characterized by high form complexity and dimensional accuracy. With regard to the mechanical properties, parts made using HIP are often much better than conventionally produced components due to their isotropic structure.

3.2.2. Powder Forging

The properties of powder metallurgical workpieces are greatly influenced by their percentage of voids and entrapments (see Figure 9). For enhanced material characteristics, a density of 100% density must be striven for.

The application of powder or sintering forging techniques can provide one solution to achieving this objective. The corresponding process flow variants are given in Figure 10. Regarding the process sequence and the equipment applied, the powder metallurgical background of the process basically conforms to shaping by sintering.

According to their manufacturing principle, the powder-forging techniques have to be assigned to the group of precision-forging methods. Depending on part geometry, either forging starting from the sintering heat or forging with inductive reheating (rapid heating up) is applied. When forging the final shape, an almost 100% density is simultaneously generated in the highly stressed part sections. The part properties resulting from manufacturing by powder forging are equivalent to or frequently even more advantageous than those of usual castings. This becomes evident especially in the dynamic characteristics.

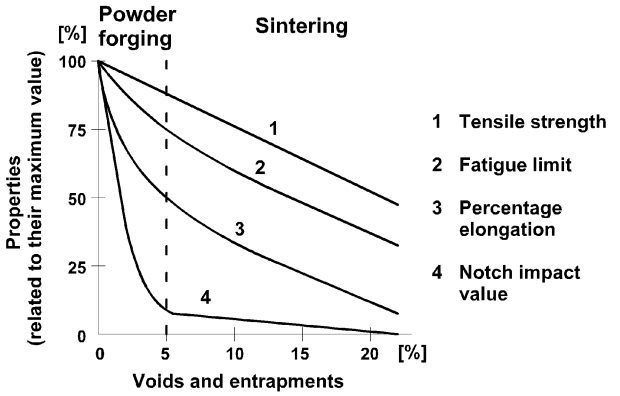

Figure 9 Workpiece Properties vs. the Percentage of Voids and Entrapments. (From Lorenz 1996)

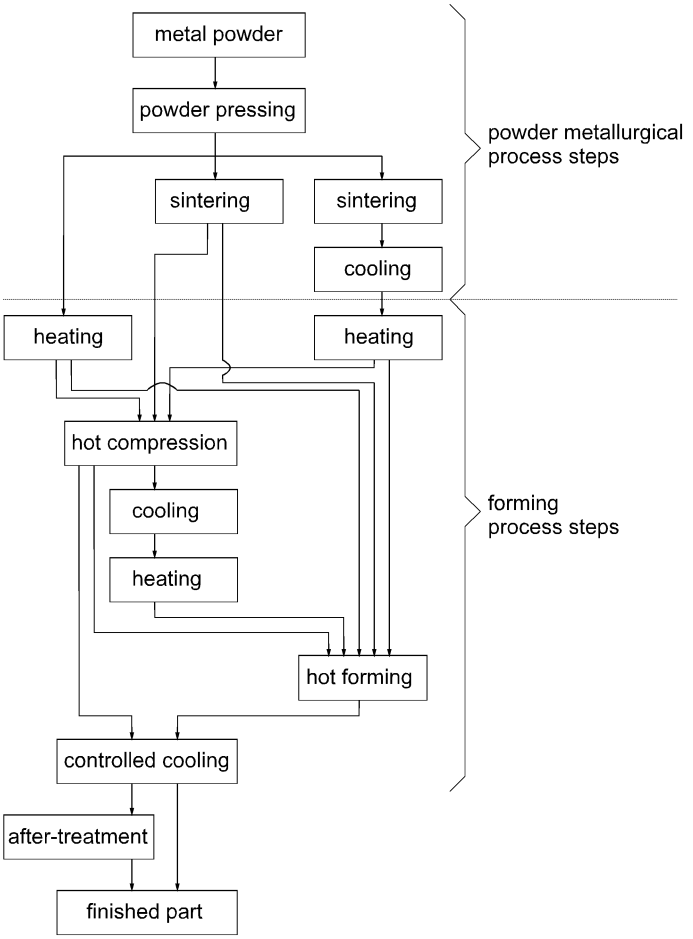

Figure 10 Powder and Sinter Forging. (From Lorenz 1996)

Figure 11 shows the stages of powder-forging processes for forming rotationally symmetrical parts.

The advantages of powder-forged parts can be summarised as follows:

- Material savings (flashless process)
- Low mass fluctuations between the individual parts
- High accuracy (IT8 to IT11)
- High surface quality
- Low distortion during heat treatment due to the isotropic structure
- High static and dynamic characteristic values

Some typical powder forging parts are shown in Figure 12.

3.3. Cold-formed Near-Net-Shape Parts: Examples of Applications

3.3.1. Extrusion

Cylindrical solid and hollow pieces including an axial direction slot of defined width and depth at the face are examples of typical mechanical engineering and car components. Parts like these can be found in diesel engines and pumps (valve tappets), in braking devices (as pushing elements), and for magnetic cores.

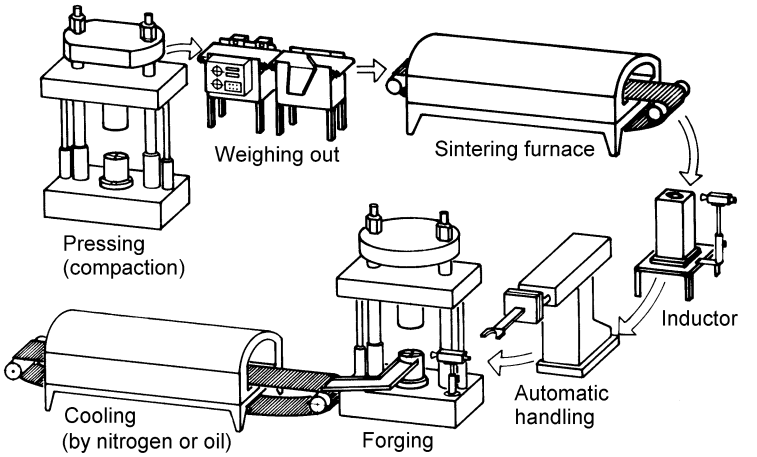

Figure 11 Powder Forging: Process Sequence. (From firm prospectus, courtesy KREBSÖGE, Radevormwald, Germany, 1994)

The valve tappet for large diesel motors made of case-hardening steel (16MnCr5), illustrated in Figure 13, is usually produced by cutting from the solid material, whereby the material is utilized at a rate of ≤40%. A near-net-shape cold-extrusion process was developed to overcome the high part-manufacturing times and low utilization of material and cope with large part quantities.

Starting from soft annealed, polished round steel, the valve tappet was cold extruded following the process chain given in Figure 14. The initial shapes were produced by cold shearing and setting, but also by sawing in the case of greater diameters. Surface treatment (phosphatizing and lubricating) of the initial forms is required for coping with the tribological conditions during forming. Near-net-shape extrusion can be carried out both in two forming steps (forward and backward extrusion) and in a one-step procedure by combined forward/backward extrusion. The number of forming steps depends on the workpiece geometry, particularly the dimensional ratios b/d and D/d.

Modified knee presses up to a nominal force of 6300 kN are employed to extrude the valve tappets. The output capacity is 25–40 parts per minute. As a result of the near-net-shape process, the material is utilized to a higher extent—about 80%. The sizes of slot width and hole diameter are delivered at an accuracy ready for installation, whereas the outer diameter is pressed at IT quality 9–10 ready for grinding. The number of process steps and part manufacturing time were reduced.

Figure 12 Workpieces Made Using Powder Forging. (From prospectus, courtesy KREBSÖGE, Radevormwald, Germany, 1994)

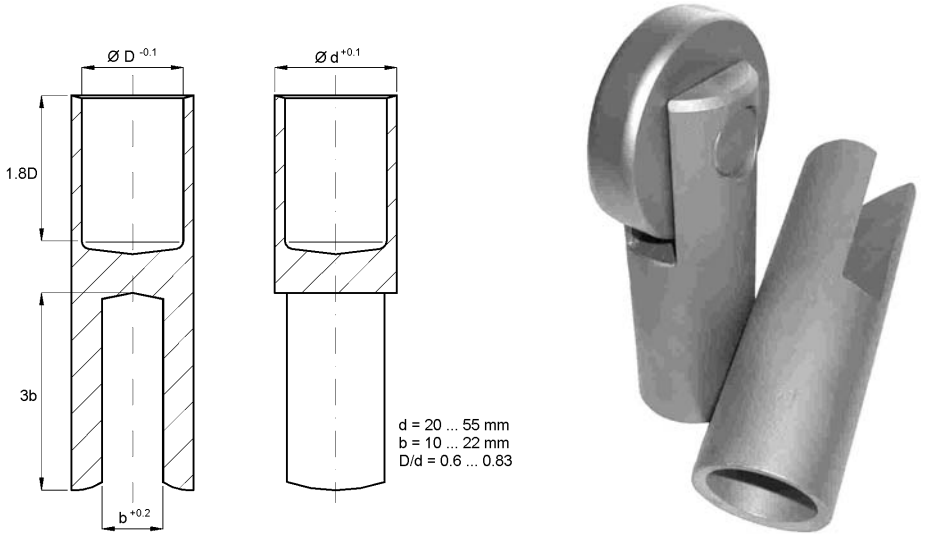

Figure 13 Valve Tappet for Large Diesel Motors: Ranges of Dimensions, Stamping Die, and Finished Part. (Courtesy ZI-Kaltumformung Oberlungwitz, Germany)

Apart from these effects, material cold solidification—caused by the nature of this technology—and continuous fiber orientation resulted in an increase in internal part strength.

3.3.2. Swaging

Swaging is a chipless incremental forming technique characterized by tool segments radially quickly pressing in an opposite direction on the closed-in workpiece. A distinction is made between the feeding method for producing long reduced profiles at relatively flat transition angles and the plunge method for locally reducing the cross-section at steep transition angles (see Figure 15).

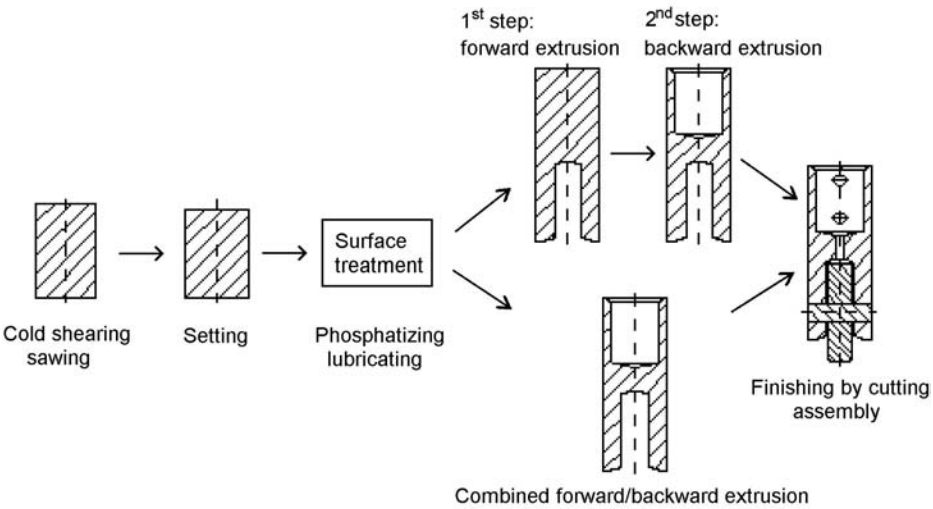

Figure 14 Process Chain to Manufacture Valve Tappets for Large Diesel Motors by Cold Forming. (Courtesy ZI Kaltumformung GmbH, Oberlungwitz, Germany)

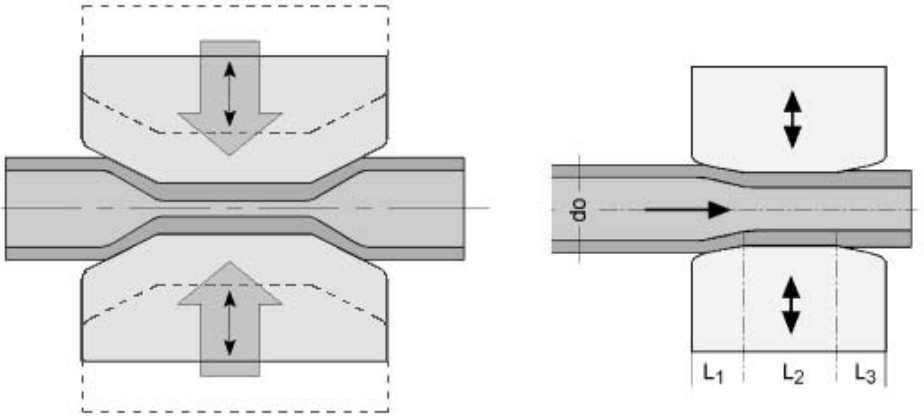

Figure 15 Schematic Diagram of Plunge and Feed Swaging.

A sequence as used in practice, from blank to nns finished part, consisting of six operations is described with the aid of the process chain shown in Figure 16. In the first process step, feed swaging is performed upon a mandrel to realize the required inner contour. The blank is moved in the working direction by oscillating tools. The forming work is executed in the intake taper. The produced cross-

Figure 16 Process Chain Illustrated by Part Stages in Car Transmission Shaft Production. (Courtesy FELSS, Königsbach-Stein, Germany)

section is calibrated in the following cylinder section. Feeding is carried out when the tools are out of contact. In the second stage of operation, the required internal serration is formed by means of a profiled mandrel. The semifinished material having been turned 180° in the third process step, the opposite workpiece flank is formed upon the mandrel by feed swaging. To further diminish the cross-section in the marked section, plunge swaging is following as the fourth process step. This is done by opening and closing the dies in a controlled way superimposed upon the actual tool stroke. The workpiece taper angles are steeper than in feed swaging. The required forming work is performed in both the taper and the cylinder. In the plunge technique, the size of the forming zone is defined by the tools' length. A mandrel shaped as a hexagon is used to realize the target geometry at one workpiece face by plunge swaging (fifth step). In the sixth and final process step, an internal thread is shaped.

The obtainable tolerances to guarantee the nns quality at the outer diameter are basically commensurate with the results achieved on precise machine tools by cutting. Depending on material, workpiece dimensions, and deformation ratio, the tolerances range from ± 0.01 mm to ± 0.1 mm. When the inner diameter is formed upon the mandrel, tolerances of <0.03 mm are obtainable.

The surfaces of swaged workpieces are characterized by very low roughness and a high bearing percentage. As a rule, for plunging, the roughness is usually $R_a < 0.1\mu$m, whereas in feed swaging, R_a is less than 1.0 μm. During plastic deformation, fiber orientation is maintained rather than interrupted as in cutting. Thus, enhanced functionality of the final product is guaranteed.

The material that can be saved and the optimization of weight are additional key issues in this forming procedure. The initial mass necessary for the production of bars and tubes diminishes because the usual cutting procedure is replaced by a procedure that redistributes the material. For an abundance of workpieces, it is even possible to substitute tubes for the bar material, thus reducing the component mass.

In swaging, the material has an almost constant cold work hardening over the entire cross-section. Nevertheless, even at the highest deformation ratios, a residual strain remains that is sufficient for a follow-up forming process.

Swaging rotationally symmetric initial shapes offers the following advantages:

- Short processing time
- High deformation ratios
- Manifold producible shapes
- Material savings
- Favourable fiber orientation
- Smooth surfaces
- Close tolerances
- Environmental friendliness because lubricant film is unnecessary
- Easy automation

Swaging can be applied to almost all metals, even sintered materials, if the corresponding material is sufficiently strained.

3.3.3. Orbital Pressing

Orbital pressing is an incremental forming technique for producing demanding parts that may also have asymmetric geometries. The method is particularly suited to nns processing due to its high achievable dimensional accuracy. The principle design of orbital pressing process chains is illustrated in Figure 17.

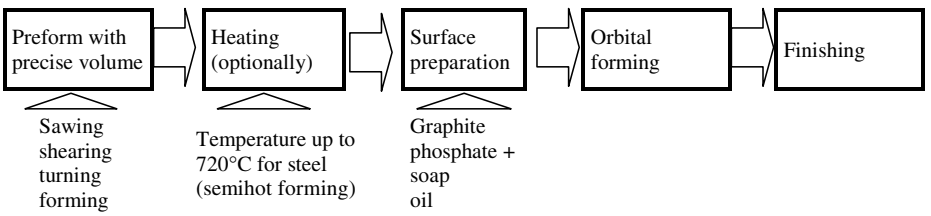

Figure 17 Process Chain for Orbital Pressing.

An accuracy of about IT 12 is typical for the upper die region. In the lower die, an accuracy up to IT 8 is achievable. Parts are reproducible at an accuracy of ± 0.05 mm over their total length. Roughness values of $R_a = 0.3$ μm can be realized at functional surfaces. The accuracies as to size and shape are mainly determined by the preform's volumetric accuracy, whereas the obtainable roughness values depend on die surface and friction.

The advantages of orbital pressing compared to nonincremental forming techniques such as extrusion are a reduced forming force (roughly by factor 10) and higher achievable deformation ratios. As a result of reducing forming forces, the requirements for die dimensioning are lowered at diminished tool costs. Orbital pressing can be economically employed for the production of small to medium part quantities. For lower dies, tool life quantities of 6,000 to 40,000 parts are obtainable. The lifetime is about four times higher for upper dies. Concerning the usual machine forces, orbital presses are usually available at 2,000, 4,000, and 6,300 kN. For special applications, manufacturing facilities up to a pressing force of 1,600,000 kN are also available.

Generally, workpieces of up to 5 kg maximum weight, 250 mm diameter, and 220 mm maximum blank height are formed of steel types with low carbon content and nonferrous metals, such as copper and aluminum alloys.

The example in Figure 18 indicates an extremely high-stressed component of a large diesel motor (part weight 1.1 kg; flange diameter 115 mm; flange height 16 mm; total height 55 mm). With the use of the orbital pressing technique, for this workpiece, the process chain—originally consisting of turning, preforging, sandblasting, and cold coining of the profile—could be reduced to only two steps. Furthermore, the cavity could be formed at a greater depth and at higher accuracy, thus yielding significantly higher load capacity, reliability, and component life. In this example, the part costs were reduced by about 60% due to the application of orbital forging.

3.4. Semihot-formed Near-Net-Shape Components: Examples of Applications

3.4.1. Semihot Extrusion

In the automotive industry, the functional parts in particular are subjected to high-quality requirements. The successful use of semihot extrusion is demonstrated, for example, by the manufacture of triple-recess hollow shafts used in homokinematic joints in the drive system. The complex inner contours of the shaft have to be produced to high accuracy and surface quality. Producing these parts by cutting is not economically viable due to the high losses of material and the high investment volume required, so the inner contour is shaped completely (net shape) by forming. In forming technology, the required inner contour tolerance of ± 0.03 mm can only by achieved by calibrating a preform of already high accuracy at room temperature. However, the material Cf 53, employed due to the necessary induction hardening of the inner contour, is characterized by poor cold formability. For that reason, shaping has to be performed at increased forming temperature but still with a high demand for accuracy. Shaping can be realized by means of a multistep semihot extrusion procedure carried out within a temperature interval between 820°C and 760°C in only one forming step. Semihot extrusion is performed on an automatic transfer press at the required accuracy, at optimum cost and also avoiding scaling. The component is shaped by semihot extrusion starting out from a cylindrical rod section without thermal and chemical pretreatment. The corresponding steps of operation are reducing the peg, upsetting the head, centering the head, and pressing and compacting the cup (see Figures 19 and 20). The advantages most relevant for calculation of profitability in comparing semihot

Figure 18 Basic Body of a Rotocup for Large Diesel Motors. (Courtesy ZI-Kaltumformung Oberlungwitz, Germany)

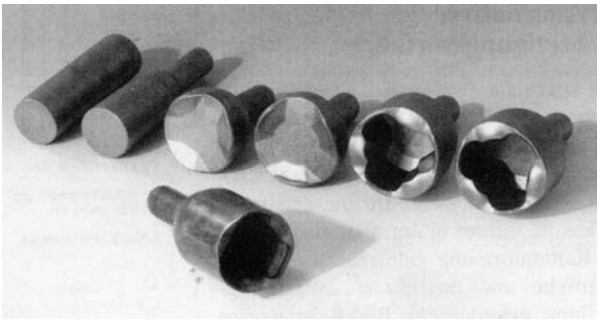

Figure 19 Original Production Stages of a Triple-Recess Hollow Shaft. (Courtesy Schuler Pressen, Göppingen, Germany)

extrusion of shafts to hot extrusion are caused by the low material and energy costs as well as postprocessing and investment expenditures.

3.4.2. Semihot Forging

Forging within the semihot forming temperature interval is usually performed as precision forging in a closed die. With closed upper and lower dies, a punch penetrates into the closed die and pushes the material into the still-free cavity. Bevel gears completely formed, including the gear being ready for installation (net shape process), are a typical example of application. Such straight bevel gears (outer diameter 60 mm or 45 mm and module about 3.5 mm) are employed in the differential gears of car driving systems. For tooth thickness, manufacturing tolerances of ± 0.05 mm have to be maintained. In forming technology, the required tolerance can only be obtained by calibrating the teeth preformed at high accuracy at room temperature. The preform's tooth flank thickness is not to exceed about 0.1 mm compared to the final dimension. The shaping requirements resulting from accuracy, shape complexity, and the solid, alloyed case-hardening steel can only be met by semihot forming. Processing starts with a rod section that is preshaped without the teeth in the first stage (see Figure 21). The upset part is of a truncated cone shape. The actual closed die forging of the teeth is carried out as a semihot operation in the second stage. The bottom (thickness about 8 mm) is pierced in the last semihot stage. The cost efficiency effects of the semihot forming process compared to precision forging carried out at hot temperatures are summarized in Table 4.

Today, differential bevel gears of accuracy classes 8 to 10 are still produced by cutting, despite their large quantity. Low-cost forming technologies perspectively represent the better alternative, even though they require relatively high development costs.

3.5. Hot-formed Near-Net-Shape Components: Examples of Applications

3.5.1. Precision Forging

Which hot-forming technique to select for a given workpiece from a low-cost manufacturing viewpoint depends mainly on the part quantity and the extent to which the forming part is similar to the finished shape. In precision forging, where the forming part can be better approximated to the finished

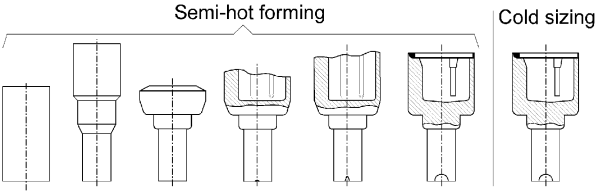

Figure 20 Semihot Forming Process Stages of a Triple-Recess Hollow Shaft. (From Körner and Knödler 1992)

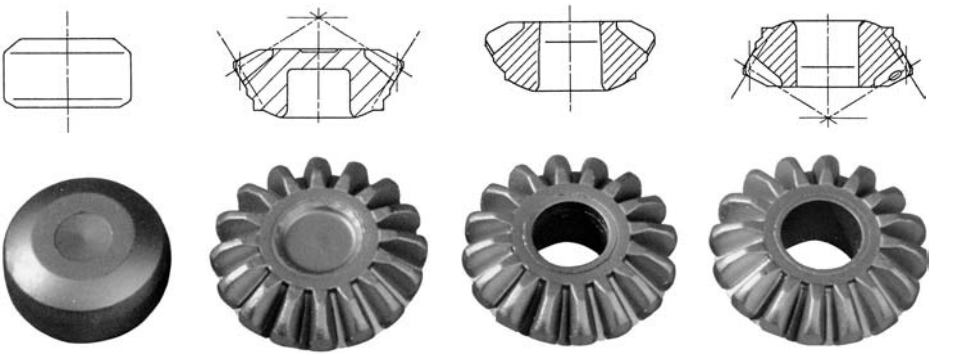

Figure 21 Production Stages of Axle-Drive Bevel Pinions. (From Körner and Knödler 1992)

part, the total cost, including tool and material costs as well as costs for the forming and cutting processes, can be decreased despite increasing blank costs.

The accuracy values obtained are above the die forge standards (e.g. in Germany, DIN 7526, forging quality E). As a goal, one process step in finishing by cutting is to be saved (this means either grinding or finishing is necessary). In forging, some dimensions of importance for the near-net-shape have closer tolerances.

The steering swivel shown in Figure 22 is an example of nns manufacturing using precision forging. The fixing points determining the spatial location are fitted to the dimensions of the finished part by additional hot calibrating.

Forged parts (hot forming) that make the subsequent cutting operation unnecessary or whose accuracy need only be enhanced at certain shape elements of the part (IT9 to IT6) by follow-up cold forming can also be produced by precision forging. Thus, formed components of even cold-pressed parts' accuracy can be made this way. This is especially important if cold forming cannot be realized due to too-high forming forces and tool stresses or too-low formability of the part material. From an economic viewpoint, precision forging is also more advantageous if the surfaces to be generated could otherwise only be produced by relatively expensive cutting techniques.

3.5.2. Hot Extrusion

Field spiders are usually made by die forging with burr and subsequent cold calibrating. High pressing forces are required due to formation of burr. The forged shape is approximated to the final shape only to a minor extent. For that reason, high forces also have to act in cold calibration. A nns manufacturing variant for field spiders consists of combining hot extrusion and cold forming.

TABLE 4 Cost-efficiency: Hot and Semihot-Forged Axle Drive Bevel Pinions in Comparison

	Hot-Forged Bevel Gear	Cost Share	Semihot-Forged Bevel Gear	Cost Share
Material	0.6 kg	16%	0.5 kg	13%
Manufacturing steps	1 Sawing, chamfering	8%	1 Sawing	6%
	2 Heating (with inert gas) Forming	33%	2 Heating (without inert gas) Forming	27%
	3 B-type graphite annealing (with inert gas)	7%	3 Controlled cooling	1%
	4 Cold calibrating	10%	4 Cold calibrating	10%
	5 Turning	17%	5 Turning	11%
Tool wear		9%		9%
Production costs		100%		77%

From Hirschvogel 1997.

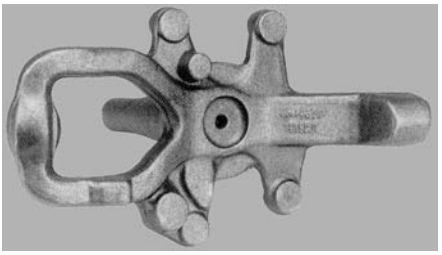

Figure 22 Precision Forging of a Steering Swivel (hot forged, simultaneously deburred, pierced and hot calibrated, weight 8.8 kg, material 41Cr4). (From Adlof 1995)

The process chain is characterized by the following procedural stages:

1. Shearing a rod section of hot-rolled round steel (unalloyed steel with low carbon content) with a mass tolerance of $\pm 1.5\%$
2. Heating in an induction heating device (780°C)
3. Hot extrusion on a 6,300-kN knee press performing the following forming stages (see also Figure 23):
   - Upsetting
   - Cross-extrusion
   - Setting of the pressed arms
   - Clipping
4. Cold forming (see Figure 24):
   - Backward extrusion of the hub
   - Forming of erected arms
   - Piercing of the hub
   - Calibrating.

An automated part-handling and special tool-cooling and lubricating system are installed to keep the forming temperatures and the tribologic conditions exactly according to the requirements for nns processes.

The advantages of hot extrusion/cold calibrating vs. die forging with burr/cold calibrating of field spiders can be summarized as follows:

Figure 23 Hot Extrusion of Field Spiders. (From Körner and Knödler 1992)

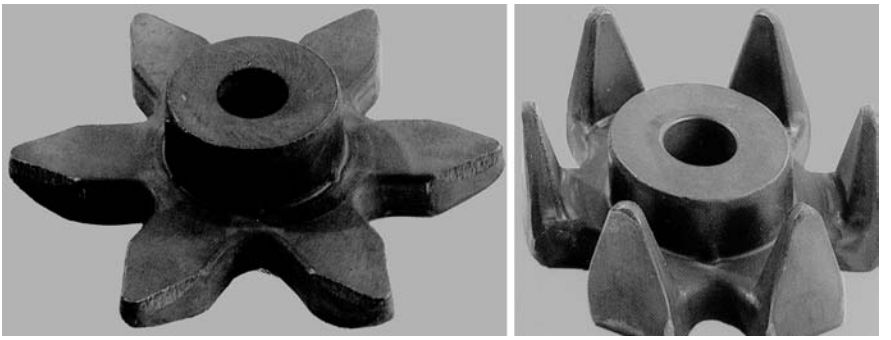

Figure 24 Cold Forming to Enhance Accuracy by Calibrating (applied to field spiders). (From Körner and Knödler 1992)

Hot extrusion:	*Die forging with burr:*
Pressing forces demand a 6,300-kN press	Pressing forces demand a 20,000-kN press
Low heating temperature (780°C)	High heating temperature (1100°C)
Descaling unnecessary	Descaling required
Cold calibrating: at 3,300 kN	Cold calibrating: at 10,000 kN

In calibrating the hot extruded part, forming is required to a lower extent due to better approximation to the final shape. This excludes the danger of cracks in the field spider.

3.5.3. Axial Die Rolling

In axial forging–die rolling, the advantages of die forging and hot rolling are linked. Disk-like parts with or without an internal hole can be manufactured. On the component, surfaces (e.g., clamping surfaces) can be shaped in nns quality, thus enabling later part finishing by cutting in only one clamping. Accuracy values of IT9 to IT11 are obtained because the axial die rolling machines are very stiff and the forming forces relatively low. Furthermore, the desired component shape can be approximated much better because no draft angles are necessary and small radii or sharp-edged contours can be formed. Within the workpiece, a favorable fiber orientation, resulting in reduced distortion after heat treatment, is achieved by burrless forming. The advantages of the nns hot-forming technology using axial die rolling vs. conventional die forging can be shown by a comparison of manufacturing costs of bevel gears for a car gear unit (see Figure 25). Cost reductions up to 22% as well as mass savings up to 35% are achieved by the nns technology.

3.6. Special Technologies: Manufacturing Examples

3.6.1 Thixoforging

Thixoforming processes make use of the favorable thixotropic material behavior in a semiliquid/semi solid state between the solid and liquid temperatures. Within this range, material cohesion, which makes the metal still able to be handled as a solid body and inserted into a die mold, is kept at a liquid rate of 40–60%. This suspension is liquefied under shear stresses during pressing into a die mold. Due to the suspension's high flowability, complex geometries can be filled at very low forces, which represents the main benefit of this technique because part shapes of intricate geometry (thin-walled components) can be produced at low forming forces.

The process stages between thixocasting and thixoforging are different only in their last stage of operation (see Figure 26). With an appropriately produced feedstock material, the strands are cut into billets, heated up quickly, and formed inside a forging or casting tool.

A component made of an aluminum wrought alloy by thixoforging is illustrated in Figure 27. The forging has a very complex geometry but it was reproducible very accurately. The thick-walled component regions as well as parts with essential differences in wall thickness are characterized by a homogeneous structure free of voids.

Industrial experience shows that components with filigree and complex part geometries, unfavorable mass distribution, undercuts, and cross-holes can be produced in one stage of operation in a near-net-shape manner by means of thixoprocesses.

Comparison of thixoforming to die casting shows the following results:

- 20% improvement in cycle times
- About 20% increase in tool life
- Raw material costs still up to 20% higher

The thixoprocesses are regarded as an interesting option for both the forging industries and foundries. With them near-net-shape technology is added to conventional procedures.
