1. INTRODUCTION

The design of workplaces and products continues to migrate from paper to the computer, where analysis accuracy, visualization, and collaboration utilities allow designs to be realized much faster and better than ever before. As the pace of this development accelerates with the increased capabilities of the software design tools, less time is spent on physical prototyping, allowing for shortened time-to-market for new products. Ergonomists, who in the past used the physical prototypes to perform human factors analyses, are now challenged to move the analysis into the virtual domain using new tools and methods. Usability, maintainability, physical ergonomic assessments, psychological perception, and procedural training are some of the human factors issues that might benefit from analysis prior to the first physical incarnation of the design. While this represents a challenge for the ergonomists, it provides an opportunity to effect change in the designs much earlier than was typically possible in the past and to take advantage of the dramatically reduced cost of design alterations in the early design phases. Commercial pressures that leverage the cost benefits offered by complete ''in-tube'' design are driving a rapid development of the available computer technologies. Human simulation technology is no exception. Contemporary human modeling software is assimilating a variety of human modeling knowledge, including population anthropometry descriptions and physical capability models. Companies are deploying these human modeling products to allow their ergonomists and designers to populate digital representations of products and workplaces efficiently with virtual human figures and ask meaningful questions regarding the likely performance of actual people in those environments. Identification of ergonomic design problems early in the design phase allows time-consuming and expensive reworking of the manufacturing process or design to be avoided.

Computerized human modeling itself has been evolving over some time. Perhaps the first attempt to develop a computer-integrated tool for performing reach tasks was performed by Vetter and Ryan for the Boeing Aircraft company in the late 1960s. This effort was referred to as the ''First Man'' program, which later became ''Boeman.'' This software was later expanded by the USAF Aerospace Medical Research Laboratory Crew Systems' Interface Division, which added the ability to simulate a variety of male and female anthropometric dimensions while seated in different types of aircraft, culminating in the software COMBIMAN. In the 1980s, this software was further developed at AMRL to address maintenance tasks, adding performance models of lifting, pulling, and pushing on various tools and objects placed in the hands, and became CrewChief. During this same time in Europe, a wide variety of models were developed, perhaps the most widely known being SAMMIE (System for Aiding Man–Machine Interaction Evaluation), developed by Case, Porter, and Bonney at Nottingham and Loughborough Universities in the United Kingdom. SAMMIE was conceived as a very general model for assessing reach, interference, and sight-line issues within a CAD environment. The details of these developments are described in greater depth elsewhere (e.g., Chaffin 2000; Bubb 1999; Badler 1993). Perhaps as a testament to the rapid development in this field, new human models that are integrated in modern CAD, 3D visualization, and automation simulation products are now the most popular and seeing the most rapid development and deployment. These include Deneb Ergo, EAI Jack, Genicom Safeworks, TecMath Ramsis, and Tecnomatix RobCAD Man.

This chapter reviews the foundation of contemporary human modeling technology for physical ergonomics and presents examples of how digital humans are currently used in industry. The chapter concludes with a discussion of the current development efforts in the area of human modeling.

2. DIGITAL HUMAN FIGURES

2.1. Kinematic Representation

Human models are varied in both their complexity and construction. Any mathematical representation of human structure, physiology, or behavior can be considered to be a human model. For example, complex models of human musculoskeletal dynamics are commonly used to study motor control issues (Winters and Woo 1990). These models are typically quite detailed to allow the dynamic effects of individual muscle activation and contraction, and hypothesized neural control strategies, to be investigated. Moreover, this detail is typically focused on one part of the body, for example the lower extremity for gait analysis, or the upper limbs for investigation of movement control. In contrast, simple, sometimes incomplete, human forms are used in the investigation of cognitive models, wherein the human form acts as an agent to effect changes in its world. The pedagogical agent developed at the University of Southern California Information Sciences Institute (Johnson et al. 2000) is an example. These models focus on the cognitive rather than motor processes and simulate the interactions among multiple humans.

For physical ergonomics investigations in digital environments, the human models need to mirror our structure, shape, and size in sufficient detail to allow the figures to assume realistically the observed postures of actual individuals performing similar tasks. Such models typically consist of an underlying kinematic linkage system that closely parallels our own skeletal structure and an attached geometric shell that duplicates our surface shape.

Today's human models have kinematic linkages that include from 30 to 148 degrees of freedom, depending on the detail provided in the hands, feet, shoulder, and spine. The joints are constructed to move like our own joints, with the appropriate number of degrees of freedom, and typically also have physiological limits on the range of motion. In more detailed models, the shoulder and spine are modeled to behave naturally, with the links moving in concert as the particular segment is manipulated. For example, the shoulder complex consisting of the sternoclavicular, acromioclavicular, and glenohumeral joints is modeled to move in a realistic pattern when the upper arm is adjusted, moving the elevation and fore–aft position of the shoulder as the arm moves through its range of motion.

2.2. Anthropometry

The internal skeletal structure and surface topography of a digital human figure influence both the qualitative and quantitative use of the figures. As an engineering tool, the accuracy of the internal link structure affects the dimensional measures made between the environment and the human figure, such as head clearance and reach. The ability of the figure to take on physiologic surface topography directly adds to the perception of reality when one is viewing a simulation. While both of these aspects are important, to date more effort has been concentrated on the accurate scaling of the link lengths in commercial human modeling. This bias is in part motivated by the large amount of traditional 1D anthropometric data available (e.g., stature, sitting height, shoulder breadth), in contrast to the largely nonexistent 3D surface contour data available. Secondly, a driving factor of human modeling in visualization environments has been to produce a system that works in near real time (Badler et al. 1993). The complexity of the figure surface description presents a burden on the real-time performance, so a balance is sought in which there is sufficient surface detail for visual reality without undue computational load. As computer hardware technology improves, the ability to add to this surface complexity is afforded.

2.2.1. Anthropometric Databases

Of the many anthropometric databases available, one of the most widely used is the U.S. Army 1988 Anthropometric Survey (ANSUR) (Gordon et al. 1988). The ANSUR study was performed by the U.S. military to provide a representative anthropometric database of the U.S. military personnel. This database has a demographic representation that matches the U.S. army, which is known to differ from the gender, racial, age, and conditioning distributions of the population as a whole. Nevertheless, the statistical measures of the ANSUR data have been estimated to be within 3% of the general U.S. civilian population (Roebuck 1995). This study contains 132 standard anthropometric measurements from approximately 9000 military personnel, of which a sample of 1774 men and 2208 females were selected to represent accurately the military population demographics. Documents that contain the individual subject data as well as the summary statistics are publicly available, so publishers of human modeling software can independently develop statistical models for figure scaling and boundary manikin generation.

Another anthropometric database available is the National Health and Nutrition Examination Survey III (NHANES 1994), which contains the dimensions of 33,994 persons ages 2 months and older, of which 17,752 are age 18 and older. While the 21 measures of this database do not provide enough information to define adequately the dimensions of most contemporary human models, the database currently represents the most comprehensive and representative database for the U.S. population. These publicly available data contain weighting information based on the most recent U.S. census (1988–1994). The census weighting data allow U.S. representative population statistics to be computed for any population selections based on gender, race, ethnicity, and age. While both the ANSUR and NHANES data describe single dimension measures taken between anthropometric landmarks, a new anthropometric survey has been initiated to provide a database of population 3D body shapes. The CAESAR project (Civilian American and European Surface Anthropometric Resource) will scan approximately 6000 individuals in the United States and Europe. These data are in the form of both traditional anthropometric measures and new 3D data from whole body laser scanners, that provide a highly detailed data cloud describing the shape of the subject surface contour (Figure 1).

Both children- and nationality-specific anthropometric databases are also available, although these databases have not been adopted to the same degree as those previously mentioned due to their limited international availability and data restrictions (Table 1).

2.2.2. Accommodation Methods

One of the advantages digital ergonomics can bring to the development process is the ability to investigate accommodation issues early in the design process. In the past, physical mockups were created and evaluated using a large subject population to arrive at accommodation metrics. This approach is both expensive and time consuming and does not lend itself to rapid evaluation of design alternatives. In the digital space, a population of figures can be used to investigate many of the same

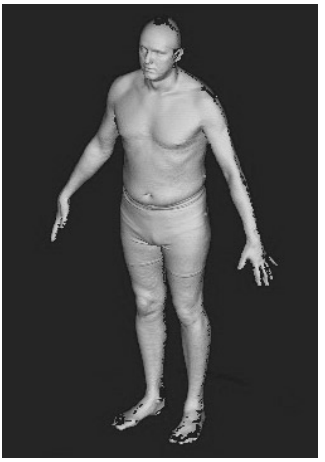

Figure 1 The CAESAR Data are Collected with Laser Body Scanners That Produce a 3D Point Cloud of Surface Topography. These data will allow accurate measures in such applications as accommodation analysis and clothing fit.

issues of clearance, visibility, reach, and comfort. Defining the sizes of the manikins to be used in the process is one of the first steps of these analyses.

To perform an accommodation study, the user defines a percentage of the population that he or she wishes to accommodate in their design or workplace and then scales representative figures using data from applicable anthropometric databases to represent the extreme dimensions of this accommodation range. As few as one measure, often stature, may be judged to be important to the design and used in the creation of the representative figures. For other applications, such as cockpit design, multiple measures, such as head clearance, eye height, shoulder breadth, leg length, and reach length, may all affect the design simultaneously. Several methods are in use to investigate the accommodation status of a design and are described below.

2.2.2.1. Monte Carlo Simulation The Monte Carlo approach randomly samples subjects from an anthropometric database to create a representative sample of the population and processes these figures through the design. Recording the success or failure of the design to accommodate each

TABLE 1 Sample of Recent Anthropometric Databases Used by Contemporary Human Models

Name	Dimensions	N (population and ages)	Survey Year	Availability
ANSUR 88	132	9,000 (U.S. Army)	1987	Summary statistics and individual subject data
NHANES III	21	33,994 (U.S. civilian ages 2 mo to 99 years)	1988–1994	Individual weighted subject data
CPSC Children	87	4,127 (U.S. children ages 2 weeks–18 years)	1975–1977	Summary statistics and individual subject data
CAESAR—3D	44 Traditional and 3D surface	~6,000 (U.S. and European)	Present	Planned: individual 3D landmark locations, summary statistics, 3D point cloud data
HQL—Japan	178	40,000 (Japanese ages 7–99 years)	1992–1994	Summary statistics and portions of individual subject data
KRISS—Korea	84	8,886 (Korean ages 6–50 years)	1992 (1997)	Dimensional statistics with display software

individual of the sample allows an indication of the percentage accommodation to be derived. This method is computationally fairly expensive because it requires that a large number of figures be generated and tested for a meaningful analysis. Also, because the distribution of sizes follows a bell-shaped distribution, many more people are close to the average than to the extremes, which results in many figures of fairly similar dimensions needlessly tested. This can make this approach somewhat inefficient.

2.2.2.2. Boundary Manikins In contrast, the boundary manikin approach can be used for multiple dimensional analysis (Zehner et al. 1993; Bittner et al. 1986). The statistics of principal components (factor analysis) can be used to identify bounding multidimensional ellipsoids that contain a portion of the population. For example a 95% hyperellipsoid can be found that defines the dimensional ranges for all variables of interest within which 95% of the population can be expected. This approach can reduce the number of manikins that need to be tested in a design to a practical number, which is beneficial in cases where the computer rendering speed or the effort to manually posture the figure is significant.

2.2.2.3. Whole-Population Analysis Both the Monte Carlo and boundary manikin approaches attempt to reduce the number of subjects that are run through the analysis while still providing statistical validity to the results. However, as computer technology improves and as models to posture the manikins realistically in the environment become available, it becomes not unreasonable to run several thousand figures through a design automatically. Because this approach does not use statistical models of the data but instead uses the measured data directly, the unexplained variability that is not captured by the statistical data modeling is avoided. This approach still requires substantial run time and is currently not a popular approach to accommodation analysis.

2.3. Human Figure Posturing

As mentioned briefly in the previous anthropometric discussion, figure posturing is a critical component, along with anthropometry, in accommodation studies. While automatic posturing methods based on empirical studies are becoming available and will be discussed in later sections, there are more fundamental lower-level tools that have been developed for general manipulation of figures in the virtual environments. Because contemporary figures may have over 100 DOF, adjustment of each joint angle individually is unworkably tedious.

2.3.1. Coupled Joints

Fortunately, the human skeleton, while infinitely adjustable, is held together by muscles and connective tissues that constrain the movement of certain joints to work as motion complexes. Examples include the shoulder, spine, and hands. While there are obvious freakish exceptions, most people cannot voluntarily dislocate their shoulders or move the carpal bones in the digits independently. Modelers take advantage of these relationships to build movement rules for these joints such that many degrees of freedom can be adjusted easily with a few angles that are defined in common human factors parlance. For example, the EAI Jack human model has 54 DOF in the spine below the neck, which can be manipulated using three standard angle definitions: flexion, extension, and axial rotation. Similarly, as described earlier, the shoulder comprises a clavicle link that moves in concert with the arm as it is manipulated, mimicking the natural kinematics of this joint. Such coupled joint complexes greatly simplify the posturing of high-degree of freedom human figures.

2.3.2. Inverse Kinematics

Even with the substantial reduction in degrees of freedom that coupled joints bring, there are still far too many degrees of freedom remaining in a contemporary figure for rapid posturing in production use. To address this, human modelers have drawn from the robotics field the concept of inverse kinematics (IK) or specifying joint kinematics based on a desired end-effector position. Inverse kinematics operates on a linked chain of segments, for example the torso, shoulder, arm, forearm, and wrist, and, given the location of the distal segment (i.e., hand), solves all of the joint postures along this chain based on some optimization criteria. For human models, these criteria include that the joints do not separate and that the joint angles remain within their physiological range of motion. Using inverse kinematics, the practitioner is able to grab the virtual figure's hand in the 3D visualization environment and manipulate its position in real time while the rest of the figure modifies its posture (i.e., torso, shoulder, arm) to satisfy the requested hand position. While the IK methods can be made to respect the physiologic range of motion limitations inherent to the joints, they tend not to have the sophistication always to select the most likely or physiologically reasonable postures. This is especially problematic when the number of joints in the joint linkage is large. If the number of degrees of freedom is too great, there is unlikely to be just one unique posture that satisfies the specified end-effector position. For specific cases, this is being addressed with empirical-based posturing models, which are discussed in greater detail below. However, even with the caveat that IK

sometimes selects inappropriate postural solutions, it is currently the most popular and rapid method of general postural manipulation in 3D environments.

2.4. Motion/Animation

While static posturing is often sufficient to analyze many ergonomic issues, such as reach, vision, clearance, and joint loading, often figure motion in the form of an animation is important. Examples include simulated training material, managerial presentations, and analyses that depend on observations of a person performing an entire task cycle, for example when assessing the efficiency a workplace layout. Realistically controlling figure motion is without question one of the most challenging aspects of human modeling. Humans are capable of an almost infinite number of different movements to accomplish the same task. Indeed, people may use several postural approaches during a single task, for example to get better leverage on a tool or gain a different vantage point for a complex assembly. This incredible postural flexibility makes it very difficult for human modeling software to predict which motions a worker will use to perform a task. Most current animation systems circumvent this dilemma by requiring the user to specify the key postures of the figure during the task. The software then transitions between these postures, driving the joint angles to change over time such that motions conform to correct times. A variety of mechanisms are used to perform the posture transitions, from predefined motion rules to inverse kinematics. Depending on the system, the level of control given to the user to define and edit the postures also varies, with some products making more assumptions than others. While built-in rules offer utility to the novice user, the inflexibility imposed by the system automatically selecting task postures can be restrictive and a source of frustration to the advanced user. In addition, the level of fidelity required in the motion varies greatly depending on the application. For applications such as the validation of a factory layout or animation of a procedure for training or communication purposes, a human motion simulation that simply looks reasonable may be sufficient. However, if sophisticated biomechanical analyses are to be run on the simulated motion, it may be necessary to generate motions that are not only visually reasonable but also obey physiologic rules. These include accurate joint velocities and accelerations, realistic positioning of the center of mass relative to the feet, and accurate specification of externally applied forces.

3. HUMAN PERFORMANCE MODELS

Human capability analysis is one of the primary motivations for simulation. Commercial modelers have implemented performance models from the academic literature into their software, taking advantage of the human figure sophistication and real-time visualization technologies. A review of the commonly available performance models reveals that independent research groups largely developed them. The development diversity is reflected in the variety of inputs that these tools require in order to provide an ergonomic assessment. This represents a challenge to the modelers as they work to seamlessly integrate these assessment tools into their animation and simulation offerings. Some tools lend themselves well to integration, such as those that can capture all required information from posture, figure, and load mass characteristics. Typically these are the tools that have as their foundation biomechanical models from which the inputs are derived. Others, which were originally intended to be used with a checklist approach, are more challenging in that they often require complex questions to be answered that are straightforward for a trained ergonomist but quite complex for a computer simulation system (Table 2).

Most often, simulation engineers expect to ask human performance questions of their simulation without having to redescribe the simulation in the language of the tool. Thus, ideally, the tools are implemented such that they can derive all the necessary information from the simulation directly. Less ideally, the engineer performing the assessment must explicitly identify details of the simulation using tool specific descriptors.

3.1. Strength

Strength assessments are a typical human performance analysis, regardless of whether the application involves manual handling tasks, serviceability investigations, or product operation. Questions of strength can be posed in a variety of ways. Designers may want to know the maximum operating force for a lever, dial, or wheel such that their target demographic will have the strength to operate it. Or the engineer may create a job design and might ask what percentage of the population would be expected to have the strength to perform the required tasks of the job. Strength data might also be used to posture virtual human figures by using an algorithm that optimally adjusts the individual joints of the manikin to produce most effectively the required forces for a task.

A large amount of strength data has been collected over the past quarter century. Most of these have been in the form of maximal voluntary exertions (MVEs) of large muscle groups. Subjects are placed in special strength testing devices (e.g., strength chairs) to isolate individual muscle groups, and standard methods controlling for repeatability and duration of effort are then used to capture the

TABLE 2 Partial List of Performance Tools Available in High-End Human Simulation Tools[a]

Performance Model	Data Source	Input Parameters	Integration Issues
NIOSH lifting equation	Waters et al. 1993	Posture and lift begin and end, object weight, hand coupling	Must determine start and end of lift. Must identify hand coupling
Low-back injury risk assessment	See Chaffin et al. 1999	Joint torques, postures	Suitable
Strength assessment	University of Michigan static strength equations	Body posture, hand loads	Suitable
	Burandt 1978 and Schultetus 1987	Body posture, hand loads	Table lookup
	Ciriello and Snook 1991	Task description, hand coupling, gender	Table lookup
	CrewChief	Gender, body size, posture, task condition	Suitable
Fatigue analysis	Rohmert 1973a, b; Laurig 1973	Joint torques, strength equations	Suitable
Metabolic energy expenditure	Garg et al. 1978	Task descriptions, gender, load description	Must identify the type of task motion (i.e., lift, carry, arm work, etc.).
Rapid upper limb assessment	McAtamney and Corlett 1993	Posture assessment, muscle use, force description	Must identify muscle use and force descriptions.
Ovako working posture	Karhu et al. 1977	Posture assessment	Suitable
Comfort	Variety of sources, including Dreyfuss 1993; Rebiffé 1966; Krist 1994	Posture assessment	Suitable

[a]The tools require different types of input that often cannot be accurately deduced from an animation sequence, requiring tool specific user input.

strength levels accurately. Strength can also be assessed while taking into account a subject's perception of the effort. These data, in which subjects' impression of the load strain is included, are called psychophysical strength data. They differ from the maximal voluntary exertions in that they are more task specific. Subjects are asked to identify the load amount they would be comfortable working with over the duration of a work shift. Typically, these are laboratory studies in which mockups of tasks very close to the actual work conditions are created and subjects are given an object to manipulate to which weight can be added. The worker has no knowledge of the weight amount (bags of lead shot in false bottoms are often used), and experimental techniques are employed to converge on the weight that the subject feels comfortable manipulating over the course of a workday. The data of Ciriello and Snook (1991) are of this nature. Finally, a few dynamic strength data have been collected. These data are complex to collect and for this reason are also the most scarce. Specific dynamic strength-testing equipment is required to control for the many variables that affect dynamic strength, including the movement velocity and posture. As a consequence of the data-collection limitations, these data are also quite restricted in terms of the range of conditions in which they can be applied, such as the prediction of dynamic strength capability for ratchet wrench push and pull operations (Pandya et al. 1992). Lately, the rise of cumulative trauma injuries for the lower arm, wrist, and hand has created a need for strength data specifically pertaining to the hand and fingers and estimates of hand fatigue. A extensive amount of data is available on grip strengths in various grip postures, but these data, because they do not adequately describe the distribution of exertion loads on the individual digits, do not lend themselves well to the estimation of hand fatigue issues. This problem is compounded by the challenge of accurately posturing the hands in digital models. There are many bones and joints that allow the complex movement of the fingers, most of which are included in contemporary human models. For example, the Jack human model has a total of 69 segments and 135 DOF, of which 32 segments and 40 DOF are in the hands alone. While a solution to the manipulation of these many degrees of freedom is presented in the section describing motion-tracking technologies, models that are able to analyze the postures and gripping conditions are still needed before hand fatigue issues can be addressed.

Whole body strength data in contemporary human models are available in a range of forms, from simple data lookup tables to statistical equations that are used in conjunction with biomechanical models to drive a measure of population strength capability. In the United States, perhaps the most widely used strength data are from the University of Michigan Center for Ergonomics (3DSSPP) and Liberty Mutual Insurance Co. (Ciriello and Snook 1991). Within the defense industry, the CrewChief strength data are also popular because the modeled strengths were obtained from military-related maintenance tasks. In Europe, particularly Germany, the data of Burandt and Schultetus are often used. As mentioned previously, a few of these data were obtained without the intent to incorporate them into human models. Instead, the data are presented in tables indexed by such factors as loading condition and gender. Those data that were collected and described with a focus toward eventual human model inclusion tend to be formulated such that all relevant information needed for a strength assessment can be deduced from the human model mass, loading, and posture information. These strength models now are very attractive to the human modeling community because they afford the real-time assessment of strength issues during a simulation without the user having to identify data-specific parameters or conditions (Table 2).

As discussed above, the availability of dynamic strength data is limited. The narrow scope of applications to which these data can be applied restricts their attractiveness to human modelers and the user community. An interesting associated note regarding these dynamic data and human models is that even if these data were more complete, the difficulty in accurately determining movement velocities from simulations would affect their use. Unless the virtual human motions are defined via motion-capture technology, the designer's guess of the movement speeds is fraught with error. Even under conditions in which actual motion capture data are used to animate the virtual figures, the velocities are derived by differentiation of the position information, which can result in noisy and unreliable input to the dynamic strength predictors. However, because people undeniably move during work and dynamic strength capability can differ greatly from static, this is clearly an area that will likely see research and technological attention in the near future.

3.2. Fatigue/Metabolic Energy Requirements

Once a simulation of a virtual human performing a task has been created, questions regarding the fatigue of the worker are commonplace. Can the worker be expected to perform at this cycle rate, or do we have to decrease the line rate or otherwise reengineer the task to avoid worker fatigue? Research suggests that whole-body fatigue increases the risk of musculoskeletal injury through premature decrease in strength. Unfortunately, the available empirical data are largely inadequate to predict a worker's fatigue level accurately. The lack of data can be explained by the large number of variables that affect fatigue, including exertion level, dynamism of the exertion, muscle temperature, previous exertion levels, the muscle groups involved, and individual conditioning. Nevertheless,

two approaches are currently in modeling practice to provide at least some level of quantitative fatigue assessment for a work task. The strongest of these from a data perspective is the use of empirical metabolic energy prediction equations, in particular the equations published by Garg et al. (1978). These equations model a series of typical industrial materials-handling motions, such as walking, lifting, carrying, reaching, and arm work. Based on motion-specific parameters and load amount, the mathematical models provide an estimate of the energy consumption in kcal/min. These data were validated on a broad range of manual handling activities and were shown to predict actual energy-consumption rates well. The energy-consumption rate can be compared with accepted standards for exertion levels, such as the NIOSH 1991 recommended limits. The guideline put forth in the development of the NIOSH 1991 lifting equation recommends a limit of 33% of the maximum aerobic capacity of 9.5 kcal/min for healthy individuals performing whole body lifts over an eight-hour day (3.1 kcal/min). For work that involves mostly the arms, NIOSH recommends a reduction of 30% from this level or approximately 2.1 kcal/min (Waters et al. 1993). If the simulated task is found to require a higher energy-consumption rate than the recommended limit, it is assumed that the task is fatiguing and must be modified.

One of the challenges for modelers in using these energy-expenditure models is in the ability to deduce automatically which equations apply to the particular motion under simulation and then to provide the appropriate equation parameters. Some models include these data as a separate tool wherein the user explicitly defines the simulation in terms of the motion sets defined and modeled by Garg et al. A criticism of the approach regardless of implementation is that the granularity of the analysis is large, making it difficult to identify the particular body area that is fatigued, and that the data do not provide information on a broad enough range of activities.

In contrast to this approach, a variety of endurance equations may be used to estimate the amount of time static exertions can be held (see Van Dieën and Vrielink 1994). These equations describe the amount of time subjects can perform static exertions at various levels of effort relative to their maximum capability. Relevant to industrial work, some of these include the effects of interspersed rest periods (Sjogaard et al. 1988). Equations to describe the amount of time required to recover from these exertions were published by Rohmert (1973a, b) and Laurig (1973). If the estimated amount of time needed to recover from an exertion exceeds the amount of time available during a job cycle, then fatigue is assumed to accumulate. The endurance relations are applied to each body area separately, requiring an estimate of exertion level, or percentage of maximum capability, at these areas. While the original subjects were strength tested to derive their strength capability, these data are not available for workers in general and an estimate of strength capability must be used. One solution is to use biomechanically based strength models. A task simulation is analyzed with regard to the postures adopted by the virtual worker, and an estimate is given to the amount of time the worker spends in each of the postural conditions. The level of exertion required is estimated utilizing the strength equations, and this information is input to the endurance equations to provide the recovery time estimate.

While the methodologies for using these endurance data within the modeling tools have been implemented and are in use, the endurance data themselves are limited, as mentioned earlier. Gender and age effects are not taken into account, nor are most of the multitude of other factors that influence fatigue. Only the exertion level under static conditions is considered. However, the need to predict quantitative assessments of worker fatigue in simulations is high enough that users of human models look for ways to obtain a metric of fatigue, working around the limitations of the foundation data. Toward this end, joint use of the energy expenditure equations, endurance equations, and stress analysis using the strength tools will currently provide the best estimate of the task injury potential from fatigue.

3.3. Low-Back Injury Risk

Low-back injury is estimated to cost the U.S. industry tens of billions annually through compensation claims, lost workdays, reduced productivity, and retraining needs (NIOSH 1997; Cats-Baril and Frymoyer 1991; Frymoyer et al. 1983). Approximately 33% of all workers' compensation costs are for musculoskeletal disorders. Experience has shown that these injuries can be avoided with the proper ergonomic intervention. Biomechanical models available can be used for job analysis either proactively, during the design phase, or reactively in response to injury incidence, to help identify the injurious situations. The most common types of injury-assessment analyses performed using human models include low-back compression force analysis and strength analysis.

Low-back pain has been well researched over the past 20 years, including epidemiological studies that have identified spinal compression force as one of the significant predictors of low-back injury. In response, sophisticated biomechanical models have been developed to estimate this compression force accurately, taking into account not only the weight of the object and the body segments but also internal forces generated by the musculature and connective tissues as they balance the external loads (e.g., Nussbaum et al. 1997; Raschke et al. 1996; Van Dieën 1997). These internal contributions

to the spinal forces can be an order of magnitude larger than the applied loads. NIOSH has recommended guidelines against which the predicted compression forces can be compared and job-design decisions can be made.

3.4. Comfort

Assessment of worker comfort using digital models can be based on both posture and performance model analysis. However, since comfort is influenced by a wide variety of interacting factors, these tools are largely insufficient to quantify the perception of comfort with accuracy. Most comfort studies performed to date have been centered around a specific task, such as VDT operation or vehicle driving (Rebiffé 1966; Grandjean 1980; Porter and Gyi 1998; Krist 1994; Dreyfuss 1993). Within the boundaries of these tasks, subjects are observed in different postures and asked to report on their comfort via a questionnaire. The joint angles are measured and correlated with the comfort rating to arrive at a postural comfort metric. Because these data are mostly collected under specific, often seated, task conditions, some caution is required to apply these to the analysis of comfort in standing postures such as materials-handling operations. In addition to the posture-based comfort assessment, a variety of the performance tools can be used to help with the assessment of comfort, including strength capability, fatigue, and posture duration information. Certainly the multifactorial nature of the comfort assessment makes it challenging, and perhaps for this reason it is seldomly used in the analysis of physical tasks.

3.5. Motion Timing

A typical simulation question regards the estimated time it will require a person to perform a task. Digital human models can draw on a wealth of predetermined time data available. Motion-timing data are collected in studies where elemental motions (walk, turn, reach, grasp, etc.) are observed performed by skilled operators in the workplace, and timed using a stopwatch. The motion time data are then published in an easily indexed form with associated movement codes. The best known of these is the methods time measurement (MTM-1) system published by the MTM Association. This system has the advantage that it has a large number of elemental motions defined, allowing for a precise partitioning of the work motions within a job task and subsequent accurate assessment of the movement time. One drawback of this high resolution is that considerable overhead is required to break the motion into the elemental movements. To address this, the MTM association as well as other groups have published grosser movement times, which combine several elemental movements into one. Several of the human modeling solutions now provide simulation solutions that can define movement duration with input from these movement time systems.

4. ERGONOMIC ANALYSIS IN DIGITAL ENVIRONMENTS

The large cost of worker injury, in both social and economic terms, has motivated considerable research in the development of models that predict potentially injurious situations in the workplace. According to the Bureau of Labor Statistics (1999), 4 out of 10 injuries and illnesses resulting in time away from work in 1997 were sprains or strains. In the following sections, the key steps in a human modelings based ergonomic assessment are outlined.

4.1. Workplace Analysis

4.1.1. Setting up the Workplace Environment

The first step to using the human simulation technology typically involves the construction of the work area to be analyzed. While pressures for integration of the CAD, process simulation, and human modeling solutions is paramount in the marketplace, at present the geometry data are mostly created in an external piece of software to the human simulation tool. This work cell layout, part and tooling geometry is mostly imported to the human modeling software from these external systems via standard file formats (e.g., IGES, VRML, STL). If the digital form of these data is not available, as may be the case in an analysis of an older existing workplace, primitive geometry-creation tools available in the human simulation environment can be used to mock up the critical parts.

4.1.2. Identify Test Population Anthropometry

Most companies have design criteria that define the percentage of the population that must be accommodated by their product and manufacturing designs. For example, all individuals ranging from a small female (5% in stature) to a large male (95% in stature) might be prescribed. Often only the extremes are tested, but a more comprehensive practice includes a figure with average-sized proportions as well because it may help to identify unexpected stature-dependent postural effects. Under more complex types of analyses that may include other ergonomic factors such as reach, the range of anthropometric dimensions comprising the digital figures (known as a cadre family) can be selected

through sophisticated multidimensional statistical methods such as the principle component analysis (PCA) mentioned earlier. The added anthropometric ranges of the figure dimensions will help to test for the effects of multiple criteria (e.g., low-back compression and reach) concurrently.

4.1.3. Accurately Posture (or Animate) the Figures at the Workplace

Research has demonstrated that the biomechanical models that predict injury risk are quite sensitive to posture (Chaffin and Erig 1991). This makes it important to pose the digital figures such that they realistically represent the actual postures or movements required by a worker. If the workplace under analysis exists, still photography or video recordings of the workers performing these tasks can be used to guide the engineer to pose the digital figures accurately. Conversely, if the workplace is still under design, the engineer may have to draw on his or her human movement intuition, or perhaps even virtual reality body tracking methods (described in Section 5), to posture the figures realistically. However, new research efforts that are expected to provide posture-prediction methodologies to aid designers with this process are underway. Currently the posturing task is left largely as the responsibility of the simulation engineer.

Depending on the human performance tool, the postural information required for an assessment may require a static posture at an instance in time, or multiple key postures at different times in the task. For example, the NIOSH lifting guide (NIOSH 1991) requires starting and ending postures of a lift to arrive at an assessment of the lift conditions. In contrast, analysis tools based on biomechanical models, such as low-back injury risk-assessment tools, can analyze loading conditions continuously for each posture throughout the simulation.

Once the geometry has been populated with the correct humans and these have been postured or animated to reflect the task, the host of ergonomic assessment tools discussed in Section 3 can be applied.

A typical manufacturing analysis includes the investigation of design for assembly and service, in which the question is asked whether the task can be performed. Can the person reach into the opening while holding the part and assemble the pieces? Can the object be reached by short and tall workers? Is there sufficient clearance for the part and the hands? Can the worker have an unobstructed view of the assembly so that it can be performed accurately? Will the worker have sufficient strength to perform the assembly task, or will it require potentially injurious exertions?

4.1.4. Service Analysis

The application of human models to the analysis of maintenance and service operations is one of the original targets of 3D human modeling. Particularly in the military and aerospace industry, the issues surrounding rapid serviceability motivated the development and use of this technology. One specific modern example can be found in the serviceability analysis of aircraft engines in the commercial airline industry, where the very dense nature of the engine packaging and the economics of service downtime make questions of how parts can be extracted for maintenance critical. These questions must be asked while the engine is still under design in CAD to avoid expensive reworks later on. Very complex software has been created to find collision-free extraction paths for virtual parts, both as validation that the part can be extracted from the surroundings and to provide training for maintenance personnel on how to perform the extraction operation. Unfortunately, these methodologies to date have not included the human, so the challenge posed to the human modeling publishers is to determine whether the part can actually be held, and extracted, with sufficient clearance for the part, fingers, and arm. Depending on the complexity of the environment, this is an incredibly difficult problem to solve without user input, and to date no solution is available that finds a solution in a reasonable amount of time. To address this, human models can be used in conjunction with immersive technologies in which the design engineer moves the virtual part in the environment with an avatar (virtual human) representing their arm and hand in the scene (see Section 5). Collision-detection capabilities of the human modeling software are used to identify if a free path can be found. This technology is now being evaluated to identify serviceability issues prior to the first physical build, and also to provide task timing estimates (cost) of performing a particular service operation (Figure 2).

4.2. Product Design

The availability of human modeling technology during the product-design phase expands the range of analyses that can be performed prior to a physical prototype construction. In the past, SAE recommended practices, or "J-standards," were among the limited tools available for benchmarking and design. These tools, derived from empirical studies of people in vehicles, provide population response models that describe such functional information as reach, eye location, and head clearance. However, these data are presented as statistical summaries of the population response, which do not maintain information on the response of any particular individual. The SAE eye-ellipse zone, for example, provides an ellipsoid that defines a region where the eye locations of a specific portion of the

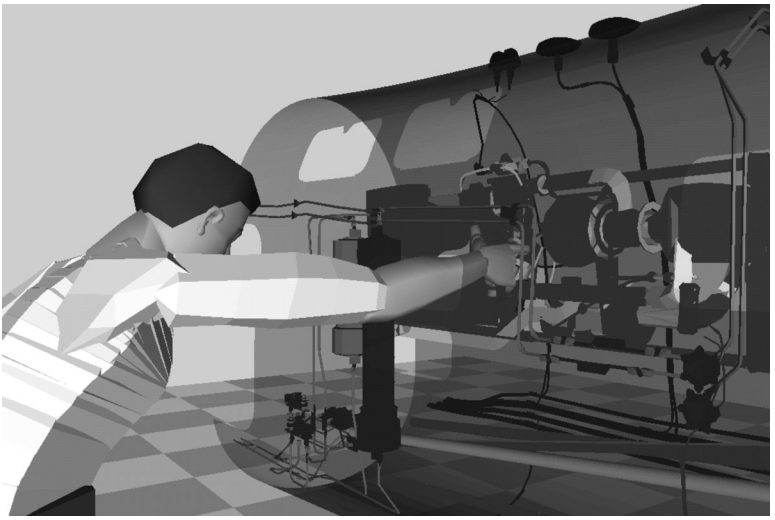

Figure 2 Serviceability Analysis of a Design Can Be Performed Prior to a Prototype Build. Here the Jack human figure is used to analyze the maintenance access to an electrical box inside of the aircraft nose cone. Eye views and collision detection can help the designer during the evaluation process. (*Courtesy EMBRAER*)

population can be expected. The specific location where a small or tall person's eyes might fall within this distribution is not defined (Figure 3). For this reason, when the behavior of a specifically sized individual or group is required, such as when a design is targeted to a specific demographic, human modeling tools can be used to answer these questions.

4.2.1. Accommodation

Once a design proposal is in place, accommodation questions can be posed. The process generally mirrors that for workplace analysis, with a few modifications.

4.2.2. Definition of the Test Population Anthropometry

Most often the accommodation needs for product design are more involved than during manufacturing ergonomic analysis because more anthropometric dimensions typically need to be taken into account. For example, the product design may have to accommodate individuals with a variety of sitting eye heights, shoulder breadths, and arm lengths. As mentioned in the sections describing anthropometric methods, statistical methods such as factor analysis (principal components) can be used to select a family of figures or boundary manikins that will adequately test the range of these multiple dimensions.

4.2.2.1. Figure Posturing Posturing a figure within the digital environment can impact the design analysis dramatically. As evidence of the importance of this issue, various posture-prediction methodologies have been developed in different industries. Pioneering work at Boeing led to a posture prediction method for the aerospace industry (Ryan and Springer 1969). In the late 1980s, a consortium of German automotive manufactures and seat suppliers sponsored the development of driver posture-prediction methodologies for the RAMSIS CAD manikin (Seidl 1993). Most recently, a global automotive industrial consortium sponsored new and more comprehensive methodologies to predict the postures of drivers and passengers through the ASPECT program (Reed 1998). These latest methods have been made available to modelers for inclusion in their software, allowing for sophisticated accommodation studies in automotive environments. Data for posture prediction in heavy truck and earth-moving equipment environments are still needed.

The boundary manikins are postured in the environment and tested for clearance, reach, vision, and comfort issues. Measurements from these boundary manikins can be used to establish design zones with which product design decisions can be made. A common technique for considering reachability, for example, is to generate zones representing the space where the boundary manikins

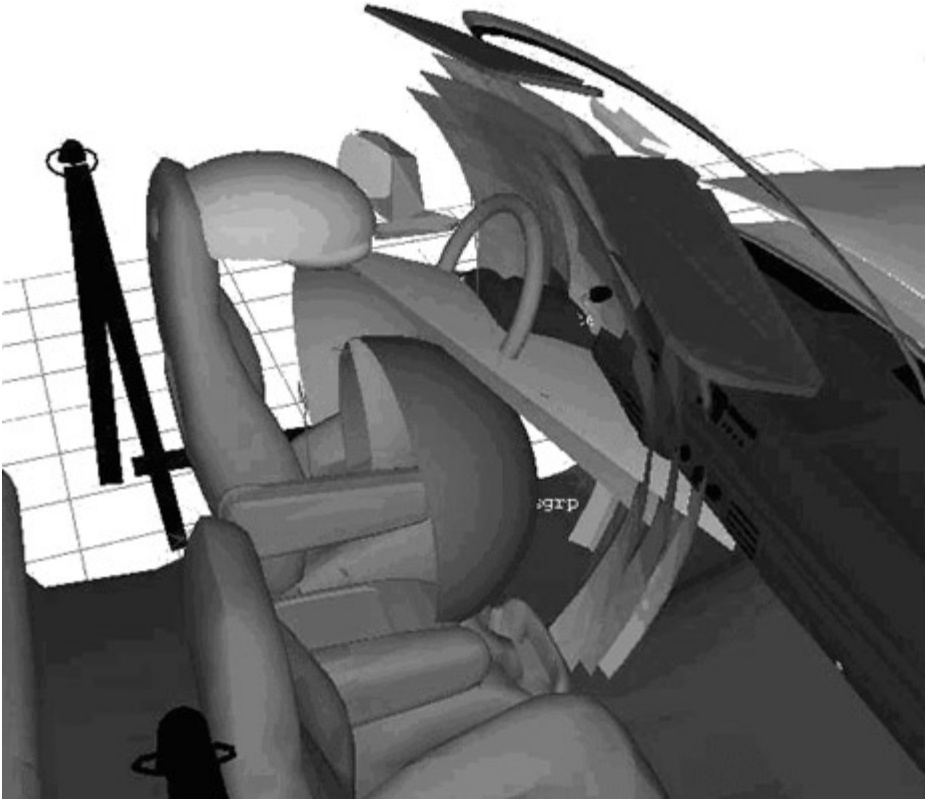

Figure 3 The SAE-J Standards Are Used Worldwide in Benchmarking and Design. The statistical summary descriptions describe posturing and functional information for a predefined population of male and female drivers. Design questions regarding a specifically sized individual cannot be asked using these zones but are suited for human simulation (see text).

can reach under different circumstances. Such reach zones can be used to make design decisions about where controls should or shouldn't be placed. An alternative approach to the sequential test of boundary manikins involves the simultaneous display of important landmark data in the form of data clouds (Figure 4). With this technique, the 3D locations of landmarks are collected either from actual subjects sitting in a mockup or from digital boundary manikins in the electronic environment. The complete set of landmarks from all the test figures is subsequently displayed as a data cloud and used in the design process. This technique provides a concise view of the population anthropometric variability, making it well suited to guide control placement and adjustment range analyses.

4.2.2. Usability

Usability can be considered part of the accommodation process. Traditionally, accommodation considered mostly the analysis of fit, and not necessarily the functional aspects of operating the product. With digital human models, this boundary is rapidly disappearing as anthropometric accommodation, vision, performance models, reach, and movement can all be analyzed using the same tool. Traditional methods such as the SAE J-standards are based on static symmetric zones for analysis, but designers are increasingly interested in taking advantage of the increased functionality modern human models provide. For automotive analyses, these more involved analyses include investigations of reach under various constraint conditions, vision coverage using mirror views, vision obscuration during head check procedures, psychological effects of roominess, obscuration, and collision. Research into natural human motion prediction provides guidelines on layout to accommodate maximally the natural motion of the operator.

Figure 4 The Anthropometric Landmark Data from Multiple Subjects Is Displayed in the Form of Data Clouds. The simultaneous view of the data allows for rapid assessment of control location and adjustment questions. (*Courtesy Dr. Jerry Duncan, John Deere Corporation*)

5. IMMERSIVE VIRTUAL REALITY

Many of the predictive technologies available for human modeling currently do not adequately answer the questions designers pose to their human modeling solutions. This limitation is especially pronounced in the areas of natural complex motion simulation and cognitive perception. As mentioned in previous sections, a designer might ask how a person will move to perform an operation, or ask if there is sufficient clearance for a person to grasp a part within the confines of surrounding parts. Situations that require nontypical, complex motions currently cannot be answered adequately with the movement prediction algorithms available. Only through the use of immersive virtual reality technology that allows the mapping of a designer's movements to an avatar in the virtual scene can these complex movement situations be adequately and efficiently analyzed. Similarly, cognitive models providing subjective perceptions of an environment, such as feelings of spaciousness, control, and safety, are not currently available, yet a designer looking through the eyes of a digital human can assess these emotions of the virtual environment under design. For these reasons, immersive virtual reality (VR) is increasingly being used in both design, and manufacturing applications. Early in a design cycle when only CAD models are available, VR can allow the design to be experienced by designers, managers, or even potential users. Such application allows problems to be identified earlier in the design cycle and can reduce the need for physical prototypes. Immersive VR usually includes a combination of motion tracking and stereo display to give the user the impression of being immersed in a 3D computer environment. Auditory and, increasingly, haptic technology are also available to add realism to the user's perspective.

Virtual reality does not necessarily require a digital human model. Simply tracking a subject's head motion is sufficient to allow the stereo view to reflect the subject's view accurately and thus provide the user with a sense of being present in the computerized world. However, the addition of a full human model, tracking the subject's body and limb movements in real time, allows for additional realism because the user can see a representation of themselves in the scene. Additional analysis is also possible with full-body motion tracking. For example, collisions between limbs and the objects in the scene can be detected so that reach and fit can be better assessed. This capability is especially useful in design for maintainability or design for assembly applications. Another area where the full body tracking can be useful is for a designer to gain experience in interacting with the design from the perspective of a very short or very tall person. By scaling the environment in proportion to the increase or decrease in anthropometric size he or she wishes to experience, the designer can evaluate such issues as clearance, visibility, and reachability of extreme-sized individuals without actually having to recruit a subject pool of these people. Real-time application of the tracked motions to the virtual human also gives observers a realistic third-person view of the human motion in relation to the design geometry.

In addition to the qualitative assessments provided by the engineer's subjective perceptions of interacting with the design, quantitative assessments are possible. Analysis tools, such as those described in Section 3, can often be run in real time while immersed. For example, an engineer can perform a virtual operation using virtual tools, while in real time the performance tools evaluate the postures, forces, and motions to derive performance metrics such as population strength capability, low-back strain, fatigue, or postural affects. The designer gets immediate feedback as to the specific actions that are likely to put the worker at an elevated risk of injury without exposing the test subject to unsafe loading conditions. The design surrounding these actions can then be assessed and modified to reduce the injury risk, all while in the digital design space. Alternatively, motions can be captured and then played back for human performance analysis or presentation purposes.

Such quantitative analyses may be performed in the context of a full immersive VR application or may simply make use of the same human motion-tracking and capture technology to assist in the generation of accurate human postures. For example, a dataglove with posture-sensing electronics incorporated can be a valuable tool with which to obtain accurate hand postures while avoiding the tedium of trying of manipulate each individual finger joint irrespective of the actual application.

5.1. Motion-Tracking Technologies

A number of technologies are available for tracking human motions, including piezioelectric strain gages, magnetic and optical. Such human motion-tracking technologies have long been used for scientific and clinical applications (e.g., Chao 1978; Davis et al. 1991). In recent years, real-time forms of these technologies have become feasible and made VR possible. In addition to VR applications, such real-time technologies have found application in the entertainment industry, enabling quick generation of realistic human movements for computer games, 3D animation, and movie special effects.

Data gloves, such as Virtual Technology, Inc.'s Cyberglove (www.virtex.com), and other such devices measure relative motion between two body segments using either fiberoptic or strain gage-based technologies. The location of the segment in space is not reported. This limitation has ramifications for how these devices are used in human models. For example, the data gloves can measure the amount of finger flexion and splay, yet these gloves do not provide information about where the hand is located relative to the body or in the scene. For this reason, they cannot be used in isolation in such applications as maintenance part extraction, where the orientation and position of the hand is equally as important as the hand posture. This global positioning information can however be captured using whole-body-tracking technologies.

Both magnetic and optical motion-tracking devices are used to capture the global spatial position of the body in space. Magnetic systems are composed of a transmitter that emits an electric field and sensors that can detect their position and orientation (six DOF) in this field. The magnetic sensors are attached to body segments (e.g., the hand, forearm, arm, torso) to determine the relative positions of adjacent body segments. These data are then used to animate a digital human figure. Magnetic systems until recently were the only systems that could track multiple segments in real time and thus are very popular for immersive applications. However, metallic objects in the environment can affect the magnetic fields emitted by these systems. The field distortion caused by metal in the surroundings, including structural metal in the floor, walls, and ceiling, can cause measurement inaccuracies. In contrast, video-based methods use retroreflecting or LED markers placed on the subject and cameras in the environment to triangulate the position of the markers. Multiple markers can be arranged on segments to derive both position and orientation of individual segments. Although multiple markers are required to obtain the same position and orientation information as one magnetic sensor, these markers are typically passive (simply balls covered with reflective material) and so do not encumber the motion of the subject as dramatically as the wires of magnetic systems. The downside of optical motion-tracking technology is that it is necessary for every marker to be seen by at least two (and preferably more) cameras. Placement of cameras to meet this requirement can be a challenge, especially in enclosed spaces such as a vehicle cab.

Examples of commercially available magnetic systems include the Ascension MotionStar (www.ascension-tech.com) and Polhemus FastTrak (www.polhemus.com). Examples of optical systems include those sold by Vicon Motion Systems (www.vicon.com), Qualysis AB (www.qualysis.com), and Motion Analysis Corp. (www.motionanalysis.com).

6. HUMAN SIMULATION CHALLENGES

As human modeling becomes an integral part of the design process, the need for visual realism and analysis sophistication also increases. For better or worse, the visual appearance of human figures plays an important role in the acceptance of the technology and the perceived confidence of the results. Efforts in several areas focus on the increased realism of the human skin form. For performance reasons, current commercial human models are "skinned" using polygonal segment representations that are either completely static or pseudostatic. The figures are composed of individual

segments, such as feet, lower and upper legs, pelvis, and torso. The segments are drawn as a collection of static polygons arranged to give the segment its anthropomorphic shape. Prudent selection of the shape at the ends of the segments allows joints to travel through the physiological range of motion without the creation of gaps. Pseudostatic skinning solutions ''stitch'' polygons between the nodes of adjacent segments in real time to avoid the skin breaking apart at the joints. These solutions can be made to look very realistic and are adequate for most ergonomic assessments and presentations. However, they do not model the natural tissue deformation that occurs at the joints throughout the range of motion. This is visually most noticeable at complex joints, such as the shoulder joint, or quantitatively at joints to which measurements are taken, such as the popliteal region of the knee. To better model these areas, a variety of methods have been described in the literature that deform the surface polygons according to parametric descriptions or underlying muscle deformation models (e.g., Scheepers et al. 1997). However, these methods have generally not been commercially adopted because they are computationally expensive and mostly unnecessary from the ergonomic analysis standpoint. Nevertheless, as the computer hardware capability increases and the availability of highly detailed whole-body-surface scans elevates the expected level of visual realism, these deformation techniques will become more prevalent.

6.1. Performance Models

6.1.1. Performance Factors

Performance models used in current commercial models are largely an amalgamation of models and data available in the ergonomics and human factors literature. As mentioned in the review of the performance models, the presentation of most of these research findings was originally not intended for integration into real-time simulation environments. The studies from which these data were derived also did not address some of the more contemporary ergonomic issues, such as the performance limitations of the elderly, cumulative trauma, shoulder injury, and movement modeling.

The aging population is elevating the need to have more specific performance models for this demographic. Questions of functional limitations resulting from decreased strength, reaction time, and joint range of motion all affect the design, both of products and workplaces. In the automotive design space, ingress/egress capability is an example of a task that may be influenced by these limitations. In the workplace, questions of strength and endurance need to be addressed. Cumulative trauma prediction presents a particular academic challenge because the etiology of the injury is largely unknown. Biomechanical factors clearly play a role but to date do not provide sufficient predictive power upon which to base a risk-assessment tool. At best, conditions associated with an increased likelihood of cumulative trauma can be flagged. Similarly, shoulder fatigue and injury prediction is not developed to the point where models incorporated into modeling software can accurately predict the injurious conditions. The significant social and economic cost of low-back injury has motivated considerable research in low-back modeling over the past 20 years. The research findings have resulted in sophisticated models and quantitative design guidelines and have allowed manufacturing organizations to reduce dramatically the incidence rates of low-back pain. Shoulder injury and cumulative trauma now need the same level of investment to mature the available data in these areas.

6.1.2. Variation Modeling

Even with the sophistication of the currently available biomechanical models, human model users are becoming increasingly interested in asking questions of these tools for which there are insufficient data. One such example is describing the expected population variability within the performance of a task. Each person will perform actions in a slightly different way, and these variations are not represented in models that describe an ''average'' response. However, human modeling simulation software is ideally suited to visualize this variability between people (i.e., data clouds). Future human performance and movement models may have this variability modeled so that it can be displayed in the human modeling environment.

6.2. Human Motion Control

One of the significant advantages contemporary human modeling tools provide in ergonomic assessments is the ability to assemble simulations of the workers performing their tasks. Simulations can add value for task-timing information, workcell layout optimization, training, and technical presentations. If we are confident of the motion realism, we can apply the posture-sensitive ergonomic assessment tools to help identify the situations with the greatest injury risk potential. Considerable effort has been spent searching for methods that accurately predict how humans move under different task and environmental conditions (Raschke et al. 1998). Dynamic simulation (Hodgkins and Pollard 1997; Popovic and Witkins 1999), statistical models (Faraway 1997), warping techniques (Bruderlin 1995; Witkins et al. 1995) and optimization (Chao and Rim 1973; Pandy and Zajac 1991) have all

been applied to this problem. However, many of the methods for simulating human motion and behavior are computationally intensive and do not lend themselves to real-time solution. While some methods show promise, no single method for modeling human motion has yet proven to be concise, flexible, and accurate. Modeling human movements accurately in constrained surroundings and when obstacles need to be avoided presents additional challenges.

6.2.1. Modeling Motion Data

Simulating human movements, whatever method is applied, requires a detailed understanding of how people really move. Much detailed research has been conducted in understanding lifting and arm movements, and the subject continues to be extensively studied (e.g., Chaffin et al. 2000). However, the wide variety of ways that humans can move and the flexibility we have to do the same task using different postural approaches create a challenge for trying to generalize these measurements to use in human modeling tools. It is one thing to measure the time sequence of joint angles involved in a typical lift task, but it is quite another to try to use these data to simulate accurately how people perform a lift under different conditions. Start and end conditions, the size, shape, or weight of the object being lifted, and obstacles that need to be avoided all influence the motion. Clearly a great deal of detailed data describing how we move under different circumstances is needed.

6.2.2. Multiple-figure Interactions

Humans do not necessarily work in isolation. Many tasks involve more than one human interacting with another. Two people carrying a single large load or manipulating the same object and one person slowing down or speeding up to avoid running into one another are just a few examples. All the motion-control challenges associated with modeling the movement of a single individual apply and are magnified when multiple individuals, each contributing differently to the task, are involved.

6.2.2.1. Interactive "Smart" Avatars Ultimately an accurate representation of humans needs to model not only how they move but how they think and make decisions about what movements to do and how they react to a given situation. Such "smart" humans would obviously aid in the generation of a complex motion sequence involving several humans and have application to the development of workplace simulations. However, at this point in time, the development of intelligent human's agents has been motivated by applications such as interactive training simulations (Badler et al. 1999), pedagogical agents (Johnson et al. 2000), intelligent characters in computer games (Funge et al. 1999), and conversational agents (Cassell and Vilhjalmsson 1999) and have not yet been applied to any great extent to workplace simulations.

7. CONCLUSION

Digital human modeling is being actively used in industries around the world to reduce the need for physical prototypes and create better and safer designs faster than was previously possible. Contemporary human modeling software tools are actively assimilating a variety of previously disconnected human modeling knowledge, including population anthropometry descriptions and physical capability models. The large amount of ergonomic and anthropometric knowledge integrated into these solutions makes them efficient tools to answer a wide variety of human factors questions of designs. At the same time, the global nature of these tools is serving to consolidate and expose research findings from around the world and steering academic research direction and focusing the presentation of the results for model inclusion. While there are many areas that can be explored using the current offering of modeling solutions, many interesting challenges remain as we work to make virtual humans as lifelike as technology and our knowledge of humans allow.

CHAPTER 42
Human Factors Audit

COLIN G. DRURY
State University of New York at Buffalo

When we audit an entity, we perform an examination of it. Dictionaries typically emphasize official examinations of (financial) accounts, reflecting the accounting origin of the term. Accounting texts go further: for example, "testing and checking the records of an enterprise to be certain that acceptable policies and practices have been consistently followed" (Carson and Carlson 1977, p. 2). In the human factors field, the term is broadened to include nonfinancial entities, but it remains faithful to the concepts of checking, acceptable policies/practices, and consistency.

Human factors audits can be applied, as can human factors itself, to both products and processes. Both applications have much in common, as any process can be considered as a product of a design procedure, but this chapter emphasizes process audits because product evaluation is covered in detail in Chapter 49. Product usability audits have their own history (e.g., Malde 1992), which is best accessed through the product design and evaluation literature (e.g., McClelland 1990).

A second point needs to be made about the scope of this chapter: the role of checklists. As will be seen, checklists have assumed importance as techniques for conducting human factors audits. They can also be used alone as evaluation devices, in applications as diverse as VDT workplaces (Cakir et al. 1980), and risk factor assessment (Keyserling et al. 1992). Hence, the structure and use of checklists will be covered in some detail independently of their use as an auditing technique.

1. THE NEED FOR AUDITING HUMAN FACTORS

Human factors or ergonomics programs have become a permanent feature of many companies, with typical examples shown in Alexander and Pulat (1985). Like any other function, human factors/ergonomics needs tools to measure its effectiveness. Earlier, when human factors operated through individual projects, evaluation could take place on a project-by-project basis. Thus, the interventions to improve apparel-sewing workplaces described by Drury and Wick (1984) could be evaluated to show changes in productivity and reductions in cumulative trauma disorder causal factors. Similarly, Hasslequist (1981) showed productivity, quality, safety, and job satisfaction following human factors

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

interventions in a computer-component assembly line. In both cases, the objectives of the intervention were used to establish appropriate measures for the evaluation.

Ergonomics/human factors, however, is no longer confined to operating in a project mode. Increasingly, the establishment of a permanent function within an industry has meant that ergonomics is more closely related to the strategic objectives of the company. As Drury et al. (1989) have observed, this development requires measurement methodologies that also operate at the strategic level. For example, as a human factors group becomes more involved in strategic decisions about identifying and choosing the projects it performs, evaluation of the individual projects is less revealing. All projects performed could have a positive impact, but the group could still have achieved more with a more astute choice of projects. It could conceivably have had a more beneficial impact on the company's strategic objectives by stopping all projects for a period to concentrate on training the management, workforce, and engineering staff to make more use of ergonomics.

Such changes in the structure of the ergonomics/human factors profession indeed demand different evaluation methodologies. A powerful network of individuals, for example, who can, and do, call for human factors input in a timely manner can help an enterprise more than a number of individually successful project outcomes. Audit programs are one of the ways in which such evaluations can be made, allowing a company to focus its human factors resources most effectively. They can also be used in a prospective, rather than retrospective, manner to help quantify the needs of the company for ergonomics/human factors. Finally, they can be used to determine which divisions, plants, departments, or even product lines are in most need of ergonomics input.

2. DESIGN REQUIREMENTS FOR AUDIT SYSTEMS

Returning to the definition of an audit, the emphasis is on checking, acceptable policies, and consistency. The aim is to provide a fair representation of the business for use by third parties. A typical audit by a certified public accountant would comprise the following steps (adapted from Koli 1994):

1. *Diagnostic investigation:* description of the business and highlighting of areas requiring increased care and high risk
2. *Test for transaction:* trace samples of transactions grouped by major area and evaluate
3. *Test of balances:* analyze content
4. *Formation of opinion:* communicate judgment in an audit report

Such a procedure can also form a logical basis for human factors audits. The first step chooses the areas of study, the second samples the system, the third analyzes these samples, and the final step produces an audit report. These define the broad issues in human factors audit design:

1. *How to sample the system:* how many samples and how these are distributed across the system
2. *What to sample:* specific factors to be measured, from biomechanical to organizational
3. *How to evaluate the sample:* what standards, good practices, or ergonomic principles to use for comparison
4. *How to communicate the results:* techniques for summarizing the findings, how far separate findings can be combined

A suitable audit system needs to address all of these issues (see Section 3), but some overriding design requirements must first be specified.

2.1. Breadth, Depth, and Application Time

Ideally, an audit system would be broad enough to cover any task in any industry, would provide highly detailed analysis and recommendations, and would be applied rapidly. Unfortunately, the three variables of breadth, depth, and application time are likely to trade off in a practical system. Thus a thermal audit (Parsons 1992) sacrifices breadth to provide considerable depth based on the heat balance equation but requires measurement of seven variables. Some can be obtained rapidly (air temperature, relative humidity), but some take longer (clothing insulation value, metabolic rate). Conversely, structured interviews with participants in an ergonomics program (Drury 1990a) can be broad and rapid but quite deficient in depth.

At the level of audit instruments such as questionnaires or checklists, there are comprehensive surveys such as the position analysis questionnaire (McCormick 1979), the Arbeitswissenschaftliche Erhebungsverfahren zur Tätikgkeitsanalyse (AET) (Rohmert and Landau 1989), which takes two to three hours to complete, or the simpler work analysis checklist (Pulat 1992). Alternatively, there are

simple single-page checklists such as the ergonomics—working position—sitting Checklist (SHARE 1990), which can be completed in a few minutes.

Analysis and reporting can range in depth from merely tabulating the number of ergonomic standards violated to expert systems that provide prescriptive interventions (Ayoub and Mital 1989).

Most methodologies fall between the various extremes given above, but the goal of an audit system with an optimum trade-off between breadth, depth and time is probably not realizable. A better practical course would be to select several instruments and use them together to provide the specific breadth and depth required for a particular application.

2.2 Use of Standards

The human factors/ergonomics profession has many standards and good practice recommendations. These differ by country (ANSI, BSI, DIN), although commonality is increasing through joint standards such as those of the International Standards Organization (ISO). Some standards are quantitative, such as heights for school furniture (BSI 1965), sizes of characters or a VDT screen (ANSI/HFS-100), and occupational exposure to noise. Other standards are more general in nature, particularly those that involve management actions to prevent or alleviate problems, such as the OSHA guidelines for meat-packing plants (OSHA 1990). Generally, standards are more likely to exist for simple tasks and environmental stressors and are hardly to be expected for the complex cognitive activities with which human factors predictions increasingly deal. Where standards exist, they can represent unequivocal elements of audit procedures, as a workplace which does not meet these standards is in a position of legal violation. A human factors program that tolerates such legal exposure should clearly be held accountable in any audit.

However, merely meeting legal requirements is an insufficient test of the quality of ergonomics/human factors efforts. Many legal requirements are arbitrary or outdated, such as weight limits for manual materials handling in some countries. Additionally, other aspects of a job with high ergonomic importance may not be covered by standards, such presence of multiple stressors, work in restricted spaces resulting in awkward postures, or highly repetitive upper extremity motions. Finally, there are many human factors good practices that are not the subject of legal standards. Examples are the NIOSH lifting equation (Waters et al. 1993), the Illuminating Engineering Society (IES) codes (1993), and the zones of thermal comfort defined by ASHRAE (1989) or Fanger (1970). In some cases, standards are available in a different jurisdiction from that being audited. As an example, the military standard MIL-1472D (DOD 1989) provides detailed standards for control and display design that are equally appropriate to process controls in manufacturing industry but have no legal weight there.

Standards, in the legal sense, are a particularly reactive phenomenon. It may take many years (any many injuries and accidents) before a standard is found necessary and agreed upon. The NIOSH lifting equation referenced above addresses a back injury problem that is far from new, yet it still has no legal force. Standards for upper extremity cumulative trauma disorder prevention have lagged disease incidence by many years. Perhaps because of busy legislative agendas, we cannot expect rapid legal reaction, unless a highly visible major disaster occurs. Human factors problems are both chronic and acute, so that legislation based on acute problems as the sole basis for auditing is unlikely ever to be effective.

Despite the lack of legislation covering many human factors concerns, standards and other instantiations of good practice do have a place in ergonomics audits. Where they exist, they can be incorporated into an audit system without becoming the only criterion. Thus, noise levels in the United States have a legal limit for hearing protection purposes of 90 dBA. But at levels far below this, noise can disrupt communications (Jones and Broadbent 1987) and distract from task performance. An audit procedure can assess the noise on multiple criteria, that is, on hearing protection and on communication interruptions, with the former criterion used on all jobs and the latter only where verbal communication is an issue.

If standards and other good practices are used in a human factors audit, they provide a quantitative basis for decision making. Measurement reliability can be high and validity self-evident for legal standards. However, it is good practice in auditing to record only the measurement used, not its relationship to the standard, which can be established later. This removes any temptation by the analyst to bend the measurement to reach a predetermined conclusion. Illumination measurements, for example, can vary considerably over a workspace, so that an audit question:

Work Surface Illumination >750 Lux ☐ yes ☐ no

could be legitimately answered either way for some workspaces by choice of sampling point. Such temptation can be removed, for example, by an audit question.

Illumination at four points on workstation:

☐ ☐ ☐ ☐ Lux

Later analysis can establish whether, for example, the mean exceeds 750 Lux or whether any of the four points fall below this level.

It is also possible to provide later analyses that combine the effects of several simple checklist responses, as in Parsons's (1992) thermal audit, where no single measure would exceed good practice even though the overall result would be cumulative heat stress.

2.3. Evaluation of an Audit System

For a methodology to be of value, it must demonstrate validity, reliability, sensitivity, and usability. Most texts that cover measurement theory treat these aspects in detail (e.g., Kerlinger 1964). Shorter treatments are found in human factors methodology texts (e.g., Drury 1990b; Osburn 1987).

Validity is the extent to which a methodology measures the phenomenon of interest. Does our ergonomics audit program indeed measure the quality of ergonomics in the plant? It is possible to measure validity in a number of ways, but ultimately all are open to argument. For example, if we do not know the true value of the quality of ergonomics in a plant, how can we validate our ergonomics audit program? Broadly, there are three ways in which validation can be tested.

Content validity is perhaps the simplest but least convincing measure. If each of the items of our measurement device displays the correct content, then validity is established. Theoretically, if we could list all of the possible measures of a phenomenon, content validity would describe how well our measurement device samples these possible measures. In practice it is assessed by having experts in the field judge each item for how well its content represents the phenomenon studied. Thus, the heat balance equation would be judged by most thermal physiologists to have a content that well represents the thermal load on an operator. Not all aspects are as easily validated!

Concurrent (or *prediction*) *validity* has the most immediate practical impact. It measures empirically how well the output of the measurement device correlates with the phenomenon of interest. Of course, we must have an independent measure of the phenomenon of interest, which raises difficulties. To continue our example, if we used the heat balance equation to assess the thermal load on operators, then there should be a high correlation between this and other measures of the effects of thermal load—perhaps measures such as frequency of temperature complaints or heat disorders: heat stroke, hyperthermia, hypothermia, and so on. In practice, however, measuring such correlations would be contaminated by, for example, propensity to report temperature problems or individual acclimatization to heat. Overall outputs from a human factors audit (if such overall outputs have any useful meaning) should correlate with other measures of ergonomic inadequacy, such as injuries, turnover, quality measures, or productivity. Alternatively, we can ask how well the audit findings agree with independent assessments of qualified human factors engineers (Keyserling et al. 1992; Koli et al. 1993) and thus validate against one interpretation of current good practice.

Finally, there is *construct validity,* which is concerned with inferences made from scores, evaluated by considering all empirical evidence and models. Thus, a model may predict that one of the variables being measured should have a particular relationship to another variable not in the measurement device. Confirming this relationship empirically would help validate the particular construct underlying our measured variable. Note that different parts of an overall measurement device can have their construct validity tested in different ways. Thus, in a board human factors audit, the thermal load could differentiate between groups of operators who do and do not suffer from thermal complaints. In the same audit, a measure of difficulty in a target aiming task could be validated against Fitts's law. Other ways to assess construct validity are those that analyze clusters or factors within a group of measures. Different workplaces audited on a variety of measures and the scores, which are then subjected to factor analysis, should show an interpretable, logical structure in the factors derived. This method has been used on large databases for job evaluation-oriented systems such as McCormick's position analysis questionnaire (PAQ) (McCormick 1979).

Reliability refers to how well a measurement device can repeat a measurement on the same sample unit. Classically, if a measurement X is assumed to be composed of a true value X_t and a random measurement error X_e, then

$$X = X_t + X_e$$

For uncorrelated X_t and X_e, taking variances gives:

$$\text{Variance } (X) = \text{variance } (X_t) + \text{variance } (X_e)$$

or

$$V(X) = V(X_t) + V(X_e)$$

We can define the reliability of the measurement as the fraction of measurement variance accounted for by true measurement variance:

$$\text{Reliability} = \frac{V(X_t)}{V(X_t) + V(X_e)}$$

Typically, reliability is measured by correlating the scores obtained through repeated measurements. In an audit instrument, this is often done by having two (or more) auditors use the instrument on the same set of workplaces. The square of the correlation coefficient between the scores (either overall scores, or separately for each logical construct) is then the reliability. Thus, PAQ was found to have an overall reliability of 0.79, tested using 62 jobs and two trained analysts (McCormick 1979).

Sensitivity defines how well a measurement device differentiates between different entities. Does an audit system for human–computer interaction find a difference between software generally acknowledged to be ''good'' and ''bad''? If not, perhaps the audit system lacks sensitivity, although of course there may truly be no difference between the systems except what blind prejudice creates. Sensitivity can be adversely affected by poor reliability, which increases the variability in a measurement relative to a fixed difference between entities, that is, gives a poor signal-to-noise ratio. Low sensitivity can also come from a floor or ceiling effect. These arise where almost all of the measurements cluster at a high or low limit. For example, if an audit question on the visual environment was:

Does illumination exceed 10 lux? ☐ yes ☐ no

then almost all workplaces could answer ''yes'' (although the author has found a number that could not meet even this low criterion). Conversely, a floor effect would be a very high threshold for illluminance. Sensitivity can arise too when validity is in question. Thus, heart rate is a valid indicator of heat stress but not of cold stress. Hence, exposure to different degrees of cold stress would be only insensitively measured by heart rate.

Usability refers to the auditor's ease of use of the audit system. Good human factors principles should be followed, such as document design guidelines in constructing checklists (Patel et al. 1993; Wright and Barnard 1975). If the instrument does not have good usability, it will be used less often and may even show reduced reliability due to auditors' errors.

3. AUDIT SYSTEM DESIGN

As outlined in Section 2, the audit system must choose a sample, measure that sample, evaluate it, and communicate the results. In this section we approach these issues systematically.

An audit system is not just a checklist; it is a methodology that often includes the technique of a checklist. The distinction needs to be made between methodology and techniques. Over three decades ago, Easterby (1967) used Bainbridge and Beishon's (1964) definitions:

Methodology: a principle for defining the necessary procedures
Technique: a means to execute a procedural step.

Easterby notes that a technique may be applicable in more than one methodology.

3.1. The Sampling Scheme

In any sampling, we must define the unit of sampling, the sampling frame, and the sample choice technique. For a human factors audit the unit of sampling is not as self-evident as it appears. From a job-evaluation viewpoint (e.g., McCormick 1979), the natural unit is the job that is composed of a number of tasks. From a medical viewpoint the unit would be the individual. Human factors studies focus on the task/operator/machine/environment (TOME) system (Drury 1992) or equivalently the software/hardware/environment/liveware (SHEL) system (ICAO 1989). Thus, from a strictly human factors viewpoint, the specific combination of TOME can become the sampling unit for an audit program.

Unfortunately, this simple view does not cover all of the situations for which an audit program may be needed. While it works well for the rather repetitive tasks performed at a single workplace, typical of much manufacturing and service industry, it cannot suffice when these conditions do not hold. One relaxation is to remove the stipulation of a particular incumbent, allowing for jobs that require frequent rotation of tasks. This means that the results for one task will depend upon the incumbent chosen, or that several tasks will need to be combined if an individual operator is of

interest. A second relaxation is that the same operator may move to different workplaces, thus changing environment as well as task. This is typical of maintenance activities, where a mechanic may perform any one of a repertoire of hundreds of tasks, rarely repeating the same task. Here the rational sampling unit is the task, which is observed for a particular operator at a particular machine in a particular environment. Examples of audits of repetitive tasks (Mir 1982; Drury 1990a) and maintenance tasks (Chervak and Drury 1995) are given below to illustrate these different approaches.

Definition of the sampling frame, once the sampling unit is settled, is more straightforward. Whether the frame covers a department, a plant, a division, or a whole company, enumeration of all sampling units is at least theoretically possible. All workplaces or jobs or individuals can in principle be listed, although in practice the list may never be up to date in an agile industry where change is the normal state of affairs. Individuals can be listed from personnel records, tasks from work orders or planning documents, and workplaces from plant layout plans. A greater challenge, perhaps, is to decide whether indeed the whole plant really is the focus of the audit. Do we include office jobs or just production? What about managers, chargehands, part-time janitors, and so on? A good human factors program would see all of these tasks or people as worthy of study, but in practice they may have had different levels of ergonomic effort expended upon them. Should some tasks or groups be excluded from the audit merely because most participants agree that they have few pressing human factors problems? These are issues that need to be decided explicitly before the audit sampling begins.

Choice of the sample from the sampling frame is well covered in sociology texts. Within human factors it typically arises in the context of survey design (Sinclair 1990). To make statistical inferences from the sample to the population (specifically to the sampling frame), our sampling procedure must allow the laws of probability to be applied. The most often-used sampling methods are:

Random sampling: Each unit within the sampling frame is equally likely to be chosen for the sample. This is the simplest and most robust method, but it may not be the most efficient. Where subgroups of interest (strata) exist and these subgroups are not equally represented in the sampling frame, one collects unnecessary information on the most populous subgroups and insufficient information on the least populous. This is because our ability to estimate a population statistic from a sample depends upon the absolute sample size and not, in most practical cases, on the population size. As a corollary, if subgroups are of no interest, then random sampling loses nothing in efficiency.

Stratified random sampling: Each unit within a particular stratum of the sampling frame is equally likely to be chosen for the sample. With stratified random sampling we can make valid inferences about each of the strata. By weighting the statistics to reflect the size of the strata within the sampling frame, we can also obtain population inferences. This is often the preferred auditing sampling method as, for example, we would wish to distinguish between different classes of tasks in our audits: production, warehouse, office, management, maintenance, security, and so on. In this way our audit interpretation could give more useful information concerning where ergonomics is being used appropriately.

Cluster sampling: Clusters of units within the sampling frame are selected, followed by random or nonrandom selection within clusters. Examples of clusters would be the selection of particular production lines within a plant (Drury 1990a) or selection of representative plants within a company or division. The difference between cluster and stratified sampling is that in cluster sampling only a subset of possible units within the sampling frame is selected, whereas in stratified sampling all of the sampling frame is used because each unit must belong to one stratum. Because clusters are not randomly selected, the overall sample results will not reflect population values, so that statistical inference is not possible. If units are chosen randomly within each cluster, then statistical inference within each cluster is possible. For example, if three production lines are chosen as clusters, and workplaces sampled randomly within each, the clusters can be regarded as fixed levels of a factor and the data subjected to analysis of variance to determine whether there are significant differences between levels of that factor. What is sacrificed in cluster sampling is the ability to make *population* statements. Continuing this example, we could state that the lighting in line A is better than in lines B or C but still not be able to make statistically valid statements about the plant as a whole.

3.2. The Data-Collection Instrument

So far we have assumed that the instrument used to collect the data from the sample is based upon measured data where appropriate. While this is true of many audit instruments, this is not the only way to collect audit data. Interviews with participants (Drury 1990a), interviews and group meetings to locate potential errors (Fox 1992), and archival data such as injury of quality records (Mir 1982) have been used. All have potential uses with, as remarked earlier, a judicious range of methods often providing the appropriate composite audit system.

One consideration on audit technique design and use is the extent of computer involvement. Computers are now inexpensive, portable, and powerful and can thus be used to assist data collection,

data verification, data reduction, and data analysis (Drury 1990a). With the advent of more intelligent interfaces, checklist questions can be answered from mouse-clicks on buttons or selection from menus, as well as the more usual keyboard entry. Data verification can take place at entry time by checking for out-of-limits data or odd data such as the ratio of luminance to illuminance, implying a reflectivity greater than 100%. In addition, branching in checklists can be made easier, with only valid follow-on questions highlighted. The checklist user's manual can be built into the checklist software using context-sensitive help facilities, as in the EEAM checklist (Chervak and Drury 1995). Computers can, of course, be used for data reduction (e.g., finding the insulation value of clothing from a clothing inventory), data analysis, and results presentation.

With the case for computer use made, some cautions are in order. Computers are still bulkier than simple pencil-and-paper checklists. Computer reliability is not perfect, so inadvertent data loss is still a real possibility. Finally, software and hardware date much more rapidly than hard copy, so results safely stored on the latest media may be unreadable 10 years later. How many of us can still read punched cards or eight-inch floppy disks? In contrast, hard-copy records are still available from before the start of the computer era.

3.2.1. Checklists and Surveys

For many practitioners the proof of the effectiveness of an ergonomics effort lies in the ergonomic quality of the TOME systems it produces. A plant or office with appropriate human–machine function allocation, well-designed workplaces, comfortable environment, adequate placement/training, and inherently satisfying jobs almost by definition has been well served by human factors. Such a facility may not have human factors specialists, just good designers of environment, training, organization, and so on working independently, but this would generally be a rare occurrence. Thus, a checklist to measure such inherently ergonomic qualities has great appeal as part of an audit system.

Such checklists are almost as old as the discipline. Burger and deJong (1964) list four earlier checklists for ergonomic job analysis before going on to develop their own, which was commissioned by the International Ergonomics Association in 1961 and is usually known as the IEA checklist. It was based in part on one developed at the Philips Health Centre by G. J. Fortuin and provided in detail in Burger and deJong's paper.

Checklists have their limitations, though. The cogent arguments put forward by Easterby (1967) provide a good early summary of these limitations, and most are still valid today. Checklists are only of use as an aid to designers of systems at the earliest stages of the process. By concentrating on simple questions, often requiring yes/no answers, some checklists may reduce human factors to a simple stimulus–response system rather than encouraging conceptual thinking. Easterby quotes Miller (1967): "I still find that many people who should know better seem to expect magic from analytic and descriptive procedures. They expect that formats can be filled in by dunces and lead to inspired insights. . . . We should find opportunity to exorcise this nonsense" (Easterby 1967, p. 554)

Easterby finds that checklists can have a helpful structure but often have vague questions, make nonspecified assumptions, and lack quantitative detail. Checklists are seen as appropriate for some parts of ergonomics analysis (as opposed to synthesis) and even more appropriate to aid operators (not ergonomists) in following procedural steps. This latter use has been well covered by Degani and Wiener (1990) and will not be further presented here.

Clearly, we should be careful, even 30 years on, to heed these warnings. Many checklists are developed, and many of these published, that contain design elements fully justifying such criticisms.

A checklist, like any other questionnaire, needs to have both a helpful overall structure and well-constructed questions. It should also be proven reliable, valid, sensitive, and usable, although precious few meet all of these criteria. In the remainder of this section, a selection of checklists will be presented as typical of (reasonably) good practice. Emphasis will be on objective, structure, and question design.

3.2.1.1. The IEA Checklist The IEA checklist (Burger and de Jong 1964) was designed for ergonomic job analysis over a wide range of jobs. It uses the concept of functional load to give a logical framework relating the physical load, perceptual load, and mental load to the worker, the environment, and the working methods/tools/machines. Within each cell (or subcell, e.g., physical load could be static or dynamic), the load was assessed on different criteria such as force, time, distance, occupational, medical, and psychological criteria. Table 1 shows the structure and typical questions. Dirken (1969) modified the IEA checklist to improve the questions and methods of recording. He found that it could be applied in a median time of 60 minutes per workstation. No data are given on evaluation of the IEA checklist, but its structure has been so influential that it included here for more than historical interest.

3.2.1.2. Position Analysis Questionnaire The PAQ is a structured job analysis questionnaire using worker-oriented elements (187 of them) to characterize the human behaviors involved in jobs (McCormick et al. 1969). The PAQ is structured into six divisions, with the first three representing the classic experimental psychology approach (information input, mental process, work output) and

TABLE 1 IEA Checklist: Structure and Typical Questions

A: Structure of the Checklist		A	B	C
Load 1. Mean 2. Peaks Intensity, Frequency, Duration		Worker	Environment	Working method, tools, machines
I. Physical load	1. Dynamic 2. Static			
II. Perceptual load	1. Perception 2. Selection, decision 3. Control of movement			
III. Mental load	1. Individual 2. Group			
B: Typical Question				
I B. Physical load/environment		2.1. Physiological Criteria		
	1. Climate: high and low temperatures 1. Are these extreme enough to affect comfort or efficiency? 2. If so, is there any remedy? 3. To what extent is working capacity adversely affected? 4. Do personnel have to be specially selected for work in this particular environment?			

the other three a broader sociotechnical view (relationships with other persons, job context, other job characteristics). Table 2 shows these major divisions, examples of job elements in each and the rating scales employed for response (McCormick 1979).

Construct validity was tested by factor analyses of databases containing 3700 and 2200 jobs, which established 45 factors. Thirty-two of these fit neatly into the original six-division framework, with the remaining 13 being classified as ''overall dimensions.'' Further proof of construct validity was based on 76 human attributes derived from the PAQ, rated by industrial psychologists and the ratings subjected to principal components analysis to develop dimensions ''which had reasonably similar attribute profiles'' (McCormick 1979, p. 204). Interreliability, as noted above, was 0.79, based on another sample of 62 jobs.

The PAQ covers many of the elements of concern to human factors engineers and has indeed much influenced subsequent instruments such as AET. With good reliability and useful (though perhaps dated), construct validity, it is still a viable instrument if the natural unit of sampling is the job. The exclusive reliance on rating scales applied by the analyst goes rather against current practice of comparison of measurements against standards or good practices.

3.2.1.3. AET (*Arbeit the Arbeitswissenschaftliche Erhebungsverfahren zur Tätikgkeitsanalyse*) The AET, published in German (Landau and Rohmert 1981) and later in English (Rohmert and Landau 1983), is the job-analysis subsystem of a comprehensive system of work studies. It covers ''the analysis of individual components of man-at-work systems as well as the description and scaling of their interdependencies'' (Rohmert and Landau 1983, pp. 9–10). Like all good techniques, it starts from a model of the system (REFA 1971, referenced in Wagner 1989), to which is added Rohmert's stress/strain concept. This latter sees strain as being caused by the intensity and duration of stresses impinging upon the operator's individual characteristics. It is seen as useful in the analysis of requirements and work design, organization in industry, personnel management, and vocational counseling and research.

AET itself was developed over many years, using PAQ as an initial starting point. Table 3 shows the structure of the survey instrument with typical questions and rating scales. Note the similarity between AET's job demands analysis and the first three categories of the PAQ and the scales used in AET and PAQ (Table 2).

Measurements of validity and reliability of AET are discussed by H. Luczak in an appendix to Landau and Rohment, although no numerical values are given. Cluster analysis of 99 AET records produced groupings which supported the AET constructs. Seeber et al. (1989) used AET along with

TABLE 2. PAQ: Structure and Typical Questions

A: Structure of the Checklist

Division	Definition	Examples of Questions
1. Information input	Where and how does the worker get the information he uses in performing his job?	1. Use of written materials 2. Near-visual differentiation
2. Mental processes	What reasoning, decision making, planning, and information processing activities are involved in performing the job?	1. Level of reasoning in problem solving 2. Coding/decoding
3. Work output	What physical activities does the worker perform and what tools or devices does he use?	1. Use of keyboard devices 2. Assembling/unassembling
4. Relationships with other persons	What relationships with other people are required in performing the job?	1. Instructing 2. Contacts with public or customers
5. Job context	In what physical or social contexts is the work performed?	1. High temperature 2. Interpersonal; conflict situations
6. Other job characteristics	What activities, conditions, or characteristics other than those described above are relevant to the job?	1. Specified work pace 2. Amount of job structure

B: Scales used to rate elements

Types of scale		Scale values	
Identification	Type of Rating	Rating	Definition
U	Extend to Use	N	Does not apply
I	Importance of the job	1	Very minor
T	Amount of Time	2	Low
P	Possibility of Occurrence	3	Average
A	Applicability (yes/no only)	4	High
S	Special code	5	Extreme

two other work-analysis methods on 170 workplaces. They found that AET provided the most differentiating aspects (suggesting sensitivity). They also measured postural complaints and showed that only the AET groupings for 152 female workers found significant differences between complaint levels, thus helping establish construct validity.

AET, like PAQ before it, has been used on many thousands of jobs, mainly in Europe. A sizable database is maintained that can be used for both norming of new jobs analyzed and analysis to test research hypotheses. It remain a most useful instrument for work analysis.

3.2.1.4. Ergonomics Audit Program (*Mir 1982; Drury 1990a*) This program was developed at the request of a multinational corporation to be able to audit its various divisions and plants as ergonomics programs were being instituted. The system developed was a methodology of which the workplace survey was one technique. Overall, the methodology used archival data or outcome measures (injury reports, personnel records, productivity) and critical incidents to rank order departments within a plant. A cluster sampling of these departments gives either the ones with highest need (if the aim is to focus ergonomic effort) or a sample representative of the plant (if the objective is an audit). The workplace survey is then performed on the sampled departments.

The workplace survey was designed based on ergonomic aspects derived from a task/operator/machine/environment model of the person at work. Each aspect formed a section of the audit, and sections could be omitted if there were clearly not relevant, for example, manual materials-handling aspects for data-entry clerks. Questions within each section were based on standards, guidelines, and models, such as the NIOSH (1981) lifting equation, *ASHRAE Handbook of Fundamentals* for thermal aspects, and Givoni and Goldman's (1972) model for predicting heart rate. Table 4 shows the major sections and typical questions.

TABLE 3 AET: Structure and Typical Questions

A: Structure of the Checklist

Part	Major Division	Section
A: Work systems analysis	1. Work objects	1.1. Material work objects
		1.2 Energy as work object
		1.3 Information as work object
		1.4 Man, animals, plants as work objects
	2. Equipment	2.1 Working equipment
		2.2 Other equipment
	3. Work environment	3.1 Physical environment
		3.2 Organizational and social environment
		3.3 Principles and methods of remuneration
B: Task analysis	1. Tasks relating to material work objects	
	2. Tasks relating to abstract work objects	
	3. Man-related tasks	
	4. Number and repetitiveness of tasks	
C: Job demand analysis	1. Demands on perception	1.1 Mode of perception
		1.2 Absolute/relative evaluation of perceived information
		1.3 Accuracy of perception
	2. Demands for decision	2.1 Complexity of decisions
		2.2 Pressure of time
		2.3 Required knowledge
	3. Demands for response/activity	3.1 Body postures
		3.2 Static work
		3.3 Heavy muscular work
		3.4 Light muscular work, active light work
		3.5 Strenuousness and frequency of moves

B: Types of scale

Code	Type of Rating
A	Does this apply?
F	Frequency
S	Significance
D	Duration

Typical Scale values

Duration Value	Definition
0	Very infrequent
1	Less than 10% of shift time
2	Less than 30% of shift time
3	30% to 60% of shift time
4	More than 60% of shift time
5	Almost continuously during whole shift

Data were entered into the computer program and a rule-based logic evaluated each section to provide messages to the user in the form of either a ''section shows no ergonomic problems'' message:

```
MESSAGE
Results from analysis of auditory aspects:
       Everything OK in this section
```

or discrepancies from a single input:

```
MESSAGE
Seats should be padded, covered with non-slip materials and have front
edge rounded
```

or discrepancies based on the integration of several inputs:

TABLE 4 Workplace Survey: Structure and Typical Questions

Section	Major Classification	Examples of Questions
1. Visual aspects		Nature of task Measure illuminance at task midfield outer field
2. Auditory aspects		Noise level, dBA Main source of noise
3. Thermal aspects		Strong radiant sources present? Wet bulb temperature (Clothing inventory)
4. Instruments, controls, displays	Standing vs. Seated Displays Labeling Coding Scales, dials, counters Control/display relationships Controls	Are controls mounted between 30 in. and 70 in. Signals for crucial visual checks Are trade names deleted? Color codes same for control & display? All numbers upright on fixed scales? Grouping by sequence or subsystem? Emergency button diameter $>$ 0.75 in.?
5. Design of workplaces	Desks Chairs Posture	Seat to underside of desk $>$ 6.7 in.? Height easily adjustable 15–21 in.? Upper arms vertical?
6. Manual materials handling	(NIOSH Lifting Guide, 1981)	Task, H, V, D, F
7. Energy expenditure		Cycle time Object weight Type of work
8. Assembly/repetitive aspects		Seated, standing, or both? If heavy work, is bench 6–16 in. below elbow height?
9. Inspection aspects		Number of fault types? Training time until unsupervised?

```
MESSAGE
The total metabolic workload is 174 watts
Intrinsic clothing insulation is 0.56 clo
Initial rectal temperature is predicted to be 36.0°C
Final rectal temperature is predicted to be 37.1°C
```

Counts of discrepancies were used to evaluate departments by ergonomics aspect, while the messages were used to alert company personnel to potential design changes. This latter use of the output as a training device for nonergonomic personnel was seen as desirable in a multinational company rapidly expanding its ergonomics program.

Reliability and validity have not been assessed, although the checklist has been used in a number of industries (Drury 1990a). The Workplace Survey has been included here because, despite its lack of measured reliability and validity, it shows the relationship between audit as methodology and checklist as technique.

3.2.1.5. ERGO, EEAM, and ERNAP (*Koli et al. 1993; Chervak and Drury 1995*) These checklists are both part of complete audit systems for different aspects of civil aircraft hangar activities. They were developed for the Federal Aviation Administration to provide tools for assessing human factors in aircraft inspection (ERGO) and maintenance (EEAM) activities, respectively. Inspection and maintenance activities are nonrepetitive in nature, controlled by task cards issued to technicians at the start of each shift. Thus, the sampling unit is the task card, not the workplace, which is highly variable between task cards. Their structure was based on extensive task analyses of inspection and maintenance tasks, which led to generic function descriptions of both types of work (Drury et al. 1990). Both systems have sampling schemes and checklists. Both are computer based with initial data collection on either hard copy or direct into a portable computer. Recently, both have been combined into a single program (ERNAP) distributed by the FAA's Office of Aviation Medicine. The structure of ERNAP and typical questions are given in Table 5.

TABLE 5 ERNAP Structure and Typical Questions

Audit Phase	Major Classification	Examples of Questions
I. Premaintenance	Documentation	Is feedforward information on faults given?
	Communication	Is shift change documented?
	Visual characteristics	If fluorescent bulbs are used, does flicker exist?
	Electric/pneumatic equipment	Do push buttons prevent slipping of fingers?
	Access equipment	Do ladders have nonskid surfaces on landings?
II. Maintenance	Documentation (M)	Does inspector sign off workcard after each task?
	Communication (M)	Explicit verbal instructions from supervisor?
	Task lighting	Light levels in four zones during task, fc.
	Thermal issues	Wet bulb temperature in hanger bay, °C
	Operator perception	Satisfied with summer thermal environment?
	Auditory issues	Noise levels at five times during task, dBA
	Electrical and pneumatic	Are controls easily differentiated by touch?
	Access equipment (M)	Is correct access equipment available?
	Hand tools	Does the tool handle end in the palm?
	Force measurements	What force is being applied, kg?
	Manual Materials handling	Does task require pushing or pulling forces?
	Vibration	What is total duration of exposure on this shift?
	Repetitive motion	Does the task require flexion of the wrist?
	Access	How often was access equipment repositioned?
	Posture	How often were following postures adopted?
	Safety	Is inspection area adequately cleaned for inspect?
	Hazardous material	Were hazardous materials signed out and in?
III. Postmaintenance	Buy back	Are discrepancy worksheets readable?

As in Mir's Ergonomics Audit Program, the ERNAP, the checklist is again modular, and the software allows formation of data files, selection of required modules, analysis after data entry is completed, and printing of audit reports. Similarly, the ERGO, EEAM, and ERNAP instruments use quantitative or Yes/No questions comparing the entered value with standards and good practice guides. Each takes about 30 minutes per task. Output is in the form of an audit report for each workplace, similar to the messages given by Mir's Workplace Survey, but in narrative form. Output in this form was chosen for compatibility with existing performance and compliance audits used by the aviation maintenance community.

Reliability of a first version of ERGO was measured by comparing the output of two auditors on three tasks. Significant differences were found at $P < 0.05$ on all three tasks, showing a lack of interrater reliability. Analysis of these differences showed them to be largely due to errors on questions requiring auditor judgment. When such questions were replaced with more quantitative questions, the two auditors had no significant disagreements on a later test. Validity was measured using concurrent validation against six Ph.D. human factors engineers who were asked to list all ergonomic issues on a power plant inspection task. The checklist found more ergonomic issues than the human factors engineers. Only a small number of issues were raised by the engineers that were missed by the checklist. For the EEAM checklist, again an initial version was tested for reliability with two auditors, and it only achieved the same outcome for 85% of the questions. A modified version was

tested and the reliability was considered satisfactory with 93% agreement. Validity was again tested against four human factors engineers, this time the checklist found significantly more ergonomic issues than the engineers without missing any issues they raised.

The ERNAP audits have been included here to provide examples of a checklist embedded in an audit system where the workplace is *not* the sampling unit. They show that non-repetitive tasks can be audited in a valid and reliable manner. In addition, they demonstrate how domain-specific audits can be designed to take advantage of human factors analyses already made in the domain.

3.2.1.6. Upper-Extremity Checklist (*Keyserling et al. 1993*) As its name suggests, this checklist is narrowly focused on biomechanical stresses to the upper extremities that could lead to cumulative trauma disorders (CTDs). It does not claim to be a full-spectrum analysis tool, but it is included here as a good example of a special-purpose checklist that has been carefully constructed and validated. The checklist (Table 6) was designed for use by management and labor to fulfill a requirement in the OSHA guidelines for meat-packing plants. The aim is to screen jobs rapidly for harmful exposures rather than to provide a diagnostic tool. Questions were designed based upon the biomechanical literature, structured into six sections. Scoring was based on simple presence or absence of a condition, or on a three-level duration score. As shown in Table 6, the two or three levels were scored as o, ·, or ∗ depending upon the stress rating built into the questionnaire. These symbols represented insignificant, moderate, or substantial exposures. A total score could be obtained by summing moderate and substantial exposures.

The upper extremity checklist was designed to be biased towards false positives, that is, to be very sensitive. It was validated against detailed analyses of 51 jobs by an ergonomics expert. Each section (except the first, which only recorded dominant hand) was considered as giving a positive screening if at least one ∗ rating was recorded. Across the various sections, there was reasonable agreement between checklist users and the expert analysis, with the checklist, being generally more sensitive, as was its aim. The original reference shows the findings of the checklist when applied to 335 manufacturing and warehouse jobs.

As a special-purpose technique in an area of high current visibility for human factors, the upper extremity checklist has proven validity, can be used by those with minimal ergonomics training for screening jobs, and takes only a few minutes per workstation. The same team has also developed

TABLE 6 Upper Extremity Checklist: Structure, Questions, and Scoring

A: Structure of the Checklist

Major Section	Examples of Questions
Worker information	Which hand is dominant?
Repetitiveness	Repetitive use of the hands and wrists? If "yes" then: Is cycle < 30 sec? Repeated for $> 50\%$ cycle?
Mechanical stress	Do hard or sharp objects put pressure localized pressure on: back or side of fingers? Palm or base of hand . . .
Force	Lift, carry, push or pull objects > 4.5 kg? If gloves worn, do they hinder gripping? . . .
Posture	Is pinch grip used? Is there wrist deviation? . . .
Tools, hand-held objects and equipment	Is vibration transmitted to the operator's hand? Does cold exhaust air blow on the hand or wrist? . . .

B. Scoring scheme

Question	Scoring		
Is there wrist deviation?	No o	Some $\surd$	$> 33\%$ cycle ∗
C. Overall evaluation Total Score	Number of $\surd$ + Number of ∗		

and validated a legs, trunk, and neck job screening procedure along similar lines (Keyserling et al. 1992).

3.2.1.7. Ergonomic Checkpoints The Workplace Improvement in Small Enterprises (WISE) methodology (Kogi 1994) was developed by the International Ergonomics Association (IEA) and the International Labour Office (ILO) to provide cost-effective solutions for smaller organizations. It consists of a training program and a checklist of potential low-cost improvements. This checklist, called ergonomics checkpoints, can be used both as an aid to discovery of solutions and as an audit tool for workplaces within an enterprise.

The 128-point checklist has now been published (Kogi and Kuorinka 1995). It covers the nine areas shown in Table 7. Each item is a statement rather than a question and is called a checkpoint. For each checkpoint there are four sections, also shown in Table 7. There is no scoring system as such; rather, each checkpoint becomes a point of evaluation of each workplace for which it is appropriate. Note that each checkpoint also covers why that improvement is important, and a description of the core issues underlying it. Both of these help the move from rule-based reasoning to knowledge-based reasoning as nonergonomists continue to use the checklist. A similar idea was embodied in the Mir (1982) ergonomic checklist.

3.2.1.8. Other Checklists The above sample of successful audit checklists has been presented in some detail to provide the reader with their philosophy, structure, and sample questions. Rather then continue in the same vein, other interesting checklists are outlined in Table 8. Each entry shows the domain, the types of issues addressed, the size or time taken in use, and whether validity and reliability have been measured. Most textbooks now provide checklists, and a few of these are cited. No claim is made that Table 8 is comprehensive. Rather, it is rather a sampling with references so that readers can find a suitable match to their needs. The first nine entries in the table are conveniently colocated in Landau and Rohmert (1989). Many of their reliability and validity studies are reported in this publication. The next entries are results of the Commission of European Communities fifth ECSC program, reported in Berchem-Simon (1993). Others are from texts and original references. The author has not personally used all of these checklists and thus cannot specifically endorse them. Also, omission of a checklist from this table implies nothing about its usefulness.

TABLE 7 Ergonomic Checkpoints: Structure, Typical Checkpoints, and Checkpoint Structure

A: Structure of the Checklist

Major Section	Typical Checkpoints
Materials handling	• Clear and mark transport ways.
Handtools	• Provide handholds, grips, or good holding points for all packages and containers.
Productive machine safety	• Use jigs and fixtures to make machine operations stable, safe, and efficient.
Improving workstation design	• Adjust working height for each worker at elbow level or slightly below it.
Lighting	• Provide local lights for precision or inspection work.
Premises	• Ensure safe wiring connections for equipment and lights.
Control of hazards	• Use feeding and ejection devices to keep the hands away from dangerous parts of machinery.
Welfare facilities	• Provide and maintain good changing, washing, and sanitary facilities to keep good hygiene and tidiness.
Work organization	• Inform workers frequently about the results of their work.

B. Structure of each checkpoint

WHY?	Reasons why improvments are important.
HOW?	Description of several actions each of which can contribute to improvement.
SOME MORE HINTS	Additional points which are useful for attaining the improvement.
POINTS TO REMEMBER	Brief description of the core element of the checkpoint.

From Kogi, private communication, November 13, 1995.

TABLE 8 A Selection of Published Checklists

Name	Authors	Coverage	Reliability	Validity
TBS	Hacker et al. 1983	Mainly mental work		vs. AET
VERA	Volpert et al. 1983	Mainly mental work		vs. AET
RNUR	RNUR, 1976	Mainly physical work		
LEST	Guèlaud. 1975	Mainly physical work		
AVISEM	AVISEM. 1977	Mainly physical work		
GESIM	GESIM. 1988	Mainly physical work		
RHIA	Leitner et al. 1987	Task hindrances, stress	0.53–0.79	vs. many
MAS	Groth. 1989	Open structure, derived from AET		vs. AET
JL and HA	Mattila and Kivi. 1989	Mental, physical work, hazards	0.87–0.95	
	Bolijn 1993	Physical work checklist for women	tested

Work Analy.	Pulat 1992	Mental and physical work		
Thermal Aud.	Parsons 1992	Thermal audit from heat balance		content
WAS	Yoshida and Ogawa, 1991	Workplace and environment	tested	vs. expert
Ergonomics	Occupational Health and Safety Authority 1990	Short workplace checklists		
	Cakir et al. 1980	VDT checklist		

First nine from Landau and Rohmert 1989; next three from Berchem-Simon 1993.

3.2.2. Other Data-Collection Methods

Not all data come from checklists and questionnaires. We can audit a human factors program using outcome measures alone (e.g., Chapter 47). However, outcome measures such as injuries, quality, and productivity are nonspecific to human factors: many other external variables can affect them. An obvious example is changes in the reporting threshold for injuries, which can lead to sudden apparent increases and decreases in the safety of a department or plant. Additionally, injuries are (or should be) extremely rare events. Thus, to obtain enough data to perform meaningful statistical analysis may require aggregation over many disparate locations and/or time periods. In ergonomics audits, such outcome measures are perhaps best left for long-term validation or for use in selecting cluster samples.

Besides outcome measures, interviews represent a possible data-collection method. Whether directed or not (e.g., Sinclair 1990) they can produce critical incidents, human factors examples, or networks of communication (e.g., Drury 1990a), which have value as part of an audit procedure. Interviews are routinely used as part of design audit procedures in large-scale operations such as nuclear power plants (Kirwan 1989) or naval systems (Malone et al. 1988).

A novel interview-based audit system was proposed by Fox (1992) based on methods developed in British Coal (reported in Simpson 1994). Here an error-based approach was taken, using interviews and archival records to obtain a sampling of actual and possible errors. These were then classified using Reason's (1990) active/latent failure scheme and orthogonally by Rasmussen's (1987) skill-, rule-, knowledge-based framework. Each active error is thus a conjunction of skill/mistake/violation with skill/rule/knowledge. Within each conjunction, performance-shaping factors can be deduced and sources of management intervention listed. This methodology has been used in a number of mining-related studies: examples will be presented in Section 4.

3.3. Data Analysis and Presentation

Human factors as a discipline covers wide range of topics, from workbench height to function allocation in automated systems. An audit program can only hope to abstract and present a part of this range. With our consideration of sampling systems and data collection devices we have seen different ways in which an unbiased abstraction can be aided. At this stage the data consist of large numbers of responses to large numbers of checklist items, or detailed interview findings. How can, or should, these data be treated for best interpretation?

Here there are two opposing viewpoints: one is that the data are best summarized across sample units, but not across topics. This is typically the way the human factors professional community treats the data, giving summaries in published papers of the distribution of responses to individual items on the checklist. In this way, findings can be more explicit, for example that the lighting is an area that needs ergonomics effort, or that the seating is generally poor. Adding together lighting and seating discrepancies is seen as perhaps obscuring the findings rather than assisting in their interpretation.

The opposite viewpoint, in many ways, is taken by the business community. For some, an overall figure of merit is a natural outcome of a human factors audit. With such a figure in hand, the relative needs of different divisions, plants, or departments can be assessed in terms of ergonomic and engineering effort required. Thus, resources can be distributed rationally from a management level. This view is heard from those who work for manufacturing and service industries, who ask after an audit "How did we do?" and expect a very brief answer. The proliferation of the spreadsheet, with its ability to sum and average rows and columns of data, has encouraged people to do just that with audit results. Repeated audits fit naturally into this view because they can become the basis for monthly, quarterly, or annual graphs of ergonomic performance.

Neither view alone is entirely defensible. Of course, summing lighting and seating needs produces a result that is logically indefensible and that does not help diagnosis. But equally, decisions must be made concerning optimum use of limited resources. The human factors auditor, having chosen an unbiased sampling scheme and collected data on (presumably) the correct issues, is perhaps in an excellent position to assist in such management decisions. But so too are other stakeholders, primarily the workforce.

Audits, however, are not the only use of some of the data-collection tools. For example, the Keyserling et al. (1993) upper extremity checklist was developed specifically as a screening tool. Its objective was to find which jobs/workplaces are in need of detailed ergonomic study. In such cases, summing across issues for a total score has an operational meaning, that is, that a particular workplace needs ergonomic help.

Where interpretation is made at a deeper level than just a single number, a variety of presentation devices have been used. These must show scores (percent of workplaces, distribution of sound pressure levels, etc.) separately but so as to highlight broader patterns. Much is now known about separate vs. integrated displays and emergent features (e.g., Wickens 1992, pp. 121–122), but the traditional profiles and spider web charts are still the most usual presentation forms. Thus, Wagner (1989) shows the AVISEM profile for a steel industry job before and after automation. The nine different issues (rating factors) are connected by lines to show emergent shapes for the old and the new jobs. Landau and Rohmert's (1981) original book on AET shows many other examples of profiles. Klimer et al. (1989) present a spider web diagram to show how three work structures influenced ten issues from the AET analysis. Mattila and Kivi (1989) present their data on the job load and hazard analysis system applied to the building industry in the form of a table. For six occupations, the rating on five different loads/hazards is presented as symbols of different sizes within the cells of the table.

There is little that is novel in the presentation of audit results: practitioners tend to use the standard tabular or graphical tools. But audit results are inherently multidimensional, so some thought is needed if the reader is to be helped towards an informed comprehension of the audit's outcome.

4. AUDIT SYSTEMS IN PRACTICE

Almost any of the audit programs and checklists referenced in previous sections give examples of their use in practice. Only two examples will be given here, as others are readily accessible. These examples were chosen because they represent quite different approaches to auditing.

4.1. Auditing a Decentralized Business

From 1992 to 1996, a major U.S.-based apparel manufacturer had run an ergonomics program aimed primarily at the reduction of workforce injuries in backs and upper extremities. As detailed in Drury et al. (1999), the company during that time was made up of nine divisions and employed about 45,000 workers. Of particular interest was the fact that the divisions enjoyed great autonomy, with only a small corporate headquarters with a single executive responsible for all risk-management activities. The company had grown through mergers and acquisitions, meaning that different divisions had different degrees of vertical integration. Hence, core functions such as sewing, pressing, and distribution were common to most divisions, while some also included weaving, dyeing, and embroidery. In addition, the products and fabrics presented quite different ergonomic challenges, from delicate undergarments to heavy jeans to knitted garments and even luggage.

The ergonomics program was similarly diverse. It started with a corporate launch by the highest-level executives and was rolled out to the divisions and then to individual plants. The pace of change was widely variable. All divisions were given a standard set of workplace analysis and modification tools (based on Drury and Wick 1984) but were encouraged to develop their own solutions to problems in a way appropriate to their specific needs.

Evaluation took place continuously, with regular meetings between representatives of plants and divisions to present results of before-and-after workplace studies. However, there was a need for a broader audit of the whole corporation aimed at understanding how much had been achieved for the multimillion-dollar investment, where the program was strong or weak, and what program needs were emerging for the future. A team of auditors visited all nine divisions, and a total of 12 plants spread across eight divisions, during 1995. This was three years after the initial corporate launch and about two years after the start of shop-floor implementation.

A three-part audit methodology was used. First, a workplace survey was developed based on elements of the program itself, supplemented by direct comparisons to ergonomics standards and good practices. Table 9 shows this 50-item survey form, with data added for the percentage of ''yes'' answers where the responses were not measures or scale values. The workplace survey was given at a total of 157 workplaces across the 12 plants. Second, a user survey (Table 10) was used in an interview format with 66 consumers of ergonomics, typically plant managers, production managers, human resource managers, or their equivalent at the division level, usually vice presidents. Finally, a total of 27 providers of ergonomics services were given a similar provider survey (Table 11) interview. Providers were mainly engineers, with three human resources specialists and one line supervisor. From these three audit methods the corporation wished to provide a time snapshot of how effectively the current ergonomics programs was meeting their needs for reduction of injury costs. While the workplace survey measured how well ergonomics was being implemented at the workplace, the user and provider surveys provided data on the roles of the decision makers beyond the workplace.

Detailed audit results are provided in Drury et al. (1999), so only examples and overall conclusions are covered in this chapter. Workplaces showed some evidence of good ergonomic practice, with generally satisfactory thermal, visual, and auditory environments. There were some significant differences ($p < 0.05$) between workplace types rather than between divisions or plants; for example, better lighting (> 700 lux) was associated with inspection and sewing. Also, higher thermal load was associated with laundries and machine load/unload. Overall, 83% of workplaces met the ASHRAE (1990) summer comfort zone criteria. As seen in Table 12, the main ergonomics problem areas were in poor posture and manual materials handling. Where operators were seated (only 33% of all workplaces) seating was relatively good. In fact, many in the workforce had been supplied with well-designed chairs as part of the ergonomics program.

To obtain a broad perspective, the three general factors at the end of Table 9 were analyzed. Apart from cycle time (W48), the questions related to workers having seen the corporate ergonomics video (W49) and having experienced a workplace or methods change (W50). Both should have received a ''yes'' response if the ergonomics program were reaching the whole workforce. In fact, both showed highly significant differences between plants ($X_8^2 = 92.0$, $p < 0.001$, and $X_8^2 = 22.2$, $p < 0.02$, respectively). Some of these differences were due to two divisions lagging in ergonomics implementation, but even beyond this were large between-plant differences. Overall, 62% of the workforce had seen the ergonomics video, a reasonable value but one with wide variance between plants and divisions. Also, 38% of workplaces had experienced some change, usually ergonomics-related, a respectable figure after only two to three years of the program.

From the user and provider surveys an enhanced picture emerged. Again, there was variability between divisions and plants, but 94% of the users defined ergonomics as fitting the job to the operator rather than training or medical management of injuries. Most users had requested an ergonomic intervention within the past two months, but other ''users'' had never in fact used ergonomics.

The solutions employed ranged widely, with a predominance of job aids such as chairs or standing pads. Other frequent categories were policy changes (e.g., rest breaks, rotation, box weight reduction) and workplace adjustment to the individual operator. There were few uses of personal aids (e.g. splints) or referrals to MDs as ergonomic solutions. Changes to the workplace clearly predominated over changes to the individual, although a strong medical management program was in place when required. When questioned about ergonomics results, all mentioned safety (or workplace comfort or ease of use), but some also mentioned others. Cost or productivity benefits were the next most common response, with a few additional ones relating to employee relations, absence/turnover, or job satisfaction. Significantly, only one respondent mentioned quality.

The major user concern at the plant level was time devoted to ergonomics by providers. At the corporate level, the need was seen for more rapid job-analysis methods and corporate policies, such as on back belts or ''good'' chairs. Overall, 94% of users made positive comments about the ergonomics program.

Ergonomics providers were almost always trained in the corporate or division training seminars, usually near the start of the program. Providers' chief concern was for the amount of time and resources they could spend on ergonomics activities. Typically, ergonomics was only one job responsibility among many. Hence, broad programs, such as new chairs or back belts, were supported enthusiastically because they gave the maximum perceived impact for the time devoted. Other solutions presented included job aids, workplace redesign (e.g., moving from seated to standing jobs for long-seam sewing), automation, rest breaks, job rotation, packaging changes, and medical man-

TABLE 9 Ergonomics Audit: Workplace Survey with Overall Data

Number			Division	Plant	Job Type
1. Postural aspects					
	Yes	No	Factor		
W1	68%		Frequent extreme motions of back, neck, shoulders, wrists		
W2	66%		Elbows raised or unsupported more than 50% of time		
W3	22%		Upper limbs contact nonrounded edges		
W4	73%		Gripping with fingers		
W5	36%		Knee/foot controls		
1.1 Seated					
	Yes	No	Factor		
W6	12%		Leg clearance restricted		
W7	21%		Feet unsupported/legs slope down		
W8	17%		Chair/table restricts thighs		
W9	22%		Back unsupported		
W10	37%		Chair height not adjustable easily		
1.2 Standing					
	Yes	No	Factor		
W11	3%		Control requires weight on one foot more than 50% time		
W12	37%		Standing surface hard		
W13	92%		Work surface height not adjustable easily		
1.3 Hand tools					
	Yes	No	Factor		
W14	77%		Tools require hand/wrist bending		
W15	9%		Tools vibrate		
W16	63%		Restricted to one-handed use		
W17	39%		Tool handle ends in palm		
W18	20%		Tool handle has nonrounded edges		
W19	56%		Tool uses only 2 or 3 fingers		
W20	9%		Requires continuous or high force		
W21	41%		Tool held continuously in one hand		
2. Vibration					
	Yes	No	Factor		
W22	14%		Vibration reaches body from any source		
3. Manual materials handling					
	Yes	No	Factor		
W23	40%		More than 5 moves per minute		
W24	36%		Loads unbalanced		
W25	14%		Lift above head		
W26	28%		Lift off floor		
W27	83%		Reach with arms		
W28	78%		Twisting		
W29	60%		Bending trunk		
W30	3%		Floor wet or slippery		
W31	0%		Floor in poor condition		
W32	17%		Area obstructs task		
W33	4%		Protective clothing unavailable		
W34	2%		Handles used

W49	62%		Seen ergonomics video		
W50	38%		Any ergonomics changes to workplace or methods		

agement. Specific needs were seen in the area of corporate or supplier help in obtaining standard equipment solutions and of more division-specific training. As with users, the practitioners enjoyed their ergonomics activity and thought it worthwhile.

Recommendations arising from this audit were that the program was reasonably effective at that time but had some long-term needs. The corporation saw itself as an industry leader and wanted to move beyond a relatively superficial level of ergonomics application. To do this would require more time resources for job analysis and change implementation. Corporate help could also be provided in developing more rapid analysis methods, standardized video-based training programs, and more standardized solutions to recurring ergonomics problems. Many of these changes have since been implemented.

On another level, the audit was a useful reminder to the company of the fact that it had incurred most of the up-front costs of a corporate ergonomics program, and was now beginning to reap the benefits. Indeed, by 1996, corporate injury costs and rates had decreased by about 20% per year after

peaking in 1993. Clearly, the ergonomics program was not the only intervention during this period, but it was seen by management as the major contributor to improvement. Even on the narrow basis of cost savings, the ergonomics program was a success for the corporation.

4.2. Error Reduction at a Colliery

In a two-year project, reported by Simpson (1994) and Fox (1992), the human error audit described in Section 3.2 was applied to two colliery haulage systems. The results of the first study will be presented here. In both systems, data collection focused on potential errors and the performance-shaping factors (PSFs) that can influence these errors. Data was collected by ''observation, discussion and measurement within the framework of the broader man-machine systems and checklist of PSFs,'' taking some 30–40 shifts at each site. The whole haulage system from surface operations to delivery at the coal face was covered.

The first study found 40 active failures (i.e., direct error precursors) and nine latent failures (i.e., dormant states predisposing the system to later errors). Four broad classes of active failures were:

1. Errors associated with locomaintenance (7 errors), e.g., fitting incorrect thermal cut-offs
2. Errors associated with locooperation (10 errors), e.g., locos not returned to service bay for 24-hour check.
3. Errors associated with loads and load security (7 errors); e.g., failure to use spacer wagons between overhanging loads
4. Errors associated with the design/operation of the haulage route (10 errors), e.g., continued use despite potentially unsafe track
5. Plus a small miscellaneous category

The latent failures were (Fox 1992):

1. Quality assurance in supplying companies
2. Supplies ordering procedures within the colliery
3. Locomotive design
4. Surface make-up of supplies
5. Lack of equipment at specific points
6. Training
7. Attitudes to safety
8. The safety inspection/reporting/action procedures

As an example from 3, Locomotive design, the control positions were not consistent across the locomotives fleet, despite all originating from the same manufacturer.

Using the slip/mistake/violation categorization, each potential error could be classified so that the preferred source of action (intervention) could be specified.

This audit led to the formation of two teams, one to tackle locomotive design issues and the other for safety reporting and action. As a result of team activities, many ergonomic actions were implemented. These included management actions to ensure a uniform wagon fleet, autonomous inspection/repair teams for tracks, and multifunctional teams for safety initiatives.

TABLE 12 Responses to Ergonomics User

Question and Issue	Corporate		Plant	
	Mgt	Staff	Mgt	Staff
1. What is Ergonomics?				
1.1 Fitting job to operator	1	6	10	5
1.2 Fitting operator to job	0	6	0	0
2. Who do you call on to get ergonomics work done?				
2.1 Plant ergonomics people	0	3	3	2
2.2 Division ergonomics people	0	4	5	2
2.3 Personnel department	3	0	0	0
2.4 Engineering department	1	8	6	11
2.5 We do it ourselves	0	2	1	0
2.6 College interns	0	0	4	2
2.7 Vendors	0	0	0	1
2.8 Everyone	0	1	0	0
2.9 Operators	0	1	0	0
2.10 University faculty	0	0	1	0
2.11 Safety	0	1	0	0
3. When did you last ask them for help?				
3.1 Never	0	4	2	0
3.2 Sometimes/infrequently	2	0	1	0
3.3 One year or more ago	0	1	4	0
3.4 One month or so ago	0	0	2	0
3.5 less than 1 month ago	1	0	3	4
5. Who else should we talk to about ergonomics?				
5.1 Engineers	0	0	3	2
5.2 Operators	1	1	2	0
5.3 Everyone	0	0	2	0
6. General Ergonomics Comments				
6.1 Ergonomics Concerns				
6.11 Workplace design for safety/ease/stress/fatigue	2	5	13	5
6.12 Workplace design for cost savings/productivity	1	0	2	1
6.13 Workplace design for worker satisfaction	1	1	0	1
6.14 Environment design	2	1	3	0
6.15 The problem of finishing early	0	0	1	1
6.16 The Seniority/bumping problem	0	3	1	0
6.2 Ergonomics program concerns				
6.21 Level of reporting of ergonomics	0	1	7	0
6.22 Communication/who does erognomics	7	1	4	0
6.23 Stability/staffing of ergonomics	0	0	10	4
6.24 General evaluation of ergonomics				
Positive	1	3	3	4
Negative	4	10	10	3
6.25 Lack of financial support for ergonomics	0	0	1	0
6.26 Lack of priority for ergonomics	2	2	1	4
6.27 Lack of awareness of ergonomics	2	1	6	1

The outcome was that the accident rate dropped from 35.40 per 100,000 person-shifts to 8.03 in one year. This brought the colliery from worst in the regional group of 15 collieries to best in the group, and indeed in the United Kingdom. In addition, personnel indicators, such as industrial relations climate and absence rates, improved.

5. FINAL THOUGHTS ON HUMAN FACTORS AUDITS

An audit system is a specialized methodology for evaluating the ergonomic status of an organization at a point in time. In the form presented here, it follows auditing practices in the accounting field, and indeed in such other fields as safety. Data is collected, typically with a checklist, analyzed, and presented to the organization for action. In the final analysis, it is the action that is important to human factors engineers, as the colliery example above shows. Such actions could be taken using other methodologies, such as active redesign by job incumbents (Wilson 1994); audits are only one method of tackling the problems of manufacturing and service industries. But as Drury (1991) points

out, industry's moves towards quality are making it more measurement driven. Audits fit naturally into modern management practice as measurement, feedback, and benchmarking systems for the human factors function.

CHAPTER 43

Design for Occupational Health and Safety

Michael J. Smith
Pascale Carayon
Ben-Tzion Karsh
University of Wisconsin-Madison

1. INTRODUCTION

Each year in the United States, thousands of employees are killed on the job, many times that number die of work-related diseases, and millions suffer a work-related injury or health disorder (BLS 1998a, 1999). According to the International Labour Organization (ILO 1998), about 250 million workers worldwide are injured annually on the job, 160 million suffer from occupational diseases, and approximately 335,0000 die each year from occupational injuries. In the United States, the occupational injury and illness incidence rates per 100 full-time workers have been generally decreasing since 1973, but as of 1998, the illness and injury rate was still 6.7 per 100 employees and the injury rate was 6.2 (BLS 1998a). There were a total of 5.9 million occupational injuries and illnesses in 1998 in private industry (BLS 1998a). These figure represented the sixth year in a row of declining injury rates. Overall lost workday rates have steadily declined from 1990 to 1998, but cases with days of restricted work activity have increased. There were just over 60000 occupational fatalities in the private sector in 1998. These work-related deaths and injuries have enormous costs. In the United States alone, it was estimated that in 1992 the direct costs (e.g., medical, property damage) totaled $65 billion and the indirect costs (e.g., lost earnings, workplace training and restaffing, time delays) totaled $106 billion (Leigh et al. 1997). Of the U.S. dollar figures presented, approximately $230 million of the direct costs and $3.46 billion of the indirect costs were related to fatal occupational injuries. Nonfatal injuries accounted for $48.9 billion in direct costs and $92.7 billion in indirect costs (the rest was cost due to death and morbidity from occupational illnesses). These estimates assumed 6500 occupational fatalities and 13.2 million nonfatal injuries.

The workplace continues to undergo rapid change with the introduction of new technologies and processes. Many new processes, such as genetic engineering and biotechnology, introduce new hazards that are challenging, particularly since we do not know much about their potential risks. Will current hazard-control methods be effective in dealing with these new hazards? Our challenge is to protect workers from harm while taking advantage of the benefits of this new technology. To achieve this, we must be ready to develop new safety and health methods to deal with new technology.

This chapter will examine the causation and prevention of occupational diseases and injuries, with an emphasis on recognizing and evaluating hazards, determining disease/injury potential, and defining effective intervention strategies. Due to the huge amount of pertinent information on each of these topic, it cannot be all inclusive. Rather, it will provide direction for establishing effective detection and control methods. Additional resources are provided in the Appendix for more detailed information about the subjects covered.

2. INTERDISCIPLINARY NATURE OF OCCUPATIONAL SAFETY AND HEALTH

Occupational health and safety has its roots in several disciplines, including such diverse fields as engineering, toxicology, epidemiology, medicine, sociology, psychology, and economics. Essentially, occupational health and safety is a multidisciplinary endeavor requiring knowledge from diverse sources to deal with the interacting factors of people, technology, the work environment, and the organization of work activities. Any successful approach for the prevention of injuries and health disorders must recognize the need to deal with these diverse factors using the best available tools from various disciplines and to organize a systematic and balanced effort. Large companies have many resources that can be called upon, but small companies do not have such resources and may need to contact local, state, and federal agencies for information, advice, and consultation.

3. A PUBLIC HEALTH MODEL FOR OCCUPATIONAL SAFETY AND HEALTH PROTECTION

Figure 1 illustrates a general public health approach for improving the safety and health of the workforce (HHS 1989). It begins with surveillance. We have to know what the hazards are and their safety and health consequences before we can establish priorities on where to apply our limited resources and develop intervention strategies. At the national level, there are statistics on occupational

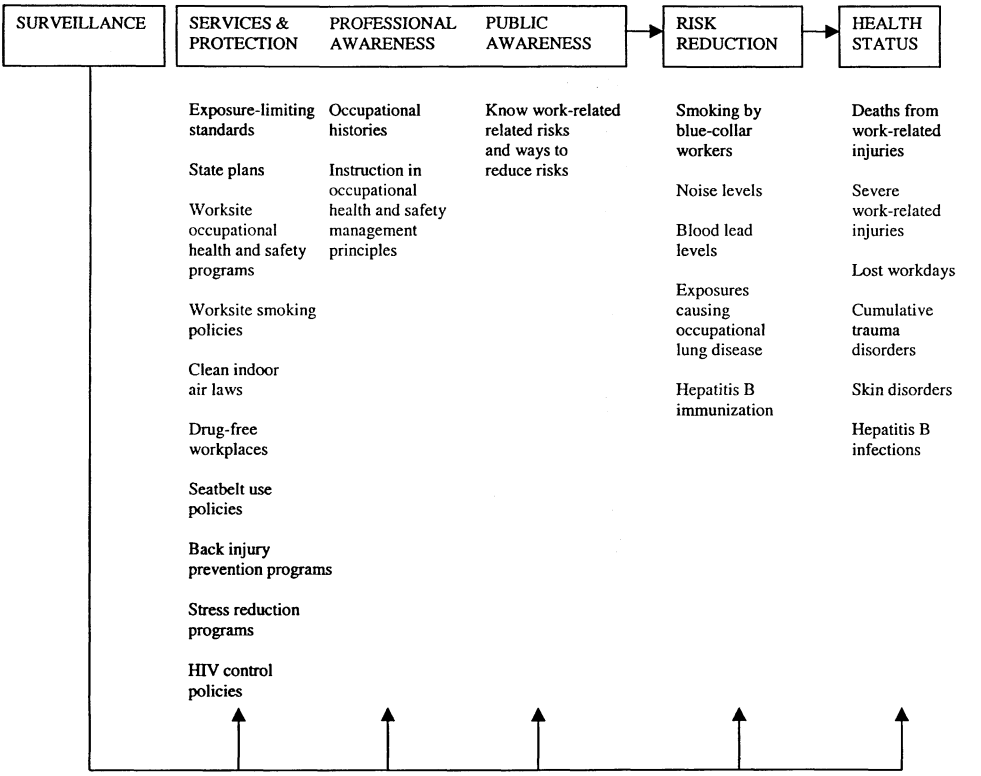

Figure 1 A Public Health Model for Improving the Safety and Health of the Workforce. (*Source:* HHS 1989)

injuries and illnesses from various sources including the U.S. Bureau of Labor Statistics, U.S. National Center for Health Statistics, and National Safety Council. These statistics provide an indication of the most hazardous jobs and industries. In addition, each state has workers' compensation statistics that can provide information about local conditions. This same kind of surveillance can be done by each company at the plant level to identify hazardous jobs and operations. Plant level exposure, hazard, and injury/illness records can be examined periodically to establish trends and determine plant hot spots that need immediate attention.

The second level of the model defines specific services and protection measures to prevent the occurrence of hazards and injuries/illnesses. It also includes services for quick and effective treatment if injury or illness should occur. For example, the safety staff keep track of the state and federal requirements regarding workplace exposure standards. The safety staff then establishes a process for enforcing the standards through inspections and correction activities. Additional plant safety and health programs deal with employee safety and health training (Cohen and Colligan 1998), emergency medical treatment facilities, and arrangements with local clinics. The basic thrust of these multifaceted approaches is to reduce or eliminate adverse workplace exposures and their consequences and provide effective treatment when injuries and illnesses occur.

At the next level of the model is the need to heighten the awareness of the professionals in the workplace who have to make the decisions that affect safety, such as the manufacturing engineers, accountants, operations managers, and supervisors. In addition, workers need to be informed so that they know about the risks and consequences of occupational exposures. There is substantial workplace experience to attest that managers and employees do not always agree on the hazardous nature of workplace exposures. It is vital that those persons who can have a direct impact on plant exposures, such as managers and employees, have the necessary information in an easily understandable and useful form to be able to make informed choices that can lead to reductions in adverse exposures. Providing the appropriate information is the first basic step for good decision making. However, it does not ensure good decisions. Knowledgeable and trained professionals are also needed to provide proper advice on how to interpret and use the information.

The next stage in the model is the reduction of risk by having known adverse agents of injury or illness controlled or removed. The reduction in risk leads to the final stage, which is an improvement in health and safety status of the workforce. This general model leads to a more specific approach that can be applied at specific workplaces.

4. A BALANCE MODEL OF OCCUPATIONAL SAFETY AND HEALTH PERFORMANCE

An important consideration in conceptualizing an approach to occupational health and safety is an understanding of the many personal and workplace factors that interact to cause exposures and accidents. Any strategy to control these exposures and accidents should consider a range of factors and their influences on each other. A model of human workplace interaction is presented in Figure 2. Each element of this model can produce hazardous exposures, for instance a work environment with chemical exposures. These elements also interact to produce hazardous exposures. Examples of these interactions are when high-workload tasks are performed in environments with chemical exposures creating greater fatigue, or more inhalation of the chemicals. Another example is when the person uses machinery and tools that have hazardous characteristics and there is high work pressure to complete the task quickly. Then, the potential for an acute injury increases. Each single factor of the balance model has specific characteristics that can influence exposures to hazards and accident potential or disease risk. At the same time, each interacts with the others to increase exposures and risks or reduce exposures and risks. The model indicates that the person is exposed to loads and hazards that create acute or chronic strains. These strains can lead directly to injury or illness, or they may increase accident potential and/or disease risk.

4.1. The Person

A wide range of individual attributes can affect exposure and accident potential. These include intellectual capabilities and aptitudes, perceptual–motor abilities, physical capabilities such as strength and endurance, current health status, susceptibilities to disease, and personality. A person's education, knowledge, and aptitude affect his or her ability to recognize hazards. They also influence how much a person will learn from training about hazards and safety. An important aspect of injury prevention is to have knowledgeable employees who can determine the potential danger of an exposure and respond appropriately. This requires some previous experience with a hazard and/or training about the nature of the hazard, its injury potential, and ways to control it. Employees must have the ability to learn and retain the information that they are given in training classes. There is a fundamental need for employees to have adequate background and education to be able to apply their intelligence and acquire new knowledge through training. Of specific importance are reading and language skills

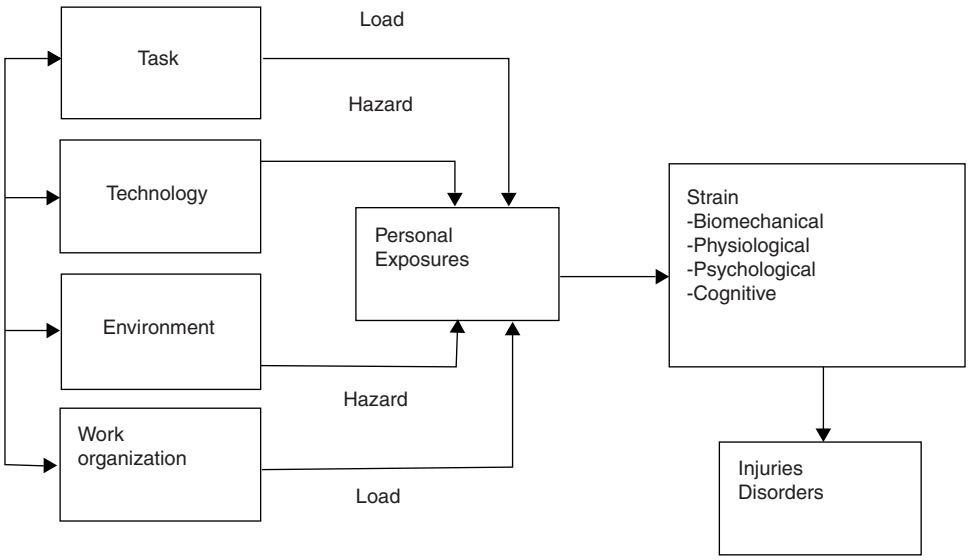

Figure 2 Model of the Work System Risk Process. (Adapted from Smith and Sainfort 1989; Smith et al. 1999)

so that employees can be trained and instructed properly. When employees lack sufficient intelligence or knowledge-acquisition skills, much greater emphasis must be placed on engineering controls.

Physiological considerations such as strength, endurance, and susceptibilities to fatigue, stress, or disease are also of importance. Some jobs demand high energy expenditure and strength requirements. For these, employees must have adequate physical resources to do the work safely.

Another example deals with a concern about women being exposed to reproductive hazards in select industries, for instance in lead processing or synthetic hormone production. Biological sensitivity to substances may increase the risk of an adverse health outcome. Where adequate protection can be provided, there is no logical reason to exclude employees on the basis of gender or biological sensitivity. However, with certain exposures the courts in the United States have ruled that biologically sensitive employees may be barred from jobs in which these biologically adverse exposures cannot be adequately controlled or guarded against.

An attribute related to physical capacity is the perceptual/motor skills of an individual, such as eye–hand coordination. These skills vary widely among individuals and may have more health and safety significance than strength or endurance because they come into play in the moment-by-moment conduct of work tasks. While strength may influence the ability to perform a specific component of a task, perceptual/motor skills are involved in all aspects of manual tasks. Thus, perceptual/motor skills affect the quality with which a task is carried out as well as the probability of a mistake that could cause an exposure or accident.

An individual attribute that should also be considered is personality. For many years it was believed that an employee's personality was the most significant factor in accident causation and that certain workers were more ''accident prone'' than other workers. There is some evidence that ''affectivity'' is related to occupational injuries (Iverson and Erwin 1997). However, in an earlier review of the accident proneness literature (Century Research Corp. 1973), it was determined that individual characteristics such as personality, age, sex, and intellectual capabilities were not significant determinants of accident potential or causation. Rather, situational considerations such as the hazard level of the job tasks and daily personal problems were more important in determining accident risk. There is some evidence that individuals are at greater or lesser risk at different times in their working careers due to these situational considerations. Such situational considerations may account for findings that younger and older employees have higher than average injury rates (Laflamme 1997; Laflamme and Menckel 1995).

It is critical that a proper fit be achieved among employees and other elements of the model. This can occur with proper hazard orientation, training, skill enhancement, ergonomic improvements, and proper engineering of the tasks, technology, and environment.

4.2. Technology and Materials

As with personal attributes, characteristics of the machinery, tools, technology, and materials used by the worker can influence the potential for an exposure or accident. One consideration is the extent to which machinery and tools influence the use of the most appropriate and effective perceptual/motor skills and energy resources. The relationship between the controls of a machine and the action of that machine dictates the level of perceptual/motor skill necessary to perform a task. The action of the controls and the subsequent reaction of the machinery must be compatible with basic human perceptual/motor patterns. If not, significant interference with performance can occur which may lead to improper responses that can cause accidents. In addition, the adequacy of feedback about the action of the machine affects the performance efficiency that can be achieved and the potential for an operational error.

The hazard characteristics of materials will affect exposure and risk. More hazardous materials inherently have a greater probability of adverse health outcomes upon exposure. Sometimes employees will be more careful when using materials that they know have a high hazard potential. But this can only be true when they are knowledgeable about the material's hazard level. If a material is very hazardous, often less-hazardous materials available can be substituted. The same is true for hazardous work processes. Proper substitution can decrease the risk of injury or illness, but care must be taken to ensure that the material or process being substituted is really safer and that it mixes well with the entire product formulation or production/assembly process.

4.3. Task Factors

The demands of a work activity and the way in which it is conducted can influence the probability of an exposure or accident. In addition, the influence of the work activity on employee attention, satisfaction, and motivation can affect behavior patterns that increase exposure and accident risk. Work task considerations can be broken into the physical requirements, mental requirements, and psychological considerations. The physical requirements influence the amount of energy expenditure necessary to carry out a task. Excessive physical requirements can lead to fatigue, both physiological and mental, which can reduce worker capabilities to recognize and respond to workplace hazards.

Typically, relatively high workloads can be tolerated for short periods of time. However, with longer exposure to heavy workloads and multiple exposures to shorter-duration heavy workloads, fatigue accumulates and worker capacity is diminished.

Other task considerations dealing with the content of the task that are related to the physical requirements include the pace or rate of work, the amount of repetition in task activities, and work pressure due to production demands. Task activities that are highly repetitive and paced by machinery rather than by the employee tend to be stressful. Such conditions also diminish an employee's attention to hazards and the capability to respond to a hazard due to boredom. These conditions may produce cumulative trauma disorders to the musculoskeletal system when the task activity cycle time is short and constant. Tasks with relatively low workload and energy expenditure can be very hazardous due to the high frequency of muscle and joint motions and boredom, which leads to employee inattention to hazards.

Psychological task content considerations, such as satisfaction with job tasks, the amount of control over the work process, participation in decision making, the ability to use knowledge and skills, the amount of esteem associated with the job, and the ability to identify with the end products of the task activity, can influence employee attention and motivation. They can also cause job stress, which can affect employee ability to attend to, recognize, and respond to hazards as well as the motivation needed to be concerned with their health and safety considerations. Negative influences can bring about emotional disturbances that limit the employee's capabilities to respond. Task considerations are a central aspect in reducing worker fatigue and stress and enhancing worker motivation for positive health and safety behavior. Tasks must be designed to fit the workforce capabilities and needs and be compatible with the other elements of the model.

4.4. The Work Environment

The work environment exposes employees to materials, chemicals, and physical agents that can cause harm or injury if the exposure exceeds safe limits. Such exposures vary widely from industry to industry, from job to job, and from task to task. Hazard exposure in the work environment influences the probability of an injury or illness, and the extent of exposure often determines the seriousness. Differences in hazard potential are a central basis for determining the rates companies pay for workers' compensation insurance. The central concept is one of relative risk. The greater the number of hazards, the more serious their potential to inflict injury or illness, then the greater the probability of an accident. The greater the probability of a serious accident, the higher the insurance premium. The hazard potential of different environmental factors can be evaluated using various federal, state, and local codes and standards for worker protection and limits established by scientific groups.

Environmental conditions can also hamper the ability of employees to use their senses (poor lighting, excessive noise) and reduce an employee's abilities to respond or react to a hazardous situation. Moderate levels of noise, high levels of heat, and the presence of dust/fumes or gases/vapors have been linked to higher risk of occupational fatalities (Barreto et al. 1997). The environment should be compatible with worker perceptual/motor, energy expenditure, and motivational needs to encourage hazard recognition, precautions, and the desire to do tasks in the proper way.

4.5. Organizational Structure

A company's health and safety performance can be influenced by management policies and procedures, the way that work tasks are organized into plant-wide activities, the style of employee supervision, the motivational climate in the plant, the amount of socialization, interaction between employees, the amount of social support employees receive, and management attitude towards safety. The last point, management attitude, has often been cited as the most critical element in a successful safety program (Cohen, 1977; Smith et al. 1978; Cleveland et al. 1979). If the individuals who manage an organization have a disregard for safety considerations, then employees tend not be very motivated to work safely. Conversely, if the management attitude is that safety considerations are paramount, that is, even more important than production goals, then managers, supervisors, and employees will put great diligence into health and safety efforts.

There are other organizational considerations important in safety performance that are related to management atmosphere and attitudes. For instance, a management structure that provides for frequent employee interaction, positive supervisor relations, and frequent social support leads to an organizational climate that is conducive to cooperative efforts in hazard recognition and control. Such a structure also allows for the motivational climate necessary to encourage appropriate safety behavior. Supervisor and coworker social support have been shown to reduce the risk of occupational injuries (Iverson and Erwin 1997).

A consistent factor in accident causation is work pressure for greater production, or faster output, or to correct problems quickly to continue production or reduce customer waiting time. This work pressure can be exacerbated by technology malfunctions, insufficient staffing, and improper work standards. Management emphasis on reducing costs, enhancing profits, and increasing stock price

often stretch the limits of the capabilities of the workforce and technology. When breakdowns occur or operations are not running normally, employees tend to take risks to keep production online or get it back online quickly. It is during these nonnormal operations that many accidents occur.

Management must provide adequate resources to meet production goals and accommodate nonnormal operations. Management must also establish policies to ensure that employees and supervisors do not take unnecessary risks to ensure production.

5. SAFETY AND HEALTH ORGANIZATIONS, AGENCIES, LAWS, AND REGULATIONS

History has shown that ensuring the safety and health of the workforce cannot be left solely to the discretion of owners and employers. There are those who take advantage of their position and power and do not provide adequate safeguards. Today this is true for only a small percentage of employers but unfortunately, even well-intentioned employers sometimes expose the workforce to hazardous conditions through ignorance of the risks. Factory safety laws were enacted in Europe in past centuries to deal with employer abuses. The basic concepts were adopted in the United States when some of the states took action in the form of factory laws and regulations, both for worker safety and for compensation in case of injury. Over the years these laws were strengthened and broadened until 1969 and 1970, when the U.S. Congress created two federal laws regulating safety and health for those employers engaged in interstate commerce in coal mining and all other private industry. In 1977, federal legislation dealing with other forms of mining was added. However, public institutions such as state and local governments and universities were not covered by the federal laws in the United States and still are not covered by federal safety legislation.

The Occupational Safety and Health Act of 1970 (OSHAct) remains the primary federal vehicle for ensuring workplace safety and health in the United States. This law requires that employers provide a place of employment free from recognized hazards to employee safety or health. The critical word is ''recognized'' because today's workplaces have many new materials and processes for which hazard knowledge is absent. This places a large responsibility on the employer to keep abreast of new knowledge and information about workplace hazards for their operations. The OSHAct established three agencies to deal with workplace safety and health. These were the Occupational Safety and Health Administration (OSHA), the National Institute for Occupational Safety and Health (NIOSH), and the Occupational Safety and Health Review Commission.

5.1. The Occupational Safety and Health Administration

OSHA, located within the U.S. Department of Labor, has the responsibility for establishing federal workplace safety and health standards and enforcing them. Over the last three decades, OSHA has developed hundreds of standards that have been published in the code of federal regulations (CFR) Section 29 CFR, subsections 1900–1928, which cover General Industry (1910), Longshoring (1918), Construction (1926), and Agriculture (1928) (http://www.osha-slc.gov/OshStd_toc/OSHA_Std_toc.html). This code is revised periodically and new standards are added continually. Current and proposed rules and standards include Process Safety Management of Highly Hazardous Chemicals (1910.119), Personal Protective Equipment (1910.132 to 1910.139), the Proposed Safety and Health Program Rule, and the Final Ergonomic Program Standard. It is important for employers to keep up with these new and revised standards. One way is to keep in frequent contact with your area office of OSHA and request that they send you updates. Another way is to subscribe to one or more of the many newsletters for occupational safety and health that provide current information and updates. A third way is to access the OSHA web page (http://www.osha.gov), which provides information about current activities, regulations, and updates.

Workplaces are required by law to be in compliance with the federal safety and health standards. Failure to do so can be the basis for federal fines in the first instance, meaning that when a violation is found, the inspector will propose a fine and an abatement period. Under some of the former state safety programs, an identified hazard did not bring a fine if it was controlled within the abatement period. Under the federal process, fines will be assessed immediately after a hazard is identified. These fines can be substantial, and the threat of such fines is felt to be an incentive for compliance with the federal standards. Many employers feel that this first-instance fine is punitive and takes resources away from abatement efforts. However, the logic of first-instance fines is to motivate employers to be proactive in looking for and correcting workplace hazards. If an employer is found to be in violation of a standard and disagrees with the inspector about this, the employer has the right to a review at higher OSHA levels. If no recourse is obtained from OSHA, then the employer has the right for review by the Occupational Safety and Health Review Commission. The employer also has the right to subsequent legal recourse through the federal courts.

Current estimates of the numbers of OSHA inspectors and workplaces indicate that the average workplace can expect an OSHA inspection about every 9 to 10 years. To apply its inspection resources in the most effective manner, OSHA has adopted a strategy to concentrate on the most hazardous

industries. Thus, these industries can expect an inspection much more often. OSHA concentrates on select high-risk industries, such as construction, and select injuries, such as cumulative trauma, which is widespread in meat processing and assembly jobs. OSHA has contracted with several state workers' compensation agencies to obtain data on the employers in these states with the greatest injury frequency and severity and uses these data to select employers for inspection. Inspections can also be triggered by a complaint from an employee or employee representative. When the inspector arrives at your workplace, you will be shown an official credential indicating that the inspector is from OSHA. It is a good policy to cooperate with the OSHA inspector. However, at the initial contact by the inspector you have the right, by ruling of the U.S. Supreme Court, to require a search warrant for entry into your workplace. Most employers provide immediate access to their facilities because requiring a search warrant may create an antagonistic situation once the warrant is obtained by the inspector.

When an inspection is triggered by a complaint, the inspector will typically only examine the hazard(s) and work areas defined in the complaint. If it is a general inspection, usually the entire workplace is examined. The first step in the inspection is a review of your injury and illness log (OSHA 300). The inspector will be looking for jobs or areas of the plant that have many injuries and illnesses. After this, the inspector will conduct a walk-through of the facility. You have the right to accompany the inspector on the inspection and point out trade secrets that you want to be kept confidential. OSHA will meet your request unless there is good reason to believe that your trade secret is not really a secret. A representative of your employees is also allowed to accompany the inspector. During the inspection the inspector will talk to employees about their working conditions and any safety and health problems they are encountering. The inspector will take notes on what is observed and heard. Some inspections are complex and require special measurements of the equipment, air contamination, noise level, or other aspects of hazard exposure. Depending on the size of the plant or store location and the number of hazards, an inspection can take from one day up to several months. At the end of the inspection, the inspector will have a closing conference with management and the employee representative to discuss what was observed and possible violations of the standards. If standards were violated, some days after the inspection you will receive a formal citation indicating the standards violated and proposed penalties via registered mail. At that time you can contest any of the proposed violations and/or penalties. These will be reviewed with you by the OSHA area director and some agreement may be reached at that time. If not, you can contest to higher levels in OSHA, and then to the Occupational Safety and Health Review Commission. The final recourse is the federal courts.

OSHA also provides professional training and short courses to safety and health professionals, employee representatives, and employees at the OSHA Training Institute and through contracts with universities, colleges, technical schools, and unions. See the OSHA website for information on training (http://www.osha.gov).

5.2. The National Institute for Occupational Safety and Health

NIOSH is a subunit of the Centers for Disease Control and Prevention (see website http://www.cdc.gov), which conducts research into the causes and cures of occupationally caused injuries and illnesses. It also has a training function that promotes the development of occupational safety and health professionals. NIOSH research covers a broad range of topics, from the toxicology of chemicals, metals, and biological agents to the causes of accidents to the psychological stress aspects of the workplace, to name a few. The results of this research are published in the scientific literature and public reports disseminated by NIOSH and the U.S. Government Printing Office. A listing of these reports is available on the NIOSH website (http://www.cdc.gov/niosh). Oftentimes enough research knowledge is accumulated to develop a recommendation for a federal safety and health standard. At that time a criteria or technical document is developed that defines the scope of the hazard(s), the evidence for adverse safety or health effects, and recommendations for exposure limits and control mechanisms. These criteria documents and technical reports are sent to OSHA for consideration as the basis for a safety and health federal standard. They also often appear in court litigation as the state-of-the-art knowledge about the hazards of products in product liability suits, even though they may not have been adopted as standards. Information on these criteria documents and NIOSH research reports is available from the U.S. Superintendent of Documents in Washington, DC, and from the NIOSH website.

NIOSH also conducts health hazard investigations in situations where employees become ill from unknown causes or where they have been exposed to agents for which only scarce knowledge is available and special expertise is needed. These investigations are triggered by a request for technical assistance from OSHA, a state health agency, a state safety agency, or a health hazard evaluation request from a company, union, or employee. NIOSH has a right of entry into workplaces for these investigations but can be required to obtain a search warrant by the company. These investigations are often much more complex than OSHA investigations and can entail extensive environmental

measurement, employee physical examinations and interviews, examinations of company records, and discussions with management. Reports are developed based on the evaluation, which include a determination of hazards and proposed methods of control. These reports may be sent to OSHA for compliance action (inspection and/or citation).

5.3. State Agencies

The state(s) in which your operation(s) are located may also have jurisdiction for enforcing occupational safety and health standards, and conducting investigations based on an agreement with OSHA. In many states the state health agency and/or labor department has agreements with OSHA to provide consultative services to employers. You can find out by contacting these agencies directly. In several states the safety and health agencies enforce safety and health rules and standards for local and state government employees, or other employees not covered by OSHA. See website http://www.cdc.gov/niosh/statosh.html.

5.4. Centers for Disease Control and Prevention

The purpose of the Centers for Disease Control and Prevention (CDC) is to promote health and quality of life by preventing and controlling disease, injury, and disability. The CDC provides limited information on occupational safety and health. For example, their web page has information about accident causes and prevention, back belts, cancer—occupational exposure, effects of workplace hazards on male reproductive health, latex allergies, needle stick, occupational injuries, teen workers, and violence in the workplace (see website http://www.cdc.gov). The Center for Health Statistics is located within CDC and provides basic health statistics on the U.S. population. This information is used to identify potential occupational health risks by occupational health researchers (see website http://www.cdc.gov/nchs).

5.5. The Bureau of Labor Statistics

The Bureau of Labor Statistics (BLS) is the principal fact-finding agency for the federal government in the broad field of labor economics and statistics (see website http://stats.bls.gov). It collects, processes, analyzes, and disseminates essential statistical data. Among the data are occupational safety and health data, including annual reports, by industry, of rates of injuries, illnesses, and fatalities (http://stats.bls.gov/oshhome.htm).

5.6. The Environmental Protection Agency

The Environmental Protection Agency (EPA) was established as an independent agency in 1970 with the purpose of protecting the air, water, and land (see website http://www.epa.gov). To this end, the EPA engages in a variety of research, monitoring, standard setting, and enforcement activities. The Agency administers 10 comprehensive environmental protection laws: the Clean Air Act (CAA); the Clean Water Act (CWA); the Safe Drinking Water Act (SDWA); the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, or Superfund); the Resource Conservation and Recovery Act (RCRA); the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA); the Toxic Substances Control Act (TSCA); the Marine Protection, Research, and Sanctuaries Act (MPRSA); Uranium Mill Tailings Radiation Control Act (UMTRCA); and the Pollution Prevention Act (PPA). The EPA's Strategic Plan for the 21st century includes 10 goals, among which is one dealing with preventing pollution and reducing risk in communities, homes, workplaces, and ecosystems. For the purposes of this chapter, we will focus on the issues related to workplaces. According to the EPA's plan (EPA 1999), over 75,000 chemicals are in commerce today, with an estimated 2,000 new chemicals and 40 genetically engineered microorganisms introduced each year. Among those are potentially toxic chemicals that may present risks to workers, such as persistent, bioaccumulative and toxic chemicals (PBTs). Reducing PBTs should lead to safer manufacturing processes and eliminate some occupational exposures. Strategies to deal with such chemicals include better management of, training about, and reduced use of pesticides; better programs to deal with the chemical industry; industrial pollution prevention; better building construction to promote quality indoor air; and industrial waste minimization.

5.7. Other Agencies and Groups

The American National Standards Institute (ANSI) was founded in 1918 and has been the administrator and coordinator of the United States private sector voluntary standardization system (see website http://www.ansi.org). ANSI does not itself develop standards but rather facilitates development by establishing consensus among qualified groups. ANSI has developed a number of occupational health- and safety-related standards, including standards related to information management for occupational safety and health (ANSI Z16.2-1995), preparation of hazardous industrial chemical material safety

data sheets (ANSI Z400.1-1998), construction safety and health audit programs (ANSI A10.39-1996), and human factors engineering of visual display terminal workstations (ANSI/HFS 100-1988).

The mission of the American Society for Testing and Materials (ASTM) is to be the foremost developer and provider of voluntary consensus standards, related technical information, and services having internationally recognized quality and applicability that (1) promote public health and safety, (2) contribute to the reliability of materials, products, systems and services, and (3) facilitate national, regional, and international commerce. See website http://www.astm.org.

The International Labour Organization (ILO) was created in 1919 and is a United Nations (UN) specialized agency that seeks the promotion of social justice and internationally recognized human and labor rights (see webpage http://www.ilo.org). The ILO formulates minimum standards of basic labor rights, such as freedom of association, the right to organize, and collective bargaining. It also provides technical assistance in areas such as vocational training and vocational rehabilitation, employment policy, working conditions, and occupational safety and health. There is a branch concerned with occupational safety and health (see website http://www.ilo.org/public/english/protection/safework/intro.htm) that focuses on reducing the number and seriousness of occupational accidents and diseases, adapting the working environment, equipment, and work processes to the physical and mental capacity of the worker, enhancing the physical, mental, and social well being of workers in all occupations, encouraging national policies and programs of member states, and providing appropriate assistance. To achieve those aims, the ILO works with government and nongovernment agencies to design and implement policies and programs to improve working conditions. The ILO is currently working on a global program for occupational safety and health.

The constitution of the World Health Organization (WHO) was approved in 1946 (see website http://www.who.org). Its goal is good health for all people. To this end, the WHO directs international health activity, promotes technical cooperation, helps governments strengthen their own health services, provides technical assistance, conducts research, and establishes international standards for biological and pharmaceutical products. They also provide information on global occupational safety and health issues (see website http://www.who.org/peh/Occupational_health/occindex.html), such as biological agents, noise, radiation, chemicals, occupational carcinogens, and allergenic agents. WHO established the international statistical classification of diseases and related health problems in occupational health. The organization has a global strategy on occupational safety and health that includes 10 priority areas:

1. Strengthening international and national policies for health at work and developing necessary policy tools
2. Developing healthy work environments
3. Developing healthy work practices and promoting health at work
4. Strengthening occupational health services
5. Establishing support services for occupational health
6. Developing occupational health standards
7. Developing human resources for occupational health
8. Establishing registration and data systems, developing information services, and raising public awareness
9. Strengthening research
10. Developing collaboration in occupational health with other services

The European Agency for Safety and Health at Work (see website http://europe.osha.eu.int/) was established in 1996 and is based in Bilbao, Spain. The Agency has put forth numerous directives for employers in its member states to follow. These include general safety requirement directives, directives regarding temporary workers, pregnant workers, and young people and directives on manual handling, work equipment, and safety signs. The agency also conducts information campaigns, such as the recently launched campaign aimed at reducing the number of work-related back injuries and other musculoskeletal disorders. Other information about occupational health and safety in the European Union can be found using HASTE (see website http://www.occuphealth.fi/e/eu/haste/), the European Union health and safety database, which lists databases from member states.

5.8. Safety and Ergonomics Program Standards

The purpose of the OSHA Proposed Safety and Health Program Rule (see website http://www.osha-slc.gov/SLTC/safetyhealth/nshp.html) is to reduce the number of job-related fatalities, illnesses, and injuries by requiring employers to establish a workplace safety and health program to ensure compliance with OSHA standards and the General Duty Clause of the OSHAct. All employers covered

under the OSHAct are covered by this rule (except construction and agriculture), and the rule applies to all hazards covered by the General Duty Clause and OSHA standards. Five elements make up the program:

1. Management leadership and employee participation
2. Hazard identification and assessment
3. Hazard prevention and control
4. Information and training
5. Evaluation of program effectiveness

Employers that already have safety and health programs with these five elements can continue using their existing programs if they are effective. Late in 2000, OSHA announced its Final Ergonomic Program Standard (see website http://www.osha-slc.gov/ergonomics-standard/index.html). The proposed Standard specifies employer's obligations to control musculoskeletal disorder (MSD) hazards and provide MSD medical management for injured employees. The Proposed Ergonomic Standard uses a program approach—that is, the proposal specifies the type of a program to set up to combat MSD, as opposed to specifying the minimum or maximum hazard levels. According to the proposed ergonomic standard, an ergonomic program consists of the following six program elements:

1. Management leadership and employee participation
2. Hazard information and reporting
3. Job hazard analysis and control
4. Training
5. MSD management
6. Program evaluation

These are similar to the elements in the proposed safety and health program rule. The proposed ergonomics standard covers workers in general industry, though construction, maritime, and agriculture operations may be covered in future rulemaking. The proposal specifically covers manufacturing jobs, manual material-handling jobs, and other jobs in general industry where MSDs occur. If an employer has an OSHA recordable MSD, the employer is required to analyze the job and control any identified MSD hazards. Public hearings were ongoing regarding the proposed ergonomic standard as of March–April of 2000 and written comments were being taken. Some states have proposed ergonomic standards to control MSDs.

The California Ergonomic Standard (see website http://www.dir.ca.gov/Title8/5110.html) went into effect on July 3, 1997. The standard targets jobs where a repetitive motion injury (RMI) has occurred and the injury can be determined to be work related and at a repetitive job. The injury must have been diagnosed by a physician. The three main elements of the California standard are work site evaluation, control of exposures that have caused RMIs, and employee training. The exact language of the standard has been undergoing review in the California judicial system.

The purpose of the Washington State Proposed Ergonomics Program Rule (see website http://www.lni.wa.gov/wisha) is to reduce employee exposure to workplace hazards that can cause or aggravate work-related musculoskeletal disorders (WMSDs). There are no requirements for medical management in the proposed rule. The proposal covers employers with caution zone jobs, which the proposed rule defines based on the presence of any one or more of a number physical job factors. For example, a caution zone job exists if the job requires ''working with the neck, back or wrist(s) bent more than 30 degrees for more than 2 hours total per workday'' (WAC 296-62-05105). The proposed standard specifies the type of ergonomic awareness education that must be provided to employees who work in caution zone jobs. The standard also states that if caution zone jobs have WMSD hazards, employers must reduce the WMSD hazards identified. Several tools are suggested that can be used to analyze the caution zone jobs for WMSD hazards, and thresholds are provided that indicate sufficient hazard reduction. The rule also states that employees should be involved in analyzing caution zone jobs and in controlling the hazards identified. This proposed rule was under review in 2000.

The proposed North Carolina Ergonomic Standard (see website http://www.dol.state.nc.us/news/ergostd.htm) was first announced in November 1998. Like the proposed national standard and California's standard, North Carolina's is a program standard without physical hazard thresholds. The proposal states employers shall provide ergonomic training within 90 days of employment and no less than every three years thereafter. It also specifies the nature of that training, which includes information on ergonomic physical hazards, MSDs that can arise from ergonomic hazards, workplace ways to control ergonomic hazards, and the importance of reporting symptoms. Under the proposed standard, if an MSD is thought to be causally related to work, the employer has to implement

TABLE 1 Descriptions of NIOSH Top Eight Occupational Disease and Injury Categories

Disease or Injury	Description
Allergic and irritant dermatitis	Allergic and irritant dermatitis (contact dermatitis) is overwhelmingly the most important cause of occupational skin diseases, which account for 15% to 20% of all reported occupational diseases. There is virtually no occupation or industry without potential exposure to the many diverse agents that cause allergic and irritant dermatitis.
Asthma and chronic obstructive pulmonary disease	Occupationally related airway diseases, including asthma and chronic obstructive pulmonary disease (COPD), have emerged as having substantial public health importance. Nearly 30% of COPD and adult asthma may be attributable to occupational exposure. Occupational asthma is now the most frequent occupational respiratory disease diagnosis. More than 20 million U.S. workers are exposed to substances that can cause airway diseases.
Fertility and pregnancy abnormalities	While more than 1000 workplace chemicals have shown reproductive effects in animals, most have not been studied in humans. In addition, most of the 4 million other chemical mixtures in commercial use remain untested. Physical and biological agents in the workplace that may affect fertility and pregnancy outcomes are practically unstudied.
Hearing loss	Occupational hearing loss may result from an acute traumatic injury, but it is far more likely to develop gradually as a result of chronic exposure to ototraumatic (damaging to the ear or hearing process) agents. Noise is the most important occupational cause of hearing loss, but solvents, metals, asphyxiants, and heat may also play a role. Exposure to noise combined with other agents can result in hearing losses greater than those resulting from exposure to noise or other agents alone.
Infectious disease	Health care workers are at risk of tuberculosis (TB), hepatitis B and C viruses, and the human immunodeficiency virus (HIV). Social service workers, corrections personnel, and other occupational groups who work regularly with populations having increased rates of TB may also face increased risk. Laboratory workers are at risk of exposure to infectious diseases when working with infective material.
Low-back disorders	Back pain is one of the most common and significant musculoskeletal problems in the world. In 1993, back disorders accounted for 27% of all nonfatal occupational injuries and illnesses involving days away from work in the United States. The economic costs of low back disorders are staggering. According to NIOSH (1996b), a recent study showed the average cost of a workers' compensation claim for a low-back disorder was $8,300, which was more than twice the average cost of $4075 for all compensable claims combined. Estimates of the total cost of low-back pain to society in 1990 were between $50 billion and $100 billion per year, with a significant share (about $11 billion) borne by the workers' compensation system. Moreover, as many as 30% of American workers are employed in jobs that routinely require them to perform activities that may increase risk of developing low-back disorders.
Musculoskeletal disorders of the upper extremities	Musculoskeletal disorders of the upper extremities (such as carpal tunnel syndrome and rotator cuff tendinitis) due to work factors are common and occur in nearly all sectors of our economy. More than $2 billion in workers' compensation costs are spent annually on these work-related problems. Musculoskeletal disorders of the neck and upper extremities due to work factors affect employees in every type of workplace and include such diverse workers as food processors, automobile and electronics assemblers, carpenters, office data-entry workers, grocery store cashiers, and garment workers. The highest rates of these disorders occur in the industries with a substantial amount of repetitive, forceful work. Musculoskeletal disorders affect the soft tissues of the neck, shoulder, elbow, hand, wrist, and fingers.

TABLE 1 (*Continued*)

Disease or Injury	Description
Traumatic injuries	During the period 1980 through 1992, more than 77,000 workers died as a result of work-related injuries. This means that an average of 16 workers die every day from injuries suffered at work. The leading causes of occupational injury fatalities over this 13-year period were motor vehicles, machines, homicides, falls, electrocutions, and falling objects. In four industries—mining, construction, transportation, and agriculture—occupational injury fatality rates were notably and consistently higher than all other industries. In 1994, 6.3 million workers suffered job-related injuries that resulted in lost work time, medical treatment other than first aid, loss of consciousness, restriction of work or motion, or transfer to another job. The leading causes of nonfatal occupational injuries involving time away from work in 1993 were overexertion, contact with objects or equipment, and falls to the same level.

engineering controls, work practice controls, and/or administrative controls to reduce the impact of the ergonomic hazards. Employee participation in the ergonomic program is encouraged.

6. DEFINING OCCUPATIONAL INJURIES AND DISEASES

Early in the 1980s, NIOSH defined the 10 most serious occupational disease and injury areas (CDC 1983). These were occupational lung diseases, musculoskeletal injuries, occupational cancers, acute trauma, cardiovascular diseases, disorders of reproduction, neurotoxic disorders, noise-induced hearing loss, dermatologic conditions, and psychological disorders. In April of 1996, NIOSH developed the National Occupational Research Agenda (NORA) (NIOSH 1996a), which identified 21 priority research areas to target and coordinate occupational safety and health research. Eight of the 21 target areas focus on occupational diseases and injuries. This was an update of the list from the early 1980s defined above. The new list identifies allergic and irritant dermatitis, asthma and chronic obstructive pulmonary disease, fertility and pregnancy abnormalities, hearing loss, infectious disease, low-back disorders, musculoskeletal disorders of the upper extremities, and traumatic injuries (NIOSH 1996b) as serious problems. More detail on each disease or condition is provided in Table 1. Table 2 provides brief descriptions of various types of occupational diseases and injuries not included in Table 1 that were highlighted previously by CDC and NIOSH.

7. WORKPLACE HAZARDS

A list of all currently recognized and potential workplace hazards would be larger than this entire Handbook. The best places to start accumulating hazard information pertinent to your operations are the OSHA standards, NIOSH criteria documents, and government reports and publications. These are available on the websites listed in this chapter and from the U.S. Superintendent of Documents in Washington, DC. The websites have a great deal of useful information. Other excellent sources of information include the National Safety Council Safety manuals, NIOSH (1984), and Best's Loss Control Guide. Other federal, state, and local agencies can also provide some aspects of occupational health and safety hazard information. At the federal level these include the Environmental Protection Agency (EPA), the National Institute for Environmental Health Sciences (NIEHS), and the Centers for Disease Control and Prevention (CDC).

It is important to comprehend the breadth and nature of occupational hazard exposures. To do this we can classify workplace hazard sources into broad categories that help us to understand their nature and potential controls. These are:

1. Physical agents such as noise and heat
2. Powered mechanical agents such as machinery and tools
3. Nonpowered mechanical agents such as hammers, axes, and knives
4. Liquid chemical agents such as benzene and toluene
5. Powdered materials such as pesticides, asbestos, sand, and coal dust
6. Gaseous or vaporous chemical agents such as nitrous oxide, carbon monoxide, and anhydrous ammonia

TABLE 2 Descriptions of Various Occupational Disorders and Diseases Not Included in Table 1

Disease or Injury	Description
Occupational lung disease	The latent period for many lung diseases can be several years. For instance, for silicosis it may be as long as 15 years and for asbestos-related diseases as long as 30 years. The lung is a primary target for disease related to toxic exposures because it is often the first point of exposure through breathing. Many chemicals and dusts are ingested through breathing. The six most severe occupational lung disorders are asbestosis, byssinosis, silicosis, coal workers' pneumoconiosis, lung cancer, and occupational asthma.
Asbestosis	This disease produces scarring of the lung tissue, which causes progressive shortness of breath. The disease continues to progress even after exposures end, and there is no specific treatment. The latent period is 10–20 years. The agent of exposure is asbestos, and insulation and shipyard workers are those most affected.
Byssinosis	This disease produces chest tightness, cough, and airway obstruction. Symptoms can be acute (reversible) or chronic. The agents of exposure are dusts of cotton, flax, and hemp, and textile workers are those most affected.
Silicosis	This is a progressive disease that produces nodular fibrosis, which inhibits breathing. The agent of exposure is free crystalline silica, and miners, foundry workers, abrasive blasting workers, and workers in stone, clay, and glass manufacture are most affected.
Coal Miners' pneumoconiosis	This disease produces fibrosis and emphysema. The agent of exposure is coal dust. The prevalence of this disorder among currently employed coal miners has been estimated at almost 5%.
Lung cancer	This disease has many symptoms and multiple pathology. There are several agents of exposure, including chromates, arsenic, asbestos, chloroethers, ionizing radiation, nickel, and polynuclear aromatic hydrocarbon compounds.
Occupational cancers	There is some debate on the significance of occupational exposures in the overall rate of cancer ranging from 4 to 20% due to occupation, yet there is good agreement that such occupational exposures can produce cancer. There are many types of cancer that are related to workplace exposures, including hemangiosarcoma of the liver; mesothelioma; malignant neoplasm of the nasal cavities, bone, larynx, scrotum, bladder, kidney, and other urinary organs; and lymphoid leukemia and erythroleukemia.
Traumatic injuries	
Amputations	The vast majority of amputations occur to the fingers. The agents of exposure include powered hand tools and powered machines. Many industries have this type of injury, as do many occupations. Machine operators are the single most injured occupation for amputations.
Fractures	Falls and blows from objects are the primary agents that cause fractures. The major sources of these injuries include floors, the ground, and metal items. This suggests falling down or being struck by an object as the primary reasons for fractures. Truck drivers, general laborers, and construction laborers were the occupations having the most fractures.
Eye loss	It was estimated that in 1982 there were over 900,000 occupational eye injuries. Most were due to particles in the eye such as pieces of metal, wood, or glass, but a smaller number were caused by chemicals in the eye. A number of occupations are affected, including those in woodworking, metalwork, construction, and agriculture.

TABLE 2 (*Continued*)

Disease or Injury	Description
Traumatic injuries	
Lacerations	Over 2,000,000 lacerations occur each year with the majority to the fingers, followed by the arms, legs, and head/neck. Lacerations occur primarily from being struck or stuck by an object or from striking against an object. The major agents of exposure include knives, sharp metal objects, saws, glass items, nails, and machines.
Cardiovascular disease	These disorders include hypertensive disease, ischemic heart disease, other forms of heart disease, and cerebrovascular disease. As with cancer, the specific contribution of occupational factors to the causation of CVD has been debated, but there is agreement that some workplace factors contribute to or cause CVD (see Smith and Sainfort 1990 for a detailed discussion of psychosocial factors and their contribution). Four main occupational sources of CVD causation are agents that affect cardiopulmonary capacity, chemicals, noise, and psychosocial stress.
Cardiopulmonary capacity reducers	Agents such as dusts, mists, heavy metals, silica, and other trace elements make the lungs work much harder than normal and can induce congestive heart failure. Metal such as beryllium, antimony, lead, and cobalt as well as silica and asbestos can produce heart disorders.
Chemicals	Some chemicals act to sensitize the heart muscle and the smooth muscle of the blood vessels, while others reduce the oxygen-carrying capacity of the blood. These include nitroglycerin, carbon monoxide, carbon disulfide, and halogenated hydrocarbons.
Noise	Studies have shown that noise can produce transient increases in blood pressure that may lead to CVD. This may be due to psychological factors related to stress reactions.
Psychosocial stress	Research from longitudinal studies of cardiovascular fitness has demonstrated a relationship between perceived job satisfaction and stress and cardiovascular illness. Epidemiological studies have shown that particular jobs with specific characteristics such as high demands and low control have a higher incidence of coronary heart disease. Organizational demands and relations, job task demands, social relationships at work, work schedule, work content features, discretionary control and participation, and physical working conditions have all been shown to influence the level of job stress (Smith 1986; Kalimo et al. 1997).
Neurotoxic disorders	Neurotoxic disorders are produced by damage to the central nervous system, damage to the peripheral nervous system, and intoxication. These cause deficits in attention, reasoning, thinking, remembering, and making judgments. They may also cause peripheral neuropathy, neuroses and psychoses, personality changes, aberrant behavior, or reduced reaction time and motor skill. One of the first workplace-related neurological disorders identified was lead poisoning, which produced palsy in workers exposed to lead dust. NIOSH publishes a list of the materials known to have neurotoxic effects.
Psychological disorders	Psychological disorders related to working conditions include sleep disturbances, mood disturbances, reduced motivation to work or recreate, somatic and psychosomatic complaints, neuroses, psychoses, and dysfunctional coping behavior. The effects of stress on an individual are influenced by the nature of the exposures and the individual's physical and psychological characteristics and coping behaviors that may accentuate or mitigate the exposure.

7. Heavy metals such as lead and mercury
8. Biological agents such as bacteria and viruses
9. Genetically engineered agents
10. Other hazards, such as wet working surfaces, unguarded floor openings, job stress, and the unsafe behavior of others

These hazards enter the body through various avenues, including inhalation into the lungs and nose, absorption through the skin and other membranes, ingestion into the throat and stomach, traumatic contact with various body surfaces and organs, and, in the case of job stress, through the cognitive mental processes. Descriptions of many of these hazards and definitions of adverse exposure levels are contained in NIOSH (1977).

Traditional hazards such as unexpected energy release and chemicals are still major concerns in the workplace. The use of lasers, robots, microwaves, x-rays, and imaging devices will become more common and will make many of the traditional problems of controlling energy release and limiting worker access to hazardous machine components even more challenging. These technologies will be even more problematic because of the complex nature of the mechanisms of energy release and the increased power of the forces involved. For instance, using x-rays for lithographic etching of computer chips could produce exposures that are substantially higher than with conventional diagnostic x-rays. The safety precautions for this type of instrument have to be much better than current standards for diagnostic equipment.

In addition to these emerging hazards, other new hazards will appear. Some will be the exotic products of genetic engineering and biotechnology, while others will be the products of our ability to harness the laws of physics and chemistry with advanced engineering designs. The future will see commercial uses of plasma gas generators for tool hardening, electron accelerators for generating tremendous power for x-ray lithography in microchip production and fusion power generation. These will become everyday tools used by thousands of workers, many of whom will not be well educated or knowledgeable about the tremendous power of the technology they will be working with.

While these physical and biological hazards will become more prevalent and dangerous than they are today, there will also be more physical and psychological work demands that can lead to psychological stress problems. Currently, the two fastest-rising workers' compensation claim areas in the United States are cumulative musculoskeletal trauma and psychological distress. The rise in these problems can generally be related to two factors: first, greater media, worker, and employer awareness and knowledge about how the workplace can contribute to such problems; and second, huge increases in workplace automation that create conditions that produce these disorders. Dealing with these stress-induced problems may be even more difficult than dealing with the biological, chemical, and physical hazards.

8. MEASURING HAZARD POTENTIAL AND SAFETY PERFORMANCE

To control occupational hazards and related illness and injuries, it is necessary to define their nature and predict when and where they will occur. This requires that some system of hazard detection be developed that can define the frequency of the hazard, its seriousness, and its amenability to control. Traditionally, two parallel systems of information have been used to attain this purpose. One is hazard identification, such as plant inspections, fault-free analysis, and employee hazard-reporting programs, which have been used to define the nature and frequency of company hazards. In this case, action is taken before an injury or illness occurs. The second system is after the fact in that it uses employee injury and company loss-control information to define problem spots based on the extent of injuries and costs to the organization. When pre- and postinjury systems have been integrated, they have been successful in predicting high-risk plant areas or working conditions where remedial programs can be established for hazard control.

8.1. Inspection Programs

Hazard identification prior to the occurrence of an occupational injury is a major goal of a hazard inspection program. In the United States, such programs have been formalized in terms of federal and state regulations that require employers to monitor and abate recognized occupational health and safety hazards. These recognized hazards are defined in the federal and state regulations that provide explicit standards of unsafe exposures. The standards can be the basis for establishing an in-plant inspection program because they specify the explicit subject matter to be investigated and corrected.

Research has shown that inspections are most effective in identifying permanent fixed physical and environmental hazards that do not vary over time. Inspections are not very effective in identifying transient physical and environmental hazards or improper workplace behaviors because these hazards may not be present when the inspection is taking place (Smith et al. 1971). A major benefit from inspections, beyond hazard recognition, is the positive motivational influence on employees. Inspec-

tions demonstrate management interest in the health and safety of employees and a commitment to a safe working environment. To capitalize on this positive motivational influence, an inspection should not be a punitive or confrontational process of placing blame. Indicating the good aspects of a work area and not just the hazards is important in this respect. It is also important to have employees participate in hazard inspections because this increases hazard-recognition skills and increases motivation for safe behavior.

The first step in an inspection program is to develop a checklist that identifies all potential hazards. A good starting point is the state and federal standards. Many insurance companies have developed general checklists of OSHA standards that can be tailored to a particular plant. These are a good source when drawing up the checklist. A systematic inspection procedure is preferred. This requires that the inspectors know what to look for and where to look for it and have the proper tools to conduct an effective assessment. It is important that the checklist be tailored to each work area after an analysis of that work area's needs has been undertaken. This analysis should determine the factors to be inspected: (1) the machinery, tools, and materials, (2) chemicals, gases, vapors, and biological agents, and (3) environmental conditions. The analysis should also determine (1) the frequency of inspections necessary to detect and control hazards, (2) the individuals who should conduct and/or participate in the inspections, and (3) the instrumentation needed to make measurements of the hazard(s).

The hazards that require inspection can be determined by (1) their potential to cause an injury or illness, (2) the potential seriousness of the injuries or illnesses, (3) the number of people exposed to the hazard, (4) the number of injuries and illnesses at a workplace related to a specific hazard, and (5) hazardous conditions defined by federal, state, and local regulations. The frequency of inspections should be based on the nature of the hazards being evaluated. For instance, once a serious fixed physical hazard has been identified and controlled, it is no longer a hazard. It will only have to be reinspected periodically to be sure the situation is still no longer hazardous. Random spot checking is another method that can indicate whether the hazard control remains effective. Other types of hazards that are intermittent will require more frequent inspection to assure proper hazard abatement. In most cases, monthly inspections are warranted, and in some cases daily inspections are reasonable.

Inspections should take place when and where the highest probability of a hazard exists, while reinspection can occur on an incidental basis to ensure that hazard control is effectively maintained. Inspections should be conducted when work processes are operating, and on a recurring basis at regular intervals. According to the National Safety Council (1974), a general inspection of an entire premises should be conducted at least once a year, except for those work areas scheduled for more frequent inspections because of their high hazard level. Because housekeeping is an important aspect of hazard control, inspection of all work areas should be conducted at least weekly for cleanliness, clutter, and traffic flow. The National Safety Council (1974) indicated that a general inspection should cover the following:

1. Plant grounds
2. Building and related structures
3. Towers, platforms, or other additions
4. Transportation access equipment and routes
5. Work areas
6. Machinery
7. Tools
8. Materials handling
9. Housekeeping
10. Electrical installations and wiring
11. Floor loading
12. Stairs and stairways
13. Elevators
14. Roofs and chimneys

We would add to this:

15. Chemicals, biological agents, radiation, etc.
16. Ergonomic stressors
17. Psychosocial stressors

Intermittent inspections are the most common type and are made at irregular intervals, usually on an ad hoc basis. Such inspections are unannounced and are often limited to a specific work area

or process. Their purpose is to keep first-line supervisors and workers alert to safety considerations and hazard detection. Such inspections do not always require a checklist. Systematic informal inspections made by first-line supervisors on a daily basis in their work area can be effective in identifying intermittent hazards and also keeping employees aware of good safety practices. Continuous inspections occur when employees are aware of safety considerations and detect and report hazards as they occur. Maintenance staff can also play a role in defining hazardous conditions while carrying out their duties of machinery repair.

As indicated above, all employees in an organization can become involved in inspecting for hazards, some formally, some informally. Technical, periodic health and safety inspections should be conducted by the plant medical, industrial hygiene, and safety staff. These persons have special expertise to define and evaluate hazards. That expertise can be supplemented by outside experts from insurance companies, government safety and health agencies, and private consultants. Conducting a formal inspection requires some planning and structure. First it must be determined what, where, and when to inspect. That decision will be based on hazard and illness/injury potential. A determination must be made whether to give prior warning to the employees in the area to be inspected. If hazards are primarily behavioral in nature, the prior warning may reduce the effectiveness of the inspection.

When conducting the inspection, the department supervisor should be asked to identify hot spots or special problem areas. A checklist can be used to identify each hazard and its nature, exact location, potential to cause serious damage, and possible control measures. During the walk-through, employee input should be solicited. Photographs and videotapes of hazards are effective in documenting the nature and potential seriousness of hazards. Once the inspection is completed, a report should be prepared that specifies pertinent information about the nature of the hazards, illness and injury potential, and abatement recommendations. This report needs to be detailed and provide step-by-step instructions for instituting hazard-control procedures in a timely manner. First, all potential hazards and their contributors should be listed. Second, the hazard identification analysis should provide solutions to deal with the hazards. The methods used to conduct the hazard identification should produce accurate estimates for the risks of harm to employees. Finally, resources should be allocated for abating the hazards and should be prioritized by those safety improvements that should yield the best results, that is, the best safety performance.

It is not sufficient simply to write up the results; they should be shared with all parties concerned in a face-to-face meeting. This meeting will give the results greater significance and serve as the basis for further interaction and possible modification of recommendations. Such meetings will enhance employee understanding and allow for in-depth discussions of the findings and recommendations. This makes the entire inspection process more relevant to supervisors and employees and facilitates the favorable acceptance of the results and any subsequent recommendations.

The quality of a hazard-identification system can be evaluated by answering the following four questions (Suokas 1993):

1. How well has the analysis identified hazards and their contributors?
2. How effectively has the analysis produced potential solutions needed in the system?
3. How accurately has the analysis estimated the risks of the system?
4. What is the cost-effectiveness of the hazard identification analysis?

8.2. Illness and Injury Statistics

There are four main uses of injury statistics: (1) to identify high-risk jobs or work areas, (2) to evaluate company health and safety performance, (3) to evaluate the effectiveness of hazard-abatement approaches, and (4) to identify factors related to illness and injury causation. An illness and injury-reporting and analysis system requires that detailed information must be collected about the characteristics of illness and injuries and their frequency and severity. The Occupational Safety and Health Act (1970) established illness and injury reporting and recording requirements that are mandatory for all employers, with certain exclusions such as small establishments and government agencies. Regulations have been developed to define how employers are to adhere to these requirements (BLS 1978).

The OSHAct requirements specify that any illness or injury to an employee that causes time lost from the job, treatment beyond first aid, transfer to another job, loss of consciousness, or an occupational illness must be recorded on a daily log of injuries and illnesses, the OSHA 300 form (previously the 200 form). This log identifies the injured person, the date and time of the injury, the department or plant location where the injury occurred, and a brief description of the occurrence of the injury, highlighting salient facts such as the chemical, physical agent, or machinery involved and the nature of the injury. An injury should be recorded on the day that it occurs, but this is not always possible with MSDs and other cumulative trauma injuries. The number of days that the person is absent from the job is also recorded upon the employee's return to work. In addition to the daily log, a more detailed form is filled out for each injury that occurs. This form provides a more detailed description of the nature of the injury, the extent of damage to the employee, the factors that could

be related to the cause of the injury, such as the source or agent that produced the injury, and events surrounding the injury occurrence. A workers' compensation form can be substituted for the OSHA 301 form (previously the 101 form) because equivalent information is gathered on these forms.

The OSHA Act injury and illness system specifies a procedure for calculating the frequency of occurrence of occupational injuries and illnesses and an index of their severity. These can be used by companies to monitor their health and safety performance. National data by major industrial categories are compiled by the U.S. Bureau of Labor Statistics annually and can serve as a basis of comparison of individual company performance within an industry. Thus, a company can determine whether its injury rate is better or worse than that of other companies in its industry. This industry-wide injury information is available on the OSHA website (http://www.osha.gov).

The OSHA system uses the following formula in determining company annual injury and illness incidence. The total number of recordable injuries is multiplied by 200,000 and then divided by the number of hours worked by the company employees. This gives an injury frequency per 100 person hours of work (injury incidence). These measures can be compared to an industry average.

$$\text{Incidence} = \frac{\text{number of recordable injuries and illnesses} \times 200{,}000}{\text{number of hours worked by company employees}}$$

where The number of recordable injuries and illnesses is taken from the OSHA 300 daily log of injuries.
The number of hours worked by employees is taken from payroll records and reports prepared for the Department of Labor or the Social Security Administration.

It is also possible to determine the severity of company injuries. Two methods are typically used. In the first, the total number of days lost due to injuries is compiled from the OSHA 300 daily log and divided by the total number of injuries recorded on the OSHA 300 daily log. This gives an average number of days lost per injury. In the second, the total number of days lost is multiplied by 200,000 and then divided by the number of hours worked by the company employees. This gives a severity index per 100 person hours of work. These measures can also be compared to an industry average.

Injury incidence and severity information can be used by a company to monitor its injury and illness performance over the years to examine improvement and the effectiveness of health and safety interventions. Such information provides the basis for making corrections in the company's approach to health and safety and can serve as the basis of rewarding managers and workers for good performance. However, it must be understood that injury statistics give only a crude indicator of safety company performance and an even cruder indicator of individual manager or worker performance. This information can be used to compare company safety performance with the industry average.

Because injuries are rare events, they do not always reflect the sum total of daily performance of company employees and managers. Thus, while they are an accurate measure of overall company safety performance, they are an insensitive measure at the individual and departmental levels. Some experts feel that more basic information has to be collected to provide the basis for directing health and safety efforts. One proposed measure is to use first-aid reports from industrial clinics. These provide information on more frequent events than the injuries required to be reported by the OSHAct. It is thought that these occurrences can provide insights into patterns of hazards and/or behaviors that may lead to the more serious injuries and that their greater number provides a larger statistical base for determining accident potential.

8.3. Incident Reporting

Another approach is for a company to keep track of all accidents whether an illness or injury is involved or not. Thus, property damage accidents without illness or injury would be recorded, as would near accidents and incidents that almost produced damage or injury. The proponents of this system feel that a large database can be established for determining accident-causation factors. As with the first-aid reports, the large size of the database is the most salient feature of this approach. A major difficulty in both systems is the lack of uniformity of recording and reporting the events of interest. The method of recording is much more diffuse because the nature of the events will differ substantially from illnesses or injuries, making their description in a systematic or comparative way difficult.

This critique is aimed not at condemning these approaches but at indicating how difficult they are to define and implement. These systems provide a larger base of incidents than the limited occurrences in injury-recording systems. The main problem is in organizing them into a meaningful pattern. A more fruitful approach than looking at these after-the-fact occurrences may be to look at the conditions that can precipitate injuries, that is, hazards. They can provide a large body of information for a statistical base and can also be organized into meaningful patterns.

9. CONTROLLING WORKPLACE HAZARDS

With the workplace hazards identified and defined, the next logical step is to eliminate or control them. Historically, there have been two predominant concepts about hazard controls. The first concept is to think of hazard control as a hierarchy of methods of control. In the hierarchy, the best control method is to eliminate the hazard through redesign or substitution. If elimination or substitution cannot be achieved, then the next-best approach is to block employee access to the hazard. Finally, if blocking cannot be achieved, then a last approach would be to warn the employees of the hazard and train them how to avoid the hazard.

A second way to conceptualize hazard control is in terms of the type of control: engineering controls, human factors controls, and organizational controls. Engineering controls include modifying the technology, workstation, tools, environment, or other physical aspects of work to eliminate, remove, substitute, or block access to the hazard.

Human factors controls deal with fitting the work activity to the employee's capabilities. Organizational controls involve things such as improving work procedures and practices, providing training, rotating employees to reduce the amount of exposure, and providing rest breaks designed to reduce the impact of hazards. All of these types of controls are not mutually exclusive and should be used together to achieve hazard reductions.

9.1. Engineering Controls

It would seem that the simplest way to deal with a hazard would be to get rid of it. This can be accomplished by redesigning a product, tool, machine, process, or environment or through substitution of a nonhazardous or less hazardous material or machine. For example, the loading of a mechanical punch press can be accomplished by placing a part directly onto the die with the employee's hand, which puts the hand directly into the point of operation. If the press should inadvertently cycle, the employee could injure his or her hand. To eliminate this hazard, a fixture can be designed so that the employee can place the part onto the fixture and then slide the fixture with the part into the point of operation. Thus, the fixture and not the employee's hand goes into the point of operation. This redesign removes the hand from the hazardous area of the machine. Likewise, a barrier guard could be put over the point of operation so that the employee's hand could not fit into the danger zone. This will be discussed in the next paragraph. Another example is substituting a less hazardous chemical for a more hazardous chemical, thereby reducing the extent of risk or the level of exposure.

The second class of engineering interventions is blocking employee access to the hazard. This can be achieved by putting up a barrier that keeps the employee from entering a hazardous area. The best example of this is fencing off an area such as high-voltage transformers. With this type of intervention, the hazard remains but access to the hazard is limited. However, often the hazardous area must be accessed for maintenance or other reasons. In this case, there are often secondary hazard controls to protect those who cross the barrier. For example, robots usually have a barrier around them to keep employees outside of their arc of swing so that they do not inadvertently come into contact with the robot's arm. But when the robot has to be programmed or maintained, an employee has to go across the barrier to access the robot. A secondary control is to have the robot automatically shut down when the barrier is breached. This is a form of interlock that keeps the hazard inactive while employees are present in the danger zone. In the case of many hazards, such as the high-voltage transformer, it may not be possible to have a secondary hazard control. Then we must rely on the knowledge, skills, and good sense of the employee and/or the person breaching the barrier. These human factor controls will be discussed below.

Containment is a form of a barrier guard that is used primarily with very dangerous chemical and physical hazards. An example is the ionizing radiation from a nuclear reactor. This radiation at the core of the reactor is restrained from leaving the reactor by lead-lined walls, but if leakage should occur through the walls, a back-up barrier contains the leakage. In the case of a closed system, the employee never comes in contact with the source (such as the reactor core) of the hazard. The system is designed through automation to protect the employee from the hazard source. Many chemical plants use the concept of a closed system of containment. The only time an employee would contact these specific deadly hazards would be in the case of a disaster in which the containment devices failed.

Another form of barrier control that looks something like a secondary hazard control is a guard, which is used to cover moving parts that are accessible by the employees—for example, inrunning nip points on a machine. Such guards are most often fixed and cannot be removed except for maintenance. Sometimes the guard needs to be moved to access the product. For example, when a power press is activated, there is a hazard at the point of operation. When the ram is activated, guards are engaged that prohibit an employee's contact with the die. When the ram is at rest, the guard can be lifted to access the product. If the guard is lifted, an interlock prohibits the ram from being activated. In this situation, there is a barrier to keep the employee from the area of the hazard only when the hazard is present. The guard allows access to the area of the hazard for loading, unloading, and other

job operations that can be carried out without activation. But when the machine energy is activated, the guard moves into place to block the employee from access to the site of the action. In the case of the robot, the hazard area is quite large and a perimeter barrier is used; but in the case of a mechanical press, the hazard area is limited to the point of operation, which is quite small.

Yet another engineering control that is important for dealing with workplace hazards is the active removal of the hazard before it contacts the employee during the work process. An example is a local scavenger ventilation system that sucks the fumes produced by an operation such as spot welding or laser surgery away from the employees. This exhausts the fumes into the air outside of the plant (surgery room) and away from the employees. The ventilation systems must comply with federal, state, and local regulations in design and in the level of emissions into the environment. Thus, the fumes may need to be scrubbed clean by a filter before being released into the open environment. A related ventilation approach is to dilute the extent of employee exposure to airborne contaminants by bringing in more fresh air from outside the plant on a regular basis. The fresh air dilutes the concentration of the contaminant to which the employee is exposed to a level that is below the threshold of dangerous exposure. The effectiveness of this approach is verified by measuring the ambient air level of contamination and employee exposure levels on a regular basis. When new materials or chemicals are introduced into the work process or when other new airborne exposures are introduced into the plant, the adequacy of the ventilation dilution approach to provide safe levels of exposure(s) must be reverified. (See Hagopian and Bastress 1976 for recommendations for ventilation guidelines.)

When guarding or removal systems (e.g., saw guards, scavenger and area ventilation) cannot provide adequate employee protection, then personal protective equipment (PPE) must be worn by the employees (safety glasses, respirator). Because it relies on compliance by the employees, this is not a preferred method of control. A cardinal rule of safety and health engineering is that the primary method of controlling hazards is through engineering controls. Human factors controls are to be used primarily when engineering controls are not practical, feasible, solely effective in hazard control, or cost effective. It is recognized that human factor controls are often necessary as adjuncts (supplements) to engineering controls and in many instances are the only feasible and effective controls.

9.2. Human Factors Controls

In the traditional scheme of hazard control, there are two elements of human factors considerations for controlling hazards: warning and training. These can also be conceptualized as informing employees about hazards and promoting safe and healthful employee behavior. Cohen and Colligan (1998) conducted a literature review of safety training effectiveness studies and found that occupational safety and health training was effective in reducing employee hazard risks and injuries.

9.2.1. Informing

Informing employees about workplace hazards has three aspects: the right to know, warnings, and instructions. Regarding the right to know, federal safety and health regulations and many state and local regulations (ordinances) specify that an employer has the obligation to inform employees of hazardous workplace exposures to chemicals, materials, or physical agents that are known to cause harm. The local requirements of reporting vary and employers must be aware of the reporting requirements in the areas where they have facilities. Generally, an employer must provide information on the name of the hazard, its potential health effects, exposure levels that produce adverse health effects, and the typical kinds of exposures encountered in the plant. In addition, if employees are exposed to a toxic agent, information about first aid and treatment should be available. For each chemical or material or physical agent classified as toxic by OSHA, employers are required to maintain a standard data sheet that provides detailed information on its toxicity, control measures, and standard operating procedures (SOPS) for using the product. A list of hazardous chemicals, materials, and physical agents is available from your local OSHA office or the OSHA website (http://www.osha.gov). These standard data sheets (some are referred to as material safety data sheets [MSDS]) must be supplied to purchasers by the manufacturer who sells the product. These data sheets must be shared by employers with employees who are exposed to the specific hazardous products, and must be available at the plant (location) as an information resource in case of an exposure or emergency. The motivation behind the right-to-know concept is that employees have a basic right to knowledge about their workplace exposures and that informed employees will make better choices and use better judgment when they know they are working with hazardous materials.

Warnings are used to convey the message of extreme danger. They are designed to catch the attention of the employee, inform the employee of a hazard, and instruct him or her in how to avoid the hazard. The OSHA regulations require that workplace warnings meet the appropriate ANSI standards, including Z35.1-1972 specifications for accident prevention signs; Z35.4-1973 specifications for informational signs complementary to ANSI Z35.1-1972; and ANSI Z53.1-1971 safety color code for marking physical hazards. These ANSI standards were revised in 1991 as Z535.1-535.4. Warnings

are primarily visual but can also be auditory, as in the case of a fire alarm. Warnings use sensory techniques that capture the attention of the employee. For instance, the use of the color red has a cultural identification with danger. The use of loud, discontinuous noise is culturally associated with emergency situations and can serve as a warning. After catching attention, the warning must provide information about the nature of the hazard. What is the hazard and what will it do to you? This provides the employee with an opportunity to assess the risk of ignoring the warning. Finally, the warning should provide some information about specific actions to take to avoid the hazard, such as ''Stay clear of the boom'' or ''Stand back 50 feet from the crane'' or ''Stay away from this area.''

Developing good warnings requires following the ANSI standards, using the results of current scientific studies and good judgment. Lehto and Miller (1986) wrote a book on warnings, and Lehto and Papastavrou (1993) define critical issues in the use and application of warnings. Laughery and Wogalter (1997) define the human factors aspects of warnings and risk perception and considerations for designing warnings. Peters (1997) discusses the critical aspects of technical communications that need to be considered from both human factors and legal perspectives. Considerations such as the level of employee's word comprehension, the placement of the warning, environmental distortions, wording of instructions, and employee sensory overload, just to name a few, must be taken into account for proper warning design and use. Even when good warnings are designed, their ability to influence employee behavior varies widely. Even so, the regulations require their use and they do provide the employee an opportunity to make a choice. Warnings should never be used in place of engineering controls. Warnings always serve as an adjunct to other means of hazard control.

Instructions provide direction to employees that will help them to avoid or deal more effectively with hazards. They are the behavioral model that can be followed to ensure safety. The basis of good instructions is the job analysis, which provides detailed information on the job tasks, environment, tools, and materials used. The job analysis will identify high-risk situations. Based on verification of the information in the job analysis, a set of instructions on how to avoid hazardous situations can be developed. The implementation of such instructions as employee behavior will be covered in the next section under training and safe behavior improvement.

9.2.2. Promoting Safe and Healthful Behavior

There are four basic human factors approaches that can be used in concert to influence employee behavior to control workplace hazards:

1. Applying methods of workplace and job design to provide working situations that capitalize on worker skills
2. Designing organizational structures that encourage healthy and safe working behavior
3. Training workers in the recognition of hazards and proper work behavior(s) for dealing with these hazards
4. Improving worker health and safety behavior through work practices improvement

Each of these approaches is based on certain principles that can enhance effective safety performance.

9.2.3. Workplace and Job Design

The sensory environment in which job tasks are carried out influences worker perceptual capabilities to detect hazards and respond to them. Being able to see or smell a hazard is an important prerequisite in dealing with it; therefore, workplaces have to provide a proper workplace sensory environment for hazard detection. This means proper illumination and noise control and adequate ventilation.

There is some evidence that appropriate illumination levels can produce significant reductions in accident rate (McCormick 1976). The environment can influence a worker's ability to perceive visual and auditory warnings such as signs or signals. To ensure the effectiveness of warnings, they should be highlighted. For visual signals, use the colors defined in the ANSI standard (Z535.1, ANSI 1991) and heightened brightness. For auditory signals, use changes in loudness, frequency, pitch, and phasing.

Work environments that are typically very loud and do not afford normal conversation can limit the extent of information exchange and may even increase the risk of occupational injury (Barreto et al. 1997). In such environments, visual signs are a preferred method for providing safety information. However, in most situations of extreme danger, an auditory warning signal is preferred because it attracts attention more quickly and thus provides for a quicker worker response. In general, warning signals should quickly attract attention, be easy to interpret, and provide information about the nature of the hazard.

Proper machinery layout, use, and design should be a part of good safety. Work areas should be designed to allow for traffic flow in a structured manner in terms of the type of traffic, the volume of traffic, and the direction of flow. The traffic flow process should support the natural progression

of product manufacture and/or assembly. This should eliminate unnecessary traffic and minimize the complexity and volume of traffic. There should be clearly delineated paths for traffic to use and signs giving directions on appropriate traffic patterns and flow.

Work areas should be designed to provide workers with room to move about in performing tasks without having to assume awkward postures or come into inadvertent contact with machinery. Task-analysis procedures can determine the most economical and safest product-movement patterns and should serve as the primary basis for determining layout of machinery, work areas, traffic flow, and storage for each workstation.

Equipment must conform to principles of proper engineering design so that the controls that activate the machine, the displays that provide feedback of machine action, and the safeguards to protect workers from the action of the machine are compliant with worker skills and expectations. The action of the machine must be compliant with the action of the controls in temporal, spatial, and force characteristics.

The layout of controls on a machine is very important for proper machinery operation, especially in an emergency. In general, controls can be arranged on the basis of (1) their sequence of use, (2) common functions, (3) frequency of use, and (4) relative importance. Any arrangement should take into consideration (1) the ease of access, (2) the ease of discrimination, and (3) safety considerations such as accidental activation. The use of a sequence arrangement of controls is often preferred because it ensures smooth, continuous movements throughout the work operation. Generally, to enhance spatial compliance, the pattern of use of controls should sequence from left to right and from top to bottom. Sometimes controls are more effective when they are grouped by common functions. Often controls are clustered by common functions that can be used in sequence so that a combination of approaches is used.

To prevent unintentional activation of controls, the following steps can be taken: (1) recess the control, (2) isolate the control to an area on the control panel where it will be hard to trip unintentionally, (3) provide protective coverings over the control, (4) provide lock-out of the control so that it cannot be tripped unless unlocked, (5) increase the force necessary to trip the control so that extra effort is necessary and/or (6) require a specific sequence of control actions such that one unintentional action does not activate the machinery.

A major deficiency in machinery design is the lack of adequate feedback to the machine operator about the machine action, especially at the point of operation. Such feedback is often difficult to provide because there typically are no sensors at the point of operation (or other areas) to determine when such action has taken place. However, an operator should have some information about the results of the actuation of controls to be able to perform effectively. Operators may commit unsafe behaviors to gain some feedback about the machine's performance as the machine is operating that may put them in contact with the point of operation. To avoid this, machinery design should include feedback of operation. The more closely this feedback reflects the timing and action of the machinery, the greater the amount of control that can be exercised by the operator. The feedback should be displayed in a convenient location for the operator at a distance that allows for easy readability.

Work task design is a consideration for controlling safety hazards. Tasks that cause employees to become fatigued or stressed can contribute to exposures and accidents. Task design has to be based on considerations that will enhance employer attention and motivation. Thus, work tasks should be meaningful in terms of the breadth of content of the work that will eliminate boredom and enhance the employee's mental state. Work tasks should be under the control of the employees, and machine-paced operations should be avoided. Tasks should not be repetitious. This last requirement is sometimes hard to achieve. When work tasks have to be repeated often, providing the employee with some control over the pacing of the task reduces stress associated with such repetition. Because boredom is also a consideration in repetitious tasks, employee attention can be enhanced by providing frequent breaks from the repetitious activity to do alternative tasks or take a rest. Alternative tasks enlarge the job and enhance the breadth of work content and employee skills.

The question of the most appropriate work schedule is a difficult matter. There is evidence that rotating-shift systems produce more occupational injuries than fixed-shift schedules (Smith et al. 1982). This implies that fixed schedules are more advantageous for injury control. However, for many younger workers (without seniority and thus often relegated to afternoon and night shifts) this may produce psychosocial problems related to family responsibilities and entertainment needs, and therefore lead to stress. Because stress can increase illness and injury potential, the gain from the fixed-shift systems may be negated by stress. This suggests that one fruitful approach may be to go to fixed shifts with volunteers working the nonday schedules. Such an approach provides enhanced biological conditions and fewer psychosocial problems.

Overtime work should be avoided because of fatigue and stress considerations. It is preferable to have a second shift of workers than to overtax the physical and psychological capabilities of employees. Since a second shift may not be economically feasible, some considerations need to be given for determining appropriate amounts of overtime. This is a judgmental determination since there is inadequate research evidence on which to base a definitive answer. It is reasonable that job tasks that

create high levels of physical fatigue and/or psychological stress should not be performed more than 10 hours in one day and 50 hours in one week. Jobs that are less fatiguing and stressful can probably be safely performed for up to 12 hours per day. There is some evidence that working more than 50 hours per week can increase the risk of coronary heart disease (Breslow and Buell 1960; Russek and Zohman 1958), and therefore working beyond 50 hours per week for extended periods should be avoided.

9.3. Organizational Design

Organizational policies and practices can have a profound influence on a company's health and safety record and the safety performance of its employees. To promote health and safety, organizational policies and practices should demonstrate that safety is an important organizational objective. The first step in this process is to establish a written organizational policy statement on health and safety. This should be followed up with written procedures to implement the policy. Such a formalized structure is the foundation on which all health and safety activities in the company are built. It provides the legitimate basis for undertaking health- and safety-related actions and curtails the frequent arguments among various levels of management about what constitutes acceptable activities. Such a policy statement also alerts employees to the importance of health and safety.

For employees, the policy statement is the declaration of an intent to achieve a goal. However, employees are skeptical of bureaucratic policies and look for more solid evidence of management commitment. Thus, the timing and sequence of health- and safety-related decisions demonstrate how the policy will be implemented and the importance of health and safety considerations. A health and safety policy with no follow-through is worthless and in fact may be damaging to employee morale by showing employees a lack of management commitment. This can backfire and can lead to poor employee safety attitudes and behaviors. Thus, an employer has to put the ''money where the mouth is'' to demonstrate commitment. If not, a policy is an empty promise.

Since physical conditions are the most obvious health and safety hazards, it is important that they be dealt with quickly to demonstrate management commitment. Relations with local, state, and federal health and safety agencies reflect on management commitment to health and safety. Companies that have written safety policies and guidelines with adequate follow-through but are constantly at odds with government health and safety officials are sending a confusing message to their employees. It is important to have a good public image and good public relations with government agencies, even through there may be specific instances of disagreement and even hostility. This positive public image will enhance employee attitudes and send a consistent message to employees about the importance of health and safety.

In this regard, organizations must ensure an adequate flow of information in the organization. The flow must be bidirectional, that is, upward as well as downward. One approach for dealing with safety communications is to establish communication networks. These are formal structures to ensure that information gets to the people who need to know the message(s) in a timely way. These networks are designed to control the amount of information flow to guard against information overload, misinformation, or a lack of needed information. Such networks have to be tailored to the specific needs of an organization. They are vital for hazard awareness and general health and safety information. For instance, in a multishift plant, information on a critical hazardous condition can be passed from shift to shift so that workers can be alerted to the hazard. Without a communication network, this vital information may not get to all affected employees and an avoidable exposure or accident could occur.

Organizational decision making is an important motivational tool for enhancing employee health and safety performance. Decisions about work task organization, work methods, and assignments should be delegated to the lowest level in the organization at which they can be logically made; that is, they should be made at the point of action. This approach has a number of benefits. For example, this level in the organization has the greatest knowledge of the work processes and operations and of their associated hazards. Such knowledge can lead to better decisions about hazard control. Diverse input to decision making from lower levels up to higher levels makes for better decisions as there are more options to work with. Additionally, this spreading of responsibility by having people participate in the inputs to decision making promotes employee and line supervisor consideration of safety and health issues. Such participation has been shown to be a motivator and to enhance job satisfaction (French 1963; Korunka et al. 1993; Lawler 1986). It also gives employees greater control over their work tasks and a greater acceptance of the decisions concerning hazard control due to the shared responsibility. All of this leads to decreased stress and increased compliance with safe behavior(s).

Organizations have an obligation to increase company health and safety by using modern personnel practices. These include appropriate selection and placement approaches, skills training, promotion practices, compensation packages, and employee-assistance programs. For safety purposes, the matching of employee skills and needs to job task requirements is an important consideration. It

is inappropriate to place employees at job tasks for which they lack the proper skills or capacity. This will increase illness and injury risk and job stress. Selection procedures must be established to obtain a properly skilled workforce. When a skilled worker is not available, training must be undertaken to increase skill levels to the proper level before a task is undertaken. This assumes that the employer has carried out a job task analysis and knows the job skills that are required. It also assumes that the employer has devised a way to test for the required skills. Once these two conditions have been met, the employer can improve the fit between employee skills and job task requirements through proper selection, placement, and training. Many union contracts require that employees with seniority be given first consideration for promotions. Such consideration is in keeping with this approach as long as the worker has the appropriate skills to do the job task or the aptitude to be trained to attain the necessary skills. If a person does not have the necessary knowledge and skills or cannot be adequately trained, there is good reason to exclude that individual from a job regardless of seniority.

9.3.1. Safety Training

Training workers to improve their skills and recognize hazardous conditions is a primary means for reducing exposures and accidents. Cohen and Colligan (1998) found that safety and health training was effective in reducing employee risk. Training can be defined as a systematic acquisition of knowledge, concepts, or skills that can lead to improved performance or behavior. Eckstrand (1964) defined seven basic steps in training: (1) defining the training objectives, (2) developing criteria measures for evaluating the training process and outcomes, (3) developing or deriving the content and materials to be learned, (4) designing the techniques to be used to teach the content, (5) integrating the learners and the training program to achieve learning, (6) evaluating the extent of learning, and (7) modifying the training process to improve learner comprehension and retention of the content. These steps provide the foundation for the application of basic guidelines that can be used for designing the training content, and integrating the content and the learner.

In defining training objectives, two levels can be established: global and specific. The global objectives are the end goals that are to be met by the training program. For instance, a global objective might be the reduction of eye injuries by 50%. The specific objectives are those that are particular to each segment of the training program, including the achievements to be reached by the completion of each segment. A specific objective might be the ability to recognize eye-injury hazards by all employees by the end of the hazard-education segment. A basis for defining training objectives is the assessment of company safety problem areas. This can be done using hazard-identification methods such as injury statistics, inspections, and hazard surveys. Problems should be identified, ranked in importance, and then used to define objectives.

To determine the success of the training process, criteria for evaluation need to be established. Hazard-identification measures can be used to determine overall effectiveness. Thus, global objectives can be verified by determining a reduction in injury incidence (such as eye injuries) or the elimination of a substantial number of eye hazards. However, it is necessary to have more sensitive measures of evaluation that can be used during the course of training to assess the effectiveness of specific aspects of the training program. This helps to determine the need to redirect specific training segments if they prove to be ineffective. Specific objectives can be examined through the use of evaluation tools. For instance, to evaluate the ability of workers to recognize eye hazards, a written or oral examination can be used. Hazards that are not recognized can be emphasized in subsequent training and retraining.

The content of the training program should be developed based on the learners' knowledge level, current skills, and aptitudes. The training content should be flexible enough to allow for individual differences in aptitudes, skills, and knowledge, as well as for individualized rates of learning. The training content should allow all learners to achieve a minimally acceptable level of health and safety knowledge and competence by the end of training. The specifics of the content deal with the skills to be learned and the hazards to be recognized and controlled.

There are various techniques that can be used to train workers. Traditionally, on-the-job training (OJT) has been emphasized to teach workers job skills and health and safety considerations. The effectiveness of such training will be influenced by the skill of the supervisor or lead worker in imparting knowledge and technique as well as his or her motivation to successfully train the worker. First-line supervisors and lead workers are not educated to be trainers and may lack the skills and motivation to do the best job. Therefore, OJT has not always been successful as the sole safety training method. Since the purpose of a safety training program is to impart knowledge and teach skills, it is important to provide both classroom experiences to gain knowledge and OJT to attain skills.

Classroom training is used to teach concepts and improve knowledge and should be carried out in small groups (not to exceed 15 employees). A small group allows for the type of instructor–student interaction needed to monitor class progress, provide proper motivation and determine each learner's comprehension level. Classroom training should be given in an area free of distractions to allow

learners to concentrate on the subject matter. Training sessions should not exceed 30 minutes, after which workers can return to their regular duties. There should be liberal use of visual aids to increase comprehension and make the training more concrete and identifiable to the learners. In addition, written materials should be provided that can be taken from the training session for study or reference away from the classroom.

For OJT the major emphasis should be on enhancing skills through observation and practice. Key workers with exceptional skills can be used as role models and mentors. Learners can observe these key workers and pick up tips from them. They then can practice what they have learned under the direction of the key workers to increase their skill, obtain feedback on their technique, and be motivated to improve.

Once the learner and the training program have been integrated, it will be necessary to evaluate the extent of learning. This can be done by testing learner knowledge and skills. Such testing should be done frequently throughout the training process to provide the learners with performance feedback and allow for program redirection as needed. Knowledge is best tested by written examinations that test acquisition of facts and concepts. Pictorial examinations (using pictures or slides of working conditions) can be used to determine hazard recognition ability. Oral questioning on a frequent basis can provide the instructor with feedback on the class comprehension of materials being presented, but should not be used for individual learner evaluation, since some learners may not be highly verbal and could be demotivated by being asked to recite. Skills testing should take place in the work area under conditions that control hazard exposures. Skills can be observed during practice sessions to determine progress under low-stress conditions.

The final stage in a training program, the success of the program having been determined, is to make modifications to improve the learning process. Such modifications should be done on a continuous basis as feedback on learner performance is acquired. In addition, at the end of the program it is necessary to determine whether the company objectives have been met. If so, should the objectives be modified? The answers to these questions can lead to modifications in the training program.

9.3.2. Hazard Reduction through Improved Work Practices

A large number of the hazards in the workplace are produced by the interaction between employees and their tools and environment. These hazards cannot be completely controlled through hazard inspection and machine guarding. They can be controlled by increasing employee recognition of the hazards and by proper worker behavior. Such behavior may be an evasive action when a hazard occurs, or it may be the use of safe work procedures to ensure that hazards will not occur. There are very few hazard-control efforts that are not in some way dependent on employee behavior. Making employees aware of hazards is meaningless if they do not choose to do something about them. For example, when controlling chemical exposures, personal protective equipment is useless if it is not worn. Likewise, an inspection system is useless if hazards are not reported or not corrected when reported. Thus, taking positive action (behavior) is central to hazard control. It is often true that there are no ideal engineering control methods to deal with a certain hazard. In such a case, it is usually necessary to use proper work practices to avoid hazardous exposure when engineering controls are not feasible. Likewise, even when engineering control will work successfully it is necessary to have employees use good work practices to get the engineering controls to work properly.

Conard (1983) has defined work practices as employee behaviors that can be simple or complex and that are related to reducing a hazardous situation in occupational activities. A series of steps can be used in developing and implementing work practices for eliminating occupational hazards:

1. The definition of hazardous work practices
2. The definition of new work practices to reduce the hazards
3. Training employees in the desired work practices
4. Testing the new work practices in the job setting
5. Installing the new work practices using motivators
6. Monitoring the effectiveness of the new work practices
7. Redefining the new work practices
8. Maintaining proper employee habits regarding work practices

In defining hazardous work practices, there are a number of sources of information that should be examined. Injury and accident reports such as the OSHA 301 Form provide information about the circumstances surrounding an injury. Often employee or management behaviors that contributed to the injury can be identified. Employees are a good source of information about workplace hazards. They can be asked to identify critical behaviors that may be important as hazard sources or hazard controls. First-line supervisors are also a good source of information because they are constantly

observing employee behavior. All of these sources should be examined; however, the most important source of information is in directly observing employees at work.

There are a number of considerations when observing employee work behaviors. First, observation must be an organized proposition. Before undertaking observations, it is useful to interview employees and first-line supervisors and examine injury records to develop a checklist of significant behaviors to be observed. This should include hazardous behaviors as well as those that are used to enhance engineering control or directly control hazards. The checklist should identify the job task being observed, the types of behaviors being examined, their frequency of occurrence, and a time frame of their occurrence. The observations should be made at random times so that employees do not change their natural modes of behavior when observed. The time of observation should be long enough for a complete cycle of behaviors associated with a work task(s) of interest to be examined. Two or three repetitions of this cycle should be examined to determine consistency in behavior with an employee and among employees. Random times of recording behavior are most effective in obtaining accurate indications of typical behavior. The recorded behaviors can be analyzed by the frequency and pattern of their occurrence as well as their significance for hazard control. Hot spots can be identified. All behaviors need to be grouped into categories in regard to hazard control efforts and then prioritized.

The next step is to define the proper work practices that need to be instilled to control the hazardous procedures observed. Sometimes the observations provide the basis for the good procedures that you want to implement. Often, however, new procedures need to be developed. There are four classes of work practices that should be considered: (1) hazard recognition and reporting, (2) housekeeping, (3) doing work tasks safely, and (4) emergency procedures. The recognition of workplace hazards requires that the employee be cognizant of hazardous conditions through training and education and that employees actively watch for these conditions. Knowledge is useless unless it is applied. These work practices ensure the application of knowledge and the reporting of observed hazards to fellow workers and supervisors. Housekeeping is a significant consideration for two reasons. A clean working environment makes it easier to observe hazards. It is also a more motivating situation that enhances the use of other work practices.

The most critical set of work practices deals with carrying out work tasks safely through correct skill use and hazard-avoidance behaviors. This is where the action is between the employee and the environment, and it must receive emphasis in instilling proper work practices. Situations occur that are extremely hazardous and require the employee to get out of the work area or stay clear of the work area. These work practices are often life-saving procedures that need special consideration because they are used only under highly stressful conditions, such as emergencies.

Each of these areas needs to have work practices spelled out. These should be statements of the desired behaviors specified in concise, easily understandable language. Statements should typically be one sentence long and should never exceed three sentences. Details should be excluded unless they are critical to the proper application of the work practice. The desired work practices having been specified, employees should be given classroom and on-the-job training to teach them the work practices. Training approaches discussed earlier should be applied. This includes classroom training as well as an opportunity for employees to test the work practices in the work setting.

To ensure the sustained use of the learned work practices, it is important to motivate workers through the use of incentives. There are many types of incentives, including money, tokens, privileges, social rewards, recognition, feedback, participation, and any other factors that motivate employees, such as enriched job tasks. Positive incentives should be used to develop consistent work practice patterns.

Research has demonstrated that the use of financial rewards in the form of increased hourly wage can have a beneficial effect on employee safety behaviors and reduced hazard exposure. One study (Smith et al. 1983; Hopkins et al. 1986) evaluated the use of behavioral approaches for promoting employee use of safe work practices to reduce their exposure to styrene. The study was conducted in three plants and had three components: (1) the development and validation of safe work practices for working with styrene in reinforced fiberglass operations, (2) the development and implementation of an employee training program for learning the safe work practices, and (3) the development and testing of a motivational technique for enhancing continued employee use of the safe work practices. Forty-three work practices were extracted from information obtained from a literature search, walk-through plant survey, interviews with employees and plant managers, and input from recognized experts in industrial safety and hygiene. The work practices were pilot tested for their efficacy in reducing styrene exposures. A majority of the work practices were found to be ineffective in reducing styrene exposures, and only those that were effective were incorporated into a worker training program.

The worker training program consisted of classroom instruction followed up with on-the-job application of the material learned in class. Nine videotapes were made to demonstrate the use of safe work practices. Basic information about each work practice and its usefulness was presented, followed by a demonstration of how to perform the work practice. Employees observed one videotape

for 15 minutes per week for nine weeks. After each showing, a discussion session was held, followed up by on-the-job application of the work practice given by the research training instructor. Once training was completed, each employee was included in the motivational program. This program was based on a financial reward of $10 per week for using the safe work practices. Observations of employee behavior were made by researchers four times daily on a random basis. These observations served as the basis for an employee's receipt of the financial reward.

The effectiveness of the training and motivational programs was measured by examining the changes in employee behavior from before the programs to the end of the study. Approximately 35% of the safe work practices were observed prior to training for the 41 employees studied in the three plants. At the end of the study, approximately 95% of the safe work practices were observed. The real significance of this increased use of safe work practices lies in the effectiveness in reducing employee exposures to styrene. The results indicated a reduction in styrene exposure from before training to the end of the study of 36%, 80%, and 65% for each plant respectively. In a follow-up evaluation a few years after the behavioral management program was discontinued, it was found that approximately 90% of the safe work practices were still being used by the employees even in the absence of rewards. The study results demonstrated the effectiveness of behavioral techniques for increasing worker use of safe work practices, as well as the effectiveness of such usage in reducing employee exposures to workplace hazards.

10. SAFETY PROGRAMS

The preceding materials provide the basis for developing an effective company hazard-control program. However, there are a number of other elements to consider in developing a safety program or upgrading your current program. These include organizational policies, managing various elements of the program, motivational practices, hazard-control procedures, dealing with employees, accident investigations, and injury recording. Aspects of each of these have already been discussed, and in this section they are integrated into an effective safety program. There has been considerable research into the necessary elements for a successful safety program (see Cohen 1977; Smith et al. 1978; Cleveland et al. 1979; Zimolong 1997) and how these elements should be applied. One primary factor emerges from every study on this subject. A safety program will not be successful unless there is a commitment to the program by top management. This dictates that there be a written organizational policy statement on the importance of safety and the general procedures the corporation intends to use to meet this policy. Having such a policy is just the first step toward effective management commitment.

Smith et al. (1978) have shown that it takes more than a written policy to ensure successful safety performance. It takes involvement on the part of all levels of management in the safety program. From the top managers it means that they must get out onto the shop floor often and talk to employees about plant conditions and safety problems. This can be on a scheduled basis, but it seems to be more effective on an informal basis. For middle managers there is a need to participate in safety program activities such as monthly hazard awareness meetings or weekly toolbox meetings. This does not necessitate active presentations by these managers, but it does mean active participation in group discussions and answering worker questions. These activities bring the upper and middle managers in touch with potential hazard sources and educates them to shop floor problems. It also demonstrates to employees that management cares about their safety and health.

Another aspect of management commitment is the level of resources that are made available for safety programming. Cohen (1977), in reviewing successful program research, found that organizational investment in full-time safety staff was a key feature to good plant safety performance. The effectiveness of safety and health staff was greater the higher they were in the management structure. The National Safety Council (1974) has suggested that plants with less than 500 employees and a low to moderate hazard level can have an effective program with a part-time safety professional. Larger plants or those with more hazards need more safety staff.

Along with funds for staffing, successful programs also make funds available for hazard abatement in a timely fashion. Thus, segregated funds are budgeted to be drawn upon when needed. This gives the safety program flexibility in meeting emergencies when funds may be hard to get quickly from operating departments. An interesting fact about companies with successful safety programs is that they are typically efficient in their resource utilization, planning, budgeting, quality control, and other aspects of general operations and include safety programming and budgeting as just another component of their overall management program. They do not single safety out or make it special; instead, they integrate it into their operations to make it a natural part of daily work activities.

Organizational motivational practices will influence employee safety behavior. Research has demonstrated that organizations that exercise humanistic management approaches have better safety performance (Cohen 1977; Smith et al. 1978; Cleveland et al. 1979). These approaches are sensitive to employee needs and thus encourage employee involvement. Such involvement leads to greater awareness and higher motivation levels conducive to proper employee behavior. Organizations that use

punitive motivational techniques for influencing safety behavior have poorer safety records than those using positive approaches. An important motivational factor is encouraging communication between various levels of the organization (employees, supervisors, managers). Such communication increases participation in safety and builds employee and management commitment to safety goals and objectives. Often informal communication is a more potent motivator and provides more meaningful information for hazard control.

An interesting research finding is that general promotional programs aimed at enhancing employee awareness and motivation, such as annual safety awards dinners and annual safety contests, are not very effective in influencing worker behavior or company safety performance (Smith et al. 1978). The major reason is that their relationship in time and subject matter (content) to actual plant hazards and safety considerations is so abstract that workers cannot translate the rewards to specific actions that need to be taken. It is hard to explain why these programs are so popular in industry despite being so ineffective. Their major selling points are that they are easy to implement and highly visible, whereas more meaningful approaches take more effort.

Another important consideration in employee motivation and improved safety behavior is training. Two general types of safety training are of central importance: skills training and training in hazard awareness. Training is a key component to any safety program because it is important to employee knowledge of workplace hazards and proper work practices and provides the skills necessary to use the knowledge and the work practices. Both formal and informal training seem to be effective in enhancing employee safety performance (Cohen and Colligan 1998). Formal training programs provide the knowledge and skills for safe work practices, while informal training by first-line supervisors and fellow employees maintains and sharpens learned skills.

All safety programs should have a formalized approach to hazard control. This often includes an inspection system to define workplace hazards, accident investigations, record keeping, a preventive maintenance program, a machine guarding program, review of new purchases to ensure compliance with safety guidelines, and housekeeping requirements. All contribute to a safety climate that demonstrates to workers that safety is important. However, the effectiveness of specific aspects of such a formalized hazard-control approach have been questioned (Cohen 1977; Smith et al. 1978). For instance, formalized inspection programs have been shown to deal with only a small percentage of workplace hazards (Smith et al. 1971). In fact, Cohen (1977) indicated that more frequent informal inspections may be more effective than more formalized approaches. However, the significance of formalized hazard-control programs is that they establish the groundwork for other programs such as work practice improvement and training. In essence, they are the foundation for other safety approaches. They are also a source of positive motivation by demonstrating management interest in employees by providing a clean workplace free of physical hazards. Smith et al. (1978) have demonstrated that sound environmental conditions are a significant contribution to company safety performance and employee motivation.

11. PARTICIPATIVE APPROACHES TO RESPOND TO THE EMERGING HAZARDS OF NEW TECHNOLOGIES

Hazard control for new technologies requires a process that will be dynamic enough to be able to deal with the increasing rate of hazards caused by technological change. Research on successful safety program performance in plants with high hazard potential has shown a number of factors that contribute to success (Cohen 1977; Smith et al. 1978). These are having a formal, structured program so people know where to go for help, management commitment and involvement in the program, good communications between supervisors and workers, and worker involvement in the safety and health activities. These considerations are important because they provide a framework for cooperation between management and employees in identifying and controlling hazards. These factors parallel the basic underlying principles of quality management, social democracy, hazard surveys, ergonomic committees, and other employee-involvement approaches that will be discussed below—that is, developing management and employee cooperation, participation, and honest exchange of ideas about problems in a controlled format.

11.1. Quality Improvement

The development of total quality management (TQM) approaches may produce some positive results with regard to occupational safety and health (Zink 1999). Power and Fallon (1999) have proposed TQM as a framework for integration of health and safety activities with other functions. They argue that the practice of safety management should include the following TQM principles: management commitment to occupational safety and health objectives, plans and policies; development of a health and safety culture; employee involvement in safety activities, such as risk assessment and training of new employees; measurement and monitoring of health and safety performance; and continuous improvement. Smith (1999) has proposed a model for integrating ergonomics, safety, and quality based on behavioral cybernetics. From a behavioral cybernetics perspective, participatory ergonomics

and safety and quality management are effective because they enable workers to control sensory feedback from job-related decisions or working conditions that affect them and in turn to generate sensory feedback for the control and benefit of other workers. Worker involvement in decision making, worker control over the production process, and job enrichment enhance the overall level of worker self-control. Use of workers as resource specialists and emphasis on skill development can benefit the integration of ergonomics, safety management, and quality management of the organization.

11.2. International Organization for Standardization

The International Organization for Standardization (ISO) has been developing technical standards over many sectors of business, industry, and technology since 1947. With the exception of ISO 9000 and ISO 14000, the vast majority of ISO standards are highly specific. They are documented agreements containing technical specifications or other precise criteria to be used consistently as rules, guidelines, or definitions of characteristics. The goal of these standards is to ensure that materials, products, processes, and services are fit for their purpose. Then in 1987 came ISO 9000, followed nearly 10 years later by ISO 14000. These two standards are very different from the majority of ISO's highly specific standards.

ISO 9000 and ISO 14000 are known as generic management system standards. Management system standards provide the organization with a model to follow in setting up and operating the management system. ISO 9000 is concerned with quality management, whereas ISO 14000 is concerned with environmental management. Quality management regards what the organization does to ensure that its products conform to the customer's requirements. Environmental management regards what the organization does to minimize harmful effects on the environment caused by its activities. Both ISO 9000 and ISO 14000 concern the way an organization goes about its work, and not directly the result of this work. That is, ISO 9000 and ISO 14000 concern processes, and not products, at least directly. Both standards provide requirements for what the organization must do to manage processes influencing quality (ISO 9000) or the processes influencing the impact on the environment (ISO 14000).

The ISO 9000 family of standards currently contains over 20 standards and documents. By the end of the year 2000, a new version of the ISO 9000 quality management standards was issued. The three primary standards in the Year 2000 ISO 9000 are:

- ISO 9000: Quality management systems—Fundamentals and vocabulary
- ISO 9001: Quality management systems—Requirements
- ISO 9004: Quality management systems—Guidance for performance improvement.

The new ISO 9000 family of quality management standards is being developed to achieve a coherent terminology with the ISO 14000 family and other management standards, including possibly an OSH management standard.

In 1996, the ISO held an international conference in Geneva to test stakeholder views on developing a standard on occupational health and safety. Given the limited support from the main stakeholders for the ISO to develop international standards in this field, ISO decided that no further action should be taken. Recently, the ISO has reopened the issue of whether to develop management system standards to help organizations meet their responsibilities. The British Standards Institution (BSI) has submitted a proposal to the ISO for creation of a new ISO technical committee on OHS management standards. The BSI has proposed to transform BS 8800, the British "noncertifiable" OHS management system guidelines, into an ISO standard. The ISO is looking into the issue of whether or not to develop an occupational health and safety management standard.

Many companies have invested considerable resources in order to obtain certification of their quality management systems according to the ISO 9000 standards. From a safety point of view, one may wonder whether the implementation of ISO 9000 management systems can encourage the development of safer and healthier work environments. In Sweden, Karltun et al. (1998) examined the influences on working conditions, following the implementation of ISO 9000 quality systems in six small and medium-sized companies. Improvements to the physical work environment triggered by the ISO implementation process were very few. There were improvements in housekeeping and production methods. Other positive aspects present in some of the companies included job enrichment and a better of understanding of employees' role and importance to production. However, the implementation of ISO 9000 was accompanied by increased physical strain, stress, and feelings of lower appreciation. According to Karltun and his colleagues (1998), improved working conditions could be triggered by the implementation of ISO quality management standards if additional goals, such as improved working conditions, are considered by top management and if a participative implementation process is used. Others have argued that quality management systems and environmental management systems can be designed to address occupational health and safety (Wettberg 1999;

Martin 1999). A study by Eklund (1995) showed a relationship between ergonomics and quality in assembly work. Tasks that had ergonomic problems (e.g., physical and psychological demands) were also the tasks that had quality deficiencies. The evidence for the integration between quality management and occupational safety and health is weak. However, there is reason to believe that improved health and safety can be achieved in the context of the implementation of ISO 9000 management standards.

11.3. Social Democracy

One framework for addressing the health and safety issues of new technology is the social democratic approach practiced in Norway and Sweden (Emery and Thorsrud 1969; Gardell 1977). This approach is based on the concept that workers have a right to participate in decisions about their working conditions and how their jobs are undertaken. In Sweden, there are two central federal laws that establish the background for health and safety. One, similar to U.S. Occupational Safety and Health Act, established agencies to develop and enforce standards as well as to conduct research. The second is the Law of Codetermination, which legislates the right of worker representatives to participate in decision making on all aspects of work. This law is effective because over 90% of the Swedish blue- and white-collar workforce belong to a labor union and the unions take the lead in representing the interests of the employees in matters pertaining to working conditions, including health and safety. The Scandinavian approach puts more emphasis on the quality of working life in achieving worker health and well being. Thus, there is emphasis on ensuring that job design and technology implementation do not produce physical and psychological stress. This produces discussion and action when safety and health problems are first reported.

11.4. Hazard Survey

Organizational and job-design experts have long proposed that employee involvement in work enhances motivation and produces production and product quality benefits (Lawler 1986). Smith and Beringer (1986) and Zimolong (1997) have recommended that employees be involved in safety programming and hazard recognition to promote safety motivation and awareness. An effective example of using this concept in health and safety is the hazard survey program (Smith 1973; Smith and Beringer 1986). Smith et al. (1971) showed that most occupational hazards were either transient or due to improper organizational or individual behavior. Such hazards are not likely to be observed during formal inspections by safety staff or compliance inspections by state or federal inspectors. The theory proposes that the way to keep on top of these transient and behavioral hazards is to have them identified on a continuous basis by the employees as they occur through employee participation.

One approach that gets employee involvement is the hazard survey. While inspection and illness/injury analysis systems can be expected to uncover a number of workplace hazards, they cannot define all of the hazards. Many hazards are dynamic and occur only infrequently. Thus, they may not be seen during an inspection or may not be reported as a causal factor in an illness or injury. To deal with hazards that involve dynamically changing working conditions and/or worker behaviors requires a continuously operating hazard-identification system. The hazard survey is a cooperative program between employees and managers to identify and control hazards. Since the employee is in direct contact with hazards on a daily basis, it is logical to use employees' knowledge of hazards in their identification. The information gathered from employees can serve as the basis of a continuous hazard identification system that can be used by management to control dynamic workplace hazards.

A central concept of this approach is that hazards exist in many forms as fixed physical conditions, as changing physical conditions, as worker behaviors, and as an operational interaction that causes a mismatch between worker behavior and physical conditions (Smith 1973). This concept defines worker behavior as a critical component in the recognition and control of all of these hazards. Involving workers in hazard recognition sensitizes them to their work environment and acts as a motivator to use safe work behaviors. Such behaviors include using safe work procedures to reduce hazard potential, using compensatory behaviors when exposed to a known hazard, or using avoidance behaviors to keep away from known hazards. The hazard survey program also establishes communication between supervisors and employees about hazards.

The first step in a hazard survey program is to formalize the lines of communication. A primary purpose of this communication network is to get critical hazard information to decision makers as quickly as possible so that action can be taken to avert an exposure or accident. Traditional communication routes in most companies do not allow for quick communication between workers and decision makers, and thus serious hazards may not be corrected before an exposure or accident occurs. Each company has an established organizational structure that can be used to set up a formalized communication network. For instance, most companies are broken into departments or work units. These can serve as the primary segments within which workers report hazards. These hazards can be dealt with at the departmental level or communicated to higher-level decision makers for action.

Once primary communication units are established, a process to communicate hazard information has to be established. This requires structure and rules. The structure of the program should be simple

so that information can flow quickly and accurately. It is important to designate a company decision maker who has the responsibility and authority to respond to serious hazards through the expenditure of company resources. Sometimes the hazards can be dealt with immediately at the departmental level by the supervisor. This is often true when large expenditures are not involved. Each department may decide to select someone in that department to serve as the primary communication source between the workers in the department and the supervisor. Hazards are reported directly to this person, who then reports them to the supervisor or, in the case of a serious hazard, immediately to the company decision maker.

It is best to have a formal procedure for recording employee-identified hazards. This can be easily accomplished by a hazard form that provides a written record of the hazard, its location, and other pertinent information, such as the number of employees exposed and possible hazard-control measures. These forms can be distributed to each employee and be available from the department committee member. Employees may wish to express their views about the existence of potential hazards anonymously on the forms. Employees should report near-miss accidents, property damage incidents, and potential injury-producing hazards. It is essential in a program such as this that employees be given anonymity if desired and that they be assured that no action will be taken against them for their participation (even if they report silly hazards).

Once hazards have been examined, rated, and ranked by the committee, some plan of action for their control should be developed either by the committee or by company management. The results of the hazards review by the committee and the action to be taken should be fed back to employees. Experience using this type of program indicates that for every 100 hazards reported, 1 is very serious, needing immediate action, 24 require attention quickly to avert a potential accident, 50 require some minor action to improve the quality of working conditions but do not concern a serious hazard, and 25 concern gripes and hassles of employees that are not related to safety hazards.

Employees are expected to fulfill the following duties in this program:

1. Examine the workplace to determine whether there are hazards
2. Report hazards on the form and return it to the department committee member or supervisor
3. Make an effort to find out what has happened to the hazard(s) reported
4. Continue to report hazards as they are observed

This program will provide continuous monitoring of safety hazards using employee input. This participation should stimulate employee awareness of safety and motivate the employees to work more safely. The continued use of the program should encourage the employees to have a vested interest in their safety and that of their fellow employees. This sense of involvement can carry over into improvement in individual work habits.

11.5. Employee/Management Ergonomics Committee

Another employee-involvement approach that could be successful in addressing some of the emerging issues of new technology is the joint union/management ergonomic committee (Hagglund 1981). This approach starts with a joint training course for union stewards and line managers about the hazards of chronic trauma and possible ergonomic interventions to resolve these problems. The course covers how to recognize ergonomic hazards, how to measure the hazard potential, and how to develop dialogue and cooperation between labor and management. This training is led by a facilitator (typically a university staff person), and is conducted at the company during work hours. Employees and supervisors are given time from their jobs to participate, which demonstrates the importance of the program. One main purpose of the training is to generate discussion between line managers/supervisors and union representatives about specific hazards and worker perceptions. This give and take develops an understanding of the other person's perspective and concerns. It often generates good solutions, especially toward the end of the course, when an understanding of the course technical material is integrated within the specific context of the plant.

After the training, an ergonomics committee composed of top management, select line management, and select union stewards is established that meets on a regular basis to discuss ergonomic problems and potential solutions. Employees with ergonomic problems can report them to a member of this committee, which typically tends to be a union steward. Semiannual retraining is given to the ergonomics committee on emerging issues that are generated by the kinds of problems being reported at the company. This approach has been extremely successful in reducing the extent of chronic trauma in electronic assembly plants in Wisconsin.

12. CONCLUSIONS

Designing for successful occupational health and safety performance requires a systematic approach. This includes understanding that the workplace is a system where changes in one element lead to influences on the other system components. It also means that efforts to make improvements must

be multifaceted and address all of the elements of the work system. Health and safety improvements begin with an understanding of the hazards, the evaluation of injury and illness experience, the development of interventions, the implementation of improvements, follow-up to evaluate the results of improvements, and continuous efforts of evaluation and improvement. Good programming starts at the top of the company and includes all levels of the organizational structure. Employee input and involvement are critical for success. Often there is a need for technical expertise when dealing with complex or new hazards. In the end, having everyone in the company alert to health and safety issues should lead to improved health and safety performance.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. OVERVIEW

The utilities of information technology are spreading into all walks of life, from the use of self-standing personal computers and networking to Internet and intranet. This technology has allowed for tremendous growth in Web-based collaboration and commerce and has expanded into information appliances (e.g., pagers, cellular phones, two-way radios) and other consumer products. It is important that these interactive systems be designed so that they are easy to learn and easy to operate, with minimal errors and health consequences and maximal speed and satisfaction. Yet it can be challenging to achieve an effective design that meets these criteria.

The design of interactive systems has evolved through several paradigm shifts. Initially, designers focused on functionality. The more a system could do, the better the system was deemed to be. This resulted in system designs whose functionality often could not be readily accessed or utilized, or tended to physically stress users (Norman 1988). For example, how many homes have you walked into where the VCR is flashing 12:00? This example shows that even devices that should be simple to configure can be designed in such a manner that users cannot readily comprehend their use. Further, the occurrence of repetitive strain injuries rose as users interacted with systems that engendered significant physical stress. The development of such systems led to a shift in design focus from functionality to usability. Usability engineering (Nielsen 1993) focuses on developing interactive systems that are ergonomically suitable for the users they support (Grandjean 1979; Smith 1984), as well as cognitively appropriate (Vicente 1999). This approach aims to ensure the ease of learning, ease of use, subjective satisfaction, and physical comfort of interactive systems. While these design goals are appropriate and have the potential to engender systems that are effective and efficient to use, system designers have found that this focus on usability does not always lead to the most user-acceptable system designs. In recent years, environmental concerns (i.e., social, organizational, and management factors) have led to design practices that incorporate a greater emphasis on studying and understanding the semantics of work environments (Vicente 1999), often through ethnographic approaches (Nardi 1997; Takahashi 1998). Through participant-observation practices, efforts are made to understand more completely the tasks, work practices, artifacts, and environment that the system will become a part of (Stanney et al. 1997). This is often achieved by designers immersing themselves in the target work environment, thereby becoming accustomed to and familiar with the various factors of interactive system design. These factors include users' capabilities and limitations (both cognitive and physical), organizational factors (e.g., management and social issues), task requirements, and environmental conditions that the work environment supports (see Figure 1). Through the familiarity gained by this involvement, designers can develop systems that are more uniquely suited to target users and the organizations for which they work.

This chapter provides guidelines and data on how to achieve these objectives through the effective design of human–computer interaction, which takes into account the human's physical, cognitive, and social abilities and limitations in reference to interacting with computers and/or computer based appliances. In doing so, it relies on the available standards, practices, and research findings. Much of it is guided by currently available technology but may also be applicable as technology changes and new applications evolve.

The overall thrust of the chapter is that good physical design of the workplace will minimize the probabilities of the occurrence of health consequences; good cognitive design will maximize the utility of interactive systems; and good social and organizational design will effectively integrate these systems into existing work domains. In general, it is suggested that human–computer interaction will be optimized when the following are observed:

- The system design is ergonomically suited to the user.
- Interactive design matches the mental models of users.
- Only information needed for decision making is presented.
- Information of a similar nature is chunked together.
- The interface is adaptive to individual differences due to innate, acquired, or circumstantial reasons.
- The system design supports existing work practices and related artifacts.

Interactive system design is thus about many interfaces; it considers how users relate to each other, how they physically and cognitively interact with systems, how they inhabit their organizations, and how these interfaces can best be supported by mediating technologies. Focusing on each of these areas highlights the need for a multidisciplinary interactive system design team. As Duffy and Salvendy (1999) have documented, in teams that consist of design and manufacturing engineers, marketing specialists, and a team leader, even when they have common goals, each member retrieves and uses different information and has a different mental model that focuses on unique aspects in achieving the same design objectives.

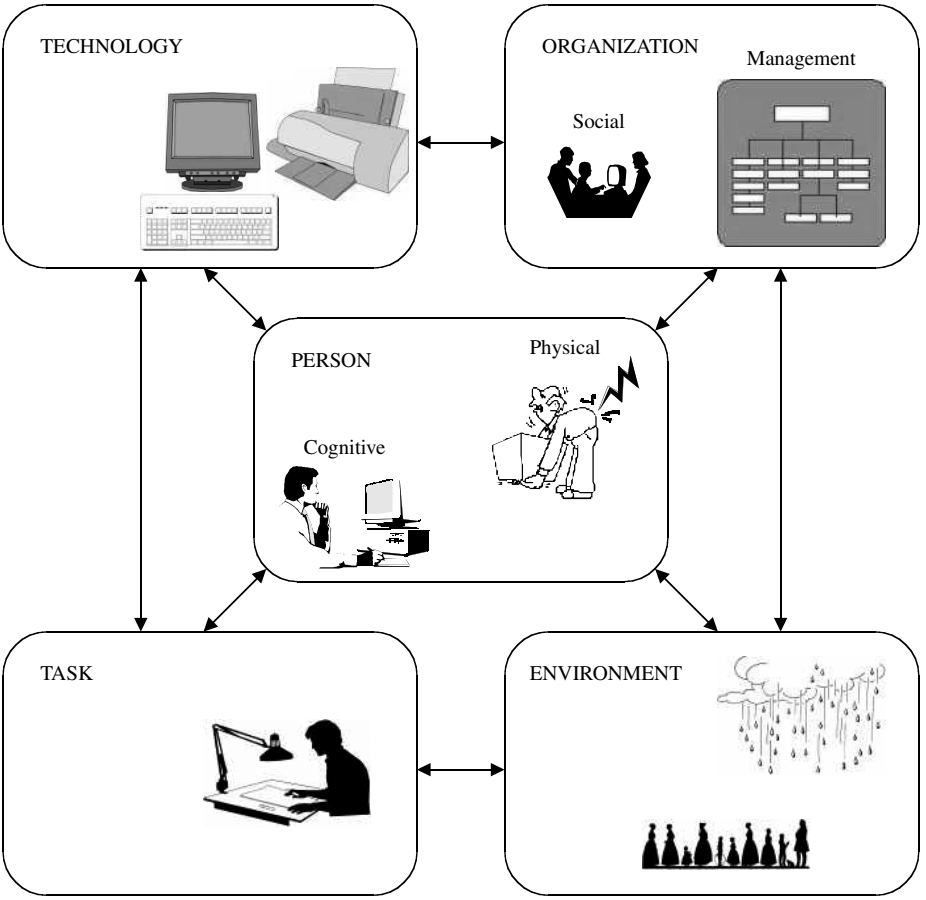

Figure 1 Model of the Work System. (Adapted from Smith and Sainfort 1989)

The following sections will focus on different aspects of interactive system design, including ergonomics, cognitive design, and social, organizational, and management factors.

2. ERGONOMICS

Ergonomics is the science of fitting the environment and activities to the capabilities, dimensions, and needs of people. Ergonomic knowledge and principles are applied to adapt working conditions to the physical, psychological, and social nature of the person. The goal of ergonomics is to improve performance while at the same time enhancing comfort, health, and safety. In particular, the efficiency of human–computer interaction, as well as the comfort, health, and safety of users, can be improved by applying ergonomic principles (Grandjean 1979; Smith 1984). However, no simple recommendations can be followed that will enhance all of these aspects simultaneously. Compromise is sometimes necessary to achieve a set of balanced objectives while ensuring user health and safety (Smith and Sainfort 1989; Smith and Cohen 1997). While no one set of rules can specify all of the necessary combinations of proper working conditions, the use of ergonomic principles and concepts can help in making the right choices.

2.1. Components of the Work System

From an ergonomic point of view, the different components of the work system (e.g., the environment, technology, work tasks, work organization, and people) interact dynamically with each other and

function as a total system (see Figure 1). Since changing any one component of the system influences the other aspects of the system, the objective of ergonomics is to *optimize the whole system* rather than maximize just one component. In an ergonomic approach, the person is the central focus and the other factors of the work system are designed to help the person be effective, motivated, and comfortable. The consideration of physical, physiological, psychological, and social needs of the person is necessary to ensure the best possible workplace design for productive and healthy human–computer interaction. Table 1 shows ergonomic recommendations for fixed desktop video display terminal (VDT) use that improve the human interface characteristics. Ergonomic conditions for laptop computer use should conform as closely as possible to the recommendations presented in Table 1.

2.2. Critical Ergonomics Issues in Human–Computer Interaction

A major feature of the ergonomics approach is that *the job task characteristics will define the ergonomic interventions* and the priorities managers should establish for workplace design requirements. The following discussion of critical areas—the technology, sensory environment, thermal environment, workstation design, and work practices—will highlight the major factors that engineers and managers should be aware of in order to optimize human–computer interaction and protect user health. Specific recommendations and guidelines will be derived from these discussions, but please be advised that the recommendations made throughout this chapter may have to be modified to account for differences in technology, personal, situational, or organizational needs at your facility, as well as improved knowledge about human–computer interaction. It cannot be overstated that these considerations represent recommendations and guidelines and not fixed specifications or standards. The realization that any one modification in any single part of the work system will affect the whole system and particularly the person (see Figure 1) is essential for properly applying the following recommendations and specifications.

2.3. Ergonomics of Computer Interfaces

Today, the primary display interfaces in human–computer interaction are the video display with a cathode ray tube and the flat panel screen. In the early 1980s, the US Centers for Disease Control (CDC 1980) and the U.S. National Academy of Sciences defined important design considerations for the use of cathode ray tubes (NAS 1983). The Japan Ergonomics Society (JES) established a Committee for Flat Panel Display Ergonomics in 1996, which proposed ergonomic guidelines for use of products with flat panels, such as liquid crystal displays (LCDs) (JES 1996). These Japanese guidelines were subsequently reviewed by the Committee on Human–Computer Interaction of the International Ergonomics Association (IEA). The JES guidelines addressed the following issues: (1) light-related environmental factors, (2) device use and posture factors, (3) environmental factors, (4) job design factors, and (5) individual user factors. These guidelines will be discussed in appropriate sections of this chapter.

The use of CRTs and flat panel displays has been accompanied by user complaints of visual fatigue, eye soreness, general visual discomfort, and various musculoskeletal complaints and discomfort with prolonged use (Grandjean 1979; Smith et al. 1981; NIOSH 1981; NAS 1983; Smith 1984; JES 1996). Guidelines for providing the proper design of the VDT and the environment in which it is used have been proposed by the Centers for Disease Control (CDC 1980) and the Human Factors and Ergonomics Society (ANSI 1988), and for the laptop and palm computer, by the Japan Ergonomics Society (JES 1996). The following sections deal with the visual environment for using desktop computers, but the discussion can be extrapolated to other types of computer use.

The major interfaces of employees with computers are the screen (CRT, flat panel), the keyboard, and the mouse. Other interfaces are being used more and more, such as voice input, pointers, hand-actuated motion devices, and apparatuses for virtual environment immersion.

2.3.1. The Screen and Viewing

Poor screen images, fluctuating and flickering screen luminances, and screen glare cause user visual discomfort and fatigue (Grandjean 1979; NAS 1983). There are a range of issues concerning readability and screen reflections. One is the adequacy of contrast between the characters and screen background. Screens with glass surfaces have a tendency to pick up glare sources in the environment and reflect them. This can diminish the contrast of images on the screen. To reduce environmental glare, the luminance ratio within the user's near field of vision should be approximately 1:3, and within the far field approximately 1:10 (NIOSH 1981). For luminance on the screen itself, the character-to-screen background luminance contrast ratio should be at least 7:1 (NIOSH 1981). To give the best readability for each operator, it is important to provide VDTs with adjustments for character contrast and brightness. These adjustments should have controls that are obvious to observe and manipulate and easily accessible from normal working position (e.g., located at the front of the screen) (NIOSH 1981).

TABLE 1 Ergonomic Recommendations for the VDT Technology, Work Environment, and Workstation

Ergonomic Consideration	Recommendation
1. Viewing screen	
a. Character/screen contrast	7:1 minimum
b. Screen character size	height = 20–22 min of visual arc width = 70–80% of height
c. Viewing distance	Usually 50 cm or less, but up to 70 cm is acceptable
d. Line refresh rate	70 hz minimum
e. Eye viewing angle from horizon	10–40° (from top to bottom gaze)
2. Illumination	
a. No hardcopy	300 lux minimum
b. With normal hard copy	500 lux
c. With poor hard copy	700 lux
d. Environmental luminance contrast	
• Near objects	1:3
• Far objects	1:10
e. Reflectance from surfaces	
• Working surface	40–60%
• Floor	30%
• Ceiling	80–90%
• Walls	40–60%
3. HVAC	
a. Temperature—winter	20–24°C (68–75°F)
b. Temperature—summer	23–27°C (73–81°F)
c. Humidity	50–60%
d. Airflow	0.15–0.25 m/sec
4. Keyboard	
a. Slope	0–15° preferred, 0–25° acceptable
b. Key top area	200 mm^2
c. Key top horizontal width	12 mm (minimum)
d. Horizontal key spacing	18–19 mm
e. Vertical key spacing	18–20 mm
f. Key force	0.25N–1.5N (0.5–0.6N preferred)
5. Workstation	
a. Leg clearance	51 cm minimum (61 cm preferred minimum)
b. Leg depth	38 cm minimum
c. Leg depth with leg extension	59 cm minimum
d. Work surface height—nonadjustable	70 cm
e. Work surface height—adjustable for one surface	70–80 cm
f. Work surface height—adjustable for two surfaces	Keyboard surface 59–71 cm Screen surface 70–80 cm
6. Chair	
a. Seat pan width	45 cm minimum
b. Seat pan depth	38–43 cm
c. Seat front tilt	5° forward to 7° backward
d. Seat back inclination	110–130°
e. Seat pan height adjustment range	38–52 cm
f. Backrest inclination	Up to 130°
g. Backrest height	45–51 cm above seat pan surface

2.3.2. Screen Character Features

Good character design can help improve image quality, which is a major factor for reducing eyestrain and visual fatigue. The proper size of a character is dependent on the task and the display parameters (brightness, contrast, glare treatment, etc.) and the viewing distance. Character size that is too small

can make reading difficult and cause the visual focusing mechanism to overwork. This produces eyestrain and visual fatigue (NAS 1983). Character heights should preferably be at least 20–22 min of visual arc, while character width should be 70–80% of the character height (Smith 1984; ANSI 1988). This approximately translates into a minimum lowercase character height of 3.5 mm with a width of 2.5 mm at a normal viewing distance of 50 cm.

Good character design and proper horizontal and vertical spacing of characters can help improve image quality. To ensure adequate discrimination between characters and good screen readability, the character spacing should be in the range of 20–50% of the character width. The interline spacing should be 50–100% of the character height (Smith 1984; ANSI 1988).

The design of the characters influences their readability. Some characters are hard to decipher, such as lowercase *g*, which looks like numeral *8*. A good font design minimizes character confusion and enhances the speed at which characters can be distinguished and read. Two excellent fonts are Huddleston and Lincoln-Mitre (NAS 1983). Most computers have a large number of fonts to select from. Computer users should choose a font that is large enough to be easy for them to read.

2.3.3. Viewing Distance

Experts have traditionally recommended a viewing distance between the screen and the operator's eye of 45–50 cm but no more than 70 cm (Grandjean 1979; Smith 1984). However, experience in field studies has shown that users may adopt a viewing distance greater than 70 cm and are still able to work efficiently and not develop visual problems. Thus, viewing distance should be determined in context with other considerations. It will vary depending on the task requirements, CRT screen characteristics, and individual's visual capabilities. For instance, with poor screen or hard copy quality, it may be necessary to reduce viewing distances for easier character recognition. Typically, the viewing distance should be 50 cm or less due to the small size of characters on the VDT screen. LNCs are often used in situations where the computer is placed on any convenient surface, for example a table at the airport waiting room. Thus, the viewing distance is defined by the available surface, not a fixed workstation. When the surface is farther away from the eyes, the font size used should be larger.

Proper viewing distance will be affected by the condition of visual capacity and by the wearing of spectacles/lenses. Persons with myopia (near-sightedness) may find that they want to move the screen closer to their eyes; while persons with presbyopia (far-sightedness) or bifocal lenses may want the screen farther away from their eyes. Many computer users who wear spectacles have a special pair of spectacles with lenses that are matched to their particular visual defect and a comfortable viewing distance to the screen. Eyecare specialist can have special spectacles made to meet computer users' screen use needs.

2.3.4. Screen Flicker and Image Stability

The stability of the screen image is another characteristic that contributes to CRT and LCD quality. Ideally, the display should be completely free of perceptible movements such as flicker or jitter (NIOSH 1981). CRT screens are refreshed a number of times each second so that the characters on the screen appear to be solid images. When this refresh rate is too low, users perceive screen flicker. LCDs have less difficulty with flicker and image stability than CRT displays. The perceptibility of screen flicker depends on illumination, screen brightness, polarity, contrast, and individual sensitivity. For instance, as we get older and our visual acuity diminishes, so too does our ability to detect flicker. A screen with a dark background and light characters has less flicker than screens with dark lettering on a light background. However, light characters on a dark background show more glare. In practice, flicker should not be observable, and to achieve this a screen refresh rate of at least 70 cycles per second needs to be achieved for each line on the CRT screen (NAS 1983; ANSI 1988). With such a refresh rate, flicker should not be a problem for either screen polarity (light on dark or dark on light). It is a good idea to test a screen for image stability. Turn the lights down, increase the screen brightness/contrast settings, and fill the screen with letters. Flickering of the entire screen or jitter of individual characters should not be perceptible, even when viewed peripherally.

2.3.5. Screen Swivel and Tilt

Reorientation of the screen around its vertical and horizontal axes can reduce screen reflections and glare. Reflections can be reduced by simply tilting the display slightly back or down or to the left or right, depending on the angle of the source of glare. These adjustments are easiest if the screen can be tilted about its vertical and horizontal axes. If the screen cannot be tilted, it should be approximately vertical to help eliminate overhead reflections, thus improving legibility and posture.

The perception of screen reflection is influenced by the tilt of the screen up or down and back and forth and by the computer user's line of sight toward the screen. If the screen is tilted toward sources of glare and these are in the computer user's line of sight to the screen, the screen images will have poorer clarity and reflections can produce disability glare (see Section 2.4.4). In fact, the

line of sight can be a critical factor in visual and musculoskeletal discomfort symptoms. When the line of sight can observe glare or reflections, then eyestrain often occurs. For musculoskeletal considerations, experts agree that the line of sight should never exceed the straight-ahead horizontal gaze, and in fact it is best to provide a downward gaze of about 10–20° from the horizontal when viewing the top of the screen and about 40° when viewing the bottom edge of the screen (NIOSH 1981; NAS 1983; Smith 1984; ANSI 1988). This will help reduce neck and shoulder fatigue and pain. These gaze considerations are much harder to obtain when using LNCs because of the smaller screen size and workstation features (eg., airport waiting room table).

2.4. The Visual Environment

2.4.1. Lighting

Lighting is an important aspect of the visual environment that influences readability and glare on the screen and viewing in the general environment. There are four types of general workplace illumination of interest to the computer user's environment:

1. *Direct radiants:* The majority of office lighting is direct radiants. These can be incandescent lights, which are most common in homes, or fluorescent lighting, which is more prevalent in workplaces and stores. Direct radiants direct 90% or more of their light toward the object(s) to be illuminated in the form of a cone of light. They have a tendency to produce glare.
2. *Indirect lighting:* This approach uses reflected light to illuminate work areas. Indirect lighting directs 90% or more of the light onto the ceiling and walls, which reflect it back into the room. Indirect lighting has the advantage of reducing glare, but supplemental lighting is often necessary, which can be a source of glare.
3. *Mixed direct radiants and indirect lighting:* In this approach, part of the light (about 40%) radiates in all directions while the rest is thrown directly or indirectly onto the ceiling and walls.
4. *Opalescent globes:* These lights give illumination equally in all directions. Because they are bright, they often cause glare.

Modern light sources used in these four general approaches to workplace illumination are typically of two kinds: electric filament lamps and fluorescent tubes. Following are the advantages and drawbacks of these two light sources:

1. *Filament lamps:* The light from filament lamps is relatively rich in red and yellow rays. It changes the apparent colors of objects and so is unsuitable when correct assessment of color is essential. Filament lamps have the further drawback of emitting heat. On the other hand, employees like their warm glow, which is associated with evening light and a cozy atmosphere.
2. *Fluorescent tubes:* Fluorescent lighting is produced by passing electricity through a gas. Fluorescent tubes usually have a low luminance and thus are less of a source of glare. They also have the ability to match their lighting spectrum to daylight, which many employees find preferable. They may also be matched to other spectrums of light that can fit office decor or employee preferences. Standard-spectrum fluorescent tubes are often perceived as a cold, pale light and may create an unfriendly atmosphere. Fluorescent tubes may produce flicker, especially when they become old or defective.

2.4.2. Illumination

The intensity of illumination or the illuminance being measured is the amount of light falling on a surface. It is a measure of the quantity of light with which a given surface is illuminated and is measured in lux. In practice, this level depends on both the direction of flow of the light and the spatial position of the surface being illuminated in relation to the light flow. Illuminance is measured in both the horizontal and vertical planes. At computer workplaces, both the horizontal and vertical illuminances are important. A document lying on a desk is illuminated by the horizontal illuminance, whereas the computer screen is illuminated by the vertical illuminance. In an office that is illuminated from overhead luminaires, the ratio between the horizontal and vertical illuminances is usually between 0.3 and 0.5. So if the illuminance in a room is said to be 500 lux, the horizontal illuminance is 500 lux while the vertical illuminance is between 150 and 250 lux (0.3 and 0.5 of the horizontal illuminance).

The illumination required for a particular task is determined by the visual requirements of the task and the visual ability of the employees concerned. In general, an illuminance in the range of 300–700 lux measured on the horizontal working surface (not the computer screen) is normally

preferable (CDC 1980; NAS 1983). The JES (1996) recommends office lighting levels ranging from 300–1,000 lux for flat panel displays. Higher illumination levels are necessary to read hard copy and lower illumination levels are better for work that just uses the computer screen. Thus, a job in which hard copy and a computer screen are both used should have a general work area illumination level of about 500–700 lux, while a job that only requires reading the computer screen should have a general work area illumination of 300–500 lux. Conflicts can arise when both hardcopy and computer screens are used by different employees who have differing job task requirements or differing visual capabilities and are working in the same area. As a compromise, room lighting can be set at the recommended lower (300 lux) or intermediate level (500 lux) and additional task lighting can be provided as needed. Task lighting refers to localized lighting at the workstation to replace or supplement ambient lighting systems used for more generalized lighting of the workplace. Task lighting is handy for illuminating hardcopy when the room lighting is set at a low level, which can hinder document visibility. Such additional lighting must be carefully shielded and properly placed to avoid glare and reflections on the computer screens and other adjacent working surfaces of other employees. Furthermore, task lighting should not be too bright in comparison to the general work area lighting since looking between these two different light levels may produce eyestrain.

2.4.3. Luminance

Luminance is a measure of the brightness of a surface, that is, the amount of light leaving the surface of an object, either reflected by the surface (as from a wall or ceiling), emitted by the surface (as from the CRT or LCD characters), or transmitted (as light from the sun that passes through translucent curtains). Luminance is expressed in units of candelas per square meter. High-intensity luminance sources (such as windows) in the peripheral field of view should be avoided. In addition, the balance among the luminance levels within the computer user's field of view should be maintained. The ratio of the luminance of a given surface or object to another surface or object in the central field of vision should be around 3:1, while the luminance ratio in the peripheral field of vision can be as high as 10:1 (NAS 1983).

2.4.4. Glare

Large differences in luminance or high-luminance lighting sources can cause glare. Glare can be classified with respect to its effects (disability glare vs. discomfort glare) or the source of glare (direct glare vs. reflected glare). Glare that results in an impairment of vision (e.g., reduction of visual acuity) is called disability glare, while discomfort glare is experienced as a source of discomfort to the viewer but does not necessarily interfere with visual performance. With regard to the source, direct glare is caused by light sources in the field of view of the computer user, while reflected glare is caused by reflections from illuminated, polished, or glossy surfaces or by large luminance differences in the visual environment. In general, glare is likely to increase with the luminance, size, and proximity of the lighting source to the line of sight.

Direct and reflected glare can be limited through one or more of the following techniques:

1. Controlling the light from windows: This can be accomplished by closing drapes, shades, and/or blinds over windows or awnings on the outside, especially during sunlight conditions.
2. Controlling the view of luminaires:
   - **(a)** By proper positioning of CRT screen with regard to windows and overhead lighting to reduce direct or reflected glare and images. To accomplish this, place VDTs parallel to windows and luminaires and between luminaires rather than underneath them.
   - **(b)** Using screen hoods to block luminaires from view.
   - **(c)** Recessing light fixtures.
   - **(d)** Using light-focusing diffusers.
3. Controlling glare at the screen surface by:
   - **(a)** Adding antiglare filters on the VDT screen.
   - **(b)** Proper adjustment up or down/left or right of the screen.
4. Controlling the lighting sources using:
   - **(a)** Appropriate glare shields or covers on the lamps.
   - **(b)** Properly installed indirect lighting systems.

Glare can also be caused by reflections from surfaces, such as working surfaces, walls, or the floor covering. These surfaces do not emit light themselves but can reflect it. The ratio of the amount of light reflected by a surface (luminance) to the amount of light striking the surface (illuminance) is called reflectance. Reflectance is unitless. The reflectance of the working surface and the office

machines should be on the order of 40–60% (ANSI 1988). That is, they should not reflect more than 60% of the illuminance striking their surface. This can be accomplished if surfaces have a matte finish.

Generally, floor coverings should have a reflectance of about 30%, ceilings, of 80–90%, and walls, 40–60%. Reflectance should increase from the floor to the ceiling. Although the control of surface reflections is important, especially with regard to glare control, it should not be at the expense of a pleasant working environment where employees feel comfortable. Walls and ceilings should not be painted dark colors just to reduce light reflectance, nor should windows be completely covered or bricked up to keep out sunlight. Other, more reasonable luminance control approaches can give positive benefits while maintaining a psychologically pleasing work environment.

2.5. The Auditory Environment

2.5.1. Noise

A major advantage of computer technology over the typewriter is less noise at the workstation. However, it is not unusual for computer users to complain of bothersome office noise, particularly from office conversation. Noise levels commonly encountered in offices are below established limits that could cause damage to hearing (i.e., below 85 dBA). The JES (1996) proposed that the noise level should not exceed 55 dBA. The expectations of office employees are for quiet work areas because their tasks often require concentration. Annoying noise can disrupt their ability to concentrate and may produce stress.

Actually, there are many sources of annoyance noise in computer operations. Fans in computers, printers, and other accessories, which are used to maintain a favorable internal device temperature, are a source of noise. Office ventilation fans can also be a source of annoyance noise. The computers themselves may be a source of noise (e.g., the click of keys or the high-pitched squeal of the CRT). The peripheral equipment associated with computers, such as printers, can be a source of noise. Problems of noise may be exacerbated in open-plan offices, in which noise is harder for the individual employee to control than in enclosed offices.

Acoustical control can rely upon ceiling, floor and wall, furniture, and equipment materials that absorb sound rather than reflect it. Ceilings that scatter, absorb, and minimize the reflection of sound waves are desirable to promote speech privacy and reduce general office noise levels. The most common means of blocking a sound path is to build a wall between the source and the receiver. Walls are not only sound barriers but are also a place to mount sound-absorbent materials. In open-plan offices, free-standing acoustical panels can be used to reduce the ambient noise level and also to separate an individual from the noise source. Full effectiveness of acoustical panels is achieved in concert with the sound-absorbent materials and finishes applied to the walls, ceiling, floor, and other surfaces. For instance, carpets not only cover the floor but also serve to reduce noise. This is achieved in two ways: (1) carpets absorb the incident sound energy and (2) gliding and shuffling movements on carpets produce less noise than on bare floors. Furniture and draperies are also important for noise reduction.

Acoustical control can also be achieved by proper space planning. For instance, workstations that are positioned too closely do not provide suitable speech privacy and can be a source of disturbing conversational noise. As a general rule, a minimum of 8–10 ft between employees, separated by acoustical panels or partitions, will provide normal speech privacy.

2.5.2. Heating, Ventilating, and Air Conditioning (HVAC)

Temperature, humidity, air flow, and air exchanges are important parameters for employees' performance and comfort.

It is unlikely that offices will produce excessive temperatures that could be physically harmful to employees. However, thermal comfort is an important consideration in employee satisfaction that can influence performance. Satisfaction is based not on the ability to tolerate extremes but on what makes an individual happy. Many studies have shown that most office employees are not satisfied with their thermal comfort. The definition of a comfortable temperature is usually a matter of personal preference. Opinions as to what is a comfortable temperature vary within an individual from time to time and certainly among individuals. Seasonal variations of ambient temperature influence perceptions of thermal comfort. Office employees sitting close to a window may experience the temperature as being too cold or hot, depending on the outside weather. It is virtually impossible to generate one room temperature in which all employees are equally well satisfied over a long period of time.

As a general rule, it is recommended that the temperature be maintained in the range of 20–24°C (68–75°F) in winter and 23–27°C (73–81°F) in summer (NIOSH 1981; Smith 1984). The JES (1996) recommends office temperatures of 20–23°C in winter and 24–27°C in summer.

Air flows across a person's neck, head, shoulders, arms, ankles, and knees should be kept low (below 0.15 m/sec in winter and below 0.25 m/sec in summer). It is important that ventilation not

produce currents of air that blow directly on employees. This is best handled by proper placement of the workstation.

Relative humidity is an important component of office climate and influences an employee's comfort and well being. Air that is too dry leads to drying out of the mucous membranes of the eyes, nose, and throat. Individuals who wear contact lenses may be made especially uncomfortable by dry air. In instances where intense, continuous near-vision work at the computer is required, very dry air has been shown to irritate the eyes. As a general rule, it is recommended that the relative humidity in office environments be at least 50% and less than 60% (NIOSH 1981; Smith 1984). The JES (1996) recommends humidity levels of 50–60%. Air that is too wet enhances the growth of unhealthy organisms (molds, fungus, bacteria) that can cause disease (legionnaires', allergies).

2.6. Computer Interfaces

Computer interfaces are the means by which users provide instructions to the computer. There are a wide variety of devices for interfacing, including keyboards, mice, trackballs, joy sticks, touch panels, light pens, pointers, tablets, and hand gloves. Any mechanical or electronic device that can be tied to a human motion can serve as a computer interface. The most common interfaces in use today are the keyboard and the mouse. The keyboard will be used as an example to illustrate how to achieve proper human–computer interfaces.

2.6.1. The Keyboard

In terms of computer interface design, a number of keyboard features can influence an employee's comfort, health, and performance. The keyboard should be detachable and movable, thus providing flexibility for independent positioning of the keyboard and screen. This is a major problem with LNCs because the keyboard is built into the top of the computer case for portability and convenience. It is possible to attach a separate, detachable keyboard to the LNC, and this should be done when the LNC is used at a fixed workstation in an office or at home. Clearly, it would be difficult to have a separate keyboard when travelling and the LNC portability feature is paramount.

The keyboard should be stable to ensure that it does not slide on the tabletop. This is a problem when an LNC is held in the user's lap or some other unstable surface. In order to help achieve a favorable user arm height positioning, the keyboard should be as thin as possible. The slope or angle of the keyboard should be between 0° and 15°, measured from the horizontal. LNCs are limited in keyboard angle because the keyboard is often flat (0°). However, some LNCs have added feet to the computer case to provide an opportunity to increase the keyboard angle. Adjustability of keyboard angle is recommended. While the ANSI standard (ANSI 1988) suggests 0–25°, we feel angles over 15° are not necessary for most activities.

The shape of the key tops must satisfy several ergonomic requirements, such as minimizing reflections, aiding the accurate location of the operator's finger, providing a suitable surface for the key legends, preventing the accumulation of dust, and being neither sharp nor uncomfortable when depressed. For instance, the surface of the key tops, as well as the keyboard itself, should have a matte finish. The key tops should be approximately 200 mm (ANSI 1988) with a minimum horizontal width of 12 mm. The spacing between the key centers should be about 18–19 mm horizontally and 18–20 mm vertically (ANSI 1988). There should be slight protrusions on select keys on the home row to provide tactile information about finger position on the keyboard.

The force to depress the key should ideally be between 0.5 N and 0.6 N (ANSI 1988). However, ranges from 0.25–1.5 N have been deemed acceptable (ANSI 1988). The HFES/ANSI-100 standard is currently being revised, and this recommendation may change soon. Some experts feel that the keying forces should be as low as feasible without interfering with motor coordination. Research has shown that light-touch keys require less operator force in depressing the key (Rempel and Gerson, 1991; Armstrong et al. 1994; Gerard et al. 1996). The light-touch force keyboards vary between 0.25–0.40 N.

Feedback from typing is important for beginning typists because it can indicate to the operator that the keystroke has been successfully completed. There are two main types of keyboard feedback: tactile and auditory. Tactile feedback can be provided by a collapsing spring that increases in tension as the key is depressed or by a snap-action mechanism when key actuation occurs. Auditory feedback (e.g., "click" or "beep") can indicate that the key has been actuated. Of course, there is also visual feedback on the computer screen. For experienced typists, the feedback is not useful, as their fingers are moving in a ballistic way that is too fast for the feedback to be useful for modifying finger action (Guggenbuhl and Krueger 1990, 1991; Rempel and Gerson 1991; Rempel et al. 1992).

The keyboard layout can be the same as that of a conventional typewriter, that is, the QWERTY design, or some other proven style, such as the DVORAK layout. However, it can be very difficult for operators to switch between keyboards with different layouts. Traditional keyboard layout has straight rows and staggered columns. Some authors have proposed curving the rows to provide a better fit for the hand to reduce biomechanical loading on the fingers (Kroemer 1972). However,

there is no research evidence that such a design provides advantages for operator's performance or health.

Punnett and Bergqvist (1997) have proposed that keyboard design characteristics can lead to upper-extremity musculoskeletal disorders. There is controversy about this contention by Punnett and Bergqvist because there are many factors involved in computer typing jobs independent of the keyboard characteristics that may contribute to musculoskeletal disorders. Some ergonomists have designed alternative keyboards in attempts to reduce the potential risk factors for musculoskeletal disorders (Kroemer 1972; Nakaseko et al. 1985; Ilg 1987). NIOSH (1997) produced a publication that describes various alternative keyboards. Studies have been undertaken to evaluate some of these alternative keyboards (Swanson et al. 1997; Smith et al. 1998). The research results indicated some improvement in hand/wrist posture from using the alternative keyboards, but no decrease in musculoskeletal discomfort.

2.6.2. Accessories

The use of a wrist rest when keying can help to minimize extension (backward bending) of the hand. A wrist rest should have a fairly broad surface (approximately 5 cm) with a rounded front edge to prevent cutting pressures on the wrist and hands. Padding further minimizes skin compression and irritation. Height adjustability is important so that the wrist rest can be set to a preferred level in concert with the keyboard height and slope. Some experts are concerned that resting the wrist on a wrist rest during keying could cause an increase in intercarpal canal pressure. They prefer that wrist rests be used only when the user is not keying for the purpose of resting the hands and wrist. Thus, they believe users need to be instructed (trained) about when and how to use a wrist rest. Arm holders are also available to provide support for the hands, wrists, and arms while keyboarding. However, these may also put pressure on structures that may produce nerve compression. As with a wrist rest, some experts feel these devices are best used only during rest from keying.

2.6.3. The Mouse

The most often-used computer pointing device is the mouse. While there are other pointing devices, such as the joystick, touch panel, trackball, and light pen, the mouse is still the most universally used of these devices. An excellent discussion of these pointing devices can be found in Bullinger et al. (1977). The mouse provides for an integration of both movement of the cursor and action on computer screen objects, simultaneously. Many mice have multiple buttons to allow for several actions to occur in sequence. The ease of motion patterns and multiple-function buttons give the mouse an advantage over other pointing devices. However, a disadvantage of the mouse is the need for tabletop space to achieve the movement function. Trankle and Deutschmann (1991) conducted a study to determine which factors influenced the speed of properly positioning a cursor with a mouse. The results indicated that the most important factors were the target size and the distance traveled. Also of lesser importance was the display size arc. The control/response ratio or the sensitivity of the control to movement was not found to be important. Recently, studies have indicated that operators have reported musculoskeletal discomfort due to mouse use (Karlqvist et al. 1994; Armstrong et al. 1995; Hagberg 1995; Fogelman and Brogmus 1995; Wells et al. 1997).

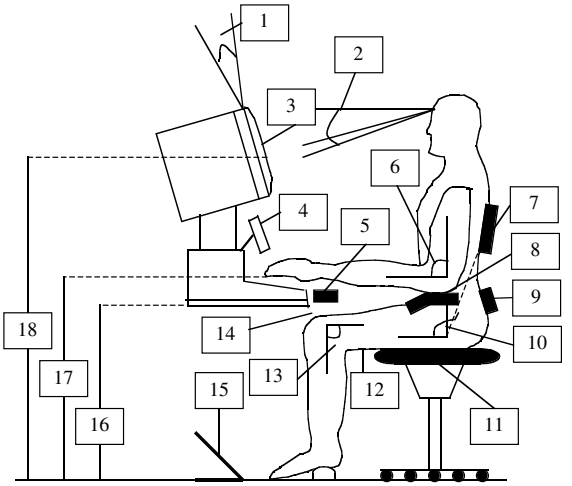
2.7. The Workstation

Workstation design is a major element in ergonomic strategies for improving user comfort and particularly for reducing musculoskeletal problems. Figure 2 illustrates the relationships among the working surface, VDT, chair, documents, and various parts of the body. Of course, this is for a fixed workstation at the office or home. Use of LNCs often occurs away from fixed workstations where it is difficult to meet the requirements described below. However, efforts should be made to meet these requirements as much as possible, even when using LNCs.

The task requirements will determine critical layout characteristics of the workstation. The relative importance of the screen, keyboard, and hard copy (i.e., source documents) depends primarily on the task, and this defines the design considerations necessary to improve operator performance, comfort, and health. Data-entry jobs, for example, are typically hard copy oriented. The operator spends little time looking at the screen, and tasks are characterized by high rates of keying. For this type of task it is logical for the layout to emphasize the keyboard, mouse, and hard copy, because these are the primary tools used in the task, while the screen is of lesser importance. On the other hand, data-acquisition operators spend most of their time looking at the screen and seldom use hard copy. For this type of task, the screen and the keyboard layout should be emphasized.

2.7.1. Working Surfaces

The size of the work surface is dependent on the task(s), documents, and technology. The primary working surface (e.g., supporting the keyboard, display, and documents) should be sufficient to: (1) permit the screen to be moved forward or backward to a comfortable viewing distance for a range



1. Screen tilt angle
2. Visual angle between the horizontal and the center of the display
3. Eye-screen distance
4. Document holder and source document
5. Wrist wrest
6. Elbow angle
7. Backrest
8. Elbow rest
9. Lumbar support
10. Seat back angle (from horizontal)
11. Seat pan angle (from horizontal)
12. Clearance between leg and seat
13. Knee angle
14. Clearance between leg and table
15. Footrest
16. Table height
17. Home row (middle row height)
18. Screen height to center of screen

Figure 2 Definitions of VDT Workstation Terminology. (Adapted from Helander 1982)

of users, (2) allow a detachable keyboard to be placed in several locations, and (3) permit source documents to be properly positioned for easy viewing. Additional working surfaces (i.e., secondary working surfaces) may be required in order to store, lay out, read, and/or write on documents or materials. Often users have more than one computer, so a second computer is placed on a secondary working surface. In such a situation, workstations are configured so that multiple pieces of equipment and source materials can be equally accessible to the user. In this case, additional working surfaces are necessary to support these additional tools and are arranged to allow easy movement while seated from one surface to another.

The tabletop should be as thin as possible to provide clearance for the user's thighs and knees. Moreover, it is important to provide unobstructed room under the working surface for the feet and legs so that users can easily shift their posture. Knee space height and width and leg depth are the three key factors for the design of clearance space under working surfaces (see Figure 2). Recommendations for minimum width for leg clearance is 51 cm, while the preferred minimum width is 61 cm (ANSI, 1988). The minimum depth under the work surface from the operator edge of the work surface should be 38 cm for clearance at the knee level and 60 cm at the toe level (ANSI 1988). A good workstation design accounts for individual body sizes and often exceeds minimum clearances to allow for free postural movement.

Table height has been shown to be an important contributor to computer user musculoskeletal problems. In particular, tables that are too high cause the keyboard to be too high for many operators. The standard desk height of 30 in. (76 cm) is often too high for most people to attain the proper arm angle when using the keyboard. This puts undue pressure on the hands, wrists, arms, shoulders, and neck. It is desirable for table heights to vary with the trunk height of the operator. Height-adjustable tables are effective for this. Adjustable multisurface tables enable good posture by allowing the keyboard and display to be independently adjusted to appropriate keying and viewing heights for each individual and each task. Tables that cannot be adjusted easily are not appropriate when used by several individuals of differing sizes. If adjustable tables are used, ease of adjustment is essential. Adjustments should be easy to make and operators should be instructed (trained) about how to adjust the workstation to be comfortable and safe.

Specifications for the height of working surfaces vary by whether the table is adjustable or fixed in height and depending on a single working surface or multiple working surfaces. Remember that adjustable-height working surfaces are strongly recommended. However, if the working surface height is not adjustable, the proper height for a nonadjustable working surface is about 70 cm (floor to top of surface) (ANSI 1988). Adjustable tables allow vertical adjustments of the keyboard and display. Some allow for independent adjustment of the keyboard and display. For single adjustable working surfaces, the working surface height adjustment should be 70–80 cm. For independently adjustable working surfaces for the keyboard and screen, the appropriate height range for the keyboard surface is 59–71 cm, and 70–80 cm for the screen (ANSI 1988).

2.7.2. The Chair

Poorly designed chairs can contribute to computer user discomfort. Chair adjustability in terms of height, seat angle, lumbar support, and armrest height and angle reduces the pressure and loading on the musculoskeleture of the back, legs, shoulders, neck, and arms. In addition, how the chair supports the movement of the user (the chair's action) helps to maintain proper seated posture and encourages good movement patterns. A chair that provides swivel action encourages movement, while backward tilting increases the number of postures that can be assumed. The chair height should be adjustable so that the feet can rest firmly on the floor with minimal pressure beneath the thighs. The minimum range of adjustment for seat height should be 38–52 cm (NAS 1983; Smith 1984; ANSI 1988). Modern chairs also provide an action that supports the back (spine) when seated. Examples of such chairs are the Leap by Steelcase, Inc. and the Aeron by Herman Miller.

To enable shorter users to sit with their feet on the floor without compressing their thighs, it may be necessary to add a footrest. A well-designed footrest has the following features: (1) it is inclined upward slightly (about 5–15°), (2) it has a nonskid surface, (3) it is heavy enough that it does not slide easily across the floor, (4) it is large enough for the feet to be firmly planted, and (5) it is portable.

The seat pan is where the user's buttocks sits on the chair. It is the part that directly supports the weight of the buttocks. The seat pan should be wide enough to permit operators to make slight shifts in posture from side to side. This not only helps to avoid static postures but also accommodates a large range of individual buttock sizes with a few seat pan widths. The minimum seat pan width should be 45 cm and the minimum depth 38–43 cm (ANSI 1988). The front edge of the chair should be well rounded downward to reduce pressure on the underside of the thighs, which can affect blood flow to the legs and feet. The seat needs to be padded to the proper firmness that ensures an even distribution of pressure on the thighs and buttocks. A properly padded seat should compress about one-half to one inch when a person sits on it.

Some experts feel that the seat front should be elevated slightly (up to 7°), while others feel it should be lowered slightly (about 5°) (ANSI 1988). There is little agreement among the experts about which is correct (Grandjean 1979, 1984). Many chair manufacturers provide adjustment of the front angle so the user can have the preferred tilt angle, either forward or backward.

The tension for leaning backward and the backward tilt angle of the backrest should be adjustable. Inclination of chair backrest is important for users to be able to lean forward or back in a comfortable manner while maintaining a correct relationship between the seat pan angle and the backrest inclination. A back seat inclination of about 110° is considered as the best position by many experts (Grandjean 1984). However, studies have shown that operators may incline backward as much as 125°. Backrests that tilt to allow an inclination of up to 125–130° are a good idea. The advantage of having an independent tilt angle adjustment is that the backrest tilt will then have little or no effect on the front seat height. This also allows operators to shift postures easily and often.

Chairs with full backrests that provide lower back (lumbar) support and upper back (lower shoulder) support are preferred. This allows employees to lean backward or forward, adopting a relaxed posture and resting the back muscles. A full backrest with a height around 45–51 cm is recommended (ANSI 1988). However, some of the newer chair designs do not have the bottom of the backrest go all the way to the seat pan. This is acceptable as long as the lumbar back is properly supported. To prevent back strain with such chairs, it is recommended that they have midback (lumbar) support since the lumbar region is one of the most highly loaded parts of the spine.

For most computer workstations, chairs with rolling castors (or wheels) are desirable. They are easy to move and facilitate the postural adjustment of users, particularly when the operator has to access equipment or materials that are on secondary working surfaces. Chairs should have a five-star base for tipping stability (ANSI 1988).

Another important chair feature is armrests. Pros and cons for the use of armrests at computer workstations have been advanced. On the one hand, some chair armrests can present problems of restricted arm movement, interference with keyboard operation, pinching of fingers between the armrest and table, restriction of chair movement such as under the work table, irritation of the arm or elbows, and adoption of awkward postures.

On the other hand, well-designed armrests or elbow rests can provide support for resting the arms to prevent or reduce fatigue, especially during breaks from typing. Properly designed armrests can overcome the problems mentioned because they can be raised, lowered, and angled to fit the user's needs. Removable armrests are an advantage because they provide greater flexibility for individual user preference, especially for users who develop discomfort and pain from the pressure of the armrest on their arms.

2.7.3. Other Workstation Considerations

An important component of the workstation that can help reduce musculoskeletal loading is a document holder. When properly designed and proportioned, document holders reduce awkward incli-

nations, as well as frequent movements up and down and back and forth of the head and neck. They permit source documents to be placed in a central location at approximately the same viewing distance and height as the computer screen. This eliminates needless head and neck movements and reduces eyestrain. In practice, some flexibility about the location, adjustment, and position of the document holder should be maintained to accommodate both task requirements and operator preferences. The document holder should have a matte finish so that it does not produce reflections or a glare source.

Privacy requirements include both visual and acoustical control of the workplace. Visual control prevents physical intrusions and distractions, contributes to protecting confidential/private conversations, and prevents the individual from feeling constantly watched. Acoustical control prevents distracting and unwanted noise—from machine or conversation—and permits speech privacy. While certain acoustical methods and materials such as free-standing panels are used to control general office noise level, they can also be used for privacy. In open-office designs they can provide workstation privacy. Generally, noise control at a computer workstation can be achieved through the following methods:

- Use of vertical barriers, such as acoustical screens or panels.
- Selection of floor, ceiling, wall, and workstation materials and finishes according to their power to control noise.
- Placement of workstations to enhance individual privacy.
- Locating workstations away from areas likely to generate noise (e.g., printer rooms, areas with heavy traffic).

Each of these methods can be used individually or combined to account for the specific visual and acoustical requirements of the task or individual employee needs. Planning for privacy should not be made at the expense of visual interest or spatial clarity. For instance, providing wide visual views can prevent the individual from feeling isolated. Thus, a balance between privacy and openness enhances user comfort, work effectiveness, and office communications. Involving the employee in decisions of privacy can help in deciding the compromises between privacy and openness.

2.8. Work Practices

Good ergonomic design of computer workstations has the potential to reduce visual and musculoskeletal complaints and disorders as well as increase employee performance. However, regardless of how well a workstation is designed, if operators must adopt static postures for a long time, they can still have performance, comfort, and health problems. Thus, designing tasks that induce employee movement in addition to work breaks can contribute to comfort and help relieve employees' fatigue.

2.8.1. Work Breaks

As a minimum, a 15-minute break from working should be taken after 2 hours of continuous computer work (CDC 1980; NIOSH 1981). Breaks should be more frequent as visual, muscular, and mental loads are high and as users complain of visual and musculoskeletal discomfort and psychological stress. With such intense, high-workload tasks, a work break of 10 minutes should be taken after 1 hour of continuous computer work. More frequent breaks for alternative work that does not pose demands similar to the primary computer work can be taken after 30 minutes of continuous computer work. Rest breaks provide an opportunity for recovery from local visual, musculoskeletal, and mental fatigue, to break from monotonous activities, or to engage in activities that provide variety in sensory, motor, and cognitive requirements.

While ergonomics considers users' physiological interface with interactive systems, cognitive design focuses on the psychological interface between users and computers. This will be addressed in the next section.

3. COGNITIVE DESIGN

3.1. Overview

Cognitive design, also referred to as cognitive engineering, is a multidisciplinary approach to system design that considers the analysis, design, and evaluation of interactive systems (Vicente 1999). Cognitive design involves developing systems through an understanding of human capabilities and limitations. It focuses on how humans process information and aims to identify users' mental models, such that supporting metaphors and analogies can be identified and designed into systems (Eberts 1994). The general goal of cognitive design is thus to design interactive systems that are predictable (i.e., respond to the way users perceive, think, and act). Through the application of this approach, human–computer interaction has evolved into a relatively standard set of interaction techniques,

including typing, pointing, and clicking. This set of ''standard'' interaction techniques is evolving, with a transition from graphical user interfaces to perceptual user interfaces that seek to more naturally interact with users through multimodal and multimedia interaction (Turk and Robertson 2000). In either case, however, these interfaces are characterized by interaction techniques that try to match user capabilities and limitations to the interface design.

Cognitive design efforts are guided by the requirements definition, user profile development, tasks analysis, task allocation, and usability goal setting that result from an intrinsic understanding gained from the target work environment. Although these activities are listed and presented in this order, they are conducted iteratively throughout the system development life cycle.

3.2. Requirements Definition

Requirements definition involves the specification of the necessary goals, functions, and objectives to be met by the system design (Eberts 1994; Rouse 1991). The intent of the requirements definition is to specify what a system should be capable of doing and the functions that must be available to users to achieve stated goals. Karat and Dayton (1995) suggest that developing a careful understanding of system requirements leads to more effective initial designs that require less redesign. Ethnographic evaluation can be used to develop a requirements definition that is necessary and complete to support the target domain (Nardi 1997).

Goals specify the desired system characteristics (Rouse 1991). These are generally qualitatively stated (e.g., automate functions, maximize use, accommodate user types) and can be met in a number of ways. Functions define what the system should be capable of doing without specifying the specifics of how the functions should be achieved. Objectives are the activities that the system must be able to accomplish in support of the specified functions. Note that the system requirements, as stated in terms of goals, functions, and objectives, can be achieved by a number of design alternatives. Thus, the requirements definition specifies what the system should be able to accomplish without specifying how this should be realized. It can be used to guide the overall design effort to ensure the desired end is achieved. Once a set of functional and feature requirements has been scoped out, an understanding of the current work environment is needed in order to design systems that effectively support these requirements.

3.3. Contextual Task Analysis

The objective of contextual task analysis is to achieve a user-centered model of current work practices (Mayhew 1999). It is important to determine how users currently carry out their tasks, which individuals they interact with, what tools support the accomplishment of their job goals, and the resulting products of their efforts. Formerly this was often achieved by observing a user or set of users in a laboratory setting and having them provide verbal protocols as they conducted task activities in the form of use cases (Hackos and Redish 1998; Karat 1988; Mayhew 1999; Vermeeren 1999). This approach, however, fails to take into consideration the influences of the actual work setting. Through an understanding of the work environment, designers can leverage current practices that are effective while designing out those that are ineffective. The results of a contextual task analysis include work environment and task analyses, from which mental models can be identified and user scenarios and task-organization models (e.g., use sequences, use flow diagrams, use workflows, and use hierarchies) can be derived (Mayhew 1999). These models and scenarios can then help guide the design of the system. As depicted in Figure 3, contextual task analysis consists of three main steps.

Effective interactive system design thus comes from a basis in direct observation of users in their work environments rather than assumptions about the users or observations of their activities in contrived laboratory settings (Hackos and Redish 1998). Yet contextual tasks analysis is sometimes overlooked because developers assume they know users or that their user base is too diverse, expensive, or time consuming to get to know. In most cases, however, observation of a small set of diverse users can provide critical insights that lead to more effective and acceptable system designs. For usability evaluations, Nielsen (1993) found that the greatest payoff occurs with just three users.

3.3.1. Background Information

It is important when planning a task analysis to first become familiar with the work environment. If analysts do not understand work practices, tools, and jargon prior to commencing a task analysis, they can easily get confused and become unable to follow the task flow. Further, if the first time users see analysts they have clipboard and pen in hand, users are likely to resist being observed or change their behaviors during observation. Analysts should develop a rapport with users by spending time with them, participating in their task activities when possible, and listening to their needs and concerns. Once users are familiar and comfortable with analysts and analysts are likewise versed on work practices, data collection can commence. During this familiarization, analysts can also capture data to characterize users.

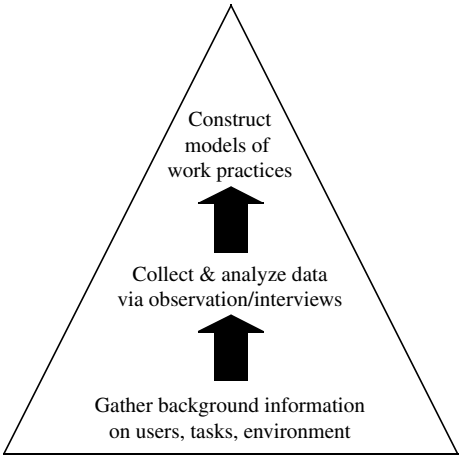


Figure 3 The Steps of Contextual Task Analysis.

3.3.2. Characterizing Users

It is ultimately the users who will determine whether a system is adopted into their lives. Designs that frustrate, stress, or annoy users are not likely to be embraced. Based on the requirements definition, the objective of designers should be to develop a system that can meet specified user goals, functions, and objectives. This can be accomplished through an early and continual focus on the target user population (Gould et al. 1997). It is inconceivable that design efforts would bring products to market without thoroughly determining who the user is. Yet developers, as they expedite system development to rush products to market, are often reluctant to characterize users. In doing so, they may fail to recognize the amount of time they spend speculating upon what users might need, like, or want in a product (Nielsen 1993). Ascertaining this information directly by querying representative users can be both more efficient and more accurate.

Information about users should provide insights into differences in their computer experience, domain knowledge, and amount of training on similar systems (Wixon and Wilson 1997). The results can be summarized in a narrative format that provides a user profile of each intended user group (e.g., primary users, secondary users, technicians and support personnel). No system design, however, will meet the requirements of all types of users. Thus, it is essential to identify, define, and characterize target users. Separate user profiles should be developed for each target user group. The user profiles can then feed directly into the task analysis by identifying the user groups for which tasks must be characterized (Mayhew 1999).

Mayhew (1999) presents a step-by-step process for developing user profiles. First, a determination of user categories is made by identifying the intended user groups for the target system. When developing a system for an organization, this information may come directly from preexisting job categories. Where those do not exist, marketing organizations often have target user populations identified for a given system or product. Next, the relevant user characteristics must be identified. User profiles should be specified in terms of psychological (e.g., attitudes, motivation), knowledge and experience (e.g., educational background, years on job), job and task (e.g., frequency of use), and physical (e.g., stature, visual impairments) characteristics (Mayhew 1999; Nielsen 1993; Wixon and Wilson 1997). While many of these user attributes can be obtained via user profile questionnaires or interviews, psychological characteristics may be best identified via ethnographic evaluation, where a sense of the work environment temperament can be obtained. Once this information is obtained, a summary of the key characteristics for each target user group can be developed, highlighting their implications to the system design. By understanding these characteristics, developers can better anticipate such issues as learning difficulties and specify appropriate levels of interface complexity. System design requirements involve an assessment of the required levels of such factors as ease of learning, ease of use, level of satisfaction, and workload for each target user group (see Table 2)

Individual differences within a user population should also be acknowledged (Egan 1988; Hackos and Redish 1998). While users differ along many dimensions, key areas of user differences have been identified that significantly influence their experience with interactive systems. Users may differ

TABLE 2 Example of a User Profile

Characteristic	Questionnaire Response	System Design Requirement
Attitude	Negative	System should be subjectively pleasing
Motivation	Generally low	Usefulness of system should be readily apparent
Education level	High school	Simplicity important; training requirements should be minimal
Computer experience	Low	High ease of learning required
Frequency of computer use	Discretionary	High ease of use required; system workload should be minimized
Typing skills	Poor	Minimize typing; use icons and visual displays
Gender	Mostly males	Consider color blindness
Age	Average = 42.5 (s.d. = 3.6)	Text and symbol size should be readily legible

in such attributes as personality, physical or cognitive capacity, motivation, cultural background, education, and training. Users also change over time (e.g., transitioning from novice to expert). By acknowledging these differences, developers can make informed decisions on whether or not to support them in their system designs. For example, marketing could determine which group of individuals it would be most profitable to target with a given system design.

3.3.3. Collecting and Analyzing Data

Contextual task analysis focuses on the behavioral aspects of a task, resulting in an understanding of the general structure and flow of task activities (Mayhew 1999; Nielsen 1993; Wixon and Wilson 1997). This analysis identifies the major tasks and their frequency of occurrence. This can be compared to cognitive task analysis, which identifies the low-level perceptual, cognitive, and motor actions required during task performance (Card et al. 1983; Corbett et al. 1997). Beyond providing an understanding of tasks and workflow patterns, the contextual task analysis also identifies the primary objects or artifacts that support the task, information needs (both inputs and outputs), workarounds that have been adopted, and exceptions to normal work activities. The result of this analysis is a task flow diagram with supporting narrative depicting user-centered task activities, including task goals; information needed to achieve these goals; information generated from achieving these goals; and task organization (i.e., subtasks and interdependencies).

Task analysis thus aims to structure the flow of task activities into a sequential list of functional elements, conditions of transition from one element to the next, required supporting tools and artifacts, and resulting products (Sheridan 1997a). There are both formal and informal techniques for task analysis (see Table 3). Such an analysis can be driven by formal models such as TAKD (task analysis for knowledge description; see Diaper 1989) or GOMS (goals, operators, methods, and selection rules; see Card et al. 1983) or through informal techniques such as interviews, observation and shadowing, surveys, and retrospectives and diaries (Jeffries 1997). With all of these methods, typically

TABLE 3 Task-Analysis Techniques for Interactive System Design

Design Objective	Task-Analysis Technique
Detailed description of task	TAKD, GOMS, interviews
Detailed description of task (when difficult to verbalize task knowledge)	Observation, shadowing
Task description for tasks with significant performance variation; determine specific task characteristics (e.g., frequency)	Surveys, observation, shadowing
Clarify task areas	Surveys, observation, shadowing, retrospectives and diaries

a domain expert is somehow queried about their task knowledge. It may be beneficial to query a range of users, from novice to expert, to identify differences in their task practices. In either case, it is important to select individuals that can readily verbalize how a task is carried out to serve as informants (Ebert 1994).

When a very detailed task analysis is required, formal techniques such as TAKD (Diaper 1989; Kirwan and Ainsworth 1992) or GOMS (Card et al. 1983) can be used to delineate task activities (see Chapter 39), TAKD uses knowledge-representation grammars (i.e., sets of statements used to described system interaction) to represent task-knowledge in a task-descriptive hierarchy. This technique is useful for characterizing complex tasks that lack fine-detail cognitive activities (Eberts 1994). GOMS is a predictive modeling technique that has been used to characterize how humans interact with computers. Through a GOMS analysis, task goals are identified, along with the operators (i.e., perceptual, cognitive, or motor acts) and methods (i.e., series of operators) to achieve those goals and the selection rules used to elect between alternative methods. The benefit of TAKD and GOMS is that they provide an in-depth understanding of task characteristics, which can be used to quantify the benefits in terms of consistency (TAKD) or performance time gains (GOMS) of one design vs. another (see Gray et al. 1993; McLeod and Sherwood-Jones 1993 for examples of the effective use of GOMS in design). This deep knowledge, however, comes at a great cost in terms of time to conduct the analysis. Thus, it is important to determine the level of task analysis required for informed design. While formal techniques such as GOMS can lead to very detailed analyses (i.e., at the perceive, think, act level), often such detail is not required for effective design. Jeffries (1997) suggests that one can loosely determine the right level of detail by determining when further decomposition of the task would not reveal any ''interesting'' new subtasks that would enlighten the design. If detailed task knowledge is not deemed requisite, informal task-analysis techniques should be adopted.

Interviews are the most common informal technique to gather task information (Jeffries 1997; Kirwan and Ainsworth 1992; Meister 1985). In this technique, informants are asked to verbalize their strategies, rationale, and knowledge used to accomplish task goals and subgoals (Ericsson and Simon 1980). As each informant's mental model of the tasks they verbalize is likely to differ, it is advantageous to interview at least two to three informants to identify the common flow of task activities. Placing the informant in the context of the task domain and having him or her verbalize while conducting tasks affords more complete task descriptions while providing insights on the environment the task is performed within. It can sometimes be difficult for informants to verbalize their task performance because much of it may be automatized (Eberts 1994). When conducting interviews, it is important to use appropriate sampling techniques (i.e., sample at the right time with enough individuals), avoid leading questions, and follow up with appropriate probe questions (Nardi 1997). While the interviewer should generally abstain from interfering with task performance, it is sometimes necessary to probe for more detail when it appears that steps or subgoals are not being communicated. Eberts (1994) suggests that the human information-processing model can be used to structure verbal protocols and determine what information is needed and what is likely being left out.

Observation during task activity or shadowing workers throughout their daily work activities are time-consuming task-analysis techniques, but they can prove useful when it is difficult for informants to verbalize their task knowledge (Jeffries 1997). These techniques can also provide information about the environment in which tasks are performed, such as tacit behaviors, social interactions, and physical demands, which are difficult to capture with other techniques (Kirwan and Ainsworth 1992).

While observation and shadowing can be used to develop task descriptions, surveys are particularly useful task-analysis tools when there is significant variation in the manner in which tasks are performed or when it is important to determine specific task characteristics, such as frequency (Jeffries 1997; Nielsen 1993). Surveys can also be used as a follow-on to further clarify task areas described via an interview. Focused observation, shadowing, retrospectives, and diaries are also useful for clarifying task areas. With retrospectives and diaries, an informant is asked to provide a retrospective soon after completing a task or to document his or her activities after several task events, the latter being a diary.

Whether formal or informal techniques are used, the objective of the task analysis is to identify the goals of users and determine the techniques they use to accomplish these goals. Norman (1988) provides a general model of the stages users go through when accomplishing goals (see Figure 4). Stanton (1998) suggests that there are three main ways in which this process can go awry: by users forgetting a required action, executing an errant action, or misperceiving or misinterpreting the current state of the system. In observing users of a vending machine, Verhoef (1988) indeed found that these types of errors occur during system interaction. In this case study, users of the vending machine failed to perceive information presented by the machine, performed actions in the wrong order, and misinterpreted tasks when they were not clearly explained or when incomplete information was provided.

By understanding the stages of goal accomplishment and the related errors that can occur, developers can more effectively design interactive systems. For example, by knowing that users perceive and interpret the system state once an action has been executed, designers can understand why it is

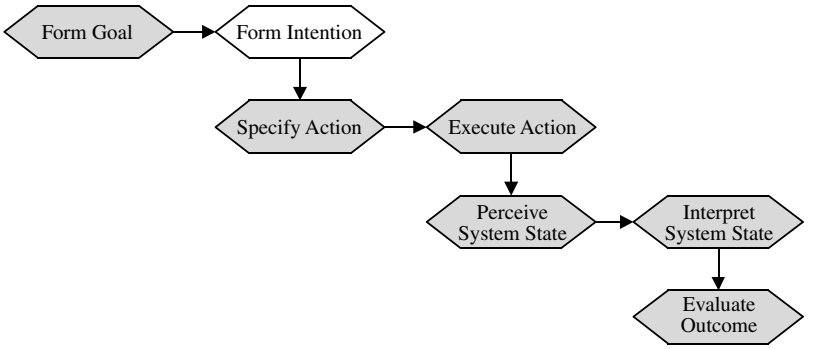

Figure 4 Stages of Goal Accomplishment.

essential to provide feedback (Nielsen 1993) to the executed action. Knowing that users often specify alternative methods to achieve a goal or change methods during the course of goal seeking, designers can aim to support diverse approaches. Further, recognizing that users commit errors emphasizes the need for undo functionality.

The results from a task analysis provide insights into the optimal structuring of task activities and the key attributes of the work environment that will directly affect interactive system design (Mayhew 1999). The analysis enumerates the tasks that users may want to accomplish to achieve stated goals through the preparation of a task list or task inventory (Hackos and Redish 1998; Jeffries 1997). A model of task activities, including how users currently think about, discuss, and perform their work, can then be devised based on the task analysis. To develop task-flow models, it is important to consider the timing, frequency, criticality, difficulty, and responsible individual of each task on the list. In seeking to conduct the analysis at the appropriate level of detail, it may be beneficial initially to limit the task list and associated model to the primary 10–20 tasks that users perform. Once developed, task models can be used to determine the functionality necessary to support in the system design. Further, once the task models and desired functionality are characterized, use scenarios (i.e., concrete task instances, with related contextual [i.e., situational] elements and stated resolutions) can be developed that can be used to drive both the system design and evaluation (Jeffries 1997).

3.3.4. Constructing Models of Work Practices

While results from the task analysis provide task-flow models, they also can provide insights on the manner in which individuals model these process flows (i.e., mental models). Mental models synthesize several steps of a process into an organized unit (Allen 1997). An individual may model several aspects of a given process, such as the capabilities of a tool or machine, expectations of coworkers, or understandings of support processes (Fischer 1991). These models allow individuals to predict how a process will respond to a given input, explain a process event, or diagnose the reasons for a malfunction. Mental models are often incomplete and inaccurate, however, so understandings based on these models can be erroneous.

As developers design systems, they will develop user models of target user groups (Allen 1997). These models should be relevant (i.e., able to make predictions as users would), accurate, adaptable to changes in user behavior, and generalizable. Proficient user modeling can assist developers in designing systems that interact effectively with users. Developers must recognize that users will both come to the system interaction with preconceived mental models of the process being automated and develop models of the automated system interaction. They must thus seek to identify how users represent their existing knowledge about a process and how this knowledge fits together in learning and performance so that they can design systems that engender the development of an accurate mental model of the system interaction (Carroll and Olson 1988). By understanding how users model processes, developers can determine how users currently think and act, how these behaviors can be supported by the interactive system design when advantageous, and how they can be modified and improved upon via system automation.

3.3.5. Task Allocation

In moving toward a system design, once tasks have been analyzed and associated mental models characterized, designers can use this knowledge to address the relationship between the human and the interactive system. Task allocation is a process of assigning the various tasks identified via the

task analysis to agents (i.e., users), instruments (e.g., interactive systems) or support resources (e.g., training, manuals, cheat sheets). It defines the extent of user involvement vs. computer automation in system interaction (Kirwan and Ainsworth 1992). In some system-development efforts, formal task allocation will be conducted; in others, it is a less explicit yet inherent part of the design process.

While there are many systematic techniques for conducting task analysis (see Kirwan and Ainsworth 1992), the same is not true of task allocation (Sheridan 1997a). Further, task allocation is complicated by the fact that seldom are tasks or subtasks truly independent, and thus their interdependence must be effectively designed into the human–system interaction. Rather than a deductive assignment of tasks to human or computer, task allocation thus becomes a consideration of the multitude of design alternatives that can support these interdependencies. Sheridan (1997a,b) delineates a number of task allocation considerations that can assist in narrowing the design space (see Table 4).

In allocating tasks, one must also consider what will be assigned to support resources. If the system is not a walk-up-and-use system but one that will require learning, then designers must identify what knowledge is appropriate to allocate to support resources (e.g., training courses, manuals, online help).

Training computer users in their new job requirements and how the technology works has often been a neglected element in office automation. Many times the extent of operator training is limited to reading the manual and learning by trial and error. In some cases, operators may have classes that go over the material in the manual and give hands-on practice with the new equipment for limited periods of time. The problem with these approaches is that there is usually insufficient time for users to develop the skills and confidence to adequately use the new technology. It is thus essential to determine what online resources will be required to support effective system interaction.

Becoming proficient in hardware and software use takes longer than just the training course time. Often several days, weeks, or even months of daily use are needed to become an expert depending on the difficulty of the application and the skill of the individual. Appropriate support resources should be designed into the system to assist in developing this proficiency. Also, it is important to remember that each individual learns at his or her own pace and therefore some differences in proficiency will be seen among individuals. When new technology is introduced, training should tie in skills from the former methods of doing tasks to facilitate the transfer of knowledge. Sometimes new skills clash with those formerly learned, and then more time for training and practice is necessary to achieve good results. If increased performance or labor savings are expected with the new technology, it is prudent not to expect results too quickly. Rather, it is wise to develop the users' skills completely if the most positive results are to be achieved.

TABLE 4 Considerations in the Task-Allocation Process

Considerations in Task Allocation	Design Issue
Check task-analysis constraints	Strict task requirements can complicate or make infeasible appropriate task allocation
Identify obvious allocations	Highly repetitive tasks are generally appropriate for automation; dealing with the unexpected or cognitively complex tasks are generally appropriate for humans
Identify expected allocations	Users' mental models may uncover expected allocation schemes
Identify the extremes	Bound the design space by assessing total computer automation vs. total human manual control solutions
Consider points between the extremes	Sheridan (1997a,b) offers a 10-point scale of allocation between the extremes that assists in assessing intermediate solutions
Consider level of specificity required by allocation	Strict assignments are ineffectual; a general principle is to leave the big picture to the human and the details to the computer
Consider sequential vs. parallel processing	Will the computer and user trade outputs of their processing or will they concurrently collaborate in task performance?
Consider the range of criteria that can be used to judge appropriate allocation	While many criteria affect overall system interaction, a small number of criteria are generally important for an individual task

3.4. Competitive Analysis and Usability Goal Setting

Once the users and tasks have been characterized, it is sometimes beneficial to conduct a competitive analysis (Nielsen 1993). Identifying the strengths and weaknesses of competitive products or existing systems allows means to leverage strengths and resolve identified weaknesses.

After users have been characterized, a task analysis performed, and, if necessary, a competitive analysis conducted, the next step in interactive system design is usability goal setting (Hackos and Redish 1998; Mayhew 1999; Nielsen 1993; Wixon and Wilson 1993). Usability objectives generally focus around effectiveness (i.e., the extent to which tasks can be achieved), intuitiveness (i.e., how learnable and memorable the system is), and subjective perception (i.e., how comfortable and satisfied users are with the system) (Eberts 1994; Nielsen 1993; Shneiderman 1992; Wixon and Wilson 1997). Setting such objectives will ensure that the usability attributes evaluated are those that are important for meeting task goals; that these attributes are translated into operational measures; that the attributes are generally holistic, relating to overall system/task performance; and that the attributes relate to specific usability objectives.

Because usability is assessed via a multitude of potentially conflicting measures, often equal weights cannot be given to every usability criterion. For example, to gain subjective satisfaction, one might have to sacrifice task efficiency. Developers should specify usability criteria of interest and provide operational goals for each metric. These metrics can be expressed as absolute goals (i.e., in terms of an absolute quantification) or as relative goals (i.e., in comparison to a benchmark system or process). Such metrics provide system developers with concrete goals to meet and a means to measure usability. This information is generally documented in the form of a usability attribute table and usability specification matrix (see Mayhew 1999).

3.5. User Interface Design

While design ideas evolve throughout the information-gathering stages, formal design of the interactive system commences once relevant information has been obtained. The checklist in Table 5 can be used to determine whether the critical information items that support the design process have been addressed. Readied with information, interactive system design generally begins with an initial definition of the design and evolves into a detailed design, from which iterative cycles of evaluation and improvement transpire (Martel 1998).

3.5.1. Initial Design Definition

Where should one commence the actual design of a new interactive system? Often designers look to existing products within their own product lines or competitors' products. This is a sound practice because it maintains consistency with existing successful products. This approach may be limiting, however, leading to evolutionary designs that lack design innovations. Where can designers obtain the ideas to fuel truly innovative designs that uniquely meet the needs of their users? Ethnographic evaluations can lead to many innovative design concepts that would never be realized in isolation of the work environment (Mountford 1990). The effort devoted to the early characterization of users and tasks, particularly when conducted in the context of the work environment, often is rewarded in terms of the generation of innovative design ideas. Mountford (1990) has provided a number of techniques to assist in eliciting design ideas based on the objects, artifacts, and other information gathered during the contextual task analysis (see Table 6).

To generate a multitude of design ideas, it is beneficial to use a parallel design strategy (Nielsen 1993), where more than one designer sets out in isolation to generate design concepts. A low level

TABLE 5 Checklist of Information Items

Identified necessary goals, functions, and objectives to be met by system design
Became familiar with practices, tools, and vernacular of work environment
Characterized user profiles in terms of psychological characteristics, knowledge and experience, job and task characteristics, and physical attributes
Acknowledged individual differences within target user population
Developed user models that are relevant, accurate, adaptable to changes in user behavior, and generalizable
Developed a user-centered model of current work practices via task analysis
Defined extent of user involvement vs. computer automation in system interaction, as well as required support resources (e.g., manuals)
Conducted a competitive analysis
Set usability goals

TABLE 6 Design Idea Generation Checklist

Are there new uses for objects and artifacts identified in the task analysis?
Could objects and artifacts be adapted to be like something else? How would this change the organizational structure of the system interaction?
Could objects and artifacts be modified to serve a new purpose?
Can tools or other features be added to objects and artifacts?
Can interaction be streamlined by subtracting from objects and artifacts?
Are there alternative metaphors that would be more appropriate for the task domain being automated? Can the basic layout of a metaphor be modified or somehow rearranged?
Can a design scheme be reversed or transposed for alternative interaction approaches?
Are there large, encompassing metaphors that could be used to characterize more of the task domain?

of effort (e.g., a few hours to a few days) is generally devoted to this idea-generation stage. Storyboarding via paper prototypes is often used at this stage because it is easy to generate and modify and is cost effective (Martel 1998). Storyboards provide a series of pictures representing how an interface may look.

3.5.2. Detailed Design

Once design alternatives have been storyboarded, the best aspects of each design can be identified and integrated into a detailed design concept. The detailed design can be realized through the use of several techniques, including specification of nouns and verbs that represent interface objects and actions, as well as the use of metaphors (Hackos and Redish 1998). The metaphors can be further refined via use scenarios, use sequences, use flow diagrams, use workflows, and use hierarchies. Storyboards and rough interface sketches can support each stage in the evolution of the detailed design.

3.5.2.1. Objects and Actions Workplace artifacts, identified via the contextual task analysis, become the objects in the interface design (Hackos and Redish 1998). Nouns in the task flow also become interface objects, while verbs become interface actions. Continuing the use of paper prototyping, the artifacts, nouns, and verbs from the task flows and related models can each be specified on a sticky note and posted to the working storyboard. Desired attributes for each object or action can be delineated on the notes. The objects and actions should be categorized and any redundancies eliminated. The narratives and categories can generate ideas on how interface objects should look, how interface actions should feel, and how these might be structurally organized around specified categories.

3.5.2.2. Metaphors Designers often try to ease the complexity of system interaction by grounding interface actions and objects and related tasks and goals in a familiar framework known as a metaphor (Neale and Carroll 1997). A metaphor is a conceptual set of familiar terms and associations (Erickson 1990). If designed into a user interface, it can be used to incite users to relate what they already know about the metaphoric concept to the system interaction, thereby enhancing the learnability of the system (Carroll and Thomas 1982).

The purpose of developing interface metaphors is to provide users with a useful orienting framework to guide their system interaction. The metaphor provides insights into the spatial properties of the user interface and the manner in which they are derived and maintained by interaction objects and actions (Carroll and Mack 1985). It stimulates systematic system interaction that may lead to greater understanding of these spatial properties. Through this understanding, users should be able to tie together a configural representation (or mental model) of the system to guide their interactions (Kay 1990).

An effective metaphor will both orient and situate users within the system interaction. It will aid without attracting attention or energy away from the automated task process (Norman 1990). Providing a metaphor should help focus users to critical cues and away from irrelevant distractions. The metaphor should also help to differentiate the environment and enhance visual access (Kim and Hirtle 1995). Parunak (1989) accomplished this in a hypertext environment by providing between-path mechanisms (e.g., backtracking capability and guided tours), annotation capabilities that allow users to designate locations that can be accessed directly (e.g., bookmarks in hypertext), and links and filtering techniques that simplify a given topology.

It is important to note that a metaphor does not have to be a literal similarity (Ortony 1979) to be effective. In fact, Gentner (1983) and Gentner and Clement (1988) suggest that people seek to identify relational rather than object attribute comparisons in comprehending metaphors. Based on

Gentner's structure-mapping theory, the aptness of a metaphor should increase with the degree to which its interpretation is relational. Thus, when interpreting a metaphor, people should tend to extend relational rather than object attribute information from the base to the target. The learning efficacy of a metaphor, however, is based on more than the mapping of relational information between two objects (Carroll and Mack 1985). Indeed, it is imperative to consider the open-endedness of metaphors and leverage the utility of not only correspondence, but also noncorrespondence in generating appropriate mental models during learning. Nevertheless, the structure-mapping theory can assist in providing a framework for explaining and designing metaphors for enhancing the design of interactive systems.

Neale and Carroll (1997) have provided a five-stage process from which design metaphors can be conceived (see Table 7). Through the use of this process, developers can generate coherent, well-structured metaphoric designs.

3.5.2.3. Use Scenarios, Use Sequences, Use Flow Diagrams, Use Workflows, and Use Hierarchies Once a metaphoric design has been defined, its validity and applicability to task goals and subgoals can be identified via use scenarios, use sequences, use flow diagrams, use workflows, and use hierarchies (see Figure 5) (Hackos and Redish 1998). Use scenarios are narrative descriptions of how the goals and subgoals identified via the contextual task analysis will be realized via the interface design. Beyond the main flow of task activities, they should address task exceptions, individual differences, and anticipated user errors. In developing use scenarios, it can be helpful to reference task allocation schemes (see Section 3.3.5). These schemes can help to define what will be achieved by users via the interface, what will be automated, and what will be rendered to support resources in the use scenarios.

If metaphoric designs are robust, they should be able to withstand the interactions demanded by a variety of use scenarios with only modest modifications required. Design concepts to address required modifications should evolve from the types of interactions envisioned by the scenarios. Once the running of use scenarios fails to generate any required design modifications, their use can be terminated.

If parts of a use scenario are difficult for users to achieve or designers to conceptualize, use sequences can be used. Use sequences delineate the sequence of steps required for a scenario subsection being focused upon. They specify the actions and decisions required of the user and the interactive system, the objects needed to achieve task goals, and the required outputs of the system interaction. Task workarounds and exceptions can be addressed with use sequences to determine if the design should support these activities. Providing detailed sequence specifications highlights steps that are not appropriately supported by the design and thus require redesign.

When there are several use sequences supported by a design, it can be helpful to develop use flow diagrams for a defined subsection of the task activities. These diagrams delineate the alternative paths and related intersections (i.e., decision points) users encounter during system interaction. The representative entities that users encounter throughout the use flow diagram become the required objects and actions for the interface design.

TABLE 7 Stages of Metaphoric Design Generation

Stage	Design Outcome
Identify system functionality	Required functions, features, and system capabilities are identified (see Section 3.2)
Generate metaphoric concepts	Artifacts and other objects in the environment identified via the contextual task analysis (see Section 3.3) can assist in generating design concepts (see Table 6)
Identify metaphor–interface matches	Identify what users do (goals and subgoals), the methods they use to accomplish these objectives (actions and objects), and map to the physical elements available in the metaphor; use cases can be used for this stage
Identify metaphor–interface mismatches	Identify where the metaphor has no analogous function for desired goals and subgoals
Determine how to manage metaphor–interface mismatches	Determine where composite metaphors or support resources are needed (e.g., online help, agent assistance) so problems related to mismatches can be averted

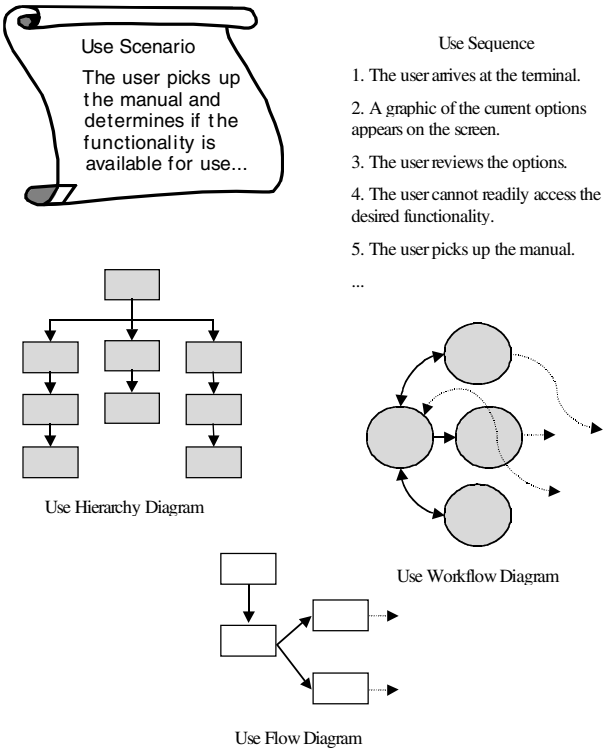

Figure 5 Design-Generation Techniques.

When interactive systems are intended to yield savings in the required level of information exchange, use workflows can be used. These flows provide a visualization of the movement of users or information objects throughout the work environment. They can clearly denote if a design concept will improve the information flow. Designers can first develop use workflows for the existing system interaction and then eliminate, combine, resequence, and simplify steps to streamline the flow of information.

Use hierarchies can be used to visualize the allocation of tasks among workers. By using sticky notes to represent each node in the hierarchy, these representations can be used to demonstrate the before- and after-task allocations. The benefits of the new task allocation engendered by the interactive system design should be readily perceived in hierarchical flow changes.

3.5.2.4. Design Support Developers can look to standards and guidelines to direct their design efforts. Standards focus on advising the look of an interface, while guidelines address the usability of the interface (Nielsen 1993). Following standards and guidelines can lead to systems that are easy to learn and use due to a standardized look and feel (Buie 1999). Developers must be careful, however, not to follow these sources of design support blindly. An interactive system can be designed strictly according to standards and guidelines yet fail to physically fit users, support their goals and tasks, and integrate effectively into their environment (Hackos and Redish 1998).

Guidelines aim at providing sets of practical guidance for developers (Brown 1988; Hackos and Redish 1998; Marcus 1997; Mayhew 1992). They evolve from the results of experiments, theory-based predictions of human performance, cognitive psychology and ergonomic design principles, and experience. Several different levels of guidelines are available to assist system development efforts, including general guidelines applicable to all interactive systems, as well as category-specific (i.e., voice vs. touch screen interfaces) and product-specific guidelines (Nielsen 1993).

Standards are statements (i.e., requirements or recommendations) about interface objects and actions (Buie 1999). They address the physical, cognitive, and affective nature of computer interaction. They are written in general and flexible terms because they must be applicable to a wide variety of applications and target user groups. International (e.g., ISO 9241), national (e.g., ANSI, BSI),

military and government (e.g., MIL-STD 1472D), and commercial (e.g., Common User Access by IBM) entities write them. Standards are the preferred approach in Europe. The European Community promotes voluntary technical harmonization through the use of standards (Rada and Ketchell 2000).

Buie (1999) has provided recommendations on how to use standards that could also apply to guidelines. These include selecting relevant standards; tailoring these select standards to apply to a given development effort; referring to and applying the standards as closely as possible in the interactive system design; revising and refining the select standards to accommodate new information and considerations that arise during development; and inspecting the final design to ensure the system design complies with the standards where feasible. Developing with standards and guidelines does not preclude the need for evaluation of the system. Developers will still need to evaluate their systems to ensure they adequately meet users' needs and capabilities.

3.5.2.5. Storyboards and Rough Interface Sketches The efforts devoted to the selection of a metaphor or composite metaphor and the development of use scenarios, use sequences, use flow diagrams, use workflows, and use hierarchies result in a plethora of design ideas. Designers can brainstorm over design concepts, generating storyboards of potential ideas for the detailed design (Vertelney and Booker 1990). Storyboards should be at the level of detail provided by use scenarios and workflow diagrams (Hackos and Redish 1998). The brainstorming should continue until a set of satisfactory storyboard design ideas has been achieved. The favored set of ideas can then be refined into a design concept via interface sketches. Sketches of screen designs and layouts are generally at the level of detail provided by use sequences. Cardboard mockups and Wizard of Oz techniques (Newell et al. 1990), the latter of which enacts functionality that is not readily available, can be used at this stage to assist in characterizing designs.

3.5.3. Prototyping

Prototypes of favored storyboard designs are developed. These are working models of the preferred designs (Hackos and Redish 1998; Vertelney and Booker 1990). They are generally developed with easy-to-use toolkits (e.g., Macromedia Director, Toolbook, SmallTalk, or Visual Basic) or simpler tools (e.g., hypercard scenarios, drawing programs, even paper or plastic mockups) rather than high-level programming languages. The simpler prototyping tools are easy to generate and modify and cost effective; however, they demonstrate little if anything in the way of functionality, may present concepts that cannot be implemented, and may require a ''Wizard'' to enact functionality. The toolkits provide prototypes that look and feel more like the final product and demonstrate the feasibility of desired functionality; however, they are more costly and time consuming to generate. Whether high- or low-end techniques are used, prototypes provide means to provide cost-effective, concrete design concepts that can be evaluated with target users (usually three to six users per iteration) and readily modified. They prevent developers from exhausting extensive resources in formal development of products that will not be adopted by users. Prototyping should be iterated until usability goals are met.

3.6. Usability Evaluation of Human–Computer Interaction

Usability evaluation focuses on gathering information about the usability of an interactive system so that this information can be used to focus redesign efforts via iterative design. While the ideal approach is to consider usability from the inception of the system development process, often it is considered in later development stages. In either case, as long as developers are committed to implementing modifications to rectify the most significant issues identified via usability-evaluation techniques, the efforts devoted to usability are generally advantageous. The benefits of usability evaluation include, but are not limited to, reduced system redesign costs, increased system productivity, enhanced user satisfaction, decreased user training, and decreased technical support (Nielsen 1993; Mayhew 1999).

There are several different usability-evaluation techniques. In some of these techniques, the information may come from users of the system (through the use of surveys, questionnaires, or specific measures from the actual use of the system), while in others, information may come from usability experts (using design walk-throughs and inspection methods). In still others, there may be no observations or user testing involved at all because the technique involves a theory-based (e.g., GOMS modeling) representation of the user (Card et al. 1983). Developers need to be able to select a method that meets their needs or combine or tailor methods to meet their usability objectives and situation. Usability-evaluation techniques have generally been classified as follows (Karat 1997; Preece 1993):

- Analytic/theory based (e.g., cognitive task analysis; GOMS)
- Expert evaluation (e.g., design walk-throughs; heuristic evaluations)
- Observational evaluation (e.g., direct observation; video; verbal protocols)
- Survey evaluation (e.g., questionnaires; structured interviews)

- Psychophysiological measures of subjective perception (e.g., EEGs; heart rate; blood pressure)
- Experimental evaluation (e.g., quantitative data; compare design alternatives)

There are advantages and disadvantages to each of these evaluative techniques (see Table 8) (Preece 1993, Karat 1997). Thus, a combination of methods is often used in practice. Typically, one would first perform an expert evaluation (e.g., heuristic evaluation) of a system to identify the most obvious usability problems. Then user testing could be conducted to identify remaining problems that were missed in the first stages of evaluation. In general, a number of factors need to be considered when selecting a usability-evaluation technique or a combination thereof (see Table 9) (Dix et al. 1993; Nielsen 1993; Preece 1993).

As technology has evolved, there has been a shift in the technoeconomic paradigm, allowing for more universal access of computer technology (Stephanidis and Salvendy 1998). Thus, individuals with diverse abilities, requirements, and preferences are now regularly utilizing interactive products. When designing for universal access, participation of diverse user groups in usability evaluation is essential. Vanderheiden (1997) has suggested a set of principles for universal design that focuses on the following: simple and intuitive use; equitable use; perceptible information; tolerance for error; accommodation of preferences and abilities; low physical effort; and space for approach and use. Following these principles should ensure effective design of interactive products for all user groups.

While consideration of ergonomic and cognitive factors can generate effective interactive system designs, if the design has not taken into consideration the environment in which the system will be used, it may still fail to be adopted. This will be addressed in the next section.

4. SOCIAL, ORGANIZATIONAL, AND MANAGEMENT FACTORS

Social, organizational, and management factors related to human–computer interaction may influence a range of outcomes at both the individual and organizational levels: stress, physical and mental health, safety, job satisfaction, motivation, and performance. Campion and Thayer (1985) showed that some of these outcomes may be conflicting. In a study of 121 blue-collar jobs, they found that enriched jobs led to higher job satisfaction but lower efficiency and reliability. The correlations between efficiency on one hand and job satisfaction and comfort on the other hand were negative. Another way of looking at all the outcomes has been proposed by Smith and Sainfort (1989). The objective of the proposed balance theory is to achieve an optimal balance among positive and negative aspects of the work system, including the person, task and organizational factors, technology, and physical environment. See Figure 1 for a model of the work system. The focus is not on a limited range of variables or aspects of the work system but on a holistic approach to the study and design of work systems. In this section we will focus on how social, organizational and management factors related to human–computer interaction influence both individual and organizational outcomes.

4.1. Social Environment

The introduction of computer technology into workplaces may change the social environment and social relationships. Interactive systems become a new element of the social environment, a new communication medium, and a new source of information. With new computer technologies there may be a shift from face-to-face interaction toward computer-mediated communication, or at least a change in how people communicate and interact. This shift may be most obvious with electronic mail and teleconferencing systems. A study of Eveland and Bikson (1988) on electronic mail shows that people connected to a network of microcomputers with electronic mail relied more on scheduled meetings than people with conventional office support, who relied more on unscheduled meetings. The impact on face-to-face interaction was not studied. A study of electronic mail by Rice and Case (1983) did not find any reduction in face-to-face interaction, but increased communications as a result of using electronic mail. Computers seem to be just another way of communicating with coworkers, subordinates, and supervisors (Rice and Case 1983). However, other studies have found that there was not only a change in quantity of communications (more or new information to and from more or new recipients), but also a change in quality of communications (Kiesler et al. (1984).

Aydin (1989) showed that the use of medical information systems for communicating physicians' medication orders from the nursing department to the pharmacy led to increased interdependence between the two departments. The change in work organization (increased interdependence) was accompanied by changes in the social environment: communication and cooperation between the two departments improved, leading to better working relationships.

Computer technologies also allow work to be performed at remote distances. Recently there has been an increase in home-based work due to technological advances in computer and network technologies. Telework or working at home is most common for clerical workers performing routine transactions and for autonomous professionals (e.g., writers, designers) (Sproull and Kiesler 1991). In general, home-based work increases social isolation from coworkers and supervisors. This not only reduces opportunities to socialize and make friends but also reduces chances for advancement

TABLE 8 Advantages and Disadvantages of Existing Usability Evaluation Techniques

Evaluation Method	Example Tools/Techniques	General Use	Advantages	Disadvantages
Analytic/theory-based	• Cognitive Task Analysis • GOMS	Used early in usability design life cycle for prediction of expert user performance.	Useful in making accurate design decisions early in the usability life cycle without the need for a prototype or costly user testing.	Narrow in focus; lack of specific diagnostic output to guide design; broad assumption on users' experience (expert) and cognitive processes; results may differ based on the evaluators' interpretation of the task.
Expert Evaluation	• Design walk-throughs • Heuristic evaluations • Process/system Checklists • Free play • Group evaluations	Used early in the design life cycle to identify *theoretical* problems that may pose actual *practical* usability problems.	Strongly diagnostic; can focus on entire system; high potential return in terms of number of usability issues identified; can assist in focusing observational evaluations.	Even the best evaluators can miss significant usability issues; results are subject to evaluator bias; does not capture real user behavior.
Observational evaluation	• Direct observation • Video • Verbal protocols • Computer logging • Think aloud techniques • Field evaluations • Ethnographic studies • Facilitated free play	Used in iterative design stage for problem identification.	Quickly highlights usability issues; verbal protocols provide significant insights; provides rich qualitative data.	Observation can affect user performance with the system; analysis of data can be time and resource consuming.

Survey evaluation	• questionnaires • Structured interviews • Ergonomics checklists • Focus groups	Used any time in the design life cycle to obtain information on users' preferences and perception of a system.	Provides insights into users' opinions and understanding of the system; can be diagnostic; rating scales can provide quantitative data; can gather data from large subject pools.	User experience important; possible user response bias (e.g., only dissatisfied users respond); response rates can be low; possible interviewer bias; analysis of data can be time and resource consuming; evaluator may not be using appropriate checklist to suit the situation.
Psychophysiological measures of satisfaction or workload	• EEGs • Heart rate • Blood pressure • Pupil dilation • Skin conductivity • Level of adrenaline in blood	Used any time in the design life cycle to obtain information on user satisfaction or workload.	Eliminate user bias by employing objective measures of user satisfaction and workload.	Invasive techniques are involved that are often intimidating and expensive for usability practitioners.
Experimental evaluation	• Quantitative measures • Alternative design comparisons • Free play • Facilitated free play	Used for competitive analysis in final testing of the system.	Powerful and prescriptive method; provides quantitative data; can provide a comparison of alternatives; reliability and validity generally good.	Experiment is generally time and resource consuming; focus can be narrow; tasks and evaluative environment can be contrived; results difficult to generalize.

TABLE 9 Factors to Consider in Selecting Usability-Evaluation Techniques

Purpose of the evaluation
Stage in the development life cycle in which the evaluation technique will be carried out
Required level of subjectivity or objectivity
Necessity or availability of test participants
Type of data that need to be collected
Information that will be provided
Required immediacy of the response
Level of interference implied
Resources that may be required or available

and promotion (OTA 1985). On the other hand, home-based work allows workers to spend more time with their family and friends, thus increasing social support from family and friends. Telework allows for increased control over work pace and variability of workload. It has been found, however, that electronic communication and telework have led to feelings of not being able to get away from work and to the augmentation (rather than substitution) of regular office hours (Sproull and Kiesler 1991; Phizacklea and Wolkowitz 1995). In addition, increased distractions and interruptions may disrupt work rhythm (OTA 1985). From a social point of view, home-based work has both negative and positive effects.

Another important social factor is intragroup relationships and relationships with coworkers. The role of computer technologies in influencing intragroup functioning is multidimensional. If workers spend a lot of time working in isolation at a computer workstation, they may have less opportunity for socialization. This may affect the group performance, especially if tasks are interdependent. On the other hand, intragroup relationships may be improved if workers gain access to better information and have adequate resources to use computers. The positive or negative effects may also vary across jobs and organizations. And they may depend on the characteristics of the interactive system (e.g., single- vs. multiple-user computer workstation).

Aronsson (1989) found that work group cohesion and possibilities for contacts with coworkers and supervisors had become worse among low-level jobs (e.g., secretary, data-entry operator, planner, office service) but had not been affected among medium- to high-level jobs. Changes in job design were related to changes in social relationships. The higher the change in intensity demands, the lower the work group cohesion and the possibilities for contacts with coworkers and supervisors. That is, increase in workload demands came along with worsening of the social environment. The negative effect was more pronounced among low-level jobs, presumably because higher-level job holders have more resources, such as knowledge, power, and access to information and can have a say in the implementation/design process as well as more control over their job.

Access to organizational resources and expertise is another important facet of the social environment for computer users. Technology can break down or malfunction, and users may need help to perform certain tasks or to learn new software. In these situations, access to organizational resources and expertise is critical for the end users, especially when they are highly dependent on the computer technology to perform their job or when they use the technology in their contact with customers. Danziger et al. (1993) have studied the factors that determine the quality of end-user computing services in a survey of 1869 employees in local governments. Three categories of factors were identified that might influence the quality of computing services: (1) the structure of service provision (e.g., centralization vs. decentralization), (2) the level of technological problems, and (3) the service orientation of computing service specialists. The results do not provide support for the argument that structural factors are most important; whether computing services are centralized or decentralized within an organization does not explain the perceived quality of computing services.

On the other hand, the results demonstrate the importance of the attitudes of the service providers. Computer specialists who are clearly user oriented, that is, who are communicative and responsive to user needs and are committed to improving existing applications and proposing appropriate new ones, seem best able to satisfy end users' criteria for higher quality computing services. Researchers emphasize the importance of a positive sociotechnical interface between end users and computing specialists, in addition to good operational performance (e.g., low incidence of technical problems).

The introduction of computers in workplaces can also change how workers interact with their supervisor and management. That change in social interaction may result in changes in social support. Sproull and Kiesler (1988) showed that electronic mail affected social relationships within organizations. Status equalization was observed in that messages from subordinates were no different than messages from supervisors. Thus, computer technologies can have positive effects on worker–management relationships because workers have easier access to their supervisors and/or feel less

restrained from communicating with their supervisors. However, expectations of rapid service and faster work completion may impose more supervisory pressure on workers (Johansson and Aronsson 1984). This is a negative effect of computer technologies on worker–supervisor relationships. A study by Yang and Carayon (1995) showed that supervisor support was an important buffer against worker stress in both low and high job demands conditions. Two hundred sixty-two computer users of three organizations participated in the study. Supervisor social support was an important buffer against worker stress; however, coworker social support did not affect worker stress.

The social environment can be influenced by computer technologies in various ways: quality, quantity, and means of communications, social isolation, extended network of colleagues, work group cohesion, quality of social interaction among workers, coworkers and supervisors, and social support. Table 10 summarizes the potential effects of computer technologies on the social environment. There are several strategies or interventions that can be applied to counteract the negative influences of computer technology on the social environment and foster positive effects.

Computerized monitoring systems have an important impact on how supervisors interact with their employees. It is natural that when supervisors are suddenly provided with instantaneous, detailed information about individual employee performance, they feels a commitment, in fact an obligation, to use this information to improve the performance of the employees. This use of hard facts in interacting with employees often changes the style of supervision. It puts inordinate emphasis on hourly performance and creates a coercive interaction. This is a critical mistake in a high-technology environment where employee cooperation is essential.

Supervision has to be helpful and supportive if employee motivation is to be maintained and stress is to be avoided. This means that supervisors should not use individual performance data as a basis for interaction. The supervisor should be knowledgeable about the technology and serve as a resource when employees are having problems. If management wants employees to ask for help, the relationship with the supervisor has to be positive (not coercive) so that the employee feels confident enough to ask for help. If employees are constantly criticized, they will shun the supervisor and problem situations that can harm productivity will go unheeded.

Employees are a good source of information about productive ways to work. Their daily contact with the job gives them insight into methods, procedures, bottlenecks, and problems. Many times they modify their individual work methods or behavior to improve their products and rate of output. Often these are unique to the individual job or employee and could not be adopted as a standardized approach or method. If work systems are set up in a rigid way, this compensatory behavior cannot occur. Further, if adverse relationships exist between supervisors and employees, the employees are unlikely to offer their innovative ideas when developers are conducting a contextual task analysis (see Section 3.3). It is in the interest of the employer to allow employees to exercise at least a nominal level of control and decision making over their own task activity. Here again, the computer hardware and software have to be flexible so that individual approaches and input can be accommodated as long as set standards of productivity are met.

One approach for providing employee control is through employee involvement and participation in making decisions about interactive system design—for instance, by helping management select ergonomic furniture through comparative testing of various products and providing preference data, or being involved in the determination of task allocations for a new job, or voicing opinions about ways to improve the efficiency of their work unit. Participation is a strong motivator to action and a good way to gain employee commitment to a work standard or new technology. Thus, participation can be used as a means of improving the social environment and foster the efficient use of interactive

TABLE 10 Potential Effects of Computer Technologies on the Social Environment

Less face-to-face interaction
More computer-mediated communication
Change in the quality of communications (status equalization, pressure)
Increased or decreased interdependence between departments/work units
Increased or decreased cooperation between departments/work units
Increased or decreased opportunities for contacts with coworkers and supervisor
Increased quantity/quality of information
Increased or decreased work group cohesion
Home-based work:
Isolation
Reduced chances for advancement and promotion
Increased/decreased social support

systems. But participation will only be effective as long as employees see tangible evidence that their input is being considered and used in a way that benefits them.

Employees who make positive contributions to the success of the organization should be rewarded for their efforts. Rewards can be administrative, social, or monetary. Administrative rewards can be such things as extra rest breaks, extended lunch periods, and special parking spaces. They identify the person as someone special and deserving. Another type of reward is social in that it provides special status to the individual. This is best exemplified by the receipt of praise from the supervisor for a job well done. This enhances personal self-esteem. If the praise is given in a group setting, it can enhance peer group esteem toward the individual. Monetary rewards can also be used, but these can be a double-edged sword because they may have to be removed during low-profit periods, and this can lead to employee resentment, thus negating the entire purpose of the reward system. Some organizations use incentive pay systems based on performance data provided by the computers. Computers can be used to keep track of worker performance continuously (Carayon 1993). That quantitative performance data can then be used to set up incentive pay systems that reward good performers. In general, incentive pay systems can lead to increase in output but at the expense of worker health (Levi 1972). Schleifer and Amick (1989) have shown how the use of a computer-based incentive system can lead to an increase in worker stress.

Different ways of improving the social environment in computerized workplaces thus include helpful and supportive managers and supervisors, increased control over one's job, employee involvement and participation, and rewards.

4.2. Organizational Factors

The way work is organized changes with the introduction of computer technologies, such as changes in workflow. Computer technologies obviously provide opportunities for reorganizing how work flows and have the potential of increasing efficiency. However, increased worker dependence on the computer is a potential problem, especially when the computer breaks down or slows down. It may affect not only performance but also stress. Organizational redesign may be one way of alleviating problems linked to dependence on the computer. Aronsson and Johansson (1987) showed that organizational rearrangement was necessary to decrease workers' dependence on the computer system by expanding their jobs with new tasks and allowing them to rotate between various tasks.

Given their technical capabilities, computers can be used to bring people closer and make them work in groups. The concept of computer-supported cooperative work is based on the expectation that the computer favors group work. Researchers in this area focus on all aspects of how large and small groups can work together in using computer technology (Greif 1988). They develop interactive systems that facilitate group work and study the social, organizational, and management impacts of computer-supported work groups. For instance, Grief and Sarin (1988) identified data-management requirements of computer group work.

New computer technologies allow work to be performed at a distance. This new work organization has some potential negative and positive effects for workers and management. Benefits for workers include increased control over work schedule and eliminating the commute to work (OTA 1985; Bailyn 1989). Constraints for workers include social isolation, increased direct and indirect costs (e.g., increased heating bill, no health insurance), lack of control over physical environment, and fewer opportunities for promotion (OTA 1985; Bailyn 1989). Benefits for employers include lowered costs (e.g., floor space, direct labor costs, and workers' benefits), more intensive use of computers (e.g., outside peak hours), increased flexibility (workers can be used when needed), and increased productivity; while problems include change in traditional management and supervision techniques and loss of control (OTA 1985).

Within organizations, the use of computer technologies has been linked to various positive and negative effects on job design (see, e.g., the case study of Buchanan and Boddy 1982). Increased workload, work pressure and demand for concentration, decreased job control, and variety are some of the negative effects (Smith et al. 1981; Buchanan and Boddy 1982; Johansson and Aronsson 1984). Increased feedback, control over one's job, and career opportunities are some of the positive effects (Buchanan and Boddy 1982). For some, such as professionals, the job-design effects of the use of computer technology may be all positive, while for others, such as clerical workers or data-entry operators, the effects may all be negative (Smith et al. 1981; Sauter et al. 1983; Johansson and Aronsson 1984).

The computer technology itself may have characteristics that can affect worker stress by inducing negative characteristics. For instance, technology characteristics such as breakdown and slowdown may increase perceived workload and work pressure and reduce the amount of control one has over work (Carayon-Sainfort 1992; Asakura and Fujigaki 1993). Carayon-Sainfort (1992) found that computer system performance was indirectly related to stress through its effect on perceived workload, work pressure and job control. Specifically, greater frequencies of computer problems were related to increases in perceived workload and work pressure as well as decreases in job control. These can

have negative effects on an organization. Asakura and Fujigaki (1993) examined the direct and indirect effects of computerization on worker well being and health in a sample of 4400 office workers. The results of their study paralleled Carayon-Sainfort (1992).

A major complaint of office employees who have undergone computerization is that their workload has increased substantially. This is most true for clerical employees, who typically have an increased number of transactions to process when computers are introduced into the work routine. This increase in transactions means more keystrokes and more time at the workstation. These can lead to greater physical effort than before and possibly more visual and muscular discomfort. This discomfort reinforces the feeling of increased workload and adds to employee dissatisfaction with the workload.

Quite often the workload of computer users is established by the data-processing department in concert with other staff departments such as human resources and line managers. An important consideration is the cost of the computer equipment and related upkeep such as software and maintenance. The processing capability of the computer(s) is a second critical element in establishing the total capacity that can be achieved. The technology cost, the capability to process work, and the desired time frame to pay for the technology are factored together to establish a staffing pattern and the required workload for each employee. This approach is based on the capacity of the computer(s) coupled with investment recovery needs and does not necessarily meet the objective of good human resource utilization. Workload should not be based solely on technological capabilities or investment recovery needs but must include important considerations of human capabilities and needs. Factors such as attentional requirements, fatigue, and stress should be taken into account in establishing the workload. A workload that is too great will cause fatigue and stress that can diminish work quality without achieving desired quantity. A workload that is too low will produce boredom and stress and also reduce quality and economic benefits of computerization.

Workload problems are not concerned solely with the immediate level of effort necessary but also deal with the issue of work pressure. This is defined as an unrelenting backlog of work or workload that will never be completed. This situation is much more stressing than a temporary increase in workload to meet a specific crisis. It produces the feeling that things will never get better, only worse. Supervisors have an important role in dealing with work pressure by acting as a buffer between the demands of the employer and the daily activities of the employees. Work pressure is a perceptual problem. If the supervisor deals with daily workload in an orderly way and does not put pressure on the employee about a pile-up of work, then the employee's perception of pressure will be reduced and the employee will not suffer from work pressure stress.

Work pressure is also related to the rate of work, or work pace. A very fast work pace that requires all of the employee's resources and skills to keep up will produce work pressure and stress. This is exacerbated when this condition occurs often. An important job-design consideration is to allow the employee to control the pace of the work rather than having this controlled automatically by the computer. This will provide a pressure valve to deal with perceived work pressure.

A primary reason for acquiring new technology is to increase individual employee productivity and provide a competitive edge. Getting more work out of employees means that fewer are needed to do the same amount of work. Often employees feel that this increased output means that they are working harder even though the technology may actually make their work easier. Using scientific methods helps establish the fairness of new work standards.

Once work standards have been established, they can serve as one element in an employee-performance-evaluation scheme. An advantage of computer technology is the ability to have instantaneous information on individual employee performance in terms of the rate of output. This serves as *one* objective measure of how hard employees are working. But managers have to understand that this is just one element of employee performance and emphasis on quantity can have an adverse effect on the quality of work. Therefore, a balanced performance-evaluation system will include quality considerations as well. These are not as easy to obtain and are not as instantaneously available as are quantity measures. However, managers must resist the temptation to emphasize quantity measures just because they are readily available. A key consideration in any employee evaluation program is the issue of fairness, just as in workload determination.

Jobs in which people use computer technology may require high mental effort. Some types of computer-mediated tasks may increase information-processing requirements and place great demands on attention, decision making, and memory. Increased levels of cognitive demands due to computer technology have been shown to influence employee stress and health (Lindstrom and Leino 1989; Czaja and Sharit 1993; Yang 1994). Several types of cognitive demands can be generated from the use of computer technology: (1) a great amount of information given in a certain unit of time, (2) abstract information being presented on the screen, and (3) difficult and concurrent tasks being performed at the same time.

Cognitive demands can be increased when the system response time is poor and the nature of workflow is not transparent to the workers. In other words, unpredictable demands and interruptions of workflow caused by system breakdowns may be difficult to deal with because of the disruptive

effect on the cognitive control process. Overall, cognitive demands are associated with job characteristics such as intensity of computer work, the type of communication, and high speed/functions of computers. The implementation of computer technology in work organizations can lead to greater demands on cognitive resources in terms of memory, attention, and decision making that may have a negative impact on worker health and work performance. If, however, computer systems have been designed with the cognitive capabilities and limitations of the user in mind (see Section 3), these issues should not occur.

There has been interest in the role of occupational psychosocial stress in the causation and aggravation of musculoskeletal disorders for computer users (Smith et al. 1981; Smith 1984; Bammer and Blignault 1988; Smith and Carayon 1995; Hagberg et al. 1995). It has been proposed that work organization factors define ergonomic risks to upper-extremity musculoskeletal problems by specifying the nature of the work activities (variety or repetition), the extent of loads, the exposure to loads, the number and duration of actions, ergonomic considerations such as workstation design, tool and equipment design, and environmental features (Smith and Carayon 1995; Carayon et al. 1999). These factors interact as a system to produce an overall load on the person (Smith and Sainfort 1989; Smith and Carayon 1995; Carayon et al. 1999), and this load may lead to an increased risk for upper extremity musculoskeletal problems (Smith and Carayon 1995; Carayon et al. 1999). There are psychobiological mechanisms that make a connection between psychological stress and musculoskeletal disorders plausible and likely (Smith and Carayon 1995; Carayon et al. 1999). At the organizational level, the policies and procedures of a company can affect the risk of musculoskeletal disorders through the design of jobs, the length of exposures to stressors, establishing work–rest cycles, defining the extent of work pressures and establishing the psychological climate regarding socialization, career, and job security (Smith et al. 1992; NIOSH 1992, 1993).

Smith et al. (1992), Theorell et al. (1991) and Faucett and Rempel (1994) have demonstrated that some of these organizational features can influence the level of self-reported upper-extremity musculoskeletal health complaints. In addition, the organization defines the nature of the task activities (work methods), employee training, availability of assistance, supervisory relations, and workstation design. All of these factors have been shown to influence the risk of upper-extremity musculoskeletal symptoms, in particular among computer users and office workers (Linton and Kamwendo 1989; Smith et al. 1992; Lim et al. 1989; Lim and Carayon. 1995; NIOSH 1990, 1992, 1993; Smith and Carayon 1995).

The amount of esteem and satisfaction an employee gets from work are tied directly to the content of the job. For many jobs, computerization brings about fragmentation and simplification that act to reduce the content of the job. Jobs need to provide an opportunity for skill use, mental stimulation, and adequate physical activity to keep muscles in tone. In addition, work has to be meaningful for the individual. It has to provide for identification with the product and the company. This provides the basis for pride in the job that is accomplished.

Computerization can provide an opportunity for employees to individualize their work. This lets them use their unique skills and abilities to achieve the required standards of output. It provides cognitive stimulation because each employee can develop a strategy to meet his or her goals. This requires that software be flexible enough to accept different types and order of input. Then it is the job of the software to transform the diverse input into the desired product. Usually computer programmers will resist such an approach because it is easier for them to program using standardized input strategies. However, such strategies build repetition and inflexibility into jobs that reduce job content and meaning.

Being able to carry out a complete work activity that has an identifiable end product is an important way to add meaningfulness to a job. When employees understand the fruits of their labor, it provides an element of identification and pride in achievement. This is in contrast to simplifying jobs into elemental tasks that are repeated over and over again. Such simplification removes meaning and job content and creates boredom, job stress, and product-quality problems. New computer systems should emphasize software that allows employees to use existing skills and knowledge to start out. These then can serve as the base for acquiring new skills and knowledge. Job activities should exercise employee mental skills and should also require a sufficient level of physical activity to keep the employee alert and in good muscle tone.

Table 11 summarizes the potential impacts of computer technologies on organizational factors. Overall, the decision about the use or design of interactive systems should include considerations for work load, work pressure, determination of work standards, job content (variety and skill use), and skill development. Computerization holds the promise of providing significant improvements in the quality of jobs, but it also can bring about organizational changes that reduce employee satisfaction and performance and increase stress. Designing interactive systems that meet both the aims of the organization and the needs of employees can be difficult. It requires attention to important aspects of work that contribute to employee self-esteem, satisfaction, motivation, and health and safety.

TABLE 11 Potential Effects of Computer Technologies on Organizational Factors

Job design:
Increased/decreased workload and work pressure
Increased demand for concentration
Increased/decreased job control and autonomy
Increased/decreased variety
Increased feedback
Increased work efficiency
Computer malfunctions and breakdowns

Incentive pay systems

4.3. Management Factors

Consideration of management factors in human–computer interaction is highly relevant in understanding the global effects of interactive systems (Clement and Gotlieb 1988). The introduction of computer technology is often accompanied by or responsible for changes in management structure. For instance, computer technologies can be used to increase workers' access to information. That move toward decentralization can lead to more decisions being made at lower levels. There has been a long debate about whether computer technology leads to centralization or decentralization of decision making (Attewell and Rule 1984; Blackler 1988). There is no clear answer to this debate: Variables such as organizational size, past experiences, management style, and work force skill level play a role in these structural effects (Attewell and Rule 1984). Furthermore, power may not be a simple zero-sum relationship. Various organizational actors may experience increased power and control opportunities after the implementation of computer technology. Information systems specialists increase their power because they have valuable expertise and knowledge, and workers may depend on them when a technical problem occurs or when they need additional training. Worker control may also increase when workers are given efficient technologies and are taught new computer skills.

The amount of information and the ease of access to information are important management factors affected by computer technologies. Electronic mail systems tend to change how information flows in organizations. Sproull and Kiesler (1988) found that electronic mail added new recipients to information being circulated and also added new information. However, one could ask about the usefulness and relevancy of the new information for organizational functioning. Information has been identified as a potent source of power (Crozier 1964). Computer technology that changes the type and amount of information available is likely to change the power distribution between various organizational actors, such as workers, supervisors, managers, computer experts, and unions. In addition, the introduction of computer technologies may create new sources of power and increase status differences between computer experts and nonexperts, between heavy computer users and light users.

Computer technologies can be used for increasing management control over production/service processes. Electronic monitoring of worker performance is an example of this effect. Computers are used to get detailed online data on worker performance to, for instance, improve work schedule and planning and increase control over worker performance. This may greatly enhance management capabilities and improve overall organizational effectiveness, but may induce stressful working conditions (Carayon 1993).

Smith et al. (1992) conducted a questionnaire survey study examining the differences in stress responses between employees who were electronically monitored while doing computer work and those who were not. Both groups performed the same jobs. The results of the surveys completed by 745 telecommunication employees showed that employees who had their performance electronically monitored perceived more stressful working conditions and more job boredom, psychological tension, anxiety, depression, anger, health complaints, and fatigue. Smith et al. (1992) suggest that the results might have been due to job-design changes associated with the monitoring.

In fact, when Carayon (1994) reanalyzed data from two job categories (255 service representatives and 266 clerks) from Smith et al. (1992), the results supported the proposition that electronic performance monitoring had an indirect effect on worker stress through its effects on job design. Carayon (1994) also reported on a second study to specifically examine whether or not electronic performance monitoring had a direct or indirect effect on worker stress. The results revealed that monitored

employees reported more supervisor feedback and control over work pace and less job content than nonmonitored employees. There were no differences between the monitored and nonmonitored groups with regard to stress or health.

The process by which computer technologies are implemented is only one of the management factors that affect the effectiveness and acceptance of computer use. Management attitudes toward the implementation of computer technologies are very important insofar as they can affect overall job and organizational design and worker perceptions, attitudes, and beliefs regarding the new technologies (Crozier 1964; Smith 1984; Blackler 1988; Kahn and Cooper 1986). Several models that link the organizational effects of computer systems to the process used to implement those systems have been proposed (Blackler and Brown 1987; Robey 1987; Flynn 1989). They all emphasize the need to identify potential technical and social impacts, advocate general planning, and emphasize the support of workers and managers for successful implementation of new computer technology.

Carayon and Karsh (2000) examined the implementation of one type of computer technology, that is, imaging technology into two organizations in the Midwest. Results showed that imaging users in the organization that utilized end-user participation in the implementation of their imaging system rated their imaging systems better and reported higher job satisfaction than imaging users in the organization that did not incorporate end-user participation in the implementation of the system. Studies by Korunka and his colleagues (Korunka et al. 1993, 1995, 1996) have also demonstrated the benefits of end-user participation in technological change on quality of working life, stress, and health.

Management needs to also consider retraining issues when introducing new computer technology. Kearsley (1989) defined three general effects of computer technology: skill twist (change in required skills), deskilling (reduction in the level of skills required to do a job), and upskilling (increase in the level of required skills). Each of these effects has different implications for retraining. For instance, skill twist requires that workers be able and willing to learn new skills. Training or retraining are critical issues for the successful implementation and use of new computer technology. Even more critical is the need for continuous retraining because of rapid changes in hardware and software capabilities of computer technologies (Smith et al. 1981; Smith 1984; Kearsley 1989). Training can serve to enhance employee performance and add new skills. Such growth in skills and knowledge is an important aspect of good job design. No one can remain satisfied with the same job activities over years and years. Training is a way to assist employees in using new technology to its fullest extent and reduce the boredom of the same old job tasks. New technology by its nature will require changes in jobs, and training is an important approach not only for keeping employees current but also in building meaning and content into their jobs.

Computer technologies have the potential to affect both positively and negatively the following management factors: organizational structure (e.g., decentralization vs. centralization), power distribution, information flow, and management control over the production process. Management's strategies for implementing new computer technologies are another important management factor to take into account to achieve optimal use of these technologies. Table 12 summarizes the potential impacts of computer technologies on management factors. Some of the negative effects of computers on management factors can be counteracted. The rest of this section proposes various means of ensuring that computerization leads to higher performance and satisfaction and lower stress.

Monitoring employee performance is a vital concern of labor unions and employees. Computers provide greatly enhanced capability to track employee performance, and this will follow from such close monitoring. Monitoring of employee performance is an important process for management. It helps to know how productive your workforce is and where bottlenecks are occurring. It is vital management information that can be used by top management to realign resources and to make important management decisions. However, it is not a good practice to provide individual employee performance information to first-line supervisors; it can lead to a coercive supervision style. To

Career development

enhance individual performance, it is helpful to give periodic feedback directly to employees about their own performance. This can be done in a noncoercive way directly by the computer on a daily basis. This will help employees judge their performance and also assist in establishing a supervisory climate that is conducive to satisfied and productive employees.

While computerized monitoring systems can be particularly effective in providing employees with feedback, the misuse of such systems can be particularly counterproductive and cause stress. The following principles contribute to the effective use of computerized monitoring for performance enhancement and reduced stress:

- Supervisors should not be involved directly in the performance feedback system. Information on the performance that is given by the computerized monitoring system should be directly fed back to the operator.
- Computerized monitoring systems should give a comprehensive picture of the operator's performance (quantity *and* quality).
- Performance information should not be used for disciplinary purposes.
- Electronic monitoring should not be used for payment purposes such as payment by keystrokes (piece rate) or bonuses for exceeding goals.

Any kind of change in the workplace produces fears in employees. New technology brings with it changes in staff and the way work is done. The fear of the unknown, in this case the new technology, can be a potent stressor. This suggests that a good strategy in introducing new technology is to keep employees well informed of expected changes and how they will affect the workplace. There are many ways to achieve this. One is to provide informational memorandums and bulletins to employees at various stages of the process of decision making about the selection of technology and, during its implementation, on how things are going. These informational outputs have to be at frequent intervals (at least monthly) and need to be straightforward and forthright about the technology and its expected effects. A popular approach being proposed by many organizational design experts is to involve employees in the selection, design, and implementation of the new technology. The benefit of this participation is that employees are kept abreast of current information, employees may have some good ideas that can be beneficial to the design process, and participation in the process builds employee commitment to the use of the technology.

A large employee fear and potent stressor is concern over job loss due to improved efficiency produced by new technology. Many research studies have demonstrated that the anticipation of job loss and not really knowing if you will be one of the losers is much more stressful and more detrimental to employee health than knowing right away about future job loss. Telling those employees who will lose their jobs early provides them with an opportunity to search for a new job while they still have a job. This gives them a better chance to get a new job and more bargaining power regarding salary and other issues. Some employers do not want to let employees know too soon for fear of losing them at an inopportune time. By not being fair and honest to employees who are laid off, employers can adversely influence the attitudes and behavior of those employees who remain.

For those employees who are retained when new technology is acquired, there is the concern that the new technology will deskill their jobs and provide less opportunity to be promoted to a better job. Often the technology flattens the organizational structure, producing similar jobs with equivalent levels of skill use. Thus, there is little chance to be promoted except into a limited number of supervisory positions, which will be less plentiful with the new technology. If this scenario comes true, then employees will suffer from the ''blue-collar blues'' that have been prevalent in factory jobs. This impacts negatively on performance and stress.

Averting this situation requires a commitment from management to enhancing job design that builds skill use into jobs as well as developing career paths so that employees have something to look forward to besides 30 years at the same job. Career opportunities have to be tailored to the needs of the organization to meet production requirements. Personnel specialists, production managers, and employees have to work together to design work systems that give advancement opportunity while utilizing technology effectively and meeting production goals. One effective technique is to develop a number of specialist jobs that require unique skills and training. Workers in these jobs can be paid a premium wage reflecting their unique skills and training. Employees can be promoted from general jobs into specialty jobs. Those already in specialty jobs can be promoted to other, more difficult specialty jobs. Finally, those with enough specialty experience can be promoted into troubleshooting jobs that allow them to rotate among specialties as needed to help make the work process operate smoothly and more productively.

Organizations should take an active role in managing new computer technologies. Knowing more about the positive and negative potential effects or influences of computerization on management factors is an important first step in improving the management of computer technologies.

4.4. An International Perspective

In order to increase the market for their products and services and thus gain increasing profitability and, where appropriate, shareholder value, corporations are penetrating the international market. This requires a number of adjustments and considerations by corporations, including consideration of standard of living, prevailing economies, government incentives and public policies, and practices in the country where products and services will be marketed. In addition, it is important to consider the characteristics of the individuals in the country where products and services will be utilized, such as differences in anthropometric (body size), social, and psychological considerations. Table 13 illustrates with regard to computer products designed in the United States and the changes that need to be made for Chinese in Mainland China (Choong and Salvendy 1998, 1999; Dong and Salvendy 1999a,b). If both versions of the product were produced, both U.S. and Chinese users would be expected to achieve the fastest possible performance time with the lowest error rates. Identifying a local expert and following international standards (Cakir and Dzida 1997) can assist in identifying the modifications required to ensure a product is well suited to each international target market.

5. ITERATIVE DESIGN

Interactive systems are meant to make work more effective and efficient so that employees can be productive, satisfied, and healthy. Good design improves the motivation of employees to work toward the betterment of the employer. The consideration of ergonomic, cognitive, social, organizational, and management factors of interactive system design must be recognized as an iterative design process. By considering these factors in an iterative manner, system designs can evolve until the desired level of performance and safety are achieved. Additional modifications and resources expenditure will then be unnecessary. This allows valuable resources to be saved or applied to other endeavors. Table 14 provides a list of general guidelines as to how these factors can be designed to create an effective, productive, healthy, and satisfying work environment.

The concept of balance is very important in managing the design, introduction, and use of computer technologies (Smith and Sainfort 1989). Negative effects or influences can be counteracted by positive aspects. For instance, if the physical design of the technology cannot be changed and is known to be flawed, decision makers and users could counteract the negative influences of such design by, for instance, providing more control over the work–rest schedule. By having control over their work–rest schedule, workers could relieve some of the physical stresses imposed by the technology by moving around. If management expects layoffs due to the introduction of computers, actions should be taken to ensure that workers are aware of these changes. Sharing information and getting valuable training or skills could be positive ways to counteract the negative effects linked to layoff. Carayon (1994) has shown that office and computer jobs can be characterized by positive and negative aspects and that different combinations of positive and negative aspects are related to different strain outcomes. A job with high job demands, but positive aspects such as skill utilization, task clarity, job control and social support, led to low boredom and a medium level of daily life stress. A job with many negative aspects of work led to high boredom, workload dissatisfaction, and daily life stress.

Another important aspect of the iterative design process is time. Changes in the workplace occur at an increasing pace, in particular with regard to computer technology. The term *continuous change* has been used to characterize the fast and frequent changes in computer technology and its impact on people and organizations (Korunka et al. 1997; Korunka and Carayon 1999). The idea behind this is that technological change is rarely, if ever, a one-time shot. Typically, technology changes are closer to continuous rather than discrete events. This is because rapid upgrades and reconfigurations to make the systems work more effectively are usually ongoing. In addition to technological changes, time has other important effects on the entire work system (Carayon 1997). In particular, the aspects of the computerized work system that affect people may change over time. In a longitudinal study

TABLE 14 Guidelines for Designing Effective Interactive Systems

Helpful and supportive supervision
Allow job task characteristics to define ergonomic interventions
Appropriate consideration of ergonomic factors, including the technology, sensory environment, thermal environment, workstation design, and work practices
Consider light-related environmental factors, device use and posture factors, environmental factors, job design factors, individual user factors
Flexibility of hardware and software design
Focusing on target user groups in design
Employee involvement and participation in decision making (design, purchasing, and implementation of hardware and software)
Implementation of sound design practices, including the use of requirements definition, user profile development, tasks analysis, and task allocation
Setting usability objectives that focus around effectiveness, intuitiveness, and subjective perception
Iterative usability evaluation
Identification of users' mental models
Identification of appropriate metaphors
Effective integration of tasks into design via use scenarios, use sequences, use flow diagrams, use workflows, and use hierarchies
Design of reward systems (administrative, social, and monetary rewards)
Setup of workload standards (scientific basis, fairness, employee involvement, and acceptance)
Job enlargement and enrichment
Electronic monitoring of worker performance (fairness, feedback to employees, supervisory style, privacy)
Continuous communication between employees and management
Implementation of change
Development of career paths
Systemic approach (organizational culture, past experiences, long-term vs. short-term approach)
Balanced approach
Monitoring of changes (continuous data collection and monitoring of employee attitudes and performance)

of computer users, Carayon and her colleagues have shown that the job characteristics related to worker strain change over time (Carayon et al. 1995). Therefore, any iterative design strategy for improving the design of interactive systems should take into account temporal factors.

The idea of balancing the negative aspects of the work system by the positive aspects implies an active role from the part of all actors involved in the process. An active role characterized by information gathering, planning, and looking for alternatives can be much more effective than a passive role in achieving efficient use of computer technologies (Haims and Carayon 1998; Wilson and Haines 1997).

This chapter has presented information and data on how to design human–computer interfaces effectively from the physical, cognitive, and social points of view. Each of these has been presented separately, but there is a definite interaction among these three aspects. For example, Eberts et al. (1990) concluded that in group computer work, when the job design was enriched, the individuals in the group better understood the other group members' cognitive style than when the job was simplified. The better understanding resulted in more effective group performance than when the cognitive styles of other group members were less understood. This illustrates an interaction effect between social and cognitive factors in human–computer interaction.

The effects of physical and cognitive interaction in human–computer interaction have been documented by Karwowski et al. (1994). They demonstrated, as a result of a highly controlled study in computer-based mail sorting, that the mode of information presentation on a computer screen and the cognitive response requirement of the user affected and changed their physical posture. Thus, if designers consider both factors in interactive system design they can optimize their interaction.

Cook and Salvendy (1999) have documented, in computer-based work, the interrelationship between social and cognitive factors. They found that increased job enrichment and increased mental workload are some of the most important variables affecting job satisfaction. This raises an interesting dilemma for designers since the cognitive scientist would argue to minimize or optimize mental workload in order to minimize training time and maximize performance. The industrial engineer would argue for minimizing mental workload because that simplifies the work and thus decreases the rate of pay that a company needs to pay for the job. And the social scientist would argue that

increasing the mental workload on the job would result in increased job satisfaction. The increased job satisfaction would, in turn, be expected to yield decreased labor turn over and decreased absenteeism, frequently resulting in increased productivity.

These interactions illustrate the type of dilemmas system developers can encounter during interactive system design. Involving a multidisciplinary team in the development process allows such opposing requirements to be addressed better. The team must be supported by ergonomists who understand physical requirements, human factors engineers who understand cognitive requirements, and management that believes in the competitive edge that can be gained by developing user-centered interactive systems. Close collaboration among these team members can lead to the development of remarkably effective and highly usable systems that are readily adopted by users.

1. INTRODUCTION

1.1. Projects and Processes

A project is an organized endeavor aimed at accomplishing a specific nonroutine or low-volume task (Shtub et al. 1994). Due to sheer size (number of man-hours required to perform the project) and specialization, teams perform most projects. In some projects the team members belong to the same organization, while in many other projects the work content of the project is divided among individuals from different organizations.

Coordination among individuals and organizations involved in a project is a complex task. To ensure success, integration of deliverables produced at different geographical locations by different individuals from different organizations at different times is required. Projects are typically performed under a time pressure, limited budgets, tight cash flow constraints, and uncertainty. Thus, a methodology is required to support the management of projects. Early efforts in developing such a methodology focused on tools. Tools for project scheduling such as the Gantt chart and the critical path method (CPM) were developed along with tools for resource allocation, project budgeting and project control (Shtub et al. 1994). The integration of different tools into a complete framework that supports project management efforts throughout the entire project life cycle (see Section 1.2 below) was achieved by the introduction of project-management processes.

A project-management process is a collection of tools and techniques that are used on a predefined set of inputs to produce a predefined set of outputs. Processes are connected to each other as the input to some of the project-management processes is created (is an output) by other processes. The collection of interrelated project-management processes forms a methodology that supports the management of projects throughout their life cycle, from the initiation of a new project to its (successful) end.

This chapter presents a collection of such interrelated processes. The proposed framework is based on the Project Management Body of Knowledge (PMBOK), developed by the Project Management Institute (PMI) (PMI 1996). The purpose of this chapter is to present the processes and the relationship between them. A detailed description of these processes is available in the PMBOK. PMI conducts a certification program based on the PMBOK. A Project Management Professional (PMP) certificate is earned by passing an exam and accumulating relevant experience in the project-management discipline.

1.2. The Project Life Cycle

Since this is a temporary effort designed to achieve a specific set of goals, it is convenient to define phases that the project goes through. The collection of these phases is defined as the project life cycle. Analogous to a living creature, a project is born (initiated), performed (lives), and terminated (dies), always following the same sequence. This simple life-cycle model of three phases is conceptually helpful in understanding the project-management processes because each process can be defined with respect to each phase. However, this simple life-cycle model is not detailed enough for implementation (in some projects each phase may span several months or years). Thus, more specific life-cycle models for families of similar projects were developed. A specific life-cycle model is a set of stages or phases that a family of projects goes through. The project's phases are performed in sequence or concurrently. The project life cycle defines the steps required to achieve the project goals as well as the content of each step. Thus, the literature on software projects is based on specific life-cycle models, such as the spiral model developed by Muench (1994), and the literature on construction projects is based on construction project life-cycle models, such as the one suggested by Morris (1981).

In the Morris (1981) model, a project is divided into four stages performed in sequence:

Stage I—feasibility. This stage terminates with a go/no-go decision for the project. It includes a formulation of the project, feasibility studies, strategy design, and strategy approval for the project.

Stage II—planning and design. This stage terminates with Major contracts Let. It includes base design, cost and schedule planning, contract definitions, and detailed planning of the project.

Stage III—production. This stage terminates with the installation substantially complete. It includes manufacturing, delivery, civil works, installation, and testing.

Stage IV—turnover and startup. This stage terminates with full operation of the facility. It includes final testing and maintenance.

Clearly this model does not fit R&D projects or software projects, while it may be very helpful for many construction projects.

With the integration of the ideas of project processes and the project life cycle, a methodology for project management emerges. The methodology is a collection of processes and a definition of

the part of each process that should be performed within each phase of the project life cycle. The responsibility to perform each process (or part of a process) can be allocated to specific individuals trained in the required tools and techniques. Furthermore, the information (input) required for each process can be delivered to the individuals responsible for the project, ensuring a well-coordinated flow of information and thus good communication between the project participants.

Templates or models of life cycles are useful for project management. When each phase is terminated with one or more completed documentable deliverables, the project-life cycle model is a simple yet very effective tool for monitoring and control of the project throughout its entire life cycle.

1.3. An Example of a Project Life Cycle

The Department of Defense uses a simple yet very popular life-cycle model for Defense acquisition (U.S. Department of Defense 1993):

Phase Number	Phase Description	Corresponding Milestone
	Determination of mission needs	Concept studies approval
0	Concept exploration and definition	Concept demonstration approval
1	Demonstration and validation	Development approval
2	Engineering and manufacturing development	Production approval
3	Production and deployment	Major modification approval as required
4	Operations and support	

2. PROJECT-MANAGEMENT PROCESSES

2.1. Definition of a Process

A process is a group of activities designed to transform a set of inputs into required outputs. There are three elements in the transformation of inputs into outputs:

1. Data and information
2. Decision making
3. Implementation and actions

A well-defined set of processes, supported by an appropriate information system (composed of a database and a model base) and implemented by a team trained in performing the processes is a cornerstone in the competitive edge of organizations.

2.2. Process Design

The design of a process is aimed at defining the following:

- Data required to support decisions, including:
  - The data sources
  - How the data should be collected
  - How the data should be stored
  - How the data should be retrieved
  - How the data should be presented as information to decision makers
- Models required to support decisions by transforming data into useful information, including:
  - Models that support routine decisions
  - Models that support ad hoc decisions
  - Models used for process control
- Data and models integration:
  - How data from the database is analyzed by the models
  - How information generated by the models is transferred and presented to decision makers

2.3. The PMBOK and Processes in the Project Life Cycle

A well-defined set of processes that applies to a large number of projects is discussed in the PMBOK (PMI 1996). Although some of the PMBOK processes may not apply to some projects, while other

PMBOK processes may need modifications in certain projects, the PMBOK is a well-accepted source of information and therefore the following definition of processes is based on the PMBOK.

The PMBOK classifies processes in two ways:

1. By sequence
   - Initiating processes
   - Planning processes
   - Executing processes
   - Controlling processes
   - Closing processes
2. By management function:
   - Processes in integration management
   - Processes in scope management
   - Processes in time management
   - Processes in cost management
   - Processes in quality management
   - Processes in human resource management
   - Processes in communication management
   - Processes in risk management
   - Processes in procurement management

The application of these processes in a specific organization requires customization, development of supporting tools, and training.

3. PROJECT INTEGRATION MANAGEMENT

3.1. Processes

Project integration management involves three processes:

1. Project plan development
2. Project plan execution
3. Overall change control

The purpose of these three processes is to ensure coordination among the various elements of the project. Coordination is achieved by getting inputs from other processes, integrating the information contained in these inputs, and providing integrated outputs to the decision makers and to other processes.

The project life-cycle model plays an important role in project integration management because project plan development is performed during the early phases of the project while project plan execution and project change control are performed during the other phases of the project. With a well-defined life-cycle model, it is possible to define the data, decision making, and activities required at each phase of the project life cycle and consequently train those responsible for performing the processes adequately.

3.2. Description

The project plan and its execution are the major outputs of this process. The plan is based on inputs from other planning processes (discussed later) such as scope planning, schedule development, resource planning, and cost estimating along with historical information and organizational policies. The project plan is continuously updated based on corrective actions triggered by approved change requests and analysis of performance measures.

Execution of the project plan produces work results—the deliverables of the project.

4. PROJECT SCOPE MANAGEMENT

4.1. Processes

Project scope management involves five processes:

1. Initiation
2. Scope planning

3. Scope definition
4. Scope verification
5. Scope change control

The purpose of these processes is to ensure that the project includes all work (and only that work) required for its successful completion.

In the following discussion, scope relates to the product scope (defined as the features and functions to be included in the product or service) and the project scope (defined as the work that must be done in order to deliver the product scope).

4.2. Description

The scope is defined based on a description of the needed product or service. Alternative products or services may exist. Based on appropriate selection criteria and a selection methodology, the best alternative is selected and a project charter is issued along with a nomination of a project manager. The project manager should evaluate different alternatives to produce the selected product or service and implement a methodology such as cost–benefit analysis to select the best alternative. Once an alternative is selected, a work breakdown structure (WBS) is developed. The WBS is a hierarchical presentation of the project scope in which the upper level is the whole project and at which the lowest-level work packages are defined. Each work package is assigned to a manager (organizational unit) responsible for its scope.

5. PROJECT TIME MANAGEMENT

5.1. Processes

Project Time Management involves five processes:

1. Activity definition
2. Activity sequencing
3. Activity duration estimating
4. Schedule development
5. Schedule control

The purpose of time management is to ensure timely completion of the project. The main output of time management is a schedule that defines what is to be done, when, and by whom. This schedule is used throughout the project execution to synchronize between people and organizations involved in the project and as a basis for control.

5.2. Description

Each work package in the WBS is decomposed into the activities required to complete its predefined scope. A list of activities is constructed and the time to complete each activity is estimated. Estimates can be deterministic (point estimates) or stochastic (distributions). Precedence relations among activities are defined, and a model such as a Gantt chart, activity on arc (AOA), or activity on nodes (AON) network is constructed (Shtub et al. 1994). An initial schedule is developed based on the model. This unconstrained schedule is a basis for estimating required resources and cash. Based on the constraint imposed by due dates, cash and resource availability, and resource requirements of other projects, a constrained schedule is developed. Further tuning of the schedule may be possible by changing the resource combination assigned to activities (these resource combinations are known as modes).

The schedule is implemented by the execution of activities. Due to uncertainty, a schedule control is required to detect deviations and decide how to react to such deviations and change requests. The schedule control system is based on performance measures such as actual completion of deliverables (milestones), actual starting time of activities, and actual finishing time of activities. Changes to the baseline schedule are required whenever a change in the project scope is implemented.

6. PROJECT COST MANAGEMENT

6.1. Processes

Project cost management involves four processes:

1. Resource planning
2. Cost estimating

3. Cost budgeting
4. Cost control

These processes are designed to provide an estimate of the cost required to complete the project scope, develop a budget based on management policies and strategy, and ensure that the project is completed within the approved budget.

6.2. Description

To complete the project activities, different resources are required. Labor, equipment, and information are examples of resources required to perform in-house activities, while money is required for outsourcing. The estimated amount of required resources as well as the timing of resource requirements are based on the activity list and the schedule. Resource allocation is performed at the lowest level of the WBS—the work package level—and requirements are aggregated to the project level and the whole-organization level. A comparison of resource requirements and resource availability is the basis of finite resource-allocation procedures (models) that assign available resources to projects and activities based on management's strategy and priorities. Resource planning results in a detailed plan specifying what resources are required for each work package. Applying the resource rates to the resource plan and adding overhead and outsourcing expenses allows a cost estimate of the project to be developed. The cost estimate is the basis for budgeting. Based on the schedule, cost estimates are time phased to allow for cash flow analysis. Furthermore, additional allocations are made, such as the management reserve required to buffer against uncertainty. The resulting budget is the baseline for project cost control.

Due to uncertainty, cost control is required to detect deviations and decide how to react to such deviations and change requests. The cost-control system is based on performance measures, such as actual cost of activities or deliverables (milestones) and actual cash flows. Changes to the baseline budget are required whenever a change in the project scope is implemented.

7. PROJECT QUALITY MANAGEMENT

7.1. Processes

Project quality management involves three processes:

1. Quality planning
2. Quality assurance
3. Quality control

The purpose of these processes is to ensure that the project will satisfy the needs for which it was undertaken. These needs are multidimensional—Garvin (1987) suggests that quality has eight dimensions or performance measures:

1. *Performance:* This dimension refers to the product or service's primary characteristics, such as the acceleration, cruising speed, and comfort of an automobile or the sound and picture clarity of a TV set. The understanding of performance required by the customer and the design of the service or product to achieve the required performance level are key factors in quality-based competition.
2. *Features:* This is a secondary aspect of performance—the characteristics that supplement the basic functioning. Garvin (1987) defines features as ''the bells and whistles'' of the product or service. The flexibility a customer has to select desired options from a large list of such options contributes to the quality of the product or service.
3. *Reliability:* This performance measure reflects the probability of a product malfunctioning or failing within a specified time period. It reflects on both the cost of maintenance and on downtime of the product.
4. *Conformance:* This is the degree to which the product or service design and operating characteristics meet established standards.
5. *Durability:* This is a measure of the economic and technical service duration of a product. It relates to the amount of use one can get from a product before it has to be replaced due to technical or economical considerations.
6. *Serviceability:* This measure reflects the speed, courtesy, competence, and ease of repair should the product fail. The reliability of a product and its serviceability complement each other. A

reliable product that rarely fails, and on those occasions fast and inexpensive service is available, has a lower downtime and better serves its owner.

7. *Aesthetics:* This is a subjective performance measure related to how the product feels, tastes, looks, or smells. It reflects individual preferences.
8. *Perceived quality:* This is another subjective measure related to the reputation of product or a service. This reputation may be based on past experience and partial information, but in many cases the customer's decisions are based on perceived quality because exact information about the other performance measures listed above is not readily available.

7.2. Description

Quality planning starts with the definition of standards or performance levels for each of the dimensions of quality. Based on the scope of the project, quality policy, standards, and regulations, a quality management plan is developed. The plan describes ''the organizational structure, responsibilities, procedures, processes, and resources needed to implement quality management'' (ISO 9000), that is, how the project management team will implement its quality policy to achieve the required quality levels. Checklists and metrics or operational definitions are also developed for each performance measure so that actual results and performance can be evaluated against specified requirements.

To provide confidence that the project will achieve the required quality level, a quality assurance process is implemented. By continuously reviewing (or auditing) the actual implementation of the plan developed during quality planning, quality assurance systematically seeks to increase the effectiveness and efficiency of the project and its results.

Actual results are monitored and controlled. This quality-control process provides input to quality assurance as well as a firm basis for acceptance (or rejection) decisions.

8. PROJECT HUMAN RESOURCE MANAGEMENT

8.1. Processes

Project human resource management involves three processes:

1. Organizational planning
2. Staff acquisition
3. Team development

These processes deal with the management of human resources during the project life cycle. The processes are aimed at making the most effective use of people involved with the project. The temporary nature of project organizations, the multidisciplinary teams required in many projects, and the participation of people from different organizations in the same project require special attention to team building, motivation, leadership, and communication in order to succeed.

8.2. Description

The work content of the project is allocated to the performing organizations by integrating the work breakdown structure (WBS) with the organizational breakdown structure (OBS) of the project. At the lowest level, these two hierarchical structures define work packages—specific work content assigned to specific organizational units. The managers of work packages are responsible for managing the building blocks of the projects. Each work package is an elementary project with a specific scope, schedule, budget, and quality requirements. Organizational planning activities are required to ensure that the total work content of the project is assigned and performed by the work packages and integration of the deliverables produced by the work packages into the final product results is possible according to the project plans. The organizational plan defines roles and responsibilities as well as staffing requirements and the OBS of the project.

Based on the organizational plan, staff assignment is performed. Availability of staff is compared to the requirements and gaps identified. These gaps are filled by staff-acquisition activities. The assignment of available staff to the project and the acquisition of new staff result in the creation of a project team that may be a combination of employees assigned full-time to the project, full-time employees assigned part-time to the project, and part-timers.

The assignment of staff to the project is the first step in the team-development process. To succeed in achieving the project goals, a team spirit is needed. The transformation of a group of people assigned to a project into a high-performance team requires leadership, communication skills, and negotiation skills as well as the ability to motivate people, coach and mentor them, and deal with conflicts in a professional yet effective way.

9. PROJECT COMMUNICATIONS MANAGEMENT

9.1. Processes

Project communications management involves four processes:

1. Communications Planning
2. Information Distribution
3. Performance reporting
4. Administrative closure

These processes are required to ensure ''timely and appropriate generation, collection, dissemination, storage, and ultimate disposition of project information'' (PMI 1996). The processes are tightly linked with organizational planning. The communication within the project team, with stakeholders, and with the external environment can take many forms, including formal and informal communication, written or verbal communication, and planned or ad hoc communication. The decision regarding communication channels, the information that should be distributed, and the best form of communication for each type of information is crucial in supporting teamwork and coordination.

9.2. Description

Communications planning is the process of selecting the communication channels, the modes of communication and the contents of the communication among project participants, stakeholders, and the environment. Taking into account the information needs, the available technology, and constraints on the availability and distribution of information, the communications-management plan specifies the frequency and the methods by which information is collected, stored, retrieved, transmitted, and presented to the parties involved in the project. Based on the plan, data-collection as well as data-storage and retrieval systems can be implemented and used throughout the project life cycle. The project communication system, which supports the transmission and presentation of information, should be designed and established early on to facilitate the transfer of information.

Information distribution is based on the communication-management plan. It is the process of implementing the plan throughout the project life cycle to ensure proper and timely information to the parties involved. In addition to the timely distribution of information, historical records are kept to enable analysis of the project records to support organizational and individual learning. Information related to performances of the project is important. Performance reporting provides stakeholders with information on the actual status of the project, current accomplishments, and forecasts of future project status and progress. Performance reporting is essential for project control because deviations between plans and actual progress trigger control actions.

To facilitate an orderly closure of each phase and of the entire project, information on actual performance levels of the project phases and product is collected and compared to the project plan and product specifications. This verification process ensures an ordered formal acceptance of the project products by the stakeholders and provides a means for record keeping that supports organizational learning.

10. PROJECT RISK MANAGEMENT

10.1. Processes

Project risk management involves four processes:

1. Risk identification
2. Risk quantification
3. Risk response development
4. Risk response control

These processes are designed to evaluate the possible risk events that might influence the project and integrate proper measures to handle uncertainty in the project-planning monitoring and control activities.

10.2. Description

A risk event is a discrete random occurrence that (if occurring) affects the project. Risk events are identified based on the difficulty to achieve the required project outcome (the characteristics of the product or service), constraints on schedules and budgets, and the availability of resources. The environment in which the project is performed is also a potential source of risk. Historical information

is an important input in the risk-identification process—knowledge gaps are a common source of risk in projects. Risks are generated by different sources, such as technology—an effort to develop, use, or integrate new technologies in a project creates a knowledge gap and consequently risks. External risks such as new laws or a strike in government agencies may generate project risks. Internal sources within the project or its stakeholders may also do so. The probability of risk events and the magnitude of their affect on the project success are estimated during the risk-quantification process. This process is aimed at an effort to rank risks in order of the probability of occurrence and the level of impact on the project. Thus, a high risk is an event that is highly probable and may cause substantial damage to the project.

Based on the magnitude of risk associated with each risk event, a risk response is developed. Several responses are used in project management, including:

- *Risk elimination:* In some projects it is possible to eliminate some risks altogether by using a different technology, a different supplier, etc.
- *Risk reduction:* If risk elimination is too expensive or impossible, risk reduction may be used by reducing the probability of a risk event or its impact or both. A typical example is redundancy in R&D projects when two mutually exclusive technologies are developed in parallel to reduce the risk that a failure in development will harm the project. Although only one of the alternative technologies will be used, the redundancy reduces the probability of a failure.
- *Risk sharing:* It is possible in some projects to share risks (and benefits) with some stakeholders such as suppliers, subcontractors, partners, or even the client. Another form of risk sharing is with an insurance company.
- *Risk absorption:* If a decision is made to absorb the risk, buffers in the form of management reserve or extra time in the schedule can be used. In addition, contingency plans may be appropriate tools to help in coping with the consequences of risk events.

Since information is collected throughout the life cycle of a project, additional information is used to continuously update the risk-management plan. Risk-response control is a continuous effort to identify new sources of risk, update the estimates regarding probabilities and impacts of risk events, and activate the risk-management plan when needed. Constantly monitoring the project progress in an effort to update the risk-management plan and activate it when necessary can reduce the impact of uncertainty and increase the probability of successful project completion.

11. PROJECT PROCUREMENT MANAGEMENT

11.1. Processes

Project procurement management involves six processes:

1. Procurement planning
2. Solicitation planning
3. Solicitation
4. Source selection
5. Contract administration
6. Contract closeout

These processes are required to acquire goods and services from outside the performing organization (from consultants, subcontractors, suppliers, etc.). The decision to acquire such goods and services (the make or buy decision) has a short-term or tactical level (project-related) impact as well as a long-term or strategic level (organization-related) impact. At the strategic level, core competencies should rarely be outsourced even when outsourcing can reduce the project cost, shorten its duration, reduce its risk, or provide higher quality. At the tactical level, outsourcing can elevate resource shortages, help in closing knowledge gaps, and increase the probability of project success.

Management of the outsourcing process from supplier selection to contract closeout is an important part of the management of many projects.

11.2. Description

The decision on what parts in the project scope and product scope to purchase from outside the performing organization, how to do it, and when to do it is critical to the success of most projects. This is not only because significant parts of many project budgets are candidates for outsourcing, but because the level of uncertainty and consequently the risk involved in outsourcing are quite different from the levels of uncertainty and risk of activities performed in-house. In order to gain a

competitive advantage from outsourcing, well-defined planning, execution, and control of outsourcing processes supported by data and models (tools) are needed.

The first step in the process is to consider what parts of the project scope and product scope to outsource. These are decisions regarding sources of capacity and know-how that can help the project in achieving its goal. A conflict may exist between the goals of the project and other goals of the stakeholders. For example, subcontracting may help a potential future competitor develop know-how and capabilities. This was the case with IBM when it outsourced the development of the Disk Operating System (DOS) for the IBM PC to Microsoft and the development of the CPU to Intel. The analysis should take into account the cost, quality, speed, risk, and flexibility of in-house vs. outsourcing. Outsourcing decisions should also take into account the long-term or strategic factors discussed earlier.

Once a decision is made to outsource, a solicitation process is required. Solicitation planning deals with the exact definition of the goods or services required, estimates of the cost and time required, and preparation of a list of potential sources. During solicitation planning, a decision model can be developed, such as a list of required attributes with a relative weight for each attribute and a scale for measuring the attributes of the alternatives. A simple scoring model, as well as more sophisticated decision support models prepared at the solicitation-planning phase, can help in reaching consensus among stakeholders and making the process more objective.

Solicitation can take many forms: a request for proposal (RFP) advertised and open to all potential sources is one extreme, while a direct approach to a single preferred (or only) source is another extreme—with many variations in between, such as the use of electronic commerce. The main output of the solicitation process is one or more proposals for the goods or services required. A well-planned solicitation-planning process followed by a well-managed solicitation process is required to make the next step, source selection, efficient and effective.

Source selection is required whenever more than one adequate source is available. If a proper selection model is developed during the solicitation-planning process and all the data required for the model are collected from the potential suppliers during the solicitation process, source selection is easy, efficient, and effective. Based on the evaluation criteria and organizational policies, proposals are evaluated and ranked. Negotiations with the highest-ranked suppliers can take place to get the best and final offer, and the process is terminated when a contract is signed. If, however, solicitation planning and the solicitation process do not yield a clear set of criteria and a selection model, source selection may become a difficult and time-consuming process; it may not end with the best supplier selected or the best possible contract signed. It is difficult to compare proposals that are not structured according to clear RFP requirements; in many cases important information is missing in the proposals.

Throughout the life cycle of a project, contracts are managed as part of the execution and change control efforts. Work results are submitted and evaluated, payments are made, and, when necessary, change requests are issued. When these are approved, changes are made to the contracts. Contract management is equivalent to the management of a work package performed in-house, and therefore similar tools are required during the contract-administration process.

Contract closeout is the closing process that signifies formal acceptance and closure. Based on the original contract and all the approved changes, the goods or services provided are evaluated and, if accepted, payment is made and the contract closed. Information collected during this process is important for future projects and supplier selection because effective management is based on such information.

12. THE LEARNING ORGANIZATION: CONTINUOUS IMPROVEMENT IN PROJECT MANAGEMENT

12.1. Individual Learning and Organizational Learning

Excellence in project management is based on the ability of individuals to initiate, plan, execute, control, and terminate the project scope and product scope successfully. The ability of individuals to master product- and project-related processes is the foundation on which organizational learning is built. Individual learning can take many forms, including the learning of verbal knowledge, intellectual skills, cognitive strategies, and attitudes. The learning mechanism can also take many forms, including learning by imitation of other people or learning by repetition of a process.

The ability of groups to improve performances by learning is also very important. Katzenbach and Smith (1993) explain how important it is to combine individual learning with team building.

A project team must combine these two learning processes in order to succeed. As it is important for each individual to learn and master his part in the product scope and in the project scope, it is equally important for the group to learn how to work as a team. Team building and organizational learning are important in the project environment. Establishing clear processes in which the input to each process is well defined and the individuals responsible for the process master the tools and techniques required to do the process right and to produce the desired output enables excellence in project management to be achieved.

12.2. Workflow and Process Design as the Basis of Learning

Successful project management requires successful planning, execution, and control of project scope and the product scope. The one-time, nonrepetitive nature of projects makes uncertainty a major factor affecting a project's success. In addition, the ability to learn by repetition is limited because most projects are unique. A key to project-management success is the exploitation of the repetitive parts of project scope. Identifying repetitive processes (repetitiveness within the project as well as repetitiveness between projects) and building an environment that supports learning and data collection enhances competitiveness in project management.

A key tool in building a learning–supporting environment is the design and implementation of a workflow-management system–a system that defines, manages, supports, and executes information-processing and decision-making processes. Each of the processes discussed in this chapter should be studied, defined, and implemented within the workflow management system. The definition includes the trigger (which initiates the process) of the process, inputs to the process, the participants in the process, the activities performed and required data processing, models used, the order or sequence of processing, and finally, process termination conditions and the process results or deliverables. The workflow-management system employs a workflow-enactment system or workflow-process engines that can create, manage, and execute multiple process instances.

By identifying the repetitive processes shared by many projects performed by an organization, it is possible to implement a workflow system that supports and even automates the repetitive processes. Automation means that the routing of each process is defined along with the input information, processing, and output information. Thus, although the product scope may vary substantially from project to project, the execution of the project scope is supported by an automatic workflow system that reduces the level of uncertainty (processes are clearly defined and the flow of information required to support these processes is automatic) and enables learning. The well-structured process can be taught to new employees or learned by repetition. In projects performed by the organization, the same processes are repeated, the same formats are used to present information, and the same models support decision making.

Definition of processes and the support of these processes by a workflow-management system are key to the success of organizations dealing repeatedly with projects.

CHAPTER 46
Computer-Aided Project Management

CARL N. BELACK
Oak Associates, Inc.

1. INTRODUCTION

Although the art of managing projects has existed for thousands of years, it is only relatively recently that modern project management techniques were developed, codified, and implemented in any consistent, methodological manner. Perhaps it is not totally coincidental that these techniques came about during the same period as the beginning of the commercial availability of computers as we know them today. As of the writing of this book, we have arrived at a point where hundreds of commercial software applications that address various aspects of the project management processes are available for purchase. For one who is unfamiliar with the wide variety of these tools on the market, the process of selecting and implementing these tools can be a daunting task. The purpose of this chapter is to help make that process somewhat more manageable.

The reader should note that the title of this chapter, ''Computer-Aided Project Management (CAPM),'' was specifically intended to allow for the discussion of the different types of tools available to facilitate the entire process of project management. To many people, the consideration of project management tools is unfortunately limited to what has become known as *project management software*. Granted, this type of tool was among the first applications developed with project management in mind, and it does address an important aspect of project management, namely scheduling and tracking. This author believes, however, that such a tool is but one among many in what we will refer to as a *computer-aided project management platform*. A CAPM platform is one that includes applications that automate many of the project management processes, not just scheduling and tracking, and it is this platform that we will discuss below.

The following pages will address the history of the development of CAPM, the use of computers in project management, and the implementation of CAPM platforms in business organizations, and will look at what we might expect of these tools in the years to come. It is hoped that this examination will help the reader better understand the use of CAPM tools while facilitating their selection and successful implementation.

2. THE HISTORY OF COMPUTER-AIDED PROJECT MANAGEMENT

While it may be difficult for some to believe (particularly for those to whom the slide rule is merely a curious artifact from an ancient civilization), modern project management techniques were at one time employed by those who did not have the advantage of using computers. In fact, some companies still don't use computers for project management in any organized fashion. And, as laborious as the work is, it is perfectly possible to put together a good project plan without the use of computers. However, having spent some time doing just that, the author can attest to the enormous amount of time and resources such an undertaking consumes. And, once changes are introduced to the initial project plan, the incremental use of time and resources expands exponentially.

In the late 1950s and early 1960s, a few companies began to develop their own internal software tools for managing projects, some of which are still in use today. With the apparent increasing need for such tools, commercial applications began to appear in the marketplace. Most of these tools were initially used by U.S. government contractors (who were required by the Department of the Energy or the Department of Defense to adhere to rules for managing government contracts) and were implemented on mainframe computers—the only computers commercially available at that time. These applications were the predecessors to tools that are still available today (although in a much different form), such as Artemis and Primavera. At the time, these tools were both difficult to learn and cumbersome to use. Since graphical user interfaces did not yet exist, command language was used to interface with the application. Nonetheless, since they enabled some automation of scheduling, tracking, and reporting activities, they were a welcome change for most project managers, who were used to performing these same tasks by hand.

The advent of commercially available PCs brought about the development of project management tools specifically aimed at the PC market. These tools (which we will refer to as low-end tools, as distinguished from the high-end tools that run on mainframes and minicomputers) were much less expensive than their high-end counterparts and were much easier to learn and to use, but also had far fewer capabilities. These tools also allowed the user to interface with the application through a rudimentary graphical user interface (GUI). These tools included software applications such as Harvard Project Manager, SuperProject, Project Manager's Workbench, and Microsoft Project. These tools were primarily aimed at the IBM-compatible marketplace. There were fewer tools available for Apple Macintosh computers, such as MacProject.

Over the past few years, the manufacturers of the high-end tools have incorporated GUIs and other devices to make their tools user friendly. At the same time, the makers of the low-end tools began building more capabilities into their applications that had previously been available only in the high-end tools. Some formerly low-end tools, such as Project Workbench, have migrated into the realm of high-end tools. And a number of high-end tool manufacturers have produced low-end tools for managing individual projects whose files can then be integrated into the high-end tools (such as Sure Trak for Primavera). As confusing as this all sounds, all of these software manufacturers have been trying to achieve the same end: to develop a tool that balances ease of learning and use with ever-increasing capabilities.

As the profession of project management began to gain acceptance in the workplace, additional applications became commercially available. These range from tools that automate other project management processes (such as risk-management tools like @Risk) to tools that help manage areas that are ancillary to, but have a direct impact upon, project management (such as multiproject resource management tools like ResSolution). With the availability of all of these different types of tools, it is often a difficult proposition deciding which tools, if any, are appropriate for a specific organization. In the next sections, we will discuss the processes that are involved in, or have an impact upon, project management and see how the use of computer tools can facilitate these processes.

3. THE PROJECT CONCENTRIC CIRCLE MODEL

In any given organization, generally two types of work activities take place. The first type, the one with which most people are familiar, is *operations* work. The activities in operations work have the following characteristics:

- They are repetitive (they occur over and over from fiscal quarter to fiscal quarter and from fiscal year to fiscal year).
- Their end result is essentially the same (production of financial reports, operations reports, etc.).

The second type, which we are addressing in this chapter, is *project* work. As one might expect, project work is characterized by work that is (1) not repetitive, but rather time limited (it has a specific beginning and end), and (2) produces a unique product or service. Project management is the set of activities involved in managing project work.

When looking at the set of processes involved in or surrounding project management, it is useful to use a framework that the author has called the Project Concentric Circle Model.* This model is depicted in Figure 1.

The model consists of three concentric circles. Each circle represents a level at which project management processes, or processes affecting the project management processes, take place. Each will be briefly discussed below.

3.1. Project Management Core Processes

The center circle represents the project management core processes, or processes that function within individual projects. The reader can find a detailed description of these processes in (PMI 1996) (PMBOK Guide). In brief, these are areas that address the following project management activities at the individual project level:

- Time management
- Scope management
- Cost management
- Risk management
- Quality management
- Human resources management
- Procurement management
- Communications management
- Integration management

The *PMBOK Guide* also describes the five project management processes throughout which activities in each above-noted area of management need to be performed. These processes are portrayed in Figure 2. It is these management areas and processes that most organizations associate with project management. And some assume that attending to these alone will ensure successful organizational project work. That, however, is a fatal error for many organizations. In order to achieve a high level of competence in project management, two other levels must also be addressed.

3.2. Project Management Support Processes

The second circle represents the project management support processes level and includes processes that occur outside of the day-to-day activities of the individual project teams. The activities within these processes generally comprise operational activities, not project activities, that support project

Figure 1 Project Concentric Circle Model.

*The reader is advised that the Project Concentric Circle Model is a copyright of Oak Associates, Inc. Any reproduction or use of the model without the express consent of Oak Associates, Inc. and the publisher is strictly prohibited.

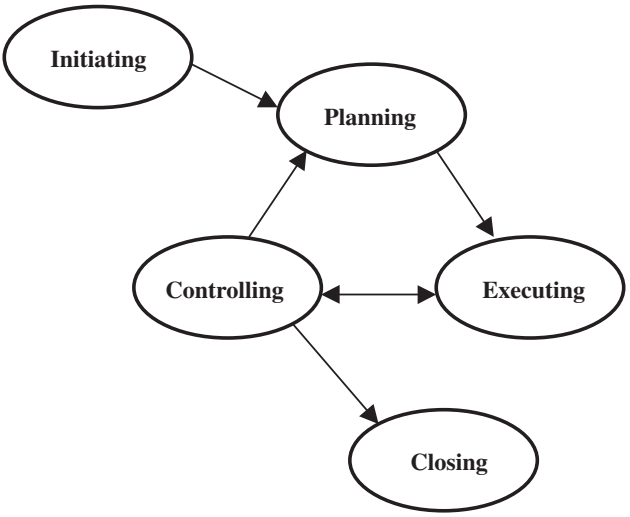

Figure 2 Project Management Processes.

work and project teams. In fact, these can best be described as processes that establish and maintain an environment in which project work can be successfully performed.

These processes can be grouped into two categories:

1. *Organizational development:* Activities that occur in these processes include assessing organizational and individual competency; development and updating of job descriptions for people at all levels of the project team; design of career paths for project managers and project team members; project manager selection and competency development; project team member selection and support; and training and mentoring.
2. *Communications and knowledge systems:* Activities that occur in the development and maintenance of these systems focus on interproject and intraproject communications; project reporting systems (for project team members, customers, and senior management); in-progress and postproject reviews and audits; development and maintenance of historical activity and estimating databases; capacity planning; project change management; and project and technical document/software configuration management.

3.3. Senior Management Leadership

The outermost circle represents processes that senior management must undertake in order to promote project-friendly corporate environments. This involves:

- Championing project management within the organization: This is done by understanding project management and project work within the organizational context; leading the change effort to enhance the role of projects and project management; prioritizing project work to enable effective resource management; and managing the portfolio of projects to ensure alignment with corporate goals.
- Creating and enabling the culture of project success: This includes fostering open and honest communication; promoting rational risk taking; supporting the need for project planning; valuing the differences of project and functional management; and encouraging ''quiet'' projects (and discouraging ''heroic'' projects).

Now that we have constructed a framework for the processes that need to work effectively in order for projects to be successful, let us look at the types of software applications that could automate many of these processes.

4. THE CAPM PLATFORM

An organization needs to have available for project managers, project teams, line managers, and senior managers a tool set that facilitates the activities of the management processes noted above.

An example of one type of tool frequently used in project management is a list of items that, when completed, would signify the completion of a project deliverable—a punch list is one such list that is regularly used to this day in construction projects. More and more, these tools are being incorporated into computer applications. In this section, we will take a look at tools that are available, or are being constructed, to automate the concentric circle processes.

4.1. Automating the Project Management Core Processes

Before proceeding, a brief word of caution is in order. It is the mistaken belief of many that in order to manage projects effectively, one merely needs to purchase a project management tool and become trained in use of the tool (the ''buy 'em a tool and send 'em to school'' approach). This is possibly the worst approach that could be taken to improve the effectiveness of project management in an organization. We have already noted that project management predated the commercially available tools to aid that endeavor, so we know that it is possible to manage projects effectively without the use of automation. The single most important thing to remember about these tools is that it is not the tool, but rather the people using the tool, who manage the projects. *In order for people to use the tools properly, they must first master the techniques upon which these tools are based.*

As an example, to develop useful data for scope, time, and cost management, the successful tool user must have a working knowledge of scope statement development; work definition (through work breakdown structures or other such techniques): activity estimating (three-point estimating of both effort and duration); precedence diagramming method (also known as project network diagramming); and progress-evaluation techniques (such as earned value). Expecting success through the use of a tool without a thorough prior grounding in these techniques is like expecting someone who has no grounding in the basics of writing (grammar, syntax, writing technique) to use a word-processing application to produce a novel. Some novels on the market notwithstanding, it just does not happen that way. With this firmly in mind, let's look at the types of tools one might use in modern project management.

4.1.1. Scope, Time, Cost, and Resource Management

The preponderance of tools on the market today are those that aid project managers in time and cost management (commonly called schedule and budget management). In addition, many of these tools include resource management. These tools can be helpful in:

- Developing activity lists (project scope) and displaying work breakdown structures
- Noting activity estimates (in some cases, calculating ''most likely'' estimates for three-point estimating techniques)
- Assigning dependencies (precedence structure) among activities
- Calculating and displaying precedence diagrams (PERT charts)
- Calculating and displaying project schedules (Gantt charts)
- Assigning individual or group resources
- Setting and displaying calendars (both for the project and for individual resources)
- Calculating project costs (for various types of resources)
- Entering time card and resource usage data

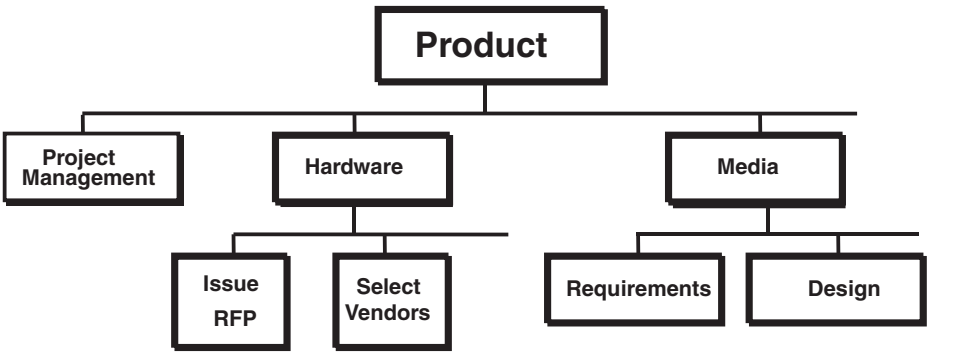

Figure 3 Work Breakdown Structure.

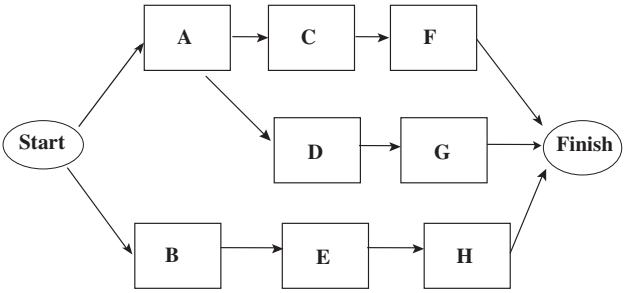

Figure 4 Precedence Diagram.

- Tracking project cost, schedule, and resource data
- Rescheduling and recalculating schedule and cost data after input of activity actual data
- Calculating and displaying project progress
- Leveling resources
- Displaying resource histograms
- Sorting and filtering for various scenarios
- Generating reports for use by various project stakeholders

These are just some of the capabilities that can be found in these tools (see the section on selecting tools below for a citation of an extended list of these capabilities). The tools that can be used for such an effort are too numerous to list. Examples of these are Microsoft Project 98, PS7, and Artemis. For some of the low-end tools (particularly for MS Project 98), there is an after-market of tools that can be used in conjunction with the primary tool to help it do its job more effectively. These range from tools like GRANEDA Dynamic (which provides an excellent graphical interface to print professional-looking precedence diagrams, Gantt charts, and work breakdown structures) to tools such as Project 98 Plus (which provides a very user-friendly interface for sorting and filtering for MS Project 98).

4.1.2. Risk Management

Since two characteristics that we have attributed to project work are its unique nature and its time limitations, projects are inherently risky. Many projects run into problems or fail altogether because an inadequate job was done around risk management. Project risk management is a three-step process that involves:

1. Identifying, assessing, and documenting all potential project risks
2. Developing risk avoidance and mitigation plans
3. Implementing these plans when the risks occur

Clearly, this is not a process that ends once the project-planning activities have been completed. Rather, project managers need to monitor and assess potential project risk throughout the entire conduct of the project.

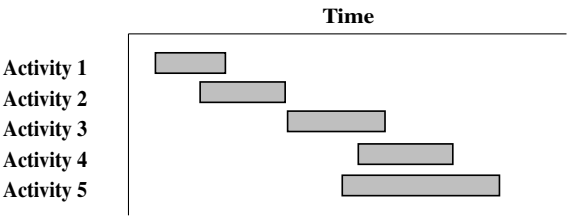

Figure 5 Gantt Chart.

	1	2	3	4	5	6	7	8	9	10	11	12
Planned Progress	20	50	110	225	425	695	875	1005	1105	1230	1260	1280
Actual Costs	30	60	151	337	567	827						
Earned Value	20	50	110	225	345	475						

Figure 6 Earned Value S Curves.

One type of risk that all project managers face is that associated with project schedules. A typical method for handling this risk is to run Monte Carlo simulations on the project precedence diagram (PERT chart). This is done by (1) assigning random durations (within predefined three-point activity estimates) to individual activities, (2) calculating project duration over and over for hundreds (sometimes thousands) of repetitions, and (3) analyzing the distribution of probable outcomes of project duration. There are a number of tools on the market that perform these tasks. Two of the most popular are @Risk and Risk+. Other fine tools are also available that perform similarly. These tools can perform simulations on practically any project calculations that lend themselves to numerical analysis. The output of these tools is the analysis of probable project durations in both numerical and graphical formats (see Figure 7).

Why is it important to use tools like these to help us manage risk? Quite simply, single-point project estimates are rarely, if ever, met. Project managers need to understand the probable range of outcomes of both project cost and duration so they can make informed decisions around a host of project issues (e.g., setting project team goals, deciding when to hire project personnel). They also need this information to set proper expectations and conduct intelligent discussions with the project team members, senior managers, and customers. The correct use of such tools can help project managers do just that.

In addition to these tools, other tools are available to help track the status of potential risk events over the course of a project. One such tool, Risk Radar, was designed to help managers of software-intensive development programs. Regardless of the intended target audience, this tool can be quite helpful for any type of project risk-tracking effort. With the proper input of risk data, it displays a

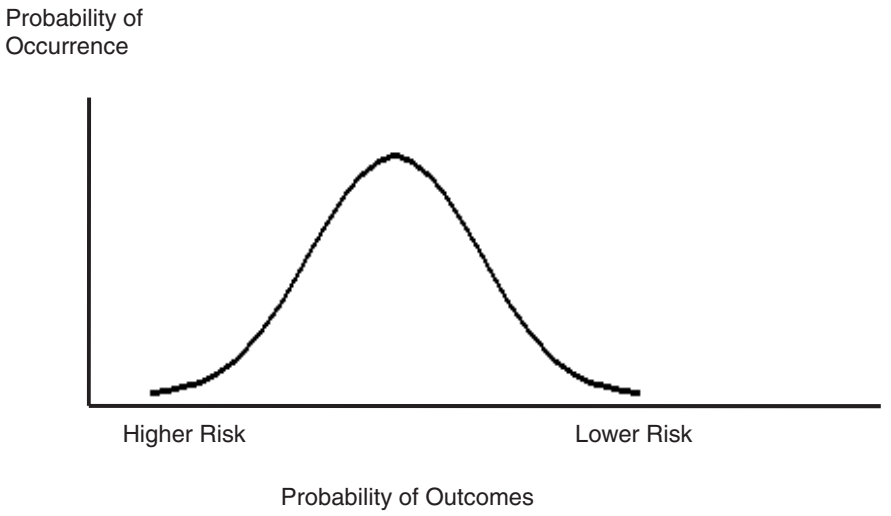

Figure 7 Project Outcome Probability Curve.

graphic depicting the number of risk events with similar risk exposure and lays them out on an easily understood grid. This is a common way to track risk. An example of a similar grid is shown below (see Figure 8).

4.1.3. Change Management

As noted earlier, there are two types of changes with which project managers need be concerned. The first is a change in the scope of work of the project. Most projects encounter scope changes during the evolution of work on the project. Since scope changes almost always result in budget and schedule changes, it is very important to track them accurately. This can usually be done by using the scope, time, cost, and resource-management software discussed above.

The second type of change is one that addresses changes in technical project documentation. Technical drawings, quality documents, and electrical wiring diagrams are examples of such documents. There are a number of tools available for these efforts, and they are as diverse as the technical functions that might employ them. They are generically known as configuration management tools. While these will not be addressed in this chapter, project functional teams should make every effort to select tools like these that will help them manage these documents so that current versions are available to all project members who need them.

4.1.4. Communications Management

Communications skills are arguably the most important skill of project management. Similarly, communications tools can be considered among the most important project tools. As noted in the *PMBOK Guide,*

> Project Communications Management includes the processes required to ensure timely and appropriate generation, collection, dissemination, storage, and ultimate disposition of project information. It provides the critical links among people, ideas, and information that are necessary for success. Everyone involved in the project must be prepared to send and receive communications in the project ''language'' and must understand how the communications they are involved in as individuals affect the project as a whole.

Tools that aid managers in project communications are not terribly different from those that are used in operations communications. They include:

- Word processors (e.g., WordPerfect, MS Word)
- Presentation tools (e.g., MS PowerPoint, Corel PRESENTS)
- Spreadsheets (e.g., Lotus 1-2-3, MS Excel)
- Individual and workgroup communications tools (e.g., e-mail, Lotus Notes)

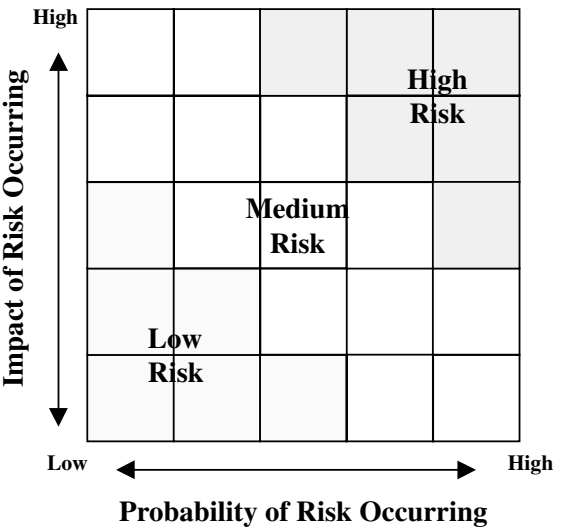

Figure 8 Project Risk Grid.

With the availability of Internet communications and the advent of tools similar to those noted above, tool sets such as these should be readily available for use by project teams.

4.2. Automating the Organizational Support Processes

Like the communications tools discussed above, tools that are useful in the organizational support processes are those that have been used for some time in operations management. Operations management processes are, after all, operations work (line or functional management) as opposed to project work (project management). Since operations management has been taught in business schools for decades, there are tools on the market that can aid in various aspects of these endeavors. While these tools are too numerous to discuss here, some have been designed with the express purpose of supporting project management activity. Among them are:

- *Multiproject resource-management tools:* These tools help line managers manage scarce resources across the many projects in which their organizations are involved. They include tools such as ResSolution* and Business Engine.
- *Project portfolio management tools:* These are tools that help senior managers balance the accomplishment of their organizational goals across the range of projects, both ongoing and potential, in their organizations. They address issues such as budget, benefits, market, product line, probability of success, technical objectives, and ROI to help them prioritize and undertake projects. One such tool that does this is the project portfolio module of Portfolio Plus.
- *Activity and project historical databases:* These are tools that help a project team and all managers more accurately estimate the outcomes of their projects. Among the many problems that arise in projects, an unrealistic expectation about project outcomes is one of the most flagrant. One reason for these unrealistic expectations is the poor quality of activity-level estimates. One way to increase the accuracy of these estimates is to employ three-point estimating techniques, which have been referred to above. An even better way of increasing the accuracy of estimates is to base them on historical data. Were one to examine the activities that are performed over time in an organization's projects, it would become apparent that many of the same types of activities are performed over and over from one project to another. In some cases, nearly 80% of these activities are repeated from one project to another. Unfortunately, in many organizations, such historical data is rarely available for project team members to use for estimating. Consequently, three-point estimating techniques need to be universally employed, project after project. Once organizations develop, maintain, and properly employ accurate activity historical databases, the need for the relatively less accurate three-point estimates (remember that single-point estimates are much less accurate than three-point estimates) will be reduced, thereby resulting in more accurate estimates at both the activity and project levels.

Finally, we should mention that while integration of all the types of tools discussed is probably technologically possible, it is not always either necessary or desirable. In fact, it is the author's belief that in some instances, particularly in the case of multiple-project resource management, it is better to do detailed management of project resources within the context of the center circle and less detailed management at a higher level within the context of the outer circles without daily integration of the two activities.

5. IMPLEMENTING CAPM

The selection, implementation, and use of these tools are not tasks to be taken lightly. And while the process may at first seem daunting, there are ways to make it easier. A number of sources can aid in the selection process. At least two publications presently do annual software surveys in which they compare the capabilities of various project management tools. Many of these tools perform the functions discussed above. These publications are *IIE Solutions,* a monthly publication of the Institute of Industrial Engineers, and *PMnet,* a monthly publication of the Project Management Institute. The National Software Testing Laboratories (NTSL) also tests and compares software programs. It makes these comparisons in over 50 categories of tool capabilities for project management software. The major areas of comparison include:

- Performance
- Versatility

*In the interest of fairness and full disclosure, the author must acknowledge that the organization in which he is a principal is a reseller of both ResSolution and Project 98 Plus software, both of which are cited in this chapter.

- Quality
- Ease of learning
- Ease of use

Individuals responsible for such selection need to ask the following types of questions:

- What is my organization trying to accomplish with this software? Will the software tools being considered meet those needs?
- How many people will be using the software—one person, a group of people, or an entire organization?
- Have the users of the software previously used any other type of project management software before? If so, what were the tools, and were they similar to any of the tools presently being considered?
- Have the users of the software been trained in project management methods, tools, and techniques?
- Are the tools being considered both easy to learn and easy to use?
- Can the tool be used as is or are modifications required?
- What type of postinstallation support is required? Will the vendor do the support or does it require an in-house support group?
- Does the tool need to be integrated with other tools being used in the organization? If so, how difficult will that integration be?
- What are the implications of introducing software of this sort into my organization? Do I need to develop a formal change management plan to get organizational buy-in for its introduction and use?

The answers to all of these questions can have a profound impact on the success of the tool in an organization. One needs to be especially careful in considering the last question. The human implications of introducing software tools in an organization are frequently underestimated. This underestimation has caused organizations to be unsuccessful in the introduction and implementation of these tools, resulting in wasted effort and dollars and in the frustration of those project stakeholders who were affected by the failed effort.

For many reasons, tool-selection processes can at times resemble religious wars. Participation in such a process is not for the fainthearted. Anyone contemplating the introduction of these tools into an organization would be well advised to develop a detailed project plan. Included in this project plan should be a plan to ease the introduction of the tool into the organization, thereby allowing for the greatest probability of a successful introduction and implementation. As with any project, a competent project team needs to be assembled with a specific individual assigned responsibility to manage the project. There should be senior management support and involvement appropriate to the effort. Expectations of all organizational stakeholders need to be set and met throughout the conduct of the project. These expectations should include (1) a detailed description of what will be done during the project, (2) who needs to be involved, and (3) how the implementation of the tool will affect members of the organization. Once project execution has begun, and throughout the course of the project, frequent progress reviews need to take place to ensure that the implementation is on schedule, on budget, and meets the needs of the project stakeholders. These efforts will go far in aiding in the integration of the tool into regular use in project and operations work

6. CAPM IN THE 21st CENTURY

With the rapid development and introduction of software onto the marketplace, some of what has been described above may soon be out of date. One thing that will surely not vanish, however, is the ever-increasing need of project managers and organizations for tools to help them accomplish their complex and difficult jobs. While once just nice to have, these tools are now a necessity. So what does the future hold for computer-aided project management?

More and more tools are expanding from those aimed at individual use to those available for workgroups. Projects are, after all, team endeavors. MS Project 2000 includes an Internet browser module called Microsoft Project Central that is aimed at allowing the collaborative involvement of project stakeholders in planning and tracking projects, as well as access to important project information. With the ever-increasing demand for accurate project information, coupled with the cross-geographical nature of many project efforts, Web-based project communications tools will surely also become a requirement and not just a convenience. The author has worked with a few companies that have already developed these tools for their internal use. It is also inevitable that at some point in the not too distant future, complete tool sets that incorporate and integrate many of the varied ca-

pabilities described in the paragraphs above will also become available for commercial use. It is only a matter of time before such software applications will be developed and appear on the shelves of your electronic shopping sites.

However, despite the advances in technology that will inevitably lead to this availability, the age-old problems of successful selection, introduction, and implementation of these tools will remain. If organizations take the time to accomplish these tasks in a cogent and supportive way, the tools will continue to be a significant benefit in the successful implementation of the project management processes.

CHAPTER 47

Work Breakdown Structure

BOAZ GOLANY
AVRAHAM SHTUB
Technion—Israel Institute of Technology

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION: DIVISION OF LABOR AND ORGANIZATIONAL STRUCTURES

1.1. Introduction

Division of labor is a management approach based on the breaking up of a process into a series of small tasks so that each task can be assigned to a different worker. Division of labor narrows the scope of work each worker has to learn enabling workers to learn new jobs quickly and providing an environment where each worker can be equipped with special tools and techniques required to do his job.

Some advantages of division of labor and specialization are:

- The fast development of a high degree of skill (specialization)
- The saving of set-up time required to change from one type of work to another
- The use of special-purpose, usually very efficient, machines, tools, and techniques developed for specific tasks.

These benefits do not come for free. Division of labor requires integration of the outputs produced by the different workers into the final product. Thus, some of the efficiency gained by specialization is lost to the additional effort of integration management required.

A common way to achieve integration is by a proper organizational structure, a structure that defines roles and responsibilities of each person as well as the inputs required and the tools and techniques used to produce that person's outputs.

This chapter discusses division of labor in projects. Section 1 deals with different organizational structures. Section 2 focuses on the work breakdown structure (WBS) as a tool that supports division of labor in projects. Section 3 discusses the relationship between the project organizational structure and the WBS, and Section 4 presents types of work breakdown structures along with a discussion on the design of a WBS. Section 5 discusses the building blocks of a WBS, known as work packages, and Section 6 discusses how the WBS should be used and managed in projects. Finally, Sections 7 and 8 present the issues of individual learning and organizational learning in the context of the support a WBS can provide to the learning process.

1.2. Organizational Structures

Organizations are as old as mankind. Survival forced people to organize into families, tribes, and communities to provide for basic needs (security, food, shelter, etc.) that a single person had difficulty providing. Kingdoms and empires of the ancient world emerged as more formal organizations. While these organizations had long-term goals, other organizations were created to achieve specific unique goals within a limited time frame. Some ambitious undertakings that required the coordinated work of many thousands of people, like the construction of the Pyramids, Great Wall of China, or the Jewish Temple, motivated the development of ad hoc organizations.

As organizations grew larger and spread geographically, communication lines and clear definitions of roles became crucial. Formal organizations based on a hierarchical structure were established. The hierarchical structure emerged due to the limited ability of a supervisor to manage too many subordinates. This phenomenon, known as the limited span of control, limits the number of subordinates one can supervise effectively. The role, responsibility, and authority of each person in the organization were defined. A typical example is documented in the Bible where Moses divided the people of Israel into groups of 10 and clustered every 10 of these basic groups into larger groups of 100, and so on. The underlying assumption in this case is that the span of control is 10. Clustering was based on family relationships. Formal authority was defined and lines of communication were established to form a hierarchical organizational structure. The idea of a formal organization, where roles are defined and communication lines are established, is a cornerstone in the modern business world. Division of labor and specialization are basic building blocks in modern organizations. There is a large variety of organizational designs; some are designed to support repetitive (ongoing) operations, while others are designed to support unique one-time efforts. A model known as the organizational structure is frequently used to represent lines of communication, authority, and responsibility in business organizations.

1.3. The Functional Structure

The functional organization is designed to support repetitive activities over a long (indefinite) period of time. It is a hierarchical structure in which roles are based on the function or specialization of the workers involved. Functions like marketing, finance, human resources, engineering, production, and logistics are common. In large organizations, each function is subdivided further, to the point that a proper span of control is achieved. For example, the marketing department can be divided geographically: marketing in Europe, the United States, Asia, and Africa. Engineering departments can be subdivided into electrical engineering, mechanical engineering, and industrial engineering. In a functional organization, the role of each organizational unit is to deal with the work content related to its function. Although fine tuning is required to define the exact border lines and interfaces between the different functions, division of labor is (naturally) along the functional lines.

An advantage of functional organization stems from the pooling together of similar resources: when all the electrical engineers are pooled together into one organizational unit, efficiency and effectiveness are achieved. Furthermore, workers in the same organizational unit (same function) share similar knowledge, education, and experience. They can learn from each other, and the flow of information within organizational units is natural. The stability of this organizational structure promotes career development to the point that people spend their entire career with the same organization moving up the hierarchical ladder while gaining expertise in their profession.

A disadvantage of this structure is its rigidity in dealing with complex tasks where different functions (or disciplines) must collaborate and the difficulty in introducing change. The flow of information between (different functions') organizational units may be difficult, causing difficulty in integration. Furthermore, customers frequently have to interact with several functions—they do not have a single point of contact.

1.4. The Project Structure

The project structure is designed to handle one-time, unique, and nonrecurrent endeavors. It is based on a task force assembled for a limited time to achieve a predefined goal. The members of the project team may come from different organizational units and have different educations and backgrounds. They have a common goal—the project success; and a common leader—the project manager. Organizations dealing with projects may adopt a flexible structure in which only a core group has a permanent structure while most of the organization is assigned to project groups.

An advantage of the project structure is its flexibility; the project team can be assembled exactly according to the task at hand. Another advantage is the creation of a single point of contact for the customer—the project manager has complete responsibility for the project and for customer satisfaction. Teamwork and coordination between people coming from different disciplines is easier to achieve when they belong to the same project, share a common goal, and have the same project manager.

The disadvantages of the project structure are related to its temporary nature—resources are not pooled and thus efficiency and effectiveness are hard to achieve. The limited life of the project's organizational structure creates anxiety and uncertainty about the future role of the team members, mainly at the final stages of the project, and information between project teams is not flowing easily.

A major problem in the project structure is division of labor. Unlike the functional organization, in which division of labor is natural because it is based on the specialization of each function, in a project there is no natural division of labor. It is important to allocate the work among the project participants in a very precise way so that the schedule and budget constraints will not be violated and resources will be efficiently and effectively utilized but not overloaded. Most importantly, it should be possible to integrate the parts of the work performed by different individuals and organizations participating in the project and to produce the deliverables required by the customers.

In the functional organizations where division of labor is based on specialization, each function performs the same set of tasks repeatedly. Due to repetition, learning is built into the process. In a project, division of labor can take many different forms and has to be designed carefully because a project is a one-time effort and improvement by repartition is not built into it.

The work breakdown structure is the tool used to divide the project work content among individuals and organizations so that efficiency and effectiveness will be achieved while ensuring the integration of work efforts to produce the project-required deliverables.

1.5. The Matrix Structure

Organizations involved in ongoing operations and multiple projects simultaneously develop hybrid structures that mix the functional organizational structure with the project structure. Although a large variety of such structures exist, most of these structures are based on a permanent functional skeleton and temporary project structures. Each project has a project manager (or coordinator) that serves as a point of contact for the customers and is responsible for the project success. A team that (typically) combines some members who are employed full time by the project and other members that belong to a functional unit and employed part time on one or more projects is assigned to the projects.

While the tasks assigned to each functional unit are repetitive and can be learned by repetition, the work content of each project must be defined and properly allocated to individuals and organizations participating in the project. The work breakdown structure (WBS) is the tool commonly used to ensure proper division of labor and integration of the project deliverables.

2. HIERARCHIES IN THE PROJECT ENVIRONMENT: THE NEED FOR A WORK BREAKDOWN STRUCTURE

2.1. Introduction

As discussed in Section 1, the natural division of labor that exists in a functional organization is missing in projects. It is important to divide the total scope of the project (all the work that has to be done in the project) among the individuals and organizations that participate in it in a proper way, a way that ensures that all the work that has to be done in the project (the project scope) is allocated to participants in the project while no other work (i.e., work that is not in the project scope) is being done. A framework composed of two hierarchical structures known as the work breakdown structure (WBS) and the organizational breakdown structure (OBS) is used for dividing the project scope amongst the participating individuals and organizations in an efficient and effective way, as discussed next.

2.2. The Scope

In a project context the term scope refers to:

- The product or service scope, defined as the features and functions to be included in the product of service
- The project scope, defined as the work that must be done in order to deliver a product or service with the specified features and functions

The project total scope is the sum of products and services it should provide. The work required to complete this total scope is defined in a document known as the statement of work, or scope of work (SOW). All the work that is required to complete the project should be listed in the SOW along with explanations detailing why the work is needed and how it relates to the total project effort.

An example of a table of contents of a SOW document is given in the Appendix. This example may be too detailed for some (small) projects, while for other (large) projects it may not cover all the necessary details. In any case, a clearly written SOW establishes the foundation for division of labor and integration.

2.3. Implementing Division of Labor in Projects

The SOW is translated into a hierarchical structure called the work breakdown structure (WBS). There are many definitions of a WBS:

1. The Project Management Institute (PMI) defines the WBS as follows: ''A deliverable–oriented grouping of project elements which organizes and defines the total scope of the project. Each descending level represents an increasingly detailed definition of a project component. Project components may be products or services'' (PMI 1996).
2. MIL-STD-881A defines WBS as ''a product-oriented family tree composed of hardware, services and data which result from project engineering efforts during the development and production of a defense material item, and, which completely defines the project, program. A WBS displays and defines the product(s) to be developed or produced and relates the elements of work to be accomplished to each other and to the end product'' (U.S. Department of Defense 1975).

Whatever definition is used, the WBS is a hierarchical structure in which the top level represents the total work content of the project while at the lowest level there are work elements or components. By allocating the lower-level elements to the participating individuals and organization, a clear definition of responsibility is created. The WBS is the tool with which division of labor is defined. It should be comprehensive—that is, cover all the work content of the project and logical—to allow clear allocation of work to the participating individual and organizations as well as integration of the deliverables produced by the participants into the project-required deliverables.

2.4. Coordination and Integration

Division of labor is required whenever the work content of the project exceeds what a single person can complete within the required time frame or when there is no single person who can master all

the knowledge and abilities required for the project. However, the following two reasons that promote division of labor may lead to the failure of the project:

1. Coordination of the work performed by different individuals and organizations is required because outputs (deliverables) of some participants provide inputs to the work of other participants in the project. For example, in a construction project, civil engineers and architects produce the design while construction workers perform construction work. However, without the plans and drawings produced by the design team, construction workers cannot do their work.
2. The ability to integrate the deliverables produced by different participants is crucial. Thus, for example, the fact that in a new car development process one team developed an outstanding new body for the car and another team developed a state-of-the-art engine does not guarantee a project's success. Only a successful integration of the engine with the car that results in a vehicle that satisfies all the requirements and specifications of the project constitutes a success. For example, if the car becomes unstable after engine assembly due to a high center of gravity caused by the location of the assembled engine, the fact that the car body is excellent and the engine performs very well does not make the project a success.

In addition to defining the division of labor in the project, the WBS should support integration and coordination. Properly designed WBS is the tool for division of labor, integration, and coordination.

3. THE RELATIONSHIP BETWEEN THE PROJECT ORGANIZATION AND THE WORK BREAKDOWN STRUCTURE

3.1. Introduction

As explained earlier in this chapter, the WBS is designed to support the division of the project scope (work content) amongst the individuals and organizations participating in the project, which is accomplished by combining the WBS with the project organizational breakdown structure (OBS). The combined framework of OBS and WBS allocates each component of the project scope defined at the lowest WBS level to an organizational unit or a specific individual responsible for it in the OBS. The emerging framework of two hierarchical structures integrated at the lowest level provides an important tool for project-planning execution and control.

3.2. Responsibility

To support division of labor, the WBS should integrate with the organizational breakdown structure (OBS) of the project. The OBS is a hierarchical structure that depicts the relationship among the organizations and individuals participating in the project. At the top level of the OBS is the project manager, and at the bottom are individuals responsible for the accomplishment of specific work content in the WBS. These subprojects allocated to responsible managers are known as work packages. The manager of a work package is an expert in its product scope and project scope. Thus, all the project-management processes at the work package level are the responsibility of the work package manager. These include tasks such as scheduling the activities of the work packages, assigning resources, estimating cost, and monitoring and control. The work package tasks related to the product scope are also the responsibility of the work package manager. These tasks are specific to the work package and may include such activities as design, manufacturing, training, testing, and support.

The assignment of responsibility to the work package managers should be based on a clear definition of the work content of the work package, including:

- Deliverables and the delivery time of each
- Required inputs to the work package (data, output from other work packages, etc.)
- Required resources to perform the work package
- Cost of performing the work package
- Tests and design reviews

When a work package is subcontracted, the definition is part of the contract. However, when the work package is performed internally, it is important to define the content of the work package as well as all other points listed above to avoid misunderstanding and a gap in expectations between the performing organization and the project manager. A special tool called the responsibility assignment matrix (RAM) relates the project organization structure to the WBS to help ensure that each element in the project scope of work is assigned to an individual. As an example, consider a project in which six work packages, A, B, C, D, E, and F, are performed by an organization with three

departments, I, II, and III. Assuming that in addition to the project manager the three department heads, the CEO, and the controller are involved in the project, an example RAM follows:

Work Package Person	A	B	C	D	E	F
CEO	S					
Controller	R	R	R	R	R	R
Project manager	A	S	S	S	S	S
Head Department I	P		I	P	I	A
Head Department II	I	P	A	P	A	
Head Department III	P	A	I	A	P	I

Legend:

- P: Participant
- A: Accountable
- R: Review required
- I: Input required
- S: Sign-off required

3.3. Authority

Along with the responsibility for on-time completion of the content of the work package and performance according to specifications, the work package managers must have proper authority. Authority may be defined as a legal or a rightful power to command or act. A clear definition of authority is important for both project scope and product scope. For example, the work package managers may have the authority to delay noncritical activities within their slack but have no authority to delay critical activities—this is the authority of the project manager only. In a similar way, the work package manager may have the authority to approve changes that do not affect the product form fit or function, while approval of all other changes is by the project manager. The authority of work package managers may differ according to their seniority in the organization, the size of the work package they are responsible for, geographical location and whether they are from the same organization as the project manager. Clear definition of authority must accompany the allocation of work packages in the WBS to individuals and organizations.

3.4. Accountability

Accountability means assuming liability for something either through a contract or by one's position of responsibility. The project manager is accountable for his own performances as well as the performances of other individuals to whom he delegates responsibility and authority over specific work content—the managers of work packages. The integration of the WBS with the OBS through the responsibility assignment matrix (RAM) is a major tool that supports the mapping of responsibility, authority, and accountability in the project.

To make the WBS an effective tool for project management, it should be properly designed and maintained throughout the project life cycle. The project's work content may be presented by different WBS models, and the decision which one to select is an important factor affecting the probability of project success.

4. THE DESIGN OF A WORK BREAKDOWN STRUCTURE AND TYPES OF WORK BREAKDOWN STRUCTURES

4.1. Introduction

The WBS serves as the taxonomy of the project. It enables all the project stakeholders—customers, suppliers, the project team itself, and others—to communicate effectively throughout the life cycle of the project. For each project, one can design the WBS in several different ways, each emphasizing a particular point of view. However, different WBS patterns call for different organizational structures or management practices during the implementation of the project. Thus, the design of the WBS at the early stage of the project life cycle may have a significant impact on the project success. Often the individuals who prepare the WBS are not aware of the crucial role they play in determining future coordination and understanding among the operational units who eventually execute the work

packages. A mismatch among the WBS, the OBS, and the management style of the project manager may lead to a poor project-completion record. Such difficulties are compounded if different parties that are involved in the project have produced different WBSs. In this section, we present alternative WBS patterns and explain their possible impact on OBS and management practices. We use an example project to illustrate different patterns and indicate their strengths and weaknesses. The example project assumes that a large multinational corporation operating in the semiconductor business has just finished evaluating existing and future markets and obtained forecasts on the demand for its products in the next five years. Based on these forecasts, the firm has decided it will need five new plants (also known as FABs) in addition to the nearly dozen it currently operates. Labor availability, wage levels, and tax regulations were chief considerations affecting the decision to construct the plants in three countries.

The various WBS formats shown below can all be useful in describing the expansion project. We denote them as WBS based on technology, life cycle, geography, and so on, according to the focus of the second level in the WBS hierarchy. By choosing the focus of that crucial level, the WBS designer determines the fundamental structure of the project. Still, the designer has to make similar decisions at the third level, fourth level, and so on, but these are secondary choices compared with the second level.

4.2. A WBS Based on Technology

Projects that are characterized by a relatively high degree of specialization, especially those associated with the high-tech sector of the economy, typically require the assignment of a leading professional to lead all the project activities that are related to a particular technology. This professional is expected to maintain the same standards of quality and performance among the different facilities. Thus, this WBS format would fit especially well organizations that are structured in a functional hierarchy (see Section 1.2). This type of WBS will be a favorite for managers preferring strong central control of the project because every activity in the different locations is reported to the headquarters (where the professionals heading the various technologies are based). Figure 1 illustrates a WBS by technology in our case.

4.3. A WBS Based on Project Life Cycle

Organizing the WBS by the various stages of the project life cycle (or, more generally, by time) is not a particularly common practice. Still, it may fit certain organizations that elect to orchestrate their activities by timing. For example, the FABs construction project may be outsourced to a number of subcontractors, starting with a subcontractor in charge of preparing detailed floor plans and construction programs, followed by another contractor charged with all the infrastructure activities, and so on. This will lead to the WBS presented in Figure 2. The work content is first broken by the major stages of the project (from design to delivery). Then each stage is further broken down to its relevant categories. This process is repeated, sometimes to 7–10 levels or even more, until we reach the final level of the work packages.

4.4. A WBS Based on Geography

Breaking the work by geography lends itself quite easily to the assignment of five plant managers, each responsible for the entire work required for establishing his plant. In a way, this amounts to breaking the project into five identical subprojects, each duplicating the activities undertaken by the others. Obviously, this will be the preferred mode when the circumstances (culture, language, type of government, law system, etc.) are dramatically different in the different countries. This type of WBS will fit decentralized management practices in which local plant managers are empowered with full authority (and responsibility) for the activities relating to their respective plants.

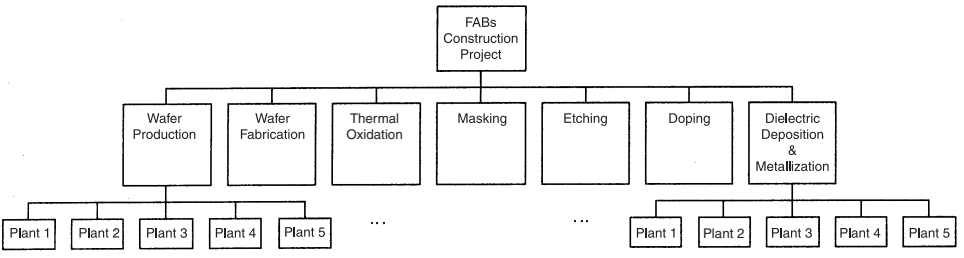

Figure 1 WBS by Technology.

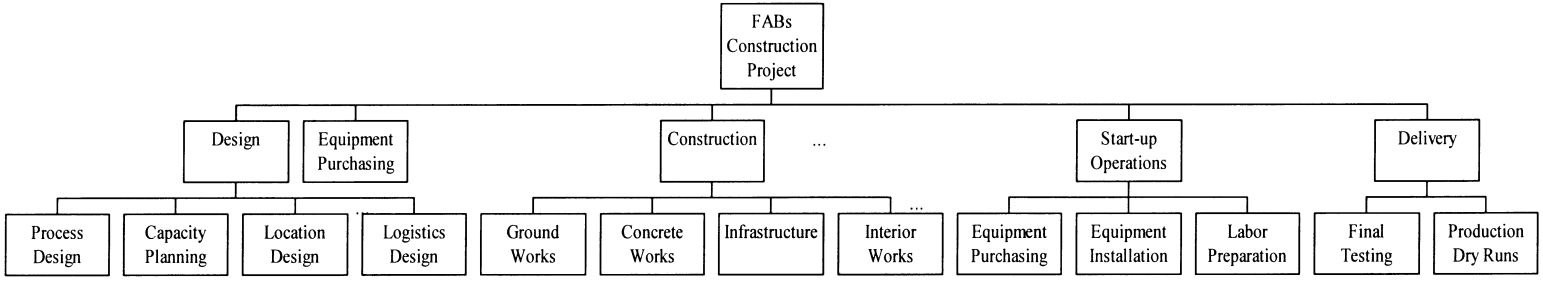

Figure 2 WBS by Project Life Cycle.

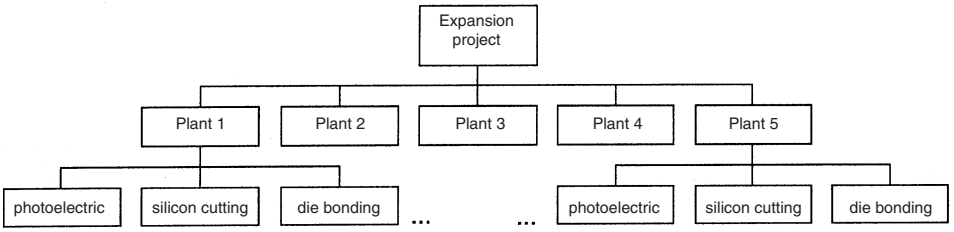

Figure 3 WBS by Geography.

4.5. Other WBS Designs

There are many other possible orientations in which a WBS can be designed. The choice among them depends on the organization charged with the project execution. For example, the growing recognition of the importance of supply chain management has caused some organizations to adopt structures that are logistics oriented. In such cases, we may find at the second level of the WBS a breakdown by logistics functions as illustrated in Figure 4. Other organizations favor structures oriented towards subsystems. That is, the entire system is divided into its major subsystems. In our case, a FAB can be divided into the warehouse subsystem (receiving and checking raw materials, packing and shipping finished goods), shop-floor subsystem (scheduling and dispatching jobs), quality control subsystem (testing components and finished units), and so on. These subsystems serve as the entities in the second level of the WBS.

4.6. Discussion

We conclude this section with a summary of the pros and cons in using a WBS to plan a project.

- *Advantages:*
  - The WBS reflects the project objectives. By listing all the activities required to accomplish these objectives, it prevents confusion and doubts as to the aim of the project.
  - The WBS creates a common database and a dictionary of common notation that serves as a reference point for all involved parties.
  - The WBS, in conjunction with the OBS, defines the way the project is to be managed. It relates each work activity to the corresponding organizational unit that is responsible for delivering the work.
  - The WBS enables smooth communications among the project team members and between them and customers, suppliers, regulators, etc.
  - The WBS serves as an archive that can later facilitate knowledge transfer to other projects or learning by new members of the workforce.
  - The WBS is an effective tool for resource management.
- *Disadvantages:*
  - The WBS requires a significant amount of effort to build and maintain.
  - The WBS encourages rigid structure for the project. Thus, it reduces managerial flexibility to initiate and lead changes during the project life cycle.

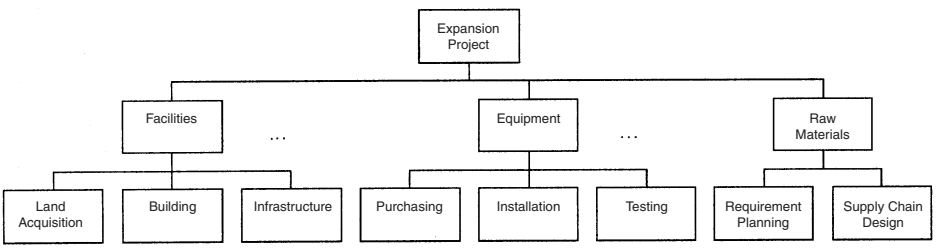

Figure 4 WBS by Logistics.

- There are many legitimate ways to view a project, and occasionally, depending on circumstances, one approach may be preferred to others. Yet the WBS forces the project designer to choose one approach and remain with it throughout the project life cycle.

5. WORK PACKAGES: DEFINITION AND USE

5.1. Introduction

At the lowest levels of the WBS and OBS, integration between the two hierarchical structures takes place. The assignment of specific work content (project scope) to a specific individual or organization creates the building bocks of the project-management framework: the work packages. In the following section, a detailed discussion of the definition and meaning of work packages is presented along with a discussion of the cost accounts that accompany each work package, translating its work content into monetary values for the purpose of budgeting and cost control.

5.2. Definition of Work Packages

The PERT Coordinating Group (1962) defined a work package (WP) as ''The work required to complete a specific job or process, such as a report, a design, a documentation requirement or portion thereof, a piece of hardware, or a service.'' PMI (1996) states: ''[A] work package is a deliverable at the lowest level of the WBS.'' Unfortunately, there is no accepted definition of the WPs nor accepted approach to link them with other related structures (foremost among them the OBS). In most cases, the WPs are defined in an informal, intuitive manner and without proper feedback loops to verify their definition.

One of the difficulties in defining the WPs is the trade-off between the level of detail used to describe the WPs and the managerial workload that is involved. On the one hand, one wishes to provide the project team with an unambiguous description of each work element to avoid unnecessary confusion, overlap, and so on. On the other hand, each WP requires a certain amount of planning, reporting, and control. Hence, as we increase the level of detail, we also increase the overhead in managing the project. To overcome this problem, some organizations set guidelines in terms of person-hours, dollar-value, or elapsed time to assist WBS designers in sizing the WPs. These guidelines are typically set to cover a broad range of activities, and therefore they ignore the specific content of each WP. Hence, they should be applied with care and with appropriate adjustments in places where the work content requires them.

Planning the work by the WPs and structuring it through the WBS is closely related to another important planning activity—costing the project. By dividing the project into small, clearly defined activities—the WPs—we provide a better information basis to estimate the costs involved. For example, consider the activity of design of the FAB processes. It is much easier to estimate its components when they are considered separately (designing the silicon melting and cooling process, silicon cutting, grounding and smoothing, etc.). Furthermore, the separate components may require different cost-estimation procedures or expertise.

Another consideration is related to the statistical nature of the cost-estimation errors. The estimation of the cost for each WP involves a random error that, assuming no particular bias, can be either positive or negative. As the cost estimates are aggregated up the WBS hierarchy, some of these errors cancel each other and the relative size of the aggregated error decreases. This observation holds as long as there is no systematic bias in the estimation procedure. If such a bias exists (e.g., if all the time and cost estimates were inflated to protect against uncertainties), then further decomposition of the WPs may eventually have a negative effect on the overall cost estimate.

In practice, in many scenarios there are limits to the precision that can be achieved in time and cost estimations. Beyond these limits, the errors remain constant (or may even grow). Thus, from the precision perspective, division into smaller WPs should be carried out as long as it improves the estimation accuracy, and not beyond that point.

5.3. Definition of Cost Accounts

Cost accounts are a core instrument used in planning and managing the financial aspects of a project. Three fundamental processes depend on the cost accounts: costing individual activities and aggregating them to the project level for the purpose of preparing project cost estimates; budgeting the project; and controlling the expenses during the project execution.

The first issue, costing the project and its activities, requires the project planner to choose certain costing procedures as well as cost classification techniques. Costing procedures range from the traditional methods to state-of-the-art techniques. For example, absorption cost accounting, a traditional method that is still quite popular, relates all costs to a specific measure (e.g., absorbing all material, equipment, energy, and management cost into the cost of a person-hour) and cost new products or services by that measure. An example of a more advanced cost accounting technique is activity-based costing (ABC), which separately analyzes each activity and measures its contribution to particular products or services.

Cost classification can be done in many ways. Each organization builds its own hierarchy of cost accounts, which is also known as the cost breakdown structure (CBS). In many cases, the CBS is closely linked to the OBS. This means that each organizational unit at the bottom level of the OBS is associated with a cost account. All the expenses planned for the various activities are accounted for through these accounts. Often we find that these cost accounts are further broken down along general accounting principles (e.g., variable vs. fixed costs or manpower, material, equipment, and subcontracting costs). Some organizations prefer to construct the CBS according to the WBS. That is, each WP is associated with a unique cost account. The latter method enables easier control over the individual activities, therefore lending itself more easily to project structure. The former approach might fit better functional structures because it is geared to maintain control over functions rather than activities. It is possible to combine these two approaches by defining the cost accounts at the lowest level of the OBS–WBS level. Then one can aggregate these accounts either by the OBS or by the WBS structures and still obtain consistent estimates at the project-wide level.

Other organizations create the CBS according to the project life cycle. Each of the major life-cycle stages (conceptual design, detailed design, production, operation, divestment) is a major cost account that is further broken down into finer accounts according to secondary criteria (e.g., detailed schedules, functional association). This form of CBS allows the most straightforward control of cost accumulation over time.

The second process, budgeting, uses the cost accounts as a vehicle to generate the project budget. A popular way to generate a budget is through a bottom-up aggregation. The cost accounts associated with individual WPs are aggregated towards a complete budget. Along the way, management may intervene in many ways that may alter the original cost estimates. For example, a ''crashing'' policy may be adopted in order to expedite certain activities as a result of exogenous considerations. This will make the respective budget line larger than the original estimate stated in the cost account. Similarly, a decision to hold certain amounts as ''management reserve'' (a common practice) will also inflate the budget above the original cost accounts. Thus, gaps may exist between the budget and the cost estimate of WPs and the WBS as a whole. However, even with these gaps, the cost accounts are the basis for building and maintaining the budget for every project.

Based on cost estimates, allocated budget, and other considerations (primarily competitive pressure), the pricing of the project is established. The project price may be above or below its cost or its budget, depending on management policies and extraneous constraints.

The third process, financial control of the project, is again based on the cost accounts. The basic control method is an ongoing comparison between actual and planned cost accumulation. Methods such as the earned value technique develop ratio measures that help the controller to analyze the schedule and cost deviations over time and employ control limits as triggers for corrective action. The control is usually performed at the WP cost account level.

6. USING THE WORK BREAKDOWN STRUCTURE: EXAMPLES

6.1. R&D Projects

Managing R&D projects is among the toughest areas in project management. These projects are characterized by a high degree of uncertainty, and consequently a large proportion of them is never completed. The importance of careful planning in this environment cannot be overstated.

The diagram in Figure 5 illustrates a WBS planned for an R&D project aimed at developing a new product. The second level of this WBS is organized by the project life cycle, and the third level corresponds to functional departments that are involved in the project.

6.2. Equipment-Replacement Projects

Every technology-intensive firm is challenged from time to time with equipment-replacement projects. This type of project is especially common in the high-tech sector, where the frequency of such projects is now measured in months rather than years. The WBS presented in Figure 6 focuses at its second level on the division among activities related to the facility and its infrastructure (requiring civil engineering expertise), activities related to the equipment itself (requiring mechanical engineering expertise), and activities related to manpower (requiring human resource expertise).

Unlike the previous example, the third level is not identical across the three entities of the second level. A greater level of detail is needed to describe the equipment-related activities, and so the corresponding WBS branch is more developed.

6.3. Military Projects

To demonstrate the wide-range applicability of the WBS concept, we close this section with an example of a military operation. An army unit (say, a brigade) is faced with a mission to capture a riverbank, construct a bridge, and secure an area (bridgehead) across the river, thus enabling the movement of a larger force in that direction. Figure 7 illustrates how this mission can be planned through WBS principles. The second level of the WBS is arranged by the major military functions

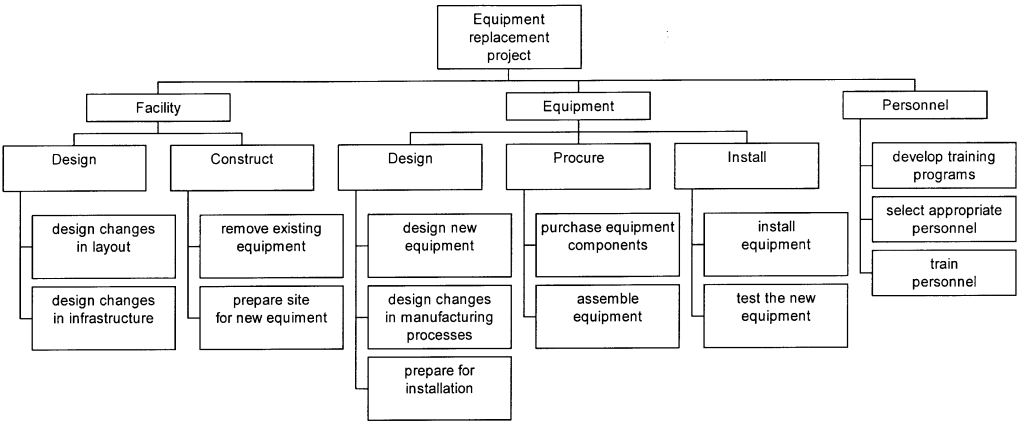

Figure 5 WBS for an R&D Project.

that are involved, and the third level is arranged by the life-cycle (illustrated here with a basic distinction between all precombat activities and during-combat activities).

7. CHANGE CONTROL OF THE WORK BREAKDOWN STRUCTURE

7.1. Introduction

Projects are often done in a dynamic environment in which technology is constantly updated and advanced. In particular, projects in high-tech organizations go through several major changes and many minor changes during their life cycle. For example, the development of a new fighter plane may take over a decade. During this time, the aircraft goes through many changes as the technology that supports it changes rapidly. It is quite common to see tens of thousands of change proposals submitted during such projects with thousands of them being implemented. Without effective control over this process, all such projects are doomed to chaos. Changing elements in the WBS (deleting or adding work packages or changing the contents of work packages) belong to an area known as configuration management (CM). CM defines a set of procedures that help organizations in maintaining information on the functional and physical design characteristics of a system or project and support the control of its related activities. CM procedures are designed to enable keeping track of what has been done in the project until a certain time, what is being done at that time, and what is planned for the future. CM is designed to support management in evaluating proposed technological

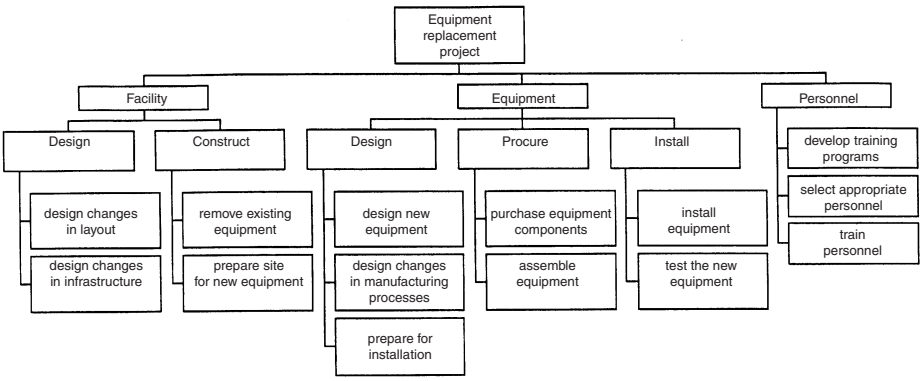

Figure 6 WBS for an Equipment-Replacement Project.

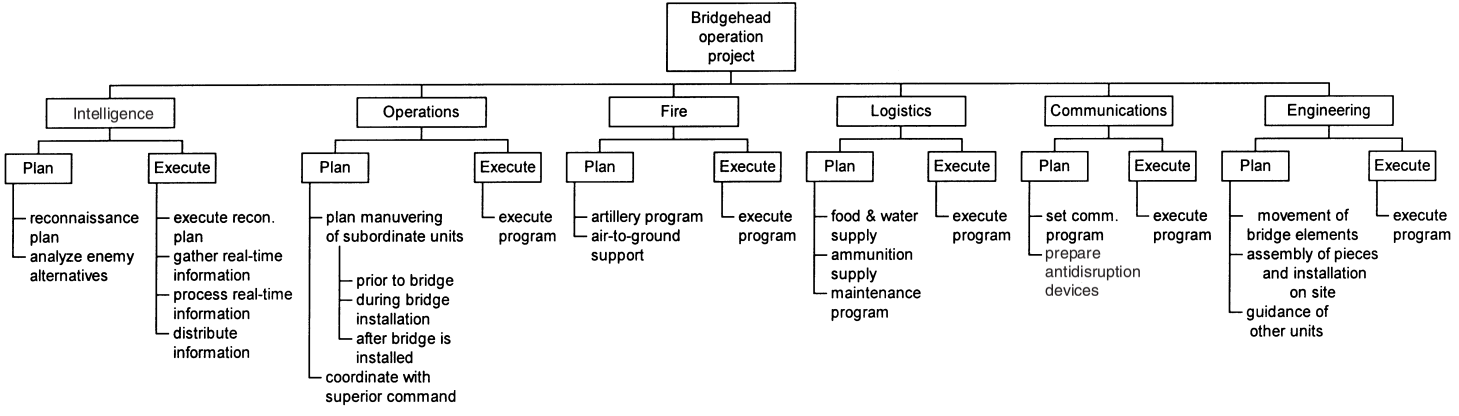

Figure 7 WBS of Military Operation.

changes. It relies on quality assurance techniques to ensure the integrity of the project (or product) and lends itself easily to concurrent engineering, where certain activities are done in parallel to shorten time-to-market and secure smooth transitions among the design, production, and distribution stages in the project life cycle. Change control involves three major procedures, which are outlined below.

7.2. Change Initiation

Changes can be initiated either within the project team or from outside sources. Either way, to keep track of such initiatives and enable organizational learning, a formal procedure of preparing and submitting a change request is necessary. A complete change request should include the following information:

- *Pointers and identifiers:* These will enable the information system to store and retrieve the data in the request. Typical data are request i.d.; date, name or originator; project i.d.; configuration item affected (e.g., work packages i.d., part number i.d.).
- *Description of change:* A technical description (textual, diagrammatic, etc.) that provides full explanation on the content of the proposed change, the motivation for the proposal, the type of change (temporary or permanent), and suggested priority.
- *Effects:* A detailed list of all possible areas that might be affected (cost, schedule, quality, etc.) along with the estimated extent of the effect.

7.3. Change Approval

Change requests are forwarded to a team of experts who are capable of evaluating and prioritizing them. This team, often known as the change control board (CCB), evaluates each proposed change, taking into account its estimated effects on the various dimensions that are involved. Foremost among these criteria are the cost, schedule, and quality (or performance) issues. However, other criteria, such as contractual agreements and environmental (or collateral) effects, are also considered. The review is done both in absolute and relative terms. Thus, a proposed change may be rejected even if it leads to overall improvement in all relevant areas if there are other changes that promise even better effects. If the board approves a change, it needs to specify whether the change is temporary or permanent. Example of temporary changes are construction of a partial pilot product for the purpose of running some tests that were not planned when the project was launched, releasing an early version of a software to a ''beta'' site to gain more insights on its performance, and so on. It can be expected that approval of temporary changes will be obtained more easily and in shorter time spans than the approval of permanent changes.

The CCB is responsible for accumulating and storing all the information on the change requests and the outcomes of the approval process. Maintaining a database that contains all the relevant information on the changes usually facilitates this process. The database should enable easy access to future queries, thus facilitating continuous organizational learning.

7.4. Change Implementation

Changes that were approved, on either a temporary or a permanent basis, are to be integrated into the project. The information on approved changes is usually disseminated to all involved parties through an engineering change order. This form contains all the information that might be required by the various functions (engineering, manufacturing, quality assurance, logistics). Proper change implementation requires the creation of feedback loops that will provide information on the impact of the implemented change. There is a need to verify that this impact is consistent with the estimated effects that were analyzed during the approval stage. These feedback mechanisms alert the system to any departure from the planned effects and help management to identify potential troubles before they actually occur. As before, the information that flows in these loops is recorded in the CM database to support further learning and improvement.

8. THE WORK BREAKDOWN STRUCTURE AND THE LEARNING ORGANIZATION

8.1. Introduction

In addition to supporting division of labor and integration, the WBS–OBS framework is an effective tool for the accumulation, storage, and retrieval of information at the individual and organizational levels. By using templates of work breakdown structures as the project dictionary, it is possible to accumulate information about the actual cost duration and risks of project activities and work packages. This information is the basis for a continuous learning process by which, from one project to the next, a database is developed to support better project planning and management as well as the training of individuals and groups. The next section discusses individual and organizational learning in the project environment.

8.2. WBS as a Dictionary for the Project

The division of labor among the parties participating in a project supports specialization. It is also an answer to the need to finish the project work content within a predetermined schedule, which is not determined by the amount of work to be performed. Due to the division of labor, it is possible to perform each part of the work content of the project by the best experts within the required time frame.

These benefits of the division of labor do not come for free—they carry the risks associated with integration. Integration of information, knowledge, and deliverables produced by the different work packages must be based on a common language to ensure a smooth and fault-free process. This common language is based on the WBS.

A well-planned WBS serves as a dictionary of a project. Because each work package is defined in terms of its work content, its deliverables, its required inputs (data, information, resources, etc.), and its relationship to other work packages within the WBS, all the stakeholders have a common reference or a common baseline. Furthermore, careful management of changes to the WBS throughout the project life cycle provides a continuous update to the project dictionary.

Learning a common language is easier if the same language is used over a long period of time and becomes a standard. Thus, organizations involved in similar projects should strive to develop a WBS template that can serve most of the projects with minor modifications. This is easier if the projects are repetitive and similar to each other. However, if there are major differences among projects, the WBS representing the project scope (as opposed to the product scope) can be standardized if the processes used for project management are standardized in the organization. Thus, by developing a standard set of project-management processes and supporting these standards by appropriate information technology tools, it is possible to standardize the project part of the WBS and make it easier to learn. A standard WBS ensures that project-management knowledge and practices are transferred between projects and become common knowledge in the organization.

8.3. Information Storage and Retrieval

The flow of information within and between projects is a key to the organizational learning process. Information generated in one project can serve other projects either by transferring people between the projects, assuming that these people carry information with them, or by a carefully planned method of information collection, storage, and retrieval. A library-like system is required to support the transfer of information, which is not based on human memory. A coding system that supports an efficient search and retrieval of information or data for the estimation of cost, duration, risks, and so on. is required. In the extreme, such a system can help the planner of a new project to identify parts of historical projects similar to the new project he or she is involved with. Such subprojects that were performed in past projects can serve as building blocks for a new project. A carefully planned WBS is a natural coding system for information collection, storage, and retrieval. Work packages performed on past projects can serve as templates or models for work packages in new projects if the same WBS is used.

Developing WBS templates for the types of projects performed by the organization enables a simple yet effective information storage and retrieval system to be developed. Even if some of the projects are unique, a good coding system based on WBS templates can help in identifying similar parts in projects, such as parts related to the project scope. The ability to retrieve complete work packages and use them as building blocks or parts of work packages and as input data for estimation models enhances the ability of organizations to compete in cost, time, and performance.

8.4. The Learning Organization

The transfer of information within or between projects or the retrieval of information from past projects provides an environment that supports the learning organization. However, in addition to these mechanisms, a system that seeks continuous improvement from project to project is required. This can be done if the life cycle of each project is examined at its final stage and conclusions are drawn regarding the pros and cons of the management tools and practices used. Based on a thorough investigation of each project at its completion, current practices can be modified and improved, new practices can be added, and, most importantly, a new body of knowledge can be created. This body of knowledge can, in turn, serve as a basis for teaching and training new project managers in how to manage a project right.

APPENDIX
Table of Contents for a SOW document

- Introduction: project scope and general description
- Type of project (development, production, construction, maintenance, etc.)
- A description of final deliverables, intermediate deliverables and delivery schedule
- Main phases in project life cycle: a short description of each phase, its deliverables and its work content
- Applicable documents
- Operational requirements
- Technical specifications
- Applicable standards
  - Applicable laws and regulations
  - Applicable procedures
  - Other applicable documents
- Development
  - Conceptual design
  - Functional design
  - Detailed design
  - Prototypes required
  - Deliverables of development phase
- Production and construction
  - Quantities to be delivered and delivery schedule
  - Accompanying documents (production documents, product documents)
- Markings and signs
  - Mechanical markings and signs
  - Electrical markings and signs
  - Other markings and signs
- Purchasing
  - Purchasing in state
  - Purchasing abroad
  - Subcontractors management
  - Suppliers management
  - Purchasing of critical and long-lead items
- Testing
  - Master plan for testing
  - Detailed plans for each test
  - Performance approval testing
  - Functional tests
  - Environmental conditions testing
  - Commercial production testing
  - Acceptance testing at the supplier's site
  - Acceptance testing at the customer's site

- Prototypes
- Reliability and maintainability
  - Anticipated reliability (calculations of MTBF)
  - Fault tree analysis (FTA)
  - Anticipated maintainability (calculations of MTTR)
  - Maintainability analysis and level of repair
- Adaptability
  - Electromagnetic (RFI/EMI) requirements and tests
  - Adaptability requirements to existing hardware and software systems.
- Integrated logistics support (ILS)
  - Engineering support (maintenance plans, maintenance during warranty, engineering support after warranty period)
  - Spare parts (during warranty period, recommended spare parts list, spare parts supply after warranty period)
  - Training (initial training in maintenance and operation, training literature and other aids, training during system life cycle)
  - Documentation: description of documentation to be supplied for training, maintenance, operation, and logistic support.
  - Project documentation: design reviews test documents, etc.
  - Data and its storage: means for data storage and retrieval during and after the project
- System's acceptance
  - Acceptance tests
  - Milestones for acceptance and payments
  - Support during acceptance and commissioning
  - Spare parts supply during acceptance
  - Support equipment for acceptance and testing
  - Packaging and shipment
- Installation at customer's site
  - Packaging and shipping requirements
  - Permissions, export and import licensing
  - Constraints in the installation site
  - Master plan for installation
  - Logistical, technical, and operational responsibility for installation
  - Acceptance testing after installation
  - Training at customer's site
  - Maintenance during installation and commissioning
- Project management: planning and control
  - Project phases
  - Deliverables of each phase
  - Work breakdown structure
  - Organizational breakdown structure
  - Work packages
  - Schedule and milestones
  - Progress reports and updates
  - Human resources, equipment, and materials
  - Data required and data supplied
  - Project budget and budget control
  - Risk identification, quantification, and management
  - Configuration management and change control
  - Milestones and related payments
  - Project monitoring system, regular reports, exception reports, meetings, and design reviews
  - Approval of subcontractors and suppliers
  - Software for project management

- Quality assurance and reliability
  - Quality assurance plan
  - Quality procedures
  - Quality and reliability analysis
  - Quality reports
  - Quality control and reviews
- Documentation
- Operational requirements
  - Technical specifications
  - Engineering reports
  - Testing procedures
  - Test results
  - Product documentation
  - Production documentation
  - Drawings
  - Definition of interfaces
  - Operation, maintenance, and installation instructions
  - Software documentation (in the software itself and in its accompanying documents)
- Warranty
- Customer-furnished equipment

CHAPTER 48

Planning and Integration of Product Development

HANS-JÖRG BULLINGER, JOACHIM WARSCHAT, JENS LEYH, AND THOMAS CEBULLA
Fraunhofer Institute of Industrial Engineering

1. INTRODUCTION

1.1. Overview

Today's market is characterized by keen international competition, increasingly complex products, and an extremely high innovation dynamic. Parallel to the shortening of innovation cycles, the life cycles of products and the time until investments pay off are decreasing.

Thus, time is presently the most challenging parameter. Fast, successful positioning of new products on the market has become vital for a company, and the development of innovative products needs to be accelerated. The production of prototypes is significant for a rapid product development (RPD) process.

One feature of this process is the coordination of work tasks within the distributed teams. It will become increasingly important to bring together the different experts. Effective and efficient project management is the basis for the way a team functions. The early integration of different experts serves as a means to develop innovative products. This is also an important factor concerning costs because the main part of the end costs are determined in the early phases of product development. To facilitate the integration of different experts and enhance the efficiency of the iterative phases, prototypes are used as cost-efficient visual models.

1.2. New RP Technologies

Generative prototyping technologies, such as stereolithography (STL), reduce prototyping lead times from a few hours to up to three months, depending on the quality required. These prototypes can serve as visual models or as models for follow-up technologies such as casting.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

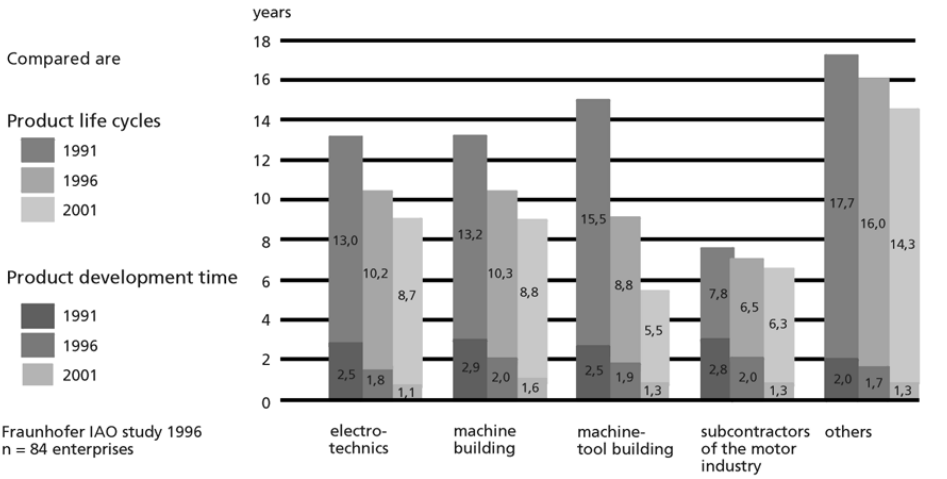

Figure 1 Product life cycles and Development Times.

New, powerful CAD technologies make it possible to check design varieties in real time employing virtual reality tools. The use of virtual prototypes, especially in the early phases of product development, enables time- and cost-efficient decision making.

1.3. Communication Technologies

ATM (asynchronous transfer mode) networks (Ginsburg 1996) and gigabit ethernet networking (Quinn and Russell 1999) enable a quick and safe exchange of relevant data and thus support the development process tremendously. The Internet provides access to relevant information from all over the world in no time, such as via the World Wide Web or e-mail messages. Communication and cooperation are further supported by CSCW tools (Bullinger et al. 1996) like videoconferencing and e-mail. The distributed teams need technical support for the development of a product to enable synchronous and asynchronous interactions. Furthermore, the Internet provides a platform for the interaction of distributed experts within the framework of virtual enterprises. The technologies used support the consciousness of working temporarily in a network, which includes, for example, the possibility of accessing the same files. All these new technologies have been the focus of scientific and industrial interest for quite a while now. However, the understanding how these new technologies can be integrated into one continuous process chain has been neglected. Combining these technologies effectively enables the product-development process to be reduced decisively. Rapid product development is a holistic concept that describes a rapid development process achieved mainly by combining and integrating innovative prototyping technologies as well as modern CSCW (computer-supported cooperative work) tools.

Objectives of the new concept of RPD are to:

- Shorten the time-to-market (from the first sketch to market launch)
- Develop innovative products by optimizing the factors of time, cost, and quality
- Increase quality from the point of view of the principle of completeness

2. CHARACTERISTICS OF RAPID PRODUCT DEVELOPMENT

2.1. The Life Cycle

Simultaneous engineering (SE) considers the complete development process and thus carries out the planning on the whole. RPD, on the other hand, considers single tasks and the respective expert team responsible for each task. SE sets up the framework within which RPD organizes the rapid, result-oriented performance of functional activities. The mere application of SE organization on the functional level leads to a disproportionate coordination expenditure.

The overall RPD approach is based on the idea of an evolutionary design cycle (Bullinger et al. 1996). In contrast to traditional approaches with defined design phases and respective documents, such as specification lists or concept matrices, the different design phases are result oriented.

The whole cycle is subject to constraints from the project environment, such as market developments, legislation, and new technologies. Late changes in customer requirements (Thomke and Reinertsen 1998) make necessary research and development (R&D) management that is able to handle these uncertainties efficiently. Furthermore, the execution of the cycle is not necessarily sequential. For example, results from the generation of prototypes can be directly incorporated into a new design phase.

The idea of evolutionary design means that previously unrecognized product requirements or technological progress be considered and incorporated. This issue leads to an important feature of RPD, namely, the abandonment of a homogeneus definition of a product throughout the project. Each product module has an individual definition. The initial concept is conceptualized for the complete product as well as the final integration of the modules. In between, changes are made through new design methods and tools.

The RPD approach will become more transparent by comparing it to the concept of SE (Bullinger and Warschat 1996). The influencable and controllable parameters of a company will serve as a frame for the comparison (see Table 1):

- Organization
- Processes
- Human and technical resources
- Product

2.2. The Organization

Organizational changes, rearrangement of processes, investment in new machines, and training of staff, as well as new solutions for product structures, are necessary to increase the effectiveness and efficiency of the product-development process.

The organization of a company defines its structures, such as the formation of organizational units and the coordination between the units. Project management, as a method that uses certain tools, influences organizational change to a large extent. Whereas SE exhibits a more or less formalized frame with milestones, RPD requires a reactive project-management methodology. The apparent plan precision within phase-oriented approaches such as SE becomes increasingly inaccurate with proceeding project progress. Hence, it will be replaced by a result-oriented approach, where the plan inaccuracy decreases with the progress of the project. For both development approaches, integration of tasks is needed, with labor being planned, controlled, and steered by one responsible person or team.

TABLE 1 Simultaneous Engineering vs. RPD

Parameter	Element	SE	RPD
Organization	Project management	Formalized	Reactive, individual
	Planning	Product-neutral plan with decreasing accuracy	Result-oriented plan with increasing accuracy
	Labor	Integrated approach	
Process	Structure	Full-process orientation	
	Innovation source	Initial product concept	Continuous improvement and redefinition of concepts
	Development cycles	Avoidance strategy	Active process element
Resources	Data integration	Static	Dynamic
	Communication and coordination media	Short paths and SE teams	Short paths and SE teams and CSCW and ASN
Product	Documents	Unique approval by responsible source	Continuous testing and redefinition of concepts
	Definition	Homogeneous according to modularization	Individual according to project progress
	Data management	Standardized product and process data (STEP)	
	Learning/experiences	For next/from previous project	Within the project

In the early phases of product development, those decisions are made that are relevant for the creation of value. The organization needs to be flexible enough to provide appropriate competencies for decisions and responsibilities.

2.3. The Process

RPD concentrates on the early phases of product development. SE already achieved the reduction of production times. RPD now aims to increase the variety of prototypes through an evolutionary iterative process in order to enable comprehensive statements to be made about the product. The interdisciplinary teams work together from the start. The key factors here are good communication and coordination of everyone involved in the process. Thus, the time for finding a solution to the following problems is reduced:

- There are no customer demands. Therefore, without any concrete forms many solutions are possible, but not the solution that is sought.
- The potential of new or alternative technologies results from the integration of experts, whose knowledge can influence the whole process.
- The changing basic conditions of the development in the course of the process make changes necessary in already finished task areas (e.g. risk estimation of market and technology).

These possible basic conditions have to be integrated into the RPD process to reduce time and costs of the whole process.

The application of processes determines the product development and its effectiveness and efficiency. Product data generation and management process can be distinguished. Hence, it is important for the SE as well as the RPD approach to achieve a process orientation in which both product data generation and management process are aligned along the value chain. In a traditional SE approach, innovation results from an initial product concept and product specification, whereas the RPD concept will be checked and redefined according to the project progress. RPD therefore makes it possible to integrate new technologies, market trends, and other factors for a much longer period. Thus, it leads to highly innovative products. Design iterations are a desirable and therefore promoted element of RPD. The change of design concepts and specifications is supported by a fitting framework, including the testing and the most-important evaluation of the design for further improvement.

2.4. The Human and Technical Resources

Common SE approaches are based on standardized and static product data integration, whereas RPD requires dynamic data management in semantic networks in order to enable short control cycles. Short paths and multidisciplinary teams for quick decisions are essential for both approaches. Moreover, RPD requires team-oriented communication systems, which open up new ways of cooperation. They need to offer support not only for management decisions, but also for decision making during the generation of product data.

In RPD, the people and machines involved are of great importance. The people involved need free space for the development within the framework of the evolutionary concept, and well as the will to use the possibilities for cooperation with other colleagues. This means a break with the Taylorized development process. The employees need to be aware that they are taking part in a continually changing process. The technical resources, especially machines with hardware and software for the production of digital and physical prototypes, have to meet requirements on the usability of data with unclear features regarding parameters. They have to be able to build first prototypes without detailed construction data. The quality of the statements that can be made by means of the prototypes depends on how concrete or detailed they are. For optimal cooperation of the single technologies, it is important to use data that can be read by all of them.

2.5. The Product

The results of the product-development process are the documents of the generated product, such as product models, calculations, certificates, plans, and bills of materials as well as the respective documents of the process, such as drawings of machine tools, process plans, and work plans. The aim of all documentation is to support information management. A documentation focusing on product and process data guarantees project transparency for all the persons involved. The standardization of the whole product data is a basic prerequisite for evolutionary and phase-oriented approaches. STEP (standard for the exchange of product model data), as probably the most promising attempt to standardize product data and application interfaces, offers applicable solutions for quite a few application fields, such as automotive and electronic design, rapid prototyping, and ship building. Documents reflecting parts of the complete product data generated, such as specifications, bills of materials, and process data, represent an important difference between SE and RPD. Whereas in an SE documents are synchronized at a certain time (e.g., milestones), the RPD process documents are subject to

persistent alteration until a certain deadline. Thus, figures can be changed or agreed upon and boundaries narrowed. The RPD approach only sets rough boundaries within which the modules mature individually. This yields in specific project-management questions, such as (re)allocation of resources or synchronization of the overall process, which are presently still subject to research (Malone and Crowston 1994). Therefore, the RPD process focusses specifically on the management of variants and versions.

3. ELEMENTS OF RAPID PRODUCT DEVELOPMENT

3.1. Process Planning

The goals of RPD are to speed up these iteration cycles, on the one hand, and promote learning within the cycle, on the other. The whole development process involves cooperating development teams that are increasingly distributed globally. The functioning of the cooperation between these teams is essential for the success of the development process. This can only be realized by effective coordination of the partial plans of each of the distributed development teams that are part of the overall product-development chain.

The decentralization of decisions and responsibilities enhances the flexibility and responsiveness of development teams significantly. Hence, planning tools used to coordinate the tasks of development teams have to fit the characteristics of a development process. Consequently, a tool that is designed for central planning approaches will not fit the requirements of a decentralized structure. Specifically, issues needed for RPD, such as coordination of decentralized teams or learning within each cycle, are not supported.

Based on the understanding of planning as the initial step for scheduling diverse processes, the planning of processes involved in complex R&D projects must be possible. The planning system has to be suitable for use in surroundings that are characterized by decentralized and multisited operations. A high grade of expression of the generated plans is based on the ability to process of incomplete and inconsistent data. Therefore, support of documentation and planning has to be integrated, too. Because separate development teams have different tasks, adaptability to the type of the development task and consideration of specific situations have to be ensured. For this reason, open and standardized data storage is fundamental for the planning system. Therefore, the team-oriented project planning system (TOPP) has been developed.

In order to ensure a high grade of expression of the plans, time relations as proposed by Allen (1991) have been used for the phase of plan definition. Logical and time-connected relations between tasks to be planned have to be described within the plan definition phase. Based on 13 Allen time relations, the results of each task are described dependent on the relations to other tasks. Therewith all necessary constraints between related tasks can be represented. This is why TOPP differs from critical path methods. This method only uses the start and the finish to describe time relations.

Each distributed team can define the relations between the tasks to be planned within their responsibility by Allen time relations (internal relations). External relations (interfaces) to other distributed development teams can also be defined. These external relations are additional constraints for the backtracking-planning algorithm that forms the basis for calculating the optimal plan.

Further, the planner uses disjunctive relations to define the constraints between tasks in order to take the requirements of uncertainty into account. For example, the planner can determine whether a task A has to start at the same time as task B, or whether task B can start at the same time as task A is finished.

If all other constraints, such as available resources, can be met, each disjunctive relation will lead to one possible plan alternative. The required resources and the expected duration of the task are added to the task to be planned in order to consider the limits of resources adequately.

The first reason for this approach is the high uncertainty and complexity of R&D and RPD projects. The definition of rules forms the basis for the use of automatic resource assignments. Therefore, abstractions and simplifications are needed, which cannot easily be obtained from complex systems such as R&D or RPD projects. Second, planners are subject to cognitive and mental limitations. Hence, the planning system has to support the planner by giving him the ability to compare plan alternatives under various circumstances.

A typical problem in multiattributive decision making is the proposed selection of one plan out of a limited number of plans characterized by specific figures. Since the figures show ordinal quality, the process of selecting the optimum can be supported by using the precedence sum method.

Planning as a complex task can normally not be solved optimally, due to the limited mental capacities of human planners. The use of models to plan projects offers many advantages:

- From a statistic point of view, the probability of finding the optimal plan increases with the number of plans.
- The comparison of plans based on specific figures offers possibilities for finding advantages and disadvantages of each plan. Additionally, the planner is not limited to one plan.

- Failures within obscure and complex structures typical of RPD are detected rather than anticipated.
- Since sensitivity for the different figures increases, there is a support mechanism with regard to the knowledge about the situation.
- The evaluation of plans based on quantifiable figures contributes to the achievement of plans.

Five different scenarios have been implemented in TOPP. A particular planning aspect is emphasized by each scenario. The scenario is defined via characteristic figures such as process coordination, process risk, and process logics. Hence, the planner is given the ability to judge all possible plans from a specific point of view.

According to the scenario, the calculation of the order of precedence always takes place in the same manner. First plans are evaluated in view of first-order criteria (FOC). If plans still show the same ranking, second-order criteria (SOC) are taken to refine the order. If a final order of precedence is still not possible, the ideal solution, defined by the best characteristic numbers of all plans, determines the order. The plan with the least difference from the optimal plan will be preferred.

Decentralized planning within rapid product development involves more than simple distribution of partial goals. Since development teams are distributed and are responsible for achieving their partial goals, different coordination mechanisms are necessary. The coordination of TOPP is based on planning with consistency corridors, an integration of phase-oriented and result-oriented planning and task-oriented planning.

By the use of characteristic numbers and planning scenarios, a new approach has been presented to support the selection of the optimal plan within complex R&D projects and rapid product development (Wörner 1998).

In general, TOPP offers a way to support planners coordinating global engineering projects of rapid product development and R&D.

3.2. Physical Prototyping

3.2.1. Rapid Prototyping

In addition to the conventional manufacturing of physical prototypes (e.g., CNC milling) the rapid prototype technologies (RPT) are gaining more and more importance. RPT makes it possible to produce a physical artifact directly from its CAD model without any tools. Thus, it is possible to build the prototype of a complex part within a few days rather than the several weeks it would take with conventional prototyping.

In the past, great effort has been put into developing RPTs, improving their processes, and increasing the accuracy of the produced parts. The most common techniques today, like stereolithography (STL), selective laser sintering (SLS), solid ground curing (SGC), and fused deposition modelling (FDM), are mainly used to produce design or geometrical prototypes. They are used primarily for aesthetic, ergonomic, and assembly studies or as pattern masters for casting or molding processes. However, up to now current materials and process limitations have hindered their use as technical or functional prototypes. To accelerate the development process, technical and functional prototypes are of great importance. Therefore, it is necessary to develop powerful technologies for rapid production of prototypes with nearly serial characteristics, for example, material or surface quality. In addition to new or improved RPTs, there are promising developments in the field of coating technologies and sheet metal and solid modeling, which will be a valuable contribution.

3.2.2. Rapid Tooling

In addition to rapid prototyping, rapid tooling has become increasingly important in recent years. It offers the possibility of building functional prototypes. Here, the material and the process of the series product is used. With rapid tooling it is possible to build tools rapidly and inexpensively for prototypes parallel to the product development process. Rapid tooling technologies help to make the process from the first sketch to the final product more efficient. A range of technologies is available, from cutting to generative methods and from milling to the direct or indirect metal laser-sintering process.

3.3. Digital Protoyping

Physical prototypes are often time and cost intensive and thus need to be reduced to a minimum. By the combining of CAD technologies, rapid prototyping, virtual reality, and reverse engineering, prototypes can be produced faster and more cheaply then before. The employment of virtual prototypes in the early phases of product development, in particular, optimizes the whole development process (Thomke and Fujimoto 1998). The strategic advantage of digital prototyping is the advancement of decisions from the test phase with physical prototypes to the early phases of product development with digital prototypes. Thus, the process of product development and testing can be considerably

ameliorated. The digital demonstration allows early modification and optimization of the prototype. Furthermore, it leads to a cost-saving increase in the variety of prototypes. By means of virtual prototypes product features can be easily verified and thus development times can be reduced enormously. Also, faults concerning fabrication or the product itself can be detected in the early development phases and thus be eliminated without great expenditures. This makes it possible to start product planning at an early stage. Due to the early overlapping of development and fabrication, additional synergy effects can be expected. Prerequisites for digital prototyping are the following three areas: CAD, simulation, and virtual reality. Simulation (Rantzau and Thomas 1996) and CAD data produce quantifiable results, whereas the connection with VR technologies enables a qualitative evaluation of the results (Figure 2).

An important component of digital prototyping is the digital mock-up (DMU), a purely digital test model of a technical product. The objective of the DMU is the current and consistent availability of multiple views of product shape, function, and technological coherences. This forms the basis on which the modeling and simulation (testing) can be performed and communicated for an improved configuration of the design. This primary digital design model is also called the virtual product. The virtual product is the reference for the development of a new product, specifically in the design and testing phase. The idea is to test the prototype regarding design, function, and efficiency before producing the physical prototype. Thus, effects of the product design can be detected in a very early phase of product development. This way, possible weaknesses of the physical prototype can be detected and corrected in the design phase, before the physical prototype is built. An enormous advantage of the DMU is the shortening of iteration cycles. The decisive changes in the digital prototype are carried out while the physical prototype is being built. During this period, the DMU process can achieve almost 100% of the required quality by means of corrections resulting from the simulation processes. The development process without DMU, on the contrary, requires further tests

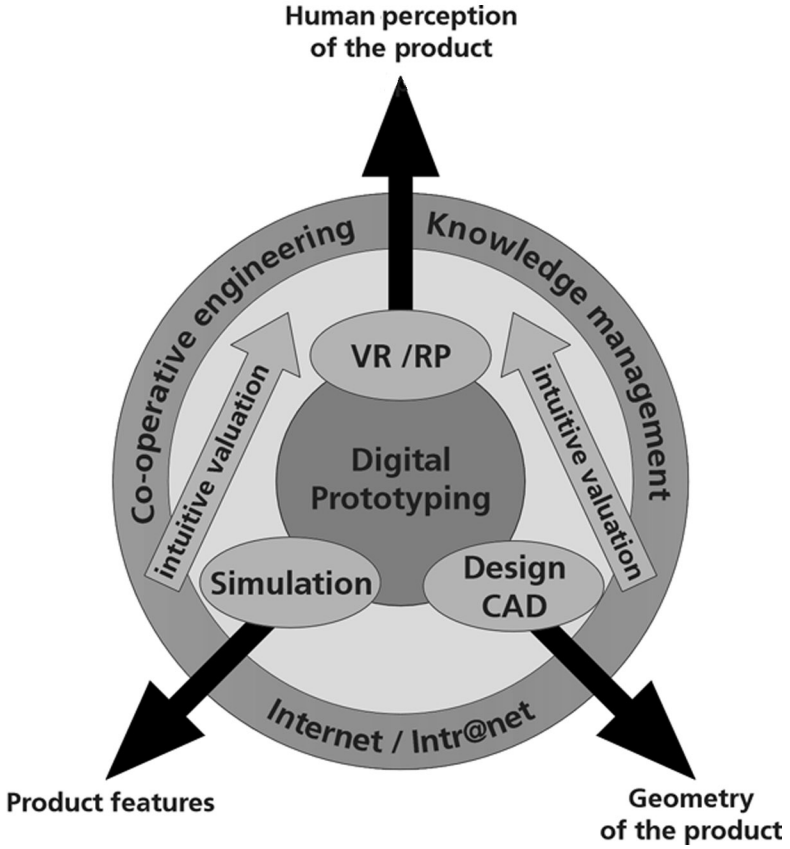

Figure 2 Application Triangle.

with several physical prototypes before the end product can be produced. This means that employing the DMU considerably reduces the time-to-market. The DMU platform also offers the possibility for a technical integration of product conception, design, construction, and packaging.

Digital prototyping offers enormous advantages to many different applications, such as aircraft construction, shipbuilding, and the motor industry. Fields of application for digital prototyping in car manufacturing are, for example:

- Evaluation of components by visualization
- Evaluation of design variations
- Estimation of the surface quality of the car body
- Evaluation of the car's interior
- Ergonomic valuation with the aid of virtual reality

To sum up, creating physical or virtual prototypes of the entire system is of utmost importance, especially in the early phases of the product-development process. The extensive use of prototypes provides a structure, a discipline and an approach that increases the rate of learning and integration within the development process.

3.4. The Engineering Solution Center

The use of recent information and communication technology, interdisciplinary teamwork, and an effective network is essential for the shortening of development times, as we have demonstrated. The prerequisites for effective cooperative work are continuous, computer-supported process chains and new visualization techniques. In the engineering solution center (ESC), recent methods and technologies are integrated into a continuous process chain, which includes all phases of product development, from the first CAD draft to the selection and fabrication of suitable prototypes to the test phase.

The ESC is equipped with all the necessary technology for fast and cost-efficient development of innovative products. Tools, like the Internet, CAD, and FEM simulations, are integrated into the continuous flow of data. Into already existing engineering systems (CAD, knowledge management, databases, etc.) computer-based information and communication technologies are integrated that support the cooperative engineering effectively. Thus, the engineering solution center offers, for example, the complete set of tools necessary for producing a DMU. A particular advantage here is that these tools are already combined into a continuous process chain. All respective systems are installed, and the required interfaces already exist. An important part of the ESC is the power wall, a recent, very effective, and cost-efficient visualization technology. It offers the possibility to project 3D CAD models and virtual prototypes onto a huge canvas. An unlimited number of persons can view the 3D simultaneously. The power wall is a cost-efficient entrance into large 3D presentations because it consists of only one canvas.

Another essential component of the ESC is the engineering/product-data management (EDM/PDM) system. The EDM encompasses holistic, structured, and consistent management of all processes and the whole data involved in the development of innovative products, or the modification

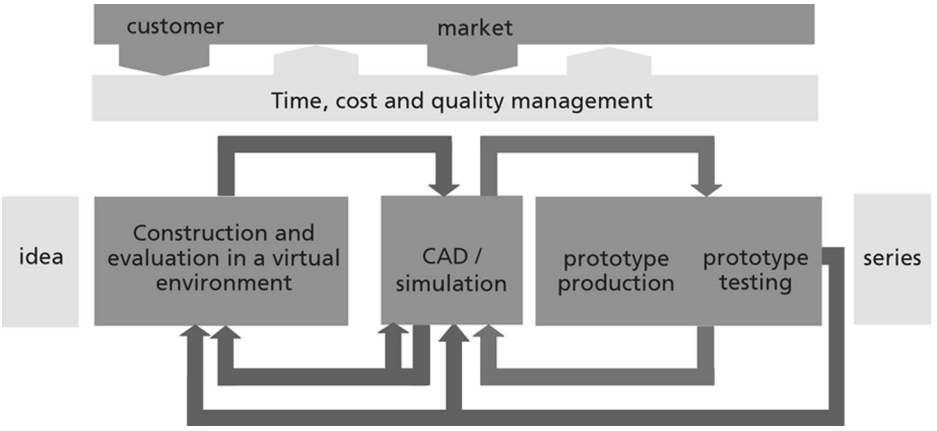

Figure 3 Digital Prototyping in the Product-Development Process.

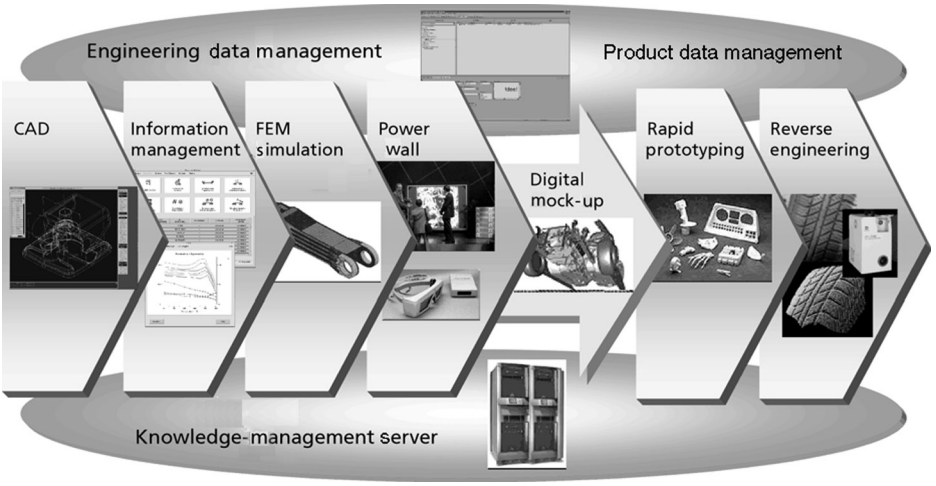

Figure 4 The Engineering Solution Center (ESC).

of already existing products, for the whole product life cycle. The EDM systems manage the processing and forwarding of the produced data. Thus, these systems are the backbone of the technical and administrative information processing. They provide interfaces to CAD systems and other computer-aided applications (CAX), such as computer-aided manufacturing (CAM), computer-aided planning (CAP), and computer-aided quality assurance (CAQ). This way, these systems enable a continuous, company-wide data flow. Inconsistent or obsolete information stocks are reduced to a minimum through the use of EDM.

The innovative approach realized here is what makes the engineering solution center so special. The ESC integrates recent technologies into a continuous process chain. By the use of virtual prototypes the time- and cost-intensive production of physical prototypes can be considerably reduced. The interplay of all methods and technologies makes it possible to achieve high development quality from the first. The virtual product, together with all the applications of virtual technologies and methods in product development and testing, is a necessary reaction to the rapidly changing requirements of the market.

4. KNOWLEDGE ENGINEERING

4.1. Communication and Cooperation

Communication is a further basis for cooperation. It guarantees the continuous exchange of data, information, and knowledge. Particularly dynamic processes, like the development of innovative products, demand great willingness to communicate from the development partners, especially when the partners have not worked together before. Project partners often complain about the great expenditure of time for meetings, telephone calls, and the creation and exchange of documents. If partners are not located nearby, resource problems mean that small and medium-sized companies can arrange personal meetings at short notice only with great difficulty. Nevertheless, face-to-face communication is important because it helps the partners to build up trust and confidence. An information exchange via phone or fax is an insufficient substitute. Especially for small companies, trust is an important factor because it gives them the ability to reduce burdensome expenditures such as frequent coordination and comprehensive documentations. The dynamic in a network of cooperating partners requires a higher degree of communication than most companies are used to because spontaneous agreements concerning the further development process are often necessary. Above all, the manner of communication between the partners has to be altered. Continuous advancement in knowledge and the time pressure put on the development of new products make quick feedback necessary if any deviations from the original planning emerge.

How can communication be improved for the movement of knowledge? There is a difference between explicit knowledge, which is documented, such as on paper or electronically, as language, sketch, or model, and implicit knowledge, which exists only in the heads of the employees.

Another distinction to be made regarding communication is that between the synchronous exchange of knowledge, where partners can communicate at the same time, and the asynchronous exchange, where the transmission and the reception of the message do not happen simultaneously, such as the sending of documents via e-mail.

In most cases of cooperation, exactly this relation is made: implicit knowledge is exchanged synchronously via phone or face to face, and explicit knowledge is exchanged asynchronously via documents. As a consequence, implicit knowledge remains undocumented and explicit knowledge is not annotated. This is a great obstacle to rapid reception of knowledge. Support here is offered by telecooperation systems, which allow communication from computer to computer. Besides documents, pictures, sketches, CAD models, and videos, language can also be exchanged. This way, documents, pictures, and so on can be explained and annotated. By using special input devices, it is possible to incorporate handwritten notes or sketches. This facilitates the documentation of implicit knowledge.

These systems have a further advantage for the integration of knowledge. Learning theory tells us that the reception of new knowledge is easier if several input channels of the learner are occupied simultaneously.

Knowledge-intensive cooperation processes need coordination that is fundamentally different from conventional regulations and control mechanisms. A particular feature of knowledge-intensive processes is that they can hardly be planned. It is impossible to know anything about future knowledge—it is not available today. The more knowledge advances in a project, the higher the probability that previous knowledge will be replaced by new knowledge. Gaining new knowledge may make a former agreement obsolete for one partner. As a consequence, it will sometimes be necessary to give up the previous procedure, with its fixed milestones, work packages, and report cycles, after a short time. The five modules of RPD can be of great help here:

1. Plan and conceive
2. Design
3. Prototyping
4. Check and
5. Evaluate

However, they do not proceed sequentially, as in traditional models. A complete product is not in a certain, exactly-defined development phase. These development projects have an interlocked, networked structure of activities. Single states are determined by occurrences, like test results, which are often caused by external sources, sometimes even in different companies. Instead of a sequential procedure, an iterative, evolutionary process is initiated. But this can function only if the framework for communication is established as described above.

Traditional product-development processes aspire to a decrease in knowledge growth with preceding development time. According to the motto ''Do it right from the start,'' one aim is usually to minimize supplementary modifications. New knowledge is not appreciated; it might provoke modifications of the original concept. RPD, on the other hand, is very much knowledge oriented. Here, the process is kept open for new ideas and changes, such as customer demands and technical improvements. This necessitates a different way of thinking and alternative processes.

Knowledge-integrated processes are designed according to standards different from those usually applied to business process reengineering. The aim is not a slimming at all costs, but rather the robustness of the process. The motto here is ''If the knowledge currently available to me is not enough to reach my target, I have enough time for the necessary qualification and I have the appropriate information technology at my disposal to fill the gap in my knowledge.''

The knowledge-management process has to be considered a direct component of the value-added process. According to Probst et al. (1997), the knowledge-management process consists of the following steps: setting of knowledge targets, identification of knowledge, knowledge acquisition, knowledge development, distribution of knowledge, use of knowledge, and preservation and evaluation of knowledge.

For each of these knowledge process modules, the three fields of organization, human resource management, and information technology are considered. After recording and evaluating the actual state, the modules are optimized with regard to these mentioned fields. The number of iterations is influenced by the mutual dependencies of the modules (Prieto et al. 1999).

From the experiences already gained from R&D cooperation projects the following conclusion can be drawn: if the knowledge-management modules are integrated into the development process and supported by a suitable IT infrastructure, the exchange of knowledge between team members becomes a customer–supplier relationship, as is the case in the value-added process itself. This enables effective and efficient coordination of the project.

4.2. Knowledge Integration

For distributed, interdisciplinary teams it is of great significance that the different persons involved in a project base their work on a common knowledge basis. The cooperating experts have to be able to acquire a basic knowledge of their partners' work contents and processes and their way of thinking in only a short time. Function models and design decisions cannot be communicated without a common basis. Knowledge integration is therefore the basis of communication and coordination in a cooperation. Without a common understanding of the most important terms and their context, it is not possible to transport knowledge to the partners. As a consequence a coordination of common activities becomes impossible. Growing knowledge integration takes time and generates costs. On the other hand, it meliorates the cooperation because few mistakes are made and results are increasingly optimal in a holistic sense. A particular feature of knowledge integration in R&D projects is its dynamic and variable character due to turbulent markets and highly dynamic technological developments. Experiences gained in the field of teamwork made clear that the first phase of a freshly formed (project) team has to be devoted to knowledge integration, for the reasons mentioned above. The task of knowledge integration is to systematize knowledge about artifacts, development processes, and cooperation partners, as well as the respective communication and coordination tools, and to make them available to the cooperation partners. The significance of knowledge integration will probably increase if the artifact is new, as in the development of a product with a new functionality or, more commonly, a highly innovative product. If the project partners have only a small intersection of project-specific knowledge, the integration of knowledge is also very important because it necessitates a dynamic process of building knowledge.

To find creative solutions, it is not enough to know the technical vocabulary of the other experts involved. Misunderstandings are often considered to be communication problems, but they can mostly be explained by the difficult process of knowledge integration.

Which knowledge has to be integrated? First, the knowledge of the different subject areas. Between cooperating subject areas, it is often not enough simply to mediate facts. In this context, four levels of knowledge have to be taken into consideration. In ascending order, they describe an increasing comprehension of coherence within a subject area.

1. Knowledge of facts (''know-what'') forms the basis for the ability to master a subject area. This knowledge primarily reflects the level of acquiring ''book knowledge.''
2. Process knowledge (''know-how'') is gained by the expert through the daily application of his knowledge. Here, the transfer of his theoretical knowledge takes place. To enable an exchange on this level, it is necessary to establish space for experiences, which allows the experts to learn together or from one another.
3. The level of system understanding (''know-why'') deals with the recognition of causal and systemic cohesion between activities and their cause and effect chains. This knowledge enables the expert to solve more complex problems that extend into other subject areas.
4. Ultimately, the level of creative action on one's own initiative, the ''care-why,'' has to be regarded (e.g., motivation). The linkage of the ''care-why'' demands a high intersection of personal interests and targets.

Many approaches to knowledge integration concentrate mainly on the second level. Transferred to the knowledge integration in a R&D cooperation, this means that it is not enough to match the know-what knowledge. The additional partial integration of the know-how and the know-why is in most cases enough for a successful execution of single operative activities. The success of the whole project, however, demands the integration of the topmost level of the care-why knowledge. A precondition here is common interests between the project partners. This is also a major difference between internal cooperation and cooperation with external partners. In transferring internal procedures to projects with external partners, the importance of the care-why is often neglected because within a company the interests of the cooperation partners do not differ very much; it is one company, after all (Warschat and Ganz 2000).

The integration process of the four levels of knowledge described above is based on the exchange of knowledge between project partners. Some knowledge is documented as CAD models or sketches, reports, and calculations. This is explicit knowledge, but a great share of knowledge is not documented and based on experience; it is implicit.

This model, developed by Nonaka and Takeuchi (1997), describes the common exchange of knowledge as it occurs in knowledge management.

5. SUMMARY AND PERSPECTIVE

The RPD concept is based fundamentally on the early and intensive cooperation of experts from different disciplines. This concept therefore makes it possible to bring together the various sources

of expert knowledge in the early phases of product development. Thus, all available sources of information can be used right from the beginning. The initial incomplete knowledge is incrementally completed by diverse experts. Cooperation within and between the autonomous multifunctional teams is of great importance here. The selection and use of suitable information and communication technology are indispensable.

Information exchange is considerably determined by the local and temporal situation of cooperation partners. If the cooperating team members are situated at one place, ordinary, natural communication is possible and sensible. Nevertheless, technical support and electronic documentation might still be helpful. In case cooperation partners are located at different places technical support is indispensable. For this, CSCW and CMC (computer-mediated communication) tools are applied, such as shared whiteboard applications, chat boxes, electronic meeting rooms, and audio/videoconferencing. The currently existing systems make it possible to bridge local barriers. However, they neglect the requirements of face-to-face communication and cooperation. For instance, it is necessary to establish appropriate local and temporal relations among team members. The communication architecture, therefore, should enable the modeling of direct and indirect interactions between individuals. Because of the dynamic of the development process, these relations change. The system should therefore possess sufficient flexibility to enable keeping track of the modifications. Furthermore, the communication basis should be able to represent information not as isolated, but as in the relevant context.

During product development, especially within creative sectors, frequent and rather short ad hoc sessions are preferred. This form of spontaneous information exchange between decentralized development teams requires computer-mediated communication and cooperation techniques, which permit a faster approach and lead to closer cooperation between experts. This results in a harmonized product development, which maintains the autonomy of decentralized teams.

Along with the short iteration cycles, the interdisciplinary teams are an essential feature of the RPD concept. They operate autonomously and are directly responsible for their respective tasks. Additionally, the increasing complexity of products and processes requires an early collaboration and coordination. Thus, it is necessary to make knowledge of technology, design, process, quality, and costs available to anyone involved in the development process.

Conventional databases are not sufficient for an adequate representation of the relevant product and process knowledge. On the one hand, current systems do not consider the dynamic of the development process sufficiently. On the other hand, it is not possible to assess the consequences of one's definition. However, this is a fundamental prerequisite for effective cooperation.

To cope with the given requirements, it is necessary to represent the knowledge in the form of an active semantic network (ASN). This is characterized by active independent objects within a connected structure, which enables the modeling of cause-and-effect relations. The objects in this network are not passive, but react automatically to modifications. This fact provides the possibility of an active and automatic distribution of modifications throughout the whole network. In contrast to conventional systems, ASN contains, in addition to causal connections, representations of methods, communication, and cooperation structures as well as the knowledge required to select the suitable manufacturing technique. Furthermore, negative and positive knowledge (rejected and followed-up alternatives) are stored therein. These acquired perceptions will support the current and future development process. The ASN should exhibit following functions and characteristics:

- Online dialog capability
- Dynamicness
- Robustness
- Version management
- Transparency

All in all, the ASN makes it possible to represent and to manage the design, quality, and cost knowledge together with the know-how of technologies and process planning in the form of the dynamic chains of cause and effect explained here. Thus, the ASN forms the basis for the concept of RPD.

CHAPTER 49

Human-Centered Product Planning and Design

WILLIAM B. ROUSE
Enterprise Support Systems

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

This chapter is concerned with designing products and systems using a methodology called human-centered design (Rouse 1991, 1994). Human-centered design is a process of ensuring that the concerns, values, and perceptions of all stakeholders in a design effort are considered and balanced. Stakeholders include users, customers, evaluators, regulators, service personnel, and so on.

Human-centered design can be contrasted with user-centered design (Billings, 1996; Booher 1990; Card et al. 1983; Norman and Draper 1986). The user is a very important stakeholder in design, often the primary stakeholder. However, the success of a product or system is usually strongly influenced by other players in the process of design, development, fielding, and ongoing use of products and systems. Human-centered design is concerned with the full range of stakeholders.

Considering and balancing the concerns, values, and perceptions of such a broad range of people presents difficult challenges. Ad hoc approaches do not consistently work—too much drops through the cracks. A systematic framework, which is comprehensive but also relatively easy to employ, is necessary for human-centered design to be practical. This chapter presents such a framework.

2. DESIGN OBJECTIVES

There are three primary objectives within human-centered design. These objectives should drive much of the designers' thinking, particularly in the earlier stages of design. Discussions in later sections illustrate the substantial impact of focusing on these three objectives.

The first objective of human-centered design is that it should enhance human abilities. This dictates that humans' abilities in the roles of interest be identified, understood, and cultivated. For example, people tend to have excellent pattern-recognition abilities. Design should take advantage of these abilities—for instance, by using displays of information that enable users to respond on a pattern-recognition basis rather than requiring more analytical evaluation of the information.

The second objective is that human-centered design should help overcome human limitations. This requires that limitations be identified and appropriate compensatory mechanisms be devised. A good illustration of a human limitation is the proclivity to make errors. Humans are fairly flexible information processors, but this flexibility can lead to ''innovations'' that are erroneous in the sense that undesirable consequences are likely to occur.

One way of dealing with this problem is to eliminate innovations, perhaps via interlocks and rigid procedures. However, this is akin to throwing out the baby with the bathwater. Instead, mechanisms are needed to compensate for undesirable consequences without precluding innovations. Such mechanisms represent a human-centered approach to overcoming the human limitation of occasional erroneous performance.

The third objective of human-centered design is that it should foster human acceptance. This dictates that stakeholders' preferences and concerns be explicitly considered in the design process. While users are certainly key stakeholders, there are other people who are also central to the process of designing, developing, and operating a system. For example, purchasers or customers are important stakeholders who often are not users. The interests of these stakeholders also have to be considered to foster acceptance by all the people involved.

3. DESIGN ISSUES

This chapter presents an overall framework and systematic methodology for pursuing the above three objectives of human-centered design. There are four design issues of particular concern within this framework.

The first concern is formulating the right problem—making sure that system objectives and requirements are right. All too often, these issues are dealt with much too quickly. There is a natural tendency to ''get on with it,'' which can have enormous negative consequences when requirements are later found to be inadequate or inappropriate.

The second issue is designing an appropriate solution. All well-engineered solutions are *not* necessarily appropriate. Considering the three objectives of human-centered design, as well as the broader context within which systems typically operate, it is apparent that the excellence of the technical attributes of a design are necessary but not sufficient to ensure that the system design is appropriate and successful.

Given the right problem and an appropriate solution, the next concern is developing it to perform well. Performance attributes should include operability, maintainability, and supportability—that is, using it, fixing it, and supplying it. Supportability includes spare parts, fuel, and, most importantly, trained personnel.

The fourth design concern is ensuring human satisfaction. Success depends on people using the system and achieving the benefits for which it was designed. However, before a system can be used, it must be purchased, usually by other stakeholders, which in turn depends on it being technically approved by yet other stakeholders. Thus, a variety of types of people have to be satisfied.

4. DESIGN METHODOLOGY

Concepts such as user-centered design, user-friendly systems, and ergonomically designed systems have been around for quite some time. Virtually everybody endorses these ideas, but very few people know what to do in order to realize the potential of these concepts. What is needed, and what this chapter presents, is a methodological framework within which human-centered design objectives can be systematically and naturally pursued.

4.1. Design and Measurement

What do successful products and systems have in common? The fact that people buy and use them is certainly a common attribute. However, sales are not a very useful measure for designers. In particular, using *lack* of sales as a way to uncover poor design choices is akin to using airplane crashes as a method of identifying design flaws—this method works, but the feedback provided is a bit late.

The question, therefore, is one of determining what can be measured early that is indicative of subsequent poor sales. In other words, what can be measured early to find out if the product or system is unlikely to fly? If this can be done early, it should be possible to change the characteristics of the product or system so as to avoid the predicted failure.

This section focuses on the issues that must be addressed and resolved for the design of a new product or system to be successful. Seven fundamental measurement issues are discussed and a framework for systematically addressing these issues is presented. This framework provides the structure within which the remainder of this chapter is organized and presented.

4.2. Measurement Issues

Figure 1 presents seven measurement issues that underlie successful design (Rouse 1987). The ''natural'' ordering of these issues depends on one's perspective. From a nuts-and-bolts engineering point of view, one might first worry about testing (i.e., getting the system to work), and save issues such as viability until much later. In contrast, most stakeholders are usually first concerned with viability and only worry about issues such as testing if problems emerge.

A central element of human-centered design is that designers should address the issues in Figure 1 in the same order that stakeholders address these issues. Thus, the *last* concern is, ''Does it run?'' The *first* concern is, ''What matters?,'' or, ''What constitutes benefits and costs?''

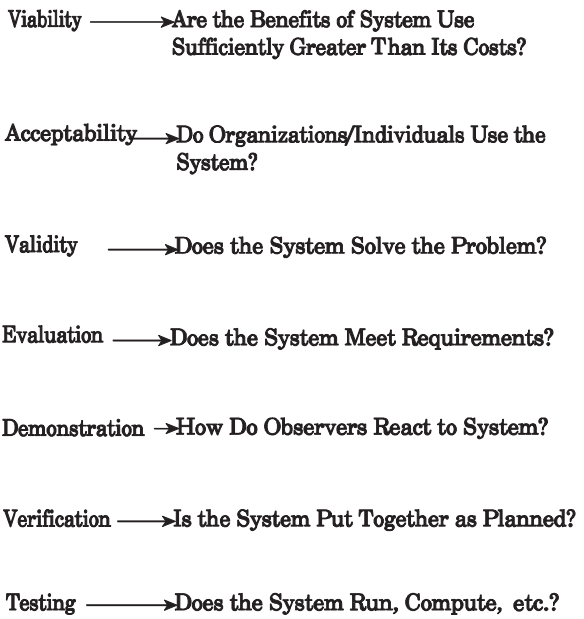

Figure 1 Measurement Issues.

4.2.1. Viability

Are the benefits of system use sufficiently greater than the costs? While this question cannot be answered empirically prior to having a design, one can determine how the question is likely to be answered. How do stakeholders characterize benefits? Are they looking for speed, throughput, an easier job, or appealing surroundings? What influences their perceptions of these characteristics? How do stakeholders characterize costs? Is it simply purchase price? Or do costs include the costs of maintenance and, perhaps, training? Are all the costs monetary?

4.2.2. Acceptability

Do organizations/individuals use the system? This is another question that cannot be answered definitively prior to having the results of design. However, one can determine in advance the factors that are likely to influence the answer. Most of these factors relate to the extent to which a product or system fits into an organization's philosophy, technology, and so on.

4.2.3. Validity

Does the product or system solve the problem? This, of course, leads to the question, what is the problem? How would you know if the problem was solved, or not solved? The nature of this question was discussed earlier in this chapter.

4.2.4. Evaluation

Does the system meet requirements? Formulation of the design problem should result in specification of requirements that must be satisfied for a design solution to be successful. Examples include speed, accuracy, throughput, and manufacturing costs.

4.2.5. Demonstration

How do observers react to the system? It is very useful to get the reactions of potential stakeholders long before the product or system is ready for evaluation. It is important, however, to pursue demonstration in a way that does not create a negative first impression.

4.2.6. Verification

Is the system put together as planned? This question can be contrasted with a paraphrase of the validation question—is the plan any good? Thus, verification is the process of determining that the system was built as intended, but it does not include the process of assessing whether or not it is a good design.

4.2.7. Testing

Does the system run, compute, and so on? This is a standard engineering question. It involves issues of physical measurement and instrumentation for hardware, and runtime inspection and debugging tools for software.

4.3. A Framework for Measurement

The discussion thus far has emphasized the diversity of measurement issues from the perspectives of both designers and stakeholders. If each of these issues were pursued independently, as if they were ends in themselves, the costs of measurement would be untenable. Yet each issue is important and should not be neglected.

What is needed, therefore, is an overall approach to measurement that balances the allocation of resources among the issues of concern at each stage of design. Such an approach should also integrate intermediate measurement results in a way that provides maximal benefit to the evolution of the design product. These goals can be accomplished by viewing measurement as a process involving the four phases shown in Figure 2.

4.3.1. Naturalist Phase

This phase involves understanding the domains and tasks of stakeholders from the perspective of individuals, the organization, and the environment. This understanding includes not only people's activities, but also prevalent values and attitudes relative to productivity, technology, and change in general. Evaluative assessments of interest include identification of difficult and easy aspects of tasks, barriers to and potential avenues of improvement, and the relative leverage of the various stakeholders in the organization.

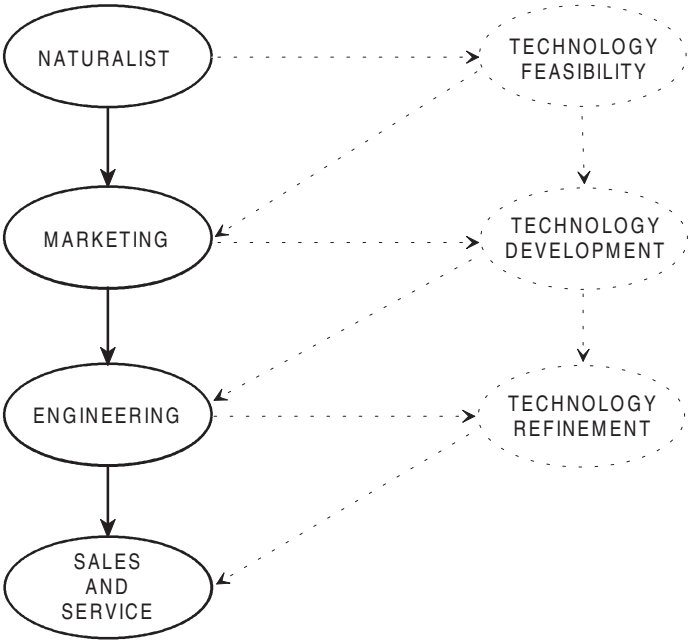

Figure 2 A Framework for Measurement.

4.3.2. Marketing Phase

Once one understands the domain and tasks of current and potential stakeholders, one is in a position to conceptualize alternative products or systems to support these people. Product concepts can be used for initial marketing in the sense of determining how users react to the concepts. Stakeholders' reactions are needed relative to validity, acceptability, and viability. In other words, one wants to determine whether or not people perceive a product concept as solving an important problem, solving it in an acceptable way, and solving it at a reasonable cost.

4.3.3. Engineering Phase

One now is in a position to begin trade-offs between desired conceptual functionality and technological reality. As indicated in Figure 2, technology development will usually have been pursued prior to and in parallel with the naturalist and marketing phases. This will have at least partially ensured that the product concepts shown to stakeholders were not technologically or economically ridiculous. However, one now must be very specific about how desired functionality is to be provided, what performance is possible, and the time and dollars necessary to provide it.

4.3.4. Sales and Service Phase

As this phase begins, the product should have successfully been tested, verified, demonstrated, and evaluated. From a measurement point of view, the focus is now on validity, acceptability, and viability. It is also at this point that one ensures that implementation conditions are consistent with the assumptions underlying the design basis of the product or system.

4.3.5. The Role of Technology

It is important to note the role of technology in the human-centered design process. As depicted in Figure 2, technology is pursued in parallel with the four phases of the design process. In fact, technology feasibility, development, and refinement usually consume the lion's share of the resources in a product or system design effort. However, technology should not drive the design process. Human-centered design objectives should drive the process and technology should support these objectives.

4.3.6. Organization for Measurement

Table 1 illustrates how the seven measurement issues should be organized, or sequenced, in the four phases. *Framing* an issue denotes the process of determining what an issue means within a particular context and defining the variables to be measured. *Planning* is concerned with devising a sequence of steps and schedule for making measurements. *Refining* involves using initial results to modify the plan, or perhaps even rethink issues and variables. Finally, *completing* is the process of making outcome measurements and interpreting results.

Table 1 provides a useful context in which to discuss typical measurement problems. There are two classes of problems of interest. The first class is *planning too late,* where, for example, failure to plan for assessing acceptability can preclude measurement prior to putting a product into use. The second class of problems is *executing too early,* where, for instance, demonstrations are executed prior to resolving test and verification issues, and potentially lead to negative initial impressions of a product or system.

5. NATURALIST PHASE

The purpose of the naturalist phase is gaining an understanding of stakeholders' domains and tasks. This includes assessing the roles of individuals, their organizations, and the environment. Also of interest is identifying barriers to change and avenues for change.

The result of the naturalist phase is a formal description of stakeholders, their tasks, and their needs. This description can take many forms, ranging from text to graphics and from straightforward descriptions to theories and hypotheses regarding stakeholders' behaviors.

This section elaborates and illustrates the process of developing descriptions of stakeholders, tasks, and needs. The descriptions resulting from the naturalist phase are the starting point for the marketing phase.

5.1. Identifying Stakeholders

Who are the stakeholders? This is the central question with which a human-centered design effort should be initiated. The answer to this question is not sufficient for success, but it is certainly necessary.

5.1.1. Stakeholder Populations

The key issue is identifying a set of people whose tasks, abilities, limitations, attitudes, and values are representative of the total population of interest. It is often necessary to sample multiple organizations to gain this understanding of the overall population. An exception to this guideline occurs when the total population of stakeholders resides in a single organization.

5.1.2. Designers as Stakeholder Surrogates

Rather than explicitly identifying stakeholders, it is common for designers to think, perhaps only tacitly, that they understand stakeholders and, therefore, can act as their surrogates. To the extent that designers are former stakeholders, this approach has some merit. However, it is inherently limited from capturing the abilities, attitudes, and aspirations of current or potential stakeholders, as well as the current or potential impact of their organizations.

5.1.3. Elusive Stakeholders

It is often argued, particularly for advanced technology efforts, that the eventual stakeholders for the product or system of interest do not yet exist—there are no incumbent stakeholders. This is very

TABLE 1 Organization of Measurement Process

Issue \ Phase	Naturalist	Marketing	Engineering	Sales and Service
Viability	Frame	Plan	Refine	Complete
Acceptability	Frame	Plan	Refine	Complete
Validity	Frame	Plan	Refine	Complete
Evaluation	–	Frame/plan	Refine/complete	–
Demonstration	–	Frame/plan	Refine/complete	–
Verification	–	Frame/plan	Refine/complete	–
Testing	–	Frame/plan	Refine/complete	–

seldom true, because there are actually extremely few products and systems that are designed from scratch. Even when designing the initial spacecraft, much was drawn from previous experiences in aircraft and submarines.

5.2. Methods and Tools for Measurement

How does one identify stakeholders, and in particular, how does one determine their needs, preferences, values, and so on? Observation is, of course, the necessary means. Initially, unstructured direct observations may be appropriate. Eventually, however, more formal means should be employed to assure unbiased, convincing results. Table 2 lists the methods and tools appropriate for answering these types of questions.

5.2.1. Magazines and Newspapers

To gain an initial perspective on what is important to a particular class of stakeholders or a particular industry, one should read what they read. Trade magazines and industry newspapers publish what interests their readers. One can capitalize on publishers' insights and knowledge by studying articles for issues and concerns. For example, is cost or performance more important? Is risk assessment, or equivalent, mentioned frequently?

One should pay particular attention to advertisements because advertisers invest heavily in trying to understand customers' needs, worries, and preferences. One can capitalize on advertisers' investments by studying the underlying messages and appeals in advertisements.

It is useful to create a file of articles, advertisements, brochures, and catalogs that appear to characterize the stakeholders of interest. Many of these types of materials can also be found on Internet websites. The contents of this file can be slowly accumulated over a period of many months before it is needed. This accumulation might be initiated in light of long-term plans to move in new directions. When these long-term plans become short-term plans, this file can be accessed, the various items juxtaposed, and an initial impression formed relatively quickly. For information available via Internet websites, this file can be readily updated when it is needed.

5.2.2. Databases

Many relatively inexpensive sources of information about stakeholders are available via online databases. This is especially true for Internet-based information sources. With these sources, a wide variety of questions can be answered. How large is the population of stakeholders? How are they distributed, organizationally and geographically? What is the size of their incomes? How do they spend it?

Such databases are also likely to have information on the companies whose advertisements were identified in magazines and newspapers. What are their sales and profits? What are the patterns of growth? Many companies make such information readily available on their Internet websites.

By pursuing these questions, one may be able to find characteristics of the advertisements of interest that discriminate between good and poor sales growth and profits. Such characteristics might include leading-edge technology, low cost, and/or good service.

5.2.3. Questionnaires

Once magazines, newspapers, and databases are exhausted as sources of information, attention should shift to seeking more specific and targeted information. An inexpensive approach is to mail, e-mail, or otherwise distribute questionnaires to potential stakeholders to assess how they spend their time, what they perceive as their needs and preferences, and what factors influence their decisions.

Questions should be brief, have easily understandable responses, and be straightforward to answer. Multiple-choice questions or answers in terms of rating scales are much easier to answer than open-ended essay questions, even though the latter may provide more information.

Low return rate can be a problem with questionnaires. Incentives can help. For example, those who respond can be promised a complete set of the results. In one effort, an excellent response rate was obtained when a few randomly selected respondents were given tickets to Disney World.

Results from questionnaires can sometimes be frustrating. Not infrequently, analysis of the results leads to new questions that one wishes had been on the original questionnaire. These new questions can, however, provide the basis for a follow-up agenda.

5.2.4. Interviews

Talking with stakeholders directly is a rich source of information. This can be accomplished via telephone or even e-mail, but face to face is much better. The use of two interviewers can be invaluable in enabling one person to maintain eye contact and the other to take notes. The use of two interviewers also later provides two interpretations of what was said.

TABLE 2 Methods and Tools for the Naturalist Phase

Methods and Tools	Purpose	Advantages	Disadvantages
Magazines and newspapers	Determine customers' and users' interests via articles and advertisements.	Use is very easy and inexpensive.	Basis and representativeness of information may not be clear.
Databases	Access demographic, product, and sales information.	Coverage is both broad and quantitative.	Available data may only roughly match information needs.
Questionnaires	Query large number of people regarding habits, needs, and preferences.	Large population can be inexpensively queried.	Low return rates and shallow nature of responses.
Interviews	In-depth querying of small number of people regarding activities, organization, and environment.	Face-to-face contact allows in-depth and candid interchange.	Difficulty of gaining access, as well as time required to schedule and conduct.
Experts	Access domain, technology, and/or methodological expertise.	Quickly able to come up to speed on topics.	Cost of use and possible inhibition on creating in-house expertise.

TABLE 3 Methods and Tools for the Marketing Phase

Methods and Tools	Purpose	Advantages	Disadvantages
Questionnaires	Query large number of people regarding preferences for product's functions.	Large population can be inexpensively queried.	Low return rates and shallow nature of responses.
Interviews	In-depth querying of small number of people regarding reactions to and likely use of product's functions.	Face-to-face contact allows in-depth exploration of nature and perceptions of product's functions and benefits.	Difficulty of gaining access, as well as time required to schedule and conduct.
Scenarios	Provide feeling for using product in terms of how functions would likely be used.	Inexpensive approach to providing rich impression of product's functions and benefits.	Written scenarios are not as compelling as visual presentation and require users' willingness to read.
Mock-ups	Provide visual look and feel of product.	Strong visual image can be created and reinforced with photographs.	Necessarily emphasize surface features which are not always product's strength.
Prototypes	Provide ability to use product, typically in a fairly limited sense.	Very powerful and compelling approach to involving potential users.	Relatively expensive and not fully portable; sometimes lead to inflated expectations.

Usually, interviewees thoroughly enjoy talking about their jobs and what types of products and systems would be useful. Often one is surprised by the degree of candor people exhibit. Consequently, interviewees usually do not like their comments tape-recorded.

It is helpful if interviewees have first filled out questionnaires, which can provide structure for the interview as they explain and discuss their answers. Questionnaires also ensure that they will have thought about the issues of concern prior to the interview. In the absence of a prior questionnaire, the interview should be carefully structured to avoid unproductive tangents. This structure should be explained to interviewees prior to beginning the interview.

5.2.5. Experts

People with specialized expertise in the domain of interest, the technology, and/or the market niche can be quite valuable. People who were formerly stakeholders within the population of interest tend to be particularly useful. These people can be accessed via e-mail or informal telephone calls (which are surprisingly successful), gathered together in invited workshops, and/or hired as consultants.

While experts' knowledge can be essential, it is very important that the limitations of experts be understood. Despite the demeanor of many experts, very few experts know everything! Listen and filter carefully.

Further, it is very unlikely that one expert can cover a wide range of needs. Consider multiple experts. This is due not only to a need to get a good average opinion. It is due to the necessity to cover multiple domains of knowledge.

5.3. Summary

The success of all of the above methods and tools depends on one particular ability of designers—the ability to listen. During the naturalist phase, the goal is understanding stakeholders rather than convincing them of the merits of particular ideas or the cleverness of the designers. Designers will get plenty of time to talk and expound in later phases of the design process. At this point, however, success depends on listening.

6. MARKETING PHASE

The purpose of the marketing phase is introducing product concepts to potential customers, users, and other stakeholders. In addition, the purpose of this phase includes planning for measurements of viability, acceptability, and validity. Further, initial measurements should be made to test plans, as opposed to the product, to uncover any problems before proceeding.

It is important to keep in mind that the product and system concepts developed in this phase are primarily for the purpose of addressing viability, acceptability, and validity. Beyond that which is sufficient to serve this purpose, minimal engineering effort should be invested in these concepts. Beyond preserving resources, this minimalist approach avoids, or at least lessens, ''ego investments'' in concepts prior to knowing whether or not the concepts will be perceived to be viable, acceptable, and valid.

These types of problem can also be avoided by pursuing more than one product concept. Potential stakeholders can be asked to react to these multiple concepts in terms of whether or not each product concept is perceived as solving an important problem, solving it in an acceptable way, and solving it at a reasonable cost. Each person queried can react to all concepts, or the population of potential stakeholders can be partitioned into multiple groups, with each group only reacting to one concept.

The marketing phase results in an assessment of the relative merits of the multiple product concepts that have emerged up to this point. Also derived is a preview of any particular difficulties that are likely to emerge later. Concepts can be modified, both technically and in terms of presentation and packaging, to decrease the likelihood of these problems.

6.1. Methods and Tools for Measurement

How does one measure the perceptions of stakeholders relative to the viability, acceptability, and validity of alternative product and system concepts? Table 3 (see page 1303) lists the appropriate methods and tools for answering this question, as well as their advantages and disadvantages.

6.1.1. Questionnaires

This method can be used to obtain the reactions of a large number of stakeholders to alternative functions and features of a product or system concept. Typically, people are asked to rate the desirability and perceived feasibility of functions and features using, for example, scales of 1 to 10. Alternatively, people can be asked to rank order functions and features.

As noted when questionnaires were discussed earlier, low return rate can be a problem. Further, one typically cannot have respondents clarify their answers, unless telephone or in person follow-ups are pursued. This tends to be quite difficult when the sample population is large.

Questionnaires can present problems if they are the only methods employed in the marketing phase. The difficulty is that responses may not discriminate among functions and features. For example, respondees may rate as 10 the desirability of all functions and features.

This sounds great—one has discovered exactly what people want! However, another interpretation is that the alternatives were not understood sufficiently for people to perceive different levels of desirability among the alternatives. Asking people to rank order items can eliminate this problem, at least on the surface. However, questionnaires are usually not sufficiently rich to provide people with real feelings for the functionality of the product or system.

6.1.2. Interviews

Interviews are a good way to follow up questionnaires, perhaps for a subset of the population sampled, if the sample was large. As noted earlier, questionnaires are a good precursor to interviews in that they cause interviewees to organize their thoughts prior to the interviews. In-person interviews are more useful than telephone or e-mail interviews because it is much easier to uncover perceptions and preferences iteratively during face-to-face interaction.

Interviews are a good means for determining people's a priori perceptions of the functionality envisioned for the product or system. It is useful to assess these a priori perceptions independently of the perceptions that one may subsequently attempt to create. This assessment is important because it can provide an early warning of any natural tendencies of potential stakeholders to perceive things in ways other than intended in the new product or system. If problems are apparent, one may decide to change the presentation or packaging of the product to avoid misperceptions.

6.1.3. Scenarios

At some point, one has to move beyond the list of words and phrases that describe the functions and features envisioned for the product or system. An interesting way to move in this direction is by using stories or scenarios that embody the functionality of interest and depict how these functions might be utilized.

These stories and scenarios can be accompanied by a questionnaire within which respondents are asked to rate the realism of the depiction. Further, they can be asked to consider explicitly, and perhaps rate, the validity, acceptability, and viability of the product functionality illustrated. It is not necessary, however, to explicitly use the words ''validity,'' ''acceptability,'' and ''viability'' in the questionnaire. Words should be chosen that are appropriate for the domain being studied—for example, viability may be an issue of cost in some domains and not in others.

It is very useful to follow up these questionnaires with interviews, or at least e-mail queries, to clarify respondents' comments and ratings. Often the explanations and clarifications are more interesting and valuable than the ratings.

6.1.4. Mock-ups

Mock-ups are particularly useful when the form and appearance of a product or system are central to stakeholders' perceptions. For products such as automobiles and furniture, form and appearance are obviously central. However, mock-ups can also be useful for products and systems where appearance does not seem to be crucial.

For example, computer-based systems obviously tend to look quite similar. The only degree of freedom is what is on the display. One can exploit this degree of freedom by producing mock-ups of displays using photographs or even viewgraphs for use with an overhead projector.

One word of caution, however. Even such low-budget presentations can produce lasting impressions. One should make sure that the impression created is such that one wants it to last. Otherwise, as noted earlier, one may not get an opportunity to make a second impression.

6.1.5. Prototypes

Prototypes are a very popular approach and, depending on the level of functionality provided, can give stakeholders hands-on experience with the product or system. For computer-based products, rapid prototyping methods and tools have become quite popular because these methods and tools enable the creation of a functioning prototype in a matter of hours.

Thus, prototyping has two important advantages. Prototypes can be created rapidly and enable hands-on interaction. With these advantages, however, come two important disadvantages.

One disadvantage is the tendency to produce ad hoc prototypes, typically with the motivation of having something to show stakeholders. It is very important that the purpose of the prototype be kept in mind. It is a device with which to obtain initial measurements of validity, acceptability, and viability. Thus, one should make sure that the functions and features depicted are those for which these measurements are needed. One should not, therefore, put something on a display simply because it is intuitively appealing. This can be a difficult impulse to avoid.

The second disadvantage is the tendency to become attached to one's prototypes. At first, a prototype is merely a device for measurement, to be discarded after the appropriate measurements are made. However, once the prototype is operational, there is a tendency for people, including the creators of the prototype, to begin to think that the prototype is actually very close to what the final product or system should be like. In such situations, it is common to hear someone say, "Maybe with just a few small changes here and there . . ."

Prototypes can be very important. However, one must keep their purpose in mind and avoid rabid prototyping! Also, care must be taken to avoid premature ego investments in prototypes. The framework for design presented in this chapter can provide the means for avoiding these pitfalls.

6.2. Summary

During the naturalist phase, the goal was to listen. In the marketing phase, one can move beyond just listening. Various methods and tools can be used to test hypotheses that emerged from the naturalist phase, and obtain potential stakeholders' reactions to initial product and system concepts.

Beyond presenting hypotheses and concepts, one also obtains initial measurements of validity, acceptability, and viability. These measurements are in terms of quantitative ratings and rankings of functions and features, as well as more free-flow comments and dialogue.

7. ENGINEERING PHASE

The purpose of the engineering phase is developing a final design of the product or system. Much of the effort in this phase involves using various design methods and tools in the process of evolving a conceptual design to a final design. In addition to synthesis of a final design, planning and execution of measurements associated with evaluation, demonstration, verification, and testing are pursued.

7.1. Four-Step Process

In this section, a four-step process for directing the activities of the engineering phase and documenting the results of these activities is discussed. The essence of this process is a structured approach to producing a series of design documents. These documents need not be formal documents. They might, for example, only be a set of presentation materials.

Beyond the value of this approach for creating a human-centered design, documentation produced in this manner can be particularly valuable for tracing design decisions back to the requirements and objectives that motivated the decisions. For example, suggested design changes are much easier to evaluate and integrate into an existing design when one can efficiently determine why the existing design is as it is.

It is important to note that the results of the naturalist and marketing phases should provide a strong head start on this documentation process. In particular, much of the objectives document can be based on the results of these phases. Further, and equally important, the naturalist and marketing phases will have identified the stakeholders in the design effort, and are likely to have initiated relationships with many of them.

7.2. Objectives Document

The first step in the process is developing the objectives document. This document contains three attributes of the product or system to be designed: goals, functions, and objectives.

Goals are characteristics of the product or system that designers, users, and customers would like the product or system to have. Goals are often philosophical choices, frequently very qualitative in nature. There are usually multiple ways of achieving goals. Goals are particularly useful for providing guidance for later choices.

Functions define what the product or system should do, but not how it should be done. Consequently, there are usually multiple ways to provide each function. The definition of functions subsequently leads to analysis of objectives.

Objectives define the activities that must be accomplished by the product or system in order to provide functions. Each function has at least 1, and often 5 to 10, objectives associated with it. Objectives are typically phrased as imperative sentences beginning with a verb.

There are two purposes for writing a formal document listing goals, functions, and objectives. First, as noted earlier, written documents provide an audit trail from initial analyses to the "as-built" product or system. The objectives document provides the foundation for all subsequent documents in the audit trail for the engineering phase. The second purpose of the objectives document is that it provides the framework—in fact, the outline—for the requirements document.

All stakeholders should be involved in the development of the objectives document. This includes at least one representative from each type of stakeholder group. This is important because this document defines what the eventual product or system will and will not do. All subsequent development

assumes that the functions and objectives in the objectives document form a necessary and complete set.

The contents of the objectives document can be based on interviews with subject-matter experts, including operators, maintainers, managers, and trainers. Baseline and analogous systems can also be valuable, particularly for determining objectives that have proven to be necessary for providing specific functions.

Much of the needed information will have emerged from the marketing phase. At the very least, one should have learned from the marketing phase what questions to ask and who to ask. All the stakeholders in the process should have been identified and their views and preferences assessed.

The level of detail in the objectives document should be such that generality is emphasized and specifics are avoided. The activities and resulting document should concentrate on what is desirable. Discussion of constraints should be delayed; budgets, schedules, people, and technology can be considered later.

7.3. Requirements Document

Once all the stakeholders agree that the objectives document accurately describes the desired functions and objectives for the product or system, the next step is to develop the requirements document. The purpose of this document is to identify all information and control requirements associated with each objective in the objectives document.

For evolutionary designs, baseline and analogous systems can be studied to determine requirements. However, if the product or system being designed has no antecedent, subject-matter expertise can be very difficult to find. In this case, answers to the above questions have to come from engineering analysis and, if necessary, validated empirically.

The requirements document should be reviewed and approved by all stakeholders in the design effort. This approval should occur prior to beginning development of the conceptual design. This document can also be very useful for determining the functional significance of future design changes. In fact, the requirements document is often used to answer downstream questions that arise concerning why particular system features exist at all.

7.4. Conceptual Design Document

The conceptual design of a product or system should accommodate *all* information and control requirements as parsimoniously as feasible within the state of the art. The conceptual design, as embodied in the conceptual design document, is the first step in defining how the final system will meet the requirements of the requirements document. The conceptual design document should describe a complete, workable system that meets all design objectives.

Realistically, one should expect considerable disagreement as the conceptual design evolves. However, the conceptual design document should not reflect these disagreements. Instead, this document should be iteratively revised until a consensus is reached. At that point, all stakeholders should agree that the resulting conceptual design is a desirable and appropriate product or system.

7.5. Detailed Design Document

The fourth and final step in the design process involves synthesizing a detailed design. Associated with the detailed design is the detailed design document. This document describes the production version of the product or system, including block diagrams, engineering drawings, parts lists, and manufacturing processes.

The detailed design document links elements of the detailed design to the functionality within the conceptual design document, which are in turn linked to the information and control requirements in the requirements document, which are in turn linked to the objectives within the objectives document. These linkages provide powerful means for efficiently revising the design when, as is quite often the case, one or more stakeholders in the design process do not like the implications of their earlier choices. With the audit trail provided by the four-step design process, evaluating and integrating changes is much more straightforward. As a result, good changes are readily and appropriately incorporated and bad changes are expeditiously rejected.

7.6. Summary

In this section, the engineering phase has been described in terms of a documentation process, including the relationships among documents. As noted earlier, this documentation need not be overly formal. For instance, documents may be simply sets of presentation materials. The key is to make intentions, assumptions, and so on explicit and to ensure that key stakeholders, or their representatives, understand, agree with, and will support the emerging design solution.

Obviously, much of the engineering phase concerns creating the contents of the documents described here. Many of the other chapters in this Handbook provide detailed guidance on these en-

gineering activities. Human-centered design is primarily concerned with ensuring that the plethora of engineering methods and tools discussed in this Handbook are focused on creating viable, acceptable, and valid design solutions.

8. SALES AND SERVICE PHASE

Initiation of the sales and service phase signals the accomplishment of several important objectives. The product or system will have been successfully tested, verified, demonstrated, and evaluated. In addition, the issues of viability, acceptability, and validity will have been framed, measurements planned, and initial measurements executed. These initial measurements, beyond the framing and planning, will have exerted a strong influence on the nature of the product or system.

8.1. Sales and Service Issues

In this phase, one is in a position to gain closure on viability, acceptability, and validity. One can make the measurements necessary to determining whether the product or system really solves the problem that motivated the design effort, solves it in an acceptable way, and provides benefits that are greater than the costs of acquisition and use. This is accomplished using the measurement plan that was framed in the naturalist phase, developed in the marketing phase, and refined in the engineering phase.

These measurements should be performed even if the product or system is presold—for example, when a design effort is the consequence of a winning proposal. In this case, even though the purchase is assured, one should pursue closure on viability, acceptability, and validity in order to gain future projects.

There are several other activities in this phase beyond measurement. One should ensure that the implementation conditions for the product or system are consistent with the assumed conditions upon which the design is based. This is also the point at which the later steps of stakeholder acceptance plans are executed, typically with a broader set of people than those who participated in the early steps of the plan. This phase also often involves technology-transition considerations in general.

The sales and service phase is also where problems are identified and remedied. To the greatest extent possible, designers should work with stakeholders to understand the nature of problems and alternative solutions. Some problems may provide new opportunities rather than indicating shortcomings of the current product or system. It is important to recognize when problems go beyond the scope of the original design effort. The emphasis then becomes one of identifying mechanisms for defining and initiating new design efforts to address these problems.

The sales and service phase also provides an excellent means for maintaining relationships. One can identify changes among stakeholders that occur because of promotions, retirements, resignations, and reorganizations. Further, one can lay the groundwork for, and make initial progress on, the naturalist phase, and perhaps the marketing phase, for the next project, product, or system.

8.2. Methods and Tools for Measurement

How does one make the final assessments of viability, acceptability, and validity? Further, how does one recognize new opportunities? Unstructured direct observation can provide important information. However, more formal methods are likely to yield more definitive results and insights. Table 4 lists the methods and tools appropriate for answering these types of questions.

8.2.1. Sales Reports

Sales are an excellent measure of success and a good indicator of high viability, acceptability, and validity. However, sales reports are a poor way of discovering a major design inadequacy. Further, when a major problem is detected in this manner, it is quite likely that one may not know what the problem is or why it occurred.

8.2.2. Service Reports

Service reports can be designed, and service personnel trained, to provide much more than simply a record of service activities. Additional information of interest concerns the specific nature of problems, their likely causes, and how stakeholders perceive and react to the problems. Stakeholders' suggestions for how to avoid or solve the problems can also be invaluable. Individuals' names, addresses, and telephone numbers can also be recorded so that they can be contacted subsequently.

8.2.3. Questionnaires

Questionnaires can be quite useful for discovering problems that are not sufficient to prompt service calls. They also can be useful for uncovering problems with the service itself. If a record is maintained of all stakeholders, this population can regularly be sampled and queried regarding problems, as well as ideas for solutions, product upgrades, and so on. As noted before, however, a primary disadvantage of questionnaires is the typical low return rate.

TABLE 4 Methods and Tools for the Sales and Service Phase

Methods and Tools	Purpose	Advantages	Disadvantages
Sales reports	Assess perceived viability of product or system.	The ultimate, bottom-line measure of success.	Information on lack of sales due to problems is likely to be too late to help.
Service reports	Assess typical problems and impact of solutions attempted.	Associate problems with customers and users and enable follow-up.	May be too late for major problems and may not explain cause.
Questionnaires	Query large number of customers and users regarding experiences with product.	Large population can be inexpensively queried.	Low return rates and shallow nature of responses.
Interviews	In-depth querying of small number of customers and users regarding experiences with product.	Face-to-face contact allows in-depth and candid interchange.	Difficulty of gaining access, as well as time required to schedule and conduct.

8.2.4. Interviews

Interviews can be a rich source of information. Stakeholders can be queried in depth regarding their experiences with the product or system, what they would like to see changed, and new products and systems they would like. This can also be an opportunity to learn how their organizations make purchasing decisions, in terms of both decision criteria and budget cycles.

While sales representatives and service personnel can potentially perform interviews, there is great value in having designers venture out to the sites where their products and systems are used. Such sorties should have clear measurement goals, questions to be answered, an interview protocol, and so on, much in the way that is described in earlier sections. If necessary, interviews can be conducted via telephone or e-mail, with only selected face-to-face interviews to probe more deeply.

8.3. Summary

The sales and service phase brings the measurement process full circle. An important aspect of this phase is using the above tools and methods to initiate the next iteration of naturalist and marketing phases. To this end, as was emphasized earlier, a primary prerequisite at this point is the ability to *listen*.

9. CONCLUSIONS

This chapter has presented a framework for human-centered design. Use of this framework will ensure a successful product or system in terms of viability, acceptability, validity, and so on. In this way, human-centered design provides the basis for translating technology opportunities into market innovations.

Purdue University

1. INTRODUCTION

The objective of design for manufacturability is to incorporate producibility issues early on in the product design stage so that the customers can be attracted and the needs of the customers can be satisfied in a short lead time and at a competitive cost. The customers' needs include satisfaction in the product with respect to its performance capabilities, quality, reliability, serviceability, aesthetics, and time of delivery.

*Parts of this chapter were originally published in Chapter 13 of the Second Edition of this Handbook authored by C. Richard Liu and the late Benjamin W. Niebel.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

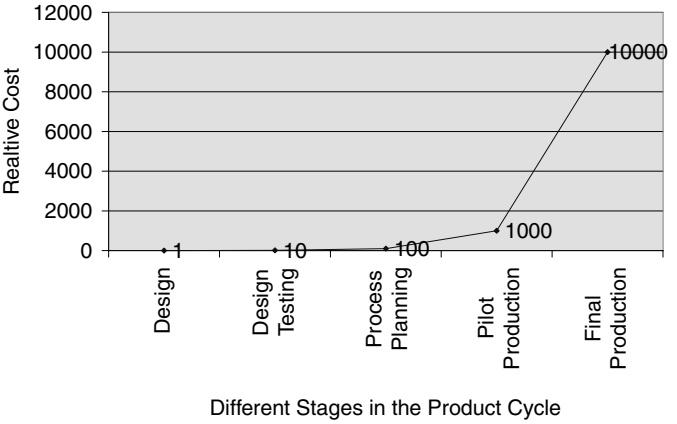

Figure 1 Comparative Cost of an Engineering Change in Different Stages in the Product Cycle. (*Source:* Shina 1991)

Conventional engineering practice in the past has resulted in separate, and sometimes isolated, activities between design and manufacturing that have proven to be time consuming and costly. A study compared the cost of any change in design in three different stages, namely, in production, manufacturing engineering, and design. The cost of a change in the production stage may be ap-

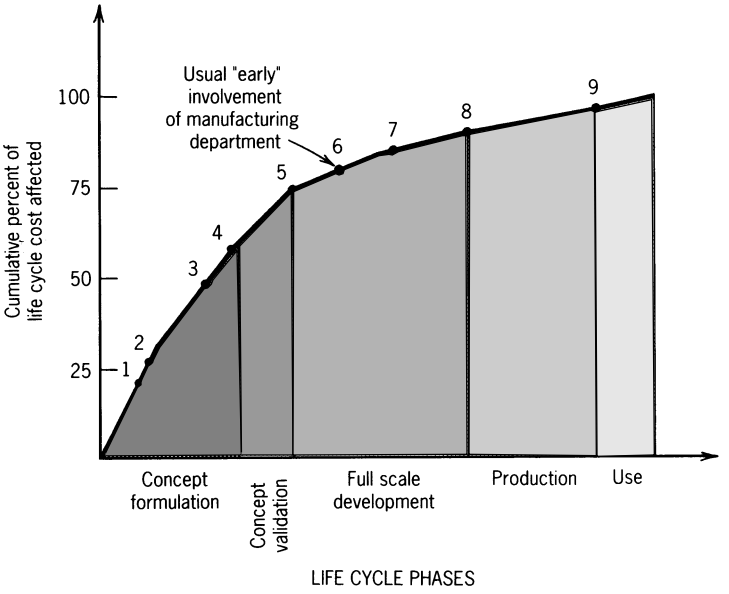

Figure 2 Life-Cycle Phases.

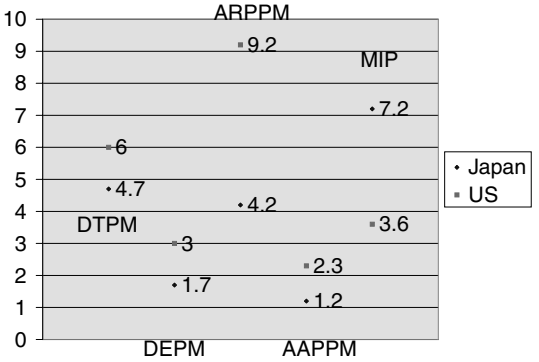

Figure 3 Comparison between Japanese and U.S. auto industry. DTPM: design time/model (multiply the number by 10 to convert the time unit into month); DEPM: design effort/model; ARPPM: average replacement period/model (years); AAPPM: average annual production/model (multiple the number by 100,000); and MIP: models in production (multiple the number by 10). (*Source:* Shina 1991).

proximately an order of magnitude more than the cost of the change made early in the manufacturing engineering stage. Figure 1 shows comparative cost of an engineering change in different stages in the product cycle. To avoid the costly changes due to manufacturability problems, factors related to manufacturing must be considered in all phases of the design process, starting with the design-conception phase. Another study (Nevins and Whitney 1989) further confirmed the importance of making the right decision early. This study indicated that in the concept formulation stage 60% of the life-cycle cost of a product has already been determined. Before full-scale development 75% of the life-cycle cost has been determined. This is illustrated in Figure 2. It is clear from the figure that the DFM needs to be considered in the early conceptual design stage to yield the maximized benefits.

The major issues in competitiveness have moved from cost to productivity to quality. The current and future major issue is time. The other issue are not less important, but the new frontier is speed: studies have shown that over 80% of market share in a new product category goes to the first two companies that get their products to market. Further studies have shown that a 20% cost overrun in the design stage of the product cycle will result in about 8% reduced profits over the lifetime of the product. A six-month overrun in time during the design stage today will result in about 34% loss over the life of the product (Brazier and Leonard 1990).

Figure 3 compares Japanese and U.S. auto design and product cycles. The competitive advantage of the Japanese auto industry results from concurrent engineering and design for manufacture (Shina 1991).

2. DESIGN AND DESIGN ALTERNATIVES

The essence of design is that it is a plan to achieve a purpose or to satisfy a need. In mechanical design, the plan is a representation, such as a set of drawings defining the configuration (geometry and material) of physical elements.

The immediate purpose of a specific set of physical elements or a specific design is the functional requirement. The design process, at this level, is to start with the known functional requirement to plan or search for the design configurations.

The design solution is almost always not unique. Conceptually, the design process can be considered a mapping process between the ''purpose space'' and the ''functional space'' and between the ''functional space'' and ''configuration space.'' The ability to develop alternative physical designs is of fundamental importance to design for manufacturability.

Alternative physical designs may be developed by knowing the functional requirement. A design, in general, can be decomposed into subfunctional requirements for each of its subsystems. Each subfunctional requirement, again, can be used to characterize and develop the design alternatives of each subsystem. By repeating this process, a functional design hierarchy can be developed with the possible design alternatives at various levels of functional requirements, for the product (the assembly), the subassembly, and parts. This design hierarchy is shown in Figure 4 (Liu and Trappey 1989).

The properties of the design hierarchy are as follows:

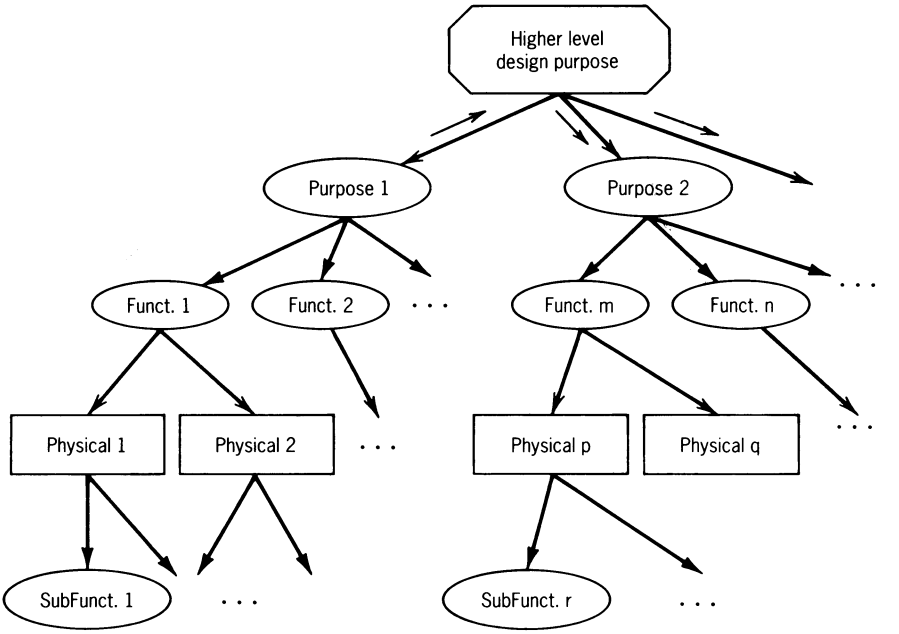

Figure 4 The Design Hierarchy with Upstream and Downstream Reasonings.

1. All the subfunctions are required to form a design, and only one among all the physical design alternatives is needed to satisfy a specific functional requirement.
2. Each and every possible physical design, for a system or a subsystem, has place in the hierarchy. Therefore, the hierarchy serves as a guide for design knowledge acquisition, as a structure for design knowledge storage, and as an indexing system for design knowledge retrieval. This has important application in serving as a software tool for concurrent engineering.
3. Upstream reasoning from the physical design can be conducted by answering the question "What is the design for?" Then the higher level functional requirement may be reached.
4. Downstream reasoning from functional requirement can be done by answering the question "How can the functional requirement be satisfied?" Then the physical design alternatives may be generated.
5. Upstream–downstream reasoning forces the designer to analyze the functional requirements and higher purposes. Thus, it can be used for managing the design process and yet, in the meantime, allow for the individual designer's creativity (see Figure 2).
6. The hierarchical system can serve as structured blackboard for design communication, consultation, and retrieval.

The application of the design hierarchy by one of the authors (Liu) has led to very significant product innovation. When the same method was applied by the students in his classes, general improvement in design creativity was observed. However, the results varied tremendously among the individuals.

More discussions and elaboration of the proposed functional–physical design hierarchy were done in Liu and Trappey (1989) and Trappey and Liu (1990).

3. DRAWINGS

Drawings represent the heart of design for manufacturing because they are the principal means of communication between the functional designer and the producer of the design. They alone control and completely delineate shape, form, fit, finish, and interchangeability requirements that lead to the most competitive procurement. An engineering drawing, when supplemented by reference specifications and standards, should permit a competent manufacturer to produce the part shown within the dimensional and surface tolerance specifications provided. It is the engineering drawing that should demonstrate the most creative design for manufacturing thinking.

Certain product specifications may not be included on the drawings in view of space constraints. Product specifications such as quality assurance checkpoints, inspection procedures, and general design criteria may be separately summarized but should always be cross-referenced on the engineering drawing. At all times the design engineer must remember that the end product drawing is the communication medium between the design engineer and the producer. It is the basis for interchangeability for repair parts; it provides the form, fit, and function to the manufacturing function.

Too often the language of drawings is incomplete. For example, chamfers may be indicated but not be dimensioned; worse yet, they may be desired but not even be shown. Frequently the finish desired is omitted. Complex coring may be incorrectly shown. The principal errors common to many designs are as follows:

1. Design is not conducive to the application of economic processing.
2. Designer has not taken advantage of group technology and creates a new design for an already existing item.
3. Design exceeds the manufacturing state of the art.
4. Design and performance specifications are not compatible.
5. Critical location surfaces have not been established.
6. Design specifies the use of inappropriate items.
7. Design specifications are not definitive.
8. Inadequate consideration has been given to measurement problems.
9. Tolerances are more restrictive than necessary.
10. Item has been overdesigned.

4. GENERAL PRINCIPLES FOR DESIGN FOR MANUFACTURABILITY

In this section we only stress some important concepts. In later sections we will review the design for basic processes. For more detailed information, see Bralla (1986) and Stillwell (1989).

1. Consider the entire product, including all its subsystems and components, and the entire spectrum of manufacturing–inspection–assembly activities. We should avoid producing improvement in one at the expense of another. For example, product design to specify the assembly operations may create difficulties in disassembling the product, thus hurting maintainability and serviceability of the product. Simplifying the component processing may create complexity in assembly.
2. Search for simplicity first in system designs, then in subsystem designs, and then in component designs. Considering simplicity in component level only will lead to missing the opportunities for significant improvement.
3. Ask whether the functional needs are absolutely necessary. Chances are the functional needs can be reduced, thus leading to significant simplifications of the configuration design and processing requirements. Example: A careful examination of the functional needs of a gear train system has led to a relaxation of the functional specifications that enables the use of a four-bar linkage as a replacement of the gear train. The impact on manufacturability is obviously very significant.

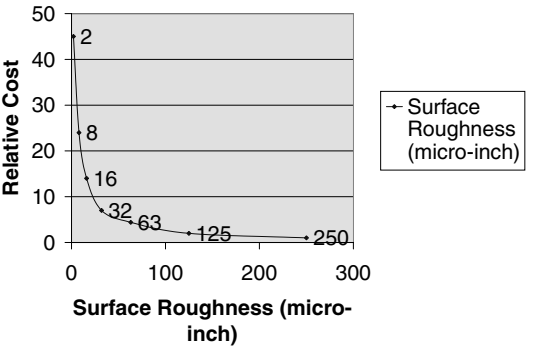

Figure 5 Relative Cost Corresponding to Different Surface Roughness. (*Source:* Bralla 1986)

4. Design for fewer parts, simpler shapes, least precision requirements, fewer manufacturing steps, and minimum information requirements. Figure 5 shows the relative cost corresponding to different surface roughness.
5. Apply the concept of design modularization and group technology. Reduce the varieties of sizes and shapes. Experience has shown that the number of hole sizes may be reduced significantly without affecting the function, thus reducing the number of sizes of drills needed.
6. Always consider standard materials, components, and subassemblies.
7. Design appropriate to the expected level of production and to fit the existing production facilities.
8. Select the shape of the raw material close to the finished designs.
9. Design for easy inspection.
10. Design for part orientation to maximize the value added in each setup.
11. Design for easy assembly and maintainability.

5. PROCESSES AND MATERIALS FOR PRODUCING THE DESIGN

The selection of the ideal processes and materials with which to produce a given design cannot be an independent activity. It must be a continuing activity that takes place throughout the design life cycle, from initial conception to production. Material selection and process selection need to be considered together; they should not be considered independently.

In considering the selection of materials for an application, it is usually possible to rule out entire classes of materials because of cost or their obvious inability to satisfy specific operational requirements. But even so, with the acceleration of material development there are so many options for the functional design engineer that optimum selection is at best difficult. The suggested procedure for organizing data related to material selection is to divide it into three categories: properties, specifications, and data for ordering.

The property category will usually provide the information that suggests the most desirable material. A property profile is recommended, where all information, such as yield point, modulus of elasticity, resistance to corrosion, and so on, is tabulated. Those materials that qualify because of their properties will stand out.

Each material will have its own specifications on the individual grades available and on their properties, applications, and comparative costs. The unique specifications of a material will distinguish it from all competing materials and will serve as the basis for quality control, planning, and inspection.

Finally, the data needed when physically placing an order need to be maintained. This includes minimum order size, quantity breakpoints, and sources of supply.

In the final selection of a material, cost of the proposed material needs to be considered—hence the need for close association between material selection and process selection in connection with design.

Design evaluation invariably is in terms of a proposed material cost, which may be derived by analyzing the involved processing steps, including setup and lead-time costs along with the preprocessed material cost.

6. DESIGN FOR BASIC PROCESSES—METAL

6.1. Liquid State

Early in the planning of the functional design, one must decide whether to start with a basic process that uses material in the liquid state, such as a casting, or in the solid state, such as a forging. If the engineer decides a part should be cast, he or she will have to decide simultaneously which casting alloy and process can most nearly meet the required dimensional tolerance, mechanical properties, and production rate at the least cost.

Casting has several distinct assets: the ability to fill a complex shape, economy when a number of similar pieces are required, and a wide choice of alloys suitable for use in highly stressed parts, where light weight is important or where corrosion may be a problem. There are inherent problems, too, including internal porosity, dimensional variations caused by shrinkage, and solid or gaseous inclusions stemming from the molding operation. However, most of these problems can be minimized by sound design for manufacturing.

Casting processes are basically similar in that the metal being formed is in a liquid or highly viscous state and is poured or injected into a cavity of a desired shape.

The following design guidelines will prove helpful in reducing casting defects, improving their reliability and assisting in their producibility:

1. When changes in sections are required, use smoothly tapered sections to reduce stress concentration. Where sections join, use generous fillets and blending radii.
2. Machining allowances should be detailed on the part drawing so as to ensure adequate stock and avoid excessive differences in casting thickness.
3. Remember that when design castings to be produced in a metal mold or die, convex forms are easy to mill but concave notches are both difficult and expensive.
4. Raised lettering is simple to cut into a metal mold or die; depressed lettering will cost considerably more.
5. Avoid the design of thin sections since they will be difficult to fill.
6. To facilitate the secondary operations of drilling and tapping, cored-through holes should have countersinking on both ends of the holes.
7. Avoid large, plain surfaces. Break up these areas with ribs or serration to avoid warpage and distortion.
8. For maximum strength, keep material away from the neutral axis. Endeavor to keep plates in tension and ribs in compression.

Table 1 identifies the important design parameters associated with the various casting processes and provides those limitations that should be incorporated by the functional designer to ensure producibility.

6.2. Solid State

A forging, as opposed to a casting, is usually used because of improved mechanical properties, which are a result of working metals into a desired configuration under impact or pressure loading. A refinement of the grain structure is another characteristic of the forging process. Hot forging breaks up the large dendritic grain structure characteristic of castings and gives the metal a refined structure, with all inclusions stretched out in the direction in which plastic flow occurs. A metal has greater load-carrying ability in the direction of its flow lines than it does across the flow lines. Consequently, a hot-formed part should be designed so that the flow lines run in the direction of the greatest load during service.

An extension of conventional forging known as precision forging can be used to acquire geometric configurations very close to the final desired shape, thus minimizing secondary machining operations.

Guidelines that should be observed in the design of forging in order to simplify its manufacturing and help ensure its reliability are as follows:

1. The maximum length of bar that can be upset in a single stroke is limited by possible buckling of the unsupported portion. The unsupported length should not be longer than three times the diameter of the bar or distance across the flats.
2. Recesses in depth up to their diameter can be easily incorporated in either or both sides of a section. Secondary piercing operations to remove the residual web should be utilized on through-hole designs.
3. Draft angle should be added to all surfaces perpendicular to the forging plane so as to permit easy removal of the forged part. Remember that outside draft angles can be smaller than inside angles since the outside surfaces will shrink away from the die walls and the inside surfaces will shrink toward bosses in the die.
4. Deeper die cavities require more draft than shallow cavities. Draft angles for hard-to-forge materials, such as titanium and nickel-base alloys, should be larger than when forging easy-to-forge materials.
5. Uniform draft results in lower-cost dies, so endeavor to specify one uniform draft on all outside surfaces and one larger draft on all inside surfaces.
6. Corner and fillet radii should be as large as possible to facilitate metal flow and minimize die wear. Usually 6 mm (0.24 in.) is the minimum radius for parts forged from high-temperature alloys, stainless steels, and titanium alloys.
7. Endeavor to keep the parting line in one plane since this will result in simpler and lower-cost dies.
8. Locate the parting lines along a central element of the part. This practice avoids deep impressions, reduces die wear, and helps ensure easy removal of the forged part from the dies.

Table 2 provides important design for manufacturing information for the major forging processes.

TABLE 1 Important Design Parameters Associated with Various Casting Processes

Design Parameter	Casting Process							
	Sand Casting							
	Green	Dry/Cold/Set	Shell	Plaster (Preheated Mold)	Investment (Preheated Mold)	Premanent Mold (Preheated Mold)	Die (Preheated Mold)	Centrifugal
Weight	100 g to 400 MT	100 g to 400 MT	100 g to 100 kg	100 g to 100 kg	Less than 1 g to 50 kg	100 g to 25 kg	Less than 1 g to 30 kg	Grams to 200 kg
Minimum section thickness	3 mm	3 mm	1.5 mm	1 mm	0.5 mm	3 mm	0.75 mm	6 mm
Allowance for machining	Ferrous—2.5–9.5 mm; nonferrous—1.5–6.5	Ferrous—2.5–9.5 mm; nonferrous—1.5–6.5 mm	Often not required; when required, 2.5–6.5 mm	0.75 mm	0.25–0.75 mm	0.80–3 mm	0.80–1.60 mm	2.50–6.5 mm
General tolerance	$\pm 0.4 \sim 6.4$ mm	$\pm 0.4 \sim 6.4$ mm	$\pm 0.08 \sim \pm 1.60$ mm	$\pm 0.13 \sim \pm 0.26$ mm	$\pm 0.05 - \pm 1.5$ mm	$\pm 0.25 - \pm 1.5$ mm	$\pm 0.025 - \pm 0.125$ mm	$\pm 0.80 - \pm 3.5$ mm
Surface finish (μrms)	6.0–24.0	6.0–24.0	1.25–6.35	0.8–1.3	0.5–2.2	2.5–6.35	0.8–2.25	2.5–13.0
Process reliability	90	90	90	90	90	90	90	90
Cored holes	Holes $<$ 6 mm	Holes $<$ 6 mm	Holes $<$ 6 mm	Holes $<$ 12 mm	Holes as small as 0.5 mm diameter	Holes as small as 5 mm diameter	Holes as small as 0.80 mm diameter	Holes as small 25 mm diameter; no undercuts
Minimum lot size	1	1	100	1	20	1000	3000	100
Draft allowances	1°–3°	1°–3°	$\frac{1}{4}$°–1°	$\frac{1}{2}$°–2°	0°–$\frac{1}{2}$°	2°–3°	2°–5°	0°–3°

TABLE 2 Important Design Parameters Associated with Various Forging Processes

Design Parameter	Forging Process				
	Open Die	Conventional Utilizing Preblocked	Closed Die	Upset	Precision Die
Size or weight	500 g to 5000 kg	Grams to 20 kg	Grams to 20 kg	20–250 mm bar	Grams to 20 kg
Allowance for finish machining	2–10 mm	2–10 mm	1–5 mm	5–10 mm	0–3 mm
Thickness tolerance	±0.6 mm −0.2 mm to +3.00 mm −1.00 mm	+0.4 mm −0.2 mm to +2.00 mm −0.75 mm	+0.3 mm −0.15 mm to +1.5 mm − 0.5 mm	—	+0.2 mm −0.1 mm to +1 mm 0.2 mm
Filet and corners	5–7 mm	3–5 mm	2–4 mm	—	1–2 mm
Surface finish (μrms)	3.9–4.5	3.8–4.5	3.2–3.8	4.5–5.0	1.25–2.25
Process reliability	95	95	95	95	95
Minimum lot size	25	1000	1500	25	2000
Draft allowance	5°–10°	3°–5°	2°–5°	—	0°–3°
Die wear tolerance	±0.075 mm/kg weight of forging	±0.075 mm/kg weight of forging	±0.075 mm/kg weight of forging		±0.075 mm/kg weight of forging
Mismathcing tolerance	±.25 mm ±0.01 mm/3 kg weight of forging	±0.25 mm ±0.01 mm/3 kg weight of forging	±0.25 mm ±0.01 mm/3 kg weight of forging	—	±0.25 mm ±0.01 mm/3 kg weight of forging
Shrinkage tolerance	±0.08 mm	±0.08 mm	±0.08 mm	—	±0.08 mm

6.3. Other Basic Processes

In addition to casting and forging, several other processes that may be considered basic since they impart the approximate finished geometry to material that is in the powdered, sheet, or rod-shape form. Notable among these are powder metallurgy, cold heading, extrusion, roll forming, press forming, spinning, electroforming, and automatic screw machine work.

In powdered metallurgy, powdered metal is placed in a die and compressed under high pressure. The resulting cold-formed part is then sintered in a furnace to a point below the melting point of its major constituent.

Cold heading involves striking a segment of cold material up to 25 mm (1 in.) in diameter in a die so that it plastically deformed to the die configuration.

Extrusion is performed by forcing heated metal through a die having an aperture of the desired shape. The extruded lengths are then cut into the desired length. From the standpoint of producibility, the following design features should be observed:

1. Very thin sections with large circumscribing area should be avoided.
2. Any thick wedge section that tapers to a thin edge should be avoided.
3. Thin sections that have close space tolerance should be avoided.
4. Sharp corners should be avoided.
5. Semiclosed shapes that necessitate dies with long, thin projections should be avoided.
6. When a thin member is attached to a heavy section, the length of the thin member should not exceed 10 times its thickness.

In roll forming, strip metal is permanently deformed by stretching it beyond its yield point. The series of rolls progressively changes the shape of the metal to the desired shape. In design, the extent of the bends in the rolls, allowance must be made for springback.

In press forming, as in roll forming, metal is stretched beyond its yield point. The original material remains about the same thickness or diameter, although it will be reduced slightly by drawing or ironing. Forming is based upon two principles:

1. Stretching and compressing material beyond the elastic limit on the outside and inside of a bend.
2. Stretching the material beyond the elastic limit without compressing the material beyond the elastic limit without stretching.

Spinning is a metal-forming process in which the work is formed over a pattern, usually made of hard wood or metal. As the mold and material are spun, a tool (resting on a steady rest) is forced against the material until the material contacts the mold. Only symmetrical shapes can be spun. The manufacturing engineer associated with this process is concerned primarily with blank development and proper feed pressure.

In electroforming, a mandrel having the desired inside geometry of the part is placed in an electroplating bath. After the desired thickness of the part is achieved, the mandrel pattern is removed, leaving the formed piece.

Automatic screw machine forming involves the use of bar stock, which is fed and cut to the desired shape.

Table 3 provides important design for manufacturing information for these basic processes.

7. DESIGN FOR SECONDARY OPERATION

Just as there should be careful analysis in the selection of the ideal basic or primary process, so must there be sound planning in the specification of the secondary processes. The parameters associated with all process planning include the size of the part, the geometric configuration or shape required, the material, the tolerance and surface finished needed, the quantity to be produced, and of course the cost. Just as there are several alternatives in the selection of a basic process, so there are several alternatives in determining how a final configuration can be achieved.

With reference to secondary removal operations, several guidelines should be observed in connection with the design of the product in order to help ensure its producibility.

1. Provide flat surfaces for entering of the drill on all holes that need to be drilled.
2. On long rods, design mating members so that male threads can be machined between centers, as opposed to female threads, where it would be difficult to support the work.
3. Always design so that gripping surfaces are provided for holding the work while machining is performed and ensure that the held piece is sufficiently rigid to withstand machining forces.
4. Avoid double fits in design for mating parts. It is much easier to maintain close tolerance when a single fit is specified.
5. Avoid specifying contours that require special form tools.
6. In metal stamping, avoid feather edges when shearing. Internal edges should be rounded, and corners along the edge of the strip stock should be sharp.
7. In metal stamping of parts that are to be subsequently press formed, straight edges should be specified, if possible, on the flat blanks.
8. In tapped blind holes, the last thread should be at least 1.5 times the thread pitch from the bottom of the hole.
9. Blind-drilled holes should end with a conical geometry to allow the use of standard drills.
10. Design the work so that diameters of external features increase from the exposed face and diameters of internal features decrease.
11. Internal corners should indicate a radius equal to the cutting tool radius.
12. Endeavor to simplify the design so that all secondary operations can be performed on one machine.
13. Design the work so that all secondary operations can be performed while holding the work in a single fixture or jig.

Table 4 provides a comparison of the basic machining operations used in performing the majority of secondary operations.

TABLE 3 Important Design Parameters Associated with Manufacturing Information for Basic Processes

Design Parmeter	Powder Metallurgy	Cold Headng	Extrusion	Roll Forming	Press Forming	Spinning	Electroforming	Automatic Screw Machine
Size	Diameter—1.5–300 mm; length —3–225 mm	Diameter—0.75–20 mm; length —1.50–250 mm	1.5–250 mm diameter	1–2000 mm	Up to 6 mm diameter	6–4000 mm	Limited to size of plating tanks	0.80 mm diameter by 1.50 mm; length to 200 mm diameter by 900 mm length
Minimun thickness	1 mm	—	1 mm	0.075 mm	0.075 mm	0.1 mm	0.0025 mm	—
Allowance for finish maching	To size	To size	To size	To size	To size	To size	To size	To size
Tolerance	Diameter—±0.025–0.125 mm; length—±0.25–0.50 mm	Diameter—−0.05–0.125 mm; length—±0.75–2.25 mm	Flatness—±0.01 mm/in. of width; wall thickness—±0.15–0.25 mm; cross section—±0.15–0.20	Cross section—±0.050–0.35 mm; length—±1.5 mm	±0.25 mm	Length—±0.12 mm; thickness—±0.05 mm	Wall thicknesses—±0.025 mm; dimension—±0.005 mm	Diameter—±0.01–.06 mm; length—±0.04–0.01 mm; 0.10 concentricity—±0.06 mm
Surface finish (μrms)	0.125–1.25	2.2–2.6	2.5–3	2.2–2.6	2.2–4.0	0.4–2.2	0.125–0.250	0.30–2.5

Inserts permitted	Yes	No	No	No	No	No	No	No
Holes permitted	Yes	No	Yes	Yes	Yes	No	Yes	Yes

TABLE 4 Machining Operations Used in Performing Secondary Operation

Process	Shape Produced	Machine	Cutting Tool	Tolerance	Surface Finish (μrms)	Relative Motion	
						Tool	Work
Turning (external)	Surface of revolution (cylindrical)	Lath, boring machine	Single point	±0.005–±0.025 mm	0.8–6.4		
Boring (external)	Cylindrical (enlarges holes)	Boring machine	Single point	±0.005–±0.025 mm	0.4–5.0		
Shaping and planing	Flat surface or slots	Shaper, planer	Single point	±0.025–±0.050 mm	0.8–6.4		
Milling (end, form, slab)	Flat and contoured surfaces and slots	Milling machine—horizontal, vertical, bed-type	Multiple points	±0.025–±0.050 mm	0.8–6.4		
Drilling	Cylindrical (originating holes (0.1–100 mm diameter)	Drill press	Twin-edge drill	±0.050–±0.100 mm	2.5–6.4		Fixed
Grinding (cylindrical surface, plunge)	Cylindrical, flat and formed	Griding machine—cylindrical, surface, thread	Multiple points	±0.0025–±0.0075 mm	0.2–3.2		
Reaming	Cylindrical (enlarging and improving finish of holes)	Drill press, turret lathe	Multiple points	±0.0125–±0.0500 mm	0.8–2.5		Fixed
Broaching	Cylindrical, flat, slots	Broaching machine, press	Multiple points	±0.005–±0.0150 mm	0.8–2.5		Fixed
Electric discharge machining	Variety of shapes depending on shape of electrode	Electric discharge machine	Single-point electrode	±0.050 mm	0.8–5.0		Fixed

Electrochemical machining	Variety of shapes; usually odd-shapped cavities of hard material	Electrochemical machine	Dissolution process	±0.050 mm	0.3–1.5	Andoic dissolution; tool is cathode	Workpiece is anode
Chemical machining	Variety of shapes; usually blanking of intricate shapes, printed circuit etching, or shallow cavities	Chemical machining machine	Chemical attack of exposed surfaces	±0.050 mm	0.6–1.8	Chemical attack of exposed surfaces	Fixed
Laser machining	Cylindrical holes as small as 5 μm	Laser beam machine	Single-wavelength beam of light	Holes are reproducible within ±3%	0.6–2.5	Fixed	Fixed
Ultrasonic machining	Same shape as tool	Machine equipped with magnetostrictive transducer, generator power supply	Shaped tool and abrasive powder	±0.025 mm	0.3–0.9		Fixed
Electron beam machining	Cylindrical slots	Electron beam machine equipped with vacuum of 10^{-4} mm of mercury	High-velocity electrons focus on workpiece	±0.025 mm	0.6–1.8		Fixed
Gear generating	Eccentric cams, ratchets, gears	Gear shaper	Single-point reciprocating	±0.013–±0.025 mm	1.8–3.8		
Hobbing	Any form that regularly repeats itself on periphery of circular part	Hobbing machine	Multiple points	±0.013–±0.025 mm	1.8–3.8		
Treplanning	Large through holes, circular grooves	Lathe-like machine	One or more single-point cutters revolving around a center	±0.13 mm	2.5–6.4		

8. DESIGN FOR BASIC PROCESSES—PLASTICS

There are more than 30 distinct families of plastic, from which evolve thousands of types and formulations that are available to the functional designer. However, in the fabrication of plastics, either thermoplastic or thermosetting, only a limited number of basic processes are available. These processes include compression molding, transfer molding, injection molding, extrusion, casting, cold molding, thermoforming, calendering, rotational molding, and blow molding. The functional designer usually gives little thought to how the part will be made. He or she is usually concerned primarily with the specific gravity, hardness, water absorption, outdoor weathering, coefficient of linear thermal expansion, elongation, flexural modulus, izod impact, deflect temperature under load, and flexural yield, tensile, shear, and compressive strengths.

8.1. Compression Molding

In compression molding, an appropriate amount of plastic compound (usually in powder form) is introduced into a heated mold, which is subsequently closed under pressure. The molding material, either thermoplastic or thermosetting, is softened by the heat and formed into a continuous mass having the geometric configuration of the mold cavity. If the material is thermoplastic, hardening is accomplished by cooling the mold. If the material is thermosetting, further heating will result in the hardening of the material.

Compression molding offers the following desirable features:

1. Thin-walled parts (less than 1.5 mm) are readily molded with this process with little warpage or dimensional deviation.
2. There will be no gate markings, which is of particular importance on small parts.
3. Less shrinkage, and more uniform, is characteristic of this molding process.
4. It is especially economical for larger parts (those weighing more than 1 kg).
5. Initial costs are less since it usually costs less to design and make a compression mold than a transfer or injection mold.
6. Reinforcing fibers are not broken up as they are in closed-mold methods such as transfer and injection. Therefore, the fabricated parts under compression molding may be both stronger and tougher.

8.2. Transfer Molding

Under transfer molding, the mold is first closed. The plastic material is then conveyed into the mold cavity under pressure from an auxiliary chamber. The molding compound is placed in the hot auxiliary chamber and subsequently forced in a plastic state through an orifice into the mold cavities by pressure. The molded part and the residue (cull) are ejected upon opening the mold after the part has hardened. Under transfer molding, there is no flash to trim; only the runner needs to be removed.

8.3. Injection Molding

In injection molding, the raw material (pellets, grains, etc.) is placed into a hopper, called the barrel, above a heated cylinder. The material is metered into the barrel every cycle so as to replenish the system for what has been forced into the mold. Pressure up to 1750 kg/cm^2 forces the plastic molding compound through the heating cylinder and into the mold cavities. Although this process is used primarily for the molding of thermoplastic materials, it can also be used for thermosetting polymers. When molding thermosets, such as phenolic resins, low barrel temperatures should be used (65–120°C). Thermoplastic barrel temperatures are much higher, usually in the range of 175–315°C.

8.4. Extrusion

Like the extrusion of metals, the extrusion of plastics involves the continuous forming of a shape by forcing softened plastic material through a die orifice that has approximately the geometric profile of the cross-section of the work. The extruded form is subsequently hardened by cooling. With the continuous extrusion process, such products as rods, tubes, and shapes of uniform cross-section can be economically produced. Extrusion to obtain a sleeve of the correct proportion almost always precedes the basic process of blow molding.

8.5. Casting

Much like the casting of metals, the casting of plastics involves introducing plastic materials in the liquid form into a mold that has been shaped to contour of the piece to be formed. The material that is used for making the mold is often flexible, such as rubber latex. Molds may also be made of nonflexible materials such as plaster. Epoxies, phenolics, and polyesters are plastics that are frequently fabricated by the casting process.

8.6. Cold Molding

Cold molding takes place when thermosetting compounds are introduced into a room-temperature steel mold that is closed under pressure. The mold is subsequently opened, and the formed article is transferred to a heating oven, where it is baked until it becomes hard.

8.7. Thermoforming

Thermoforming is restricted to thermoplastic materials. Here sheets of the plastic material are heated and drawn over a mold contour so that the work takes the shape of the mold. Thermosetting may also be done by passing the stock between a sequence of rolls that produce the desired contour. Most thermoplastic materials become soft enough for thermoforming between 135 and 220°C. The plastic sheet that was obtained by calendering or extrusion can be brought to the correct thermoforming temperature by infrared radiant heat, electrical resistance heating, or ovens using gas or fuel oil.

8.8. Calendering

Calendering is the continuous production of a thin sheet by passing thermoplastic compounds between a series of heated rolls. The thickness of the sheet is determined by adjusting the distance between the rolls. After passing between the final set of rolls, the thin plastic sheet is cooled before being wound into large rolls for storage.

8.9. Blow Molding

In blow molding, a tube of molten plastic material, the parison, is extruded over an apparatus called the blow pipe and is then encased in a split mold. Air is injected into this hot section of extruded stock through the blow pipe. The stock is then blown outward, where it follows the contour of the mold. The part is then cooled, the mold opened, and the molded part ejected. In very heavy sections, carbon dioxide or liquid nitrogen may be used to hasten the cooling. This process is widely used in molding high- and low-density polyethylene, nylon, polyvinyl chloride (PVC), polypropylene, polystyrene, and polycarbonates.

8.10. Parameters Affecting the Selection of the Optimum Basic Process

Selecting the optimum basic process in the production of a given plastic design will have a significant bearing on the success of that design. The principal parameters that should be considered in the selection decision include the plastic material to be used, the geometry or configuration of the part, the quantity to be produced, and the cost.

If the functional designer cannot identify the exact plastic material that is to be used, he or she should be able to indicate whether a thermoplastic or thermosetting resin is being considered. This information alone will be most helpful. Certainly both thermoforming and blow molding are largely restricted to thermosetting resins, as is transfer molding. Injection molding is used primarily for producing large-volume thermoplastic moldings, and extrusion for large-volume thermoplastic continuous shapes.

Geometry or shape also has a major impact on process selection. Unless a part has a continuous cross-section, it would not be extruded; unless it were relatively thin walled and bottle shaped, it would not be blow molded. Again, calendering is restricted to flat sheet or strip designs, and the use of inserts is restricted to the molding processes.

The quantity to be produced also has a major role in the selection decision. Most designs can be made by simple compression molding, yet this method would not be economical if the quantity were large and material were suitable for injection molding.

The following design for manufacturing points apply to the processing of plastics:

1. Holes less than 1.5 mm diameter should not be molded but should be drilled after molding.
2. Depth of blind holes should be limited to twice their diameter.
3. Holes should be located perpendicular to the parting line to permit easy material removal from the mold.
4. Undercuts should be avoided in molded parts since they require either a split mold or a removable core section.
5. The section thickness between any two holes should be greater than 3 mm.
6. Boss heights should not be more than twice their diameter.
7. Bosses should be designed with at least a 5° taper on each side for easy withdrawal from the mold.
8. Bosses should be designed with radii at both the top and the base.
9. Ribs should be designed with at least a 2–5° taper on each side.

TABLE 5 Basic Processes Used to Fabricate Plastics and Their Principal Parameters

	Parameter									
Process	Shape Produced	Machine	Mold or Tool	Material	Typical Tolerance	Minimum Wall Thickness	Ribs	Draft	Inserts	Minimim Quantity Requirements
Calendering	Continuous sheet for film	Multiple-roll calender	None	Thermoplastic	0.05–0.200 mm depending on material	None		None	None	Low
Extrusion	Continuous form such as rods, tubes, filaments, and simple shapes	Extrusion press	Hardened steel die	Thermoplastic	0.01–0.30 mm depending on material	None		None	Possible to extrude over or around wire insert	Low (tooling is inexpensive)
Compression molding	Simple outlines and plain cross sections	Compression press	Hardened tool steel mold	Thermoplatic or thermosetting	0.04–0.25 mm depending on material	1.25			Yes	Low
Transfer molding	Complex geometrics possible	Transfer press	Hardened tool steel mold	Thermosetting	0.04–0.25 mm depending on material	1.5 mm	3°–5° taper; height $<$ 3 times wall thickness	$\frac{1}{2}$°–5°	Yes	High
Injection molding	Complex geometrics possible	Injection press	Hardened tool steel mold	Thermoplastic or thermosetting	0.04–0.25 mm depending on material	1.25 mm	2°–5° taper; height = $1\frac{1}{2}$ times wall thickness; width $\frac{1}{2}$ of wall thickness	$\frac{1}{4}$°–4°	Yes	High
Casting	Simple outlines and plain cross sections	None	Metal mold or expoxy mold	Thermosetting	0.10–0.50 mm depending on material	2.0 mm			Yes	Low to medium depending on mold
Cold molding	Simple outlines and plain cross sections	None	Mold of wood, plaster, or steel	Thermosetting	0.01–0.05 mm depending on material	2.0 mm			Yes	Low

Blow molding	Thin walled and bottle shaped	Pneumatic blow molding machine	Tool steel mold	Thermoplastic				No	High
Rotational molding	Full enclosures or semienclosures (hollow objects)	Rotomolding system	Cast aluminum or fabricated metal	Thermoplastic, limited thermosetting	0.03–0.60 mm	3.0 mm		No	Medium
Filament winding	Tubes, piping, tanks	Filament winding machine	Must have axis about which the filament can be wound	Sing-end continuous strand glass fiber and thermoplastic	0.20–0.50 mm	3.0 mm			Medium

10. Ribs should be designed with radii at both the top and the base.
11. Ribs should be designed at a height of 1.5 times the wall thickness. The rib width of the base should be half the wall thickness.
12. Outside edges at the parting line should be designed without a radius. Fillets should be specified at the base ribs and bosses and on corners and should be not less than 0.8 mm.
13. Inserts should be at right angles to the parting line and of a design that allows both ends to be supported in the mold.
14. A draft or taper of 1–2° should be specified on the vertical surfaces or walls parallel with the direction of mold pressure.
15. Cavity numbers should be engraved in the mold. The letters should be 2.4 mm high and 0.18 mm deep.
16. Threading below 8 mm diameter should be cut after molding.

Table 5 identifies the major parameters associated with basic processes used to fabricate thermoplastic and thermosetting resins.

9. DESIGN FOR ASSEMBLY

The goal of DFA is to ease the assembly of the product. Boothroyd et al. (1994) propose a method for DFA that involves two principal steps:

- Designing with as few parts as possible. This is accomplished by analyzing parts pairwise to determine whether the two parts can be created as a single piece rather than as an assembly.
- Estimating the costs of handling and assembling each part using the appropriate assembly process to generate costs figures to analyze the cost savings through DFA.
- In addition to the assembly cost reductions through DFA, there are reductions in part costs that are more significant. Other benefits of DFA include improved reliability and reduction in inventory and production control costs. Consequently, DFA should be applied regardless of the assembly cost and product volume.

10. COMPUTER SOFTWARE TOOLS: OBJECT-ORIENTED PROGRAMMING AND KNOWLEDGE-BASED SYSTEMS

Modern CAD/CAM systems and computer-aided processing planning systems for machining are well known and are very important for integrating design and manufacturing. However, more work is needed to develop them into tools for helping design for manufacturability. We need a software system that can be easily modulized, expanded, alternated in its structures and contents, and integrated partially or fully. The key technology is a recently developed style and structure of programming called object-oriented programming (OOP).

Object-oriented programming supports four unique object functions or properties:

1. *Abstraction:* Abstraction is done by the creation of a ''class protocol description'' that defines the properties of any object that is an instance of that class.
2. *Encapsulation:* An object encapsulates all the properties (data and messages) of the specific instance of the class.
3. *Inheritance:* Some classes are subordinate to others and are called subclasses. Subclasses are considered to be special cases of the class under which they are grouped in the hierarchy. The variables and methods defined in the higher-level classes will be automatically inherited by the lower-level classes.
4. *Polymorphism:* Allows us to send the same message to different objects in different levels of class hierarchy. Each object responds in a way that is inherited or redefined with respect to the object's characteristics.

With these properties, integrated and expandable software for supporting designs, including design for manufacturability, can be developed. An example is shown in Trappey and Liu (1990), who developed a system shell for design using the object-oriented programming language, SMALLTALK-80 (Goldberg 1984).

Another key software technology for design for manufacturability, such as automated rule checking, is knowledge-based systems, or expert systems. The general methodology for building these systems roughly consists of five steps: identification, conceptualization, formalization, implementation, and testing (Hayes-Roth et al. 1983). An example of this approach for fixture design for machining is shown in Ferreira et al. (1985).

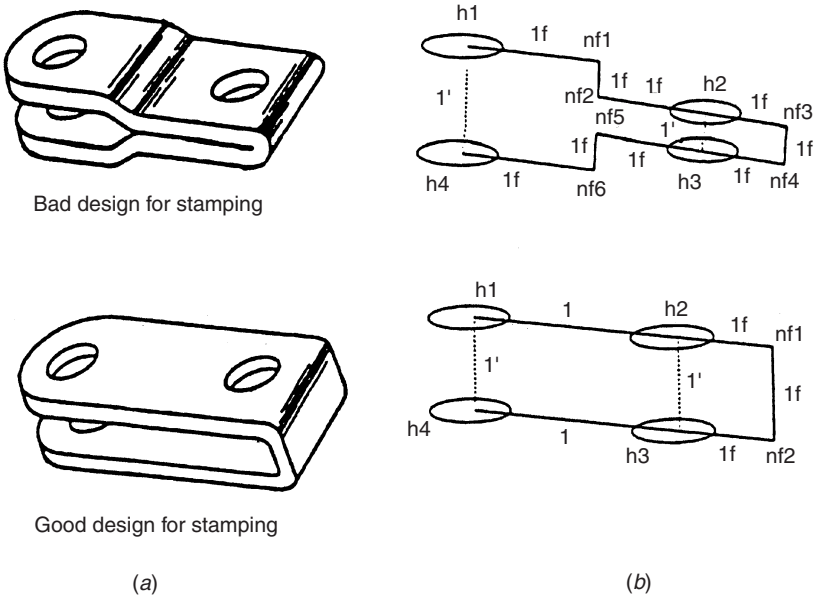

Figure 6 Parts and Their Sketching Abstractions. (*a*) Examples of stamping parts. (*b*) Parts-sketching abstraction that facilitates manufacturability evaluation in conceptual design. (Reprinted from *Robotics and Computer-Integrated Manufacturing,* Vol. 13, No. 3, A. Mukherjee and C. R. Liu, "Conceptual Design, Manufacturability Evaluation and Preliminary Process Planning Using Function–Form Relationships in Stamped Metal Parts," p. 258, Copyright 1997, with permission from Elesevier Science)

Current CAD systems have been oriented to detail design, while the application of DFM guidelines to early design stages yields the largest benefits. Research is needed to lay the foundation for the CAD system for conceptual design so that DFM and CAD can be integrated successfully. Mukherjee and Liu (1995) propose a promising method. In the proposed representation, called sketching abstraction, the discretionary geometry of the part having functional relevance is captured using functional features, while the nondiscretionary geometry is represented using a linkage mechanism. The functional features are related to the part function using data structures called function–form matrices. They attempt to bridge the gap between function and form representations and provide the designer with a tool that can be used for generating design alternatives. Figure 6 is an example of this representation, which facilitates manufacturability evaluation in conceptual design (Mukherjee and Liu 1997).

11. ORGANIZATIONAL ISSUES

Design for manufacturability is to be implemented in an industrial environment. Therefore, we are concerned with (1) increasing the individual engineer's knowledge in both the areas of design and manufacturing and (2) facilitating better and early communication between design and manufacturing groups. To increase the individual engineer's knowledge, training courses for manufacturability guidelines specific and nonspecific to the company concerned should be established. Examples, good and bad, are always helpful. Rotation of job responsibilities between design and manufacturing engineers, when feasible, is also a good way to increase an engineer's knowledge in design for manufacturability.

To facilitate better and early communication, product and process design should be managed in an integrated manner. For small companies, short product life cycle, or simple products, integrated product and process design task force may prove to be effective. For large companies, long product life cycle, or complex products, product and process engineering should be integrated within one organizational unit, or at least have a close working relationship. In large projects, computer tools may prove to be necessary. The computer tools now available are expert system software shells, CAD/CAM systems, and object-oriented programming tools, as discussed in Section 9.

In managing integrated product and process designs, there are several points worth considering:

1. Select a competent, strong project manager.
2. Quickly develop constraints for the product design and process selection at various levels by the effort of the entire team, that is, list the impossible and infeasible first.
3. Develop the product profile and specification through the team effort, remembering the purpose of a design, and list three other alternatives for every design, be it a subsystem or a component.
4. Aim high, recognizing that quality and cost need not be compromised when development time is compressed.
5. Give enough authorization to the team manager so that quick decisions can be made.

CHAPTER 51

Managing Professional Services Projects

BARRY M. MUNDT
The Strategy Facilitation Group

FRANCIS J. SMITH
Francis J. Smith Management Consultants

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. PROJECT MANAGEMENT IN THE PROFESSIONAL SERVICES CONTEXT

1.1. Professional Services Defined

Professional services are knowledge- and experience-based activities, performed by appropriately qualified individuals or teams, that are intended to result in predefined, desired outputs and/or outcomes. Such services can be performed for a fee by one professional enterprise for the benefit of another enterprise (the external client), such as accounting, management consulting, engineering, legal, and marketing services; or they can be performed within an enterprise for the benefit of that enterprise (the internal client), such as new product development, strategic analysis, operations improvement, and systems development/implementation (for example, an industrial engineering department in a manufacturing company or financial institution would be considered a professional services organization in this context). The delivery of a professional service typically is supported by the application of information technology and the use of appropriate data/knowledge bases.

1.2. Project Management Defined

Project management is the planning, organizing, guiding, and monitoring of organizational resources that are necessary to successfully produce one or more desired outputs or outcomes (often called deliverables). It encompasses management of project risks, issues, and changes, as well as product/deliverable configuration and quality.

A project is:

- A unique venture with a defined beginning and end
- Carried out by people to meet a specific objective or set of objectives
- Defined within the parameters of scope, schedule, cost, and quality

Project management does not include the management of ongoing tasks and/or repetitive functions.

1.3. Managing Professional Services Projects

Most of the work done by professional service organizations is performed as, and can be defined in terms of, projects. Often the desired deliverables and outcomes of a professional services project can be somewhat fuzzy, conceptual, and less tangible when compared to, say, a more concrete construc-

tion project. This causes project time and cost to be more difficult to estimate during project planning; accordingly, progress during project execution tends to be more difficult to measure.

Regardless, a project team is formed to produce a definite set of deliverables within a certain time frame for a specified cost (budget). The project team is led by a project manager, who is responsible for ensuring that the objectives of the project are achieved on time and within budget.

2. THE PROJECT MANAGER

A project manager typically is someone who has a wide breadth and depth of knowledge and experience in a number of areas. He or she also is someone who is skilled in working with teams, leverages relationships judiciously, and is knowledgeable in the use of tools and techniques that aid in accomplishing his or her role.

2.1. The Project Manager's Role

The project manager facilitates the team-building process and collaborates with the project team to create and execute the project plan. The project manager also acts as the liaison between the team and the client. He or she continually monitors the progress of the project and reports project status periodically to both the client and other interested stakeholders. The project manager works to ensure that the client is satisfied and that the project is completed within the parameters of scope, schedule, cost, and quality.

2.2. Project Manager Characteristics

A project manager's characteristics differ from those of the typical functional manager. For example, functional managers usually:

- Are specialists
- Function as technical supervisors
- Are skilled at analysis and analytical approaches
- Maintain line control over team members

Project managers, on the other hand, typically:

- Are generalists with wide experience and knowledge
- Coordinate teams of specialists from a variety of technical areas
- Have technical expertise in one or two areas
- Are skilled at synthesis and the systems approach
- Do not have line control over the project team members

2.3. Identifying Project Manager Candidates

Project managers can be persons working for the professional enterprise who are reassigned to the project manager position for the life of a given project or for a specified period of time. Project manager candidates may also come from outside the organization. For example, they may be contracted by the organization to serve as the project manager for a specific project.

Project managers may come from almost any educational background, although the industrial engineering curriculum is probably the most relevant. In any case, a successful project manager candidate should be able to demonstrate significant experience in the position. Additional qualifications might include project manager certification, which is awarded to qualified persons by organizations such as the Project Management Institute.

3. OVERVIEW OF THE PROJECT MANAGEMENT PROCESS

3.1. The Phases of Project Management

The project management process includes four phases:

- Phase I: project definition
- Phase II: project planning
- Phase III: project monitoring and control
- Phase IV: project close

Each phase has its purpose and the phases are linked in order. In fact, Phases I through III tend to be iterative. For example, some level of project planning is required to develop reasonably accurate,

high-level estimates of project time and cost during project definition. Likewise, during project execution, the monitoring and control process may identify situations that will require changes in the project plan and possibly even in the project definition.

3.3. Relationship of Phases to the Delivery of Professional Services

In the professional services context, the project definition serves as the proposal to the client or the statement of work (SOW) issued by the client. Subsequent to any negotiations, the client formally accepts the proposal (or the firm formally accepts the SOW); in many cases a formal contract is executed, often incorporating the proposal or SOW. Detailed project planning then begins.

The project plan sets out the work steps, schedule, resources, and budget necessary to successfully conduct the project. The plan then becomes the basis for routinely monitoring and measuring progress during project execution and applying appropriate controls, when necessary, to make sure the project stays on track.

The project close phase seeks to determine whether the client is satisfied with the results of the work and ensures that the client understands and agrees that the project has been completed.

4. PHASE I: PROJECT DEFINITION

4.1. Project Definition Purpose

Project definition is arguably the most important phase of a project. It entails defining the objectives, scope, and deliverables of the project; selecting the most appropriate approach; developing high-level estimates of time and cost; defining the project-management process; and identifying and addressing potential problems and risks. The project-definition phase ensures that the stakeholders and project team have a common understanding of the project's purpose, objectives, and benefits. Many failed projects have been linked to inadequate development of a project definition.

A sound project definition enables the organization to begin the project in a systematic manner; it sets the tone and establishes the project's direction, opens channels of communication, forms a basis for client and stakeholder trust, and tends to bring to the surface any client concerns or challenges. The risks of not having a sound project definition include false starts, inadequate communication, confusion among the participants, and failure to meet the client's and other stakeholders' expectations.

4.2. The Project Definition Team

A core team is established to prepare the project definition (and usually the subsequent project plan). The core team may include the project manager, functional personnel, technical personnel, and possibly other professionals drawn from outside the firm.

Expectations need to be communicated clearly to the core team members, including their accountability for the project deliverables and outcomes as well as their required time commitment throughout the life of the project. The time commitment, which might be full time during the development of the project definition and the project plan, should also be explained to the core team members' supervisors (performance managers).

The specific technical expertise required of the core team members is dependent upon the nature of the project. However, at a minimum, they should have a sufficient top-level understanding of the technical issues to be able to define and plan the project effectively as well as to manage the resources that may be recruited to work on the project.

4.3. Project Definition Components

A project definition should contain at least the following components:

- Project objectives (outcomes)
- Scope
- Deliverables (outputs)
- Approach
- Resource and infrastructure requirements
- High-level time and cost estimates
- Project risks

Each of these components is described below. Examples are provided based on a typical project to identify, evaluate, and select a manufacturing business planning and control software system. Software evaluation and selection assistance is a fairly common professional service provided by consulting

firms to clients (in this example, ABC Manufacturing, Inc.). This example project will be carried throughout this chapter to illustrate the various aspects of professional services project management.

4.3.1. Project Objectives (Outcomes)

Objectives are the destination, target, or aim of the project. They are needed to clarify the client's and other stakeholder's expectations. They also help to:

- Establish a common vision
- Guide the team during project plan development and execution
- Keep the team focused as the project progresses
- Provide a basis for communications during the project
- Establish a means for assessing success at the completion of the project

Good objectives state what will be achieved and/or the results sought, not how the team will get there. They are specific, unambiguous, and measurable, containing a time frame for the intended achievements. Examples of outcome-oriented objectives include: select a business planning and control software system in six months; implement the selected business planning and control software system in 18 months; increase product throughput by 50% in two years; decrease inventory investment by 75% by year end.

4.3.2. Scope

The statement of scope sets the boundaries of the project, in that it defines the confines, the reach, and/or the extent of the areas to be covered. It clarifies what will be included in the project and, if necessary, states specifically what will *not* be included.

Scope may be defined in terms such as geographical coverage, range of deliverables, quality level, and time period. The statement of scope must be clear, concise, and complete, as it will serve as the basis for determining if and when out-of-scope work is being conducted during project execution. In the professional services field, performance of unauthorized, out-of-scope work on a project usually will result in a budget overrun, unrecovered fees and expenses from the client, and unsatisfactory project financial results. Potential out-of-scope work should be identified *before* it is performed and negotiated as additional work, along with its attendant cost and schedule requirements.

An example of a scope statement is: ''Assist ABC Company in selecting an appropriate business planning and control software and hardware system and implementing the selected system. The assistance will include defining business system requirements, evaluating system alternatives, making a selection that will support manufacturing and accounting functions, and facilitating the implementation of the selected system.''

4.3.3. Deliverables (Outputs)

A deliverable is anything produced on a project that supports achievement of the project objectives. It is any measurable, tangible, verifiable outcome, result, or item that is produced to complete a task, activity, or project. The term is sometimes used in a more narrow context when it refers to an external deliverable (handed over to a stakeholder or client and subject to approval).

Examples of deliverables are system requirements definition document; request for proposal (RFP) document; systems-evaluation criteria; software and hardware configuration design; system-implementation project plan; and facilitation assistance during the system-implementation process.

4.3.4. Project Approach

The project approach defines the general course of action that will be taken to accomplish the project objectives. For example, the project approach may be defined in such terms as the methodology to be used, the timing/phases of the project, and/or the types of technology and human resources to be applied. The approach section of the project definition explains, in general, how the project will be carried out.

An example of an approach statement for developing a system requirements definition document is: ''We will conduct interviews with personnel in each functional area to develop and define the system requirements, based on a system requirements profile. We will provide advice in the definition of critical system requirements, such as system performance (timing, volumes, and the like). This phase will culminate with the development of a system requirements definition document.''

4.3.5. Resource and Infrastructure Requirements

Resource and infrastructure requirements for professional service projects typically fall into any of three categories: human resources, facilities and equipment, and information technology (including knowledge bases). Human resource requirements, often the major cost of a project, should be defined

in terms of the roles, responsibilities, and skills that are needed for the project to be successful. The roles and responsibilities then are translated into a depiction and/or description of the planned organization structure for the project.

Arguably the most important role in the project is that of the project sponsor, the person who authorizes or "legitimizes" the project (often referred to simply as "the client"). If the sponsor is not committed to the project, the chances of successful completion are reduced. Sponsorship often can be extended by the formation of a project steering committee, which, if constructed properly, can be particularly useful in clearing barriers that are likely to come up during project execution.

An example of a resource and infrastructure requirements statement might be: "We will require designation of a project team leader to assist in scheduling interviews; arranging for the collection of information, reports, and documentation; and assisting in the coordination of administrative support. Knowledge of existing systems is also important to provide valuable background information. In addition, office space with a telephone and computer access to the internet is required."

4.3.6. High-Level Time/Cost Estimates

The purpose of high-level time/cost estimates is to gauge and validate project size. A high-level estimate sets out resource and staffing levels by project phase or activity and elapsed time by activity.

High-level time/cost estimates are top-down estimates made while developing the project definition. A high-level estimate can be developed by reviewing and drawing upon estimates from previous similar projects and any estimates developed in project definition work sessions. Assumptions, initial estimates, and associated calculations should be documented. During project planning (Phase II), detail calculations are summed and compared to the high-level figures as a way of validating the estimates.

An example of a high-level time/cost estimate is: "It is estimated that it will take 14 weeks to reach the point at which software has been selected. Once the hardware and software are installed, it will take approximately 10 months to implement the system. Based on the scope of work and the approach, it is estimated that the project will cost $350,000 to $375,000."

4.3.7. Project Risks

A project risk is any factor that challenges the project team's ability to manage the budget, resources, time, and quality of the project deliverables and acceptance of the deliverables. Risks would include any factors that could disrupt the project. They are uncertainties or vulnerabilities that could cause the team to deviate from the project plan.

Risks may be managed through a risk management plan. Establishment of such a plan entails identifying the risks, determining the potential impacts, defining preventive actions, estimating the costs (both monetary and nonmonetary) required to reduce the risks to acceptable levels, developing contingency plans, and obtaining management's commitment to the risk management plan.

Risk management is valuable in that it minimizes the unfavorable impact of unplanned incidents on a project. It enhances the probability of successful project implementation, creates a sense of urgency when unplanned incidents occur, and facilitates their timely and effective resolution.

Risk management typically involves assessing a number of dimensions of each identified risk. These dimensions include:

- The impact of the risk if it were to occur
- The likelihood that the risk will occur
- How difficult it would be to detect the risk

Each of these dimensions can be assessed separately for a specific area of risk and assigned a numerical low-to-high rating. The three dimension ratings then can be combined (e.g., averaged or added) to produce a relative risk value for the area, which can be compared with the ratings of other identified project risk areas to determine where emphasis needs to be placed in the risk management plan.

One way of judging overall project risk is through a constraint matrix, where three levels of flexibility (low, medium, high) are charted against the elements of schedule, scope, and cost. The purpose of a constraint matrix is to assess the degree of relative flexibility within a given project and the related risk. For example, a project profile that exhibits low flexibility in all three elements (schedule, scope, and cost) is a profile associated with high-risk projects and one that will demand extra careful management.

An example of a project risk management statement is: "A mechanism is provided for identifying and assessing any adverse consequences of a tentative system selection so their effects can be controlled during implementation. A structured approach will be used for developing relative priorities of individual requirements. Shortfalls in the functionality of a tentative selection will be evaluated. Alternative solutions to providing the functionality will be considered and the impact on the effect-

iveness of the overall system will be evaluated prior to making a final selection. Additionally, arrangements for holding the source code in escrow will ensure the availability of the source code in the event the software company cannot sustain ongoing viability.''

5. PHASE II: PROJECT PLANNING

5.1. Project Planning Purpose

The purpose of project planning is to confirm the project scope and objectives; develop the project organization, schedule, and budget; secure the necessary resources; and create clear expectations about the project organization, timing, budget, and resources.

The project workplan should clearly identify the deliverables that will be prepared and the tasks that need to be performed in order to prepare them. The project planning team uses the project definition as the beginning point for preparing the project workplan. The workplan is typically broken down into phases, activities, and tasks. Deliverables and resources are usually defined at the task level.

5.2. The Project Planning Team

A key member of the project planning team is the project manager because he or she will have primary responsibility for executing the project plan. The project planning team may also include one or more members of the project definition team to ensure that the thinking that went into defining the project is reflected in the project plan. If the project definition team is not represented on the project planning team, a draft of the project plan should be reviewed by one or more project definition team members.

Other members of the project planning team might include appropriate technical specialists and others who may be team members during project execution.

5.3. Project Planning Components

There are seven main steps in creating a project workplan:

1. Confirm objectives and scope.
2. Develop work breakdown structure.
3. Develop a detail task list.
4. Assign personnel to tasks.
5. Develop time estimates and a preliminary schedule of tasks.
6. Determine the critical path.
7. Balance the detailed workplan.

Each of these steps is described below.

5.3.1. Confirm Objectives and Scope

Often there can be a significant time period between the completion of project definition and the initiation of detailed project planning, which may result in divergent views as to the purpose of the project. It is important that there be full agreement regarding the objectives and scope of the project before the workplan is prepared. The project manager should seek confirmation of the objectives and scope based on input from the sponsor and/or the steering committee as well as the project-definition team members. If there are differences, the project manager should rely on the sponsor to settle them.

5.3.2. Develop Work Breakdown Structure

Developing a work breakdown structure entails expanding the project phases or deliverables into the major activities that need to occur to complete each phase and defining the tasks that need to occur to complete each activity.

Steps for developing a work breakdown structure and examples are presented in Table 1.

The work breakdown structure can encompass more than the three levels shown in Table 1, depending on the nature and complexity of the work to be done. For example, if the work effort has been done many times previously and/or is routine, it may not require more than three levels of detail (phase/activity/task). Conversely, work that is less familiar or more complex may require additional levels of detail to gain a full understanding of the work that must be done.

A work statement (often called a work package) then is prepared to describe the effort for each task or subtask at the lowest level of the work breakdown structure. Each work statement should be designed to ensure that the related task or subtask:

TABLE 1 Developing a Work Breakdown Structure

Steps in Developing a Work Breakdown Structure	Examples
1. Draw out the phases of the project or organize it by major project deliverables.	Phases: • Analysis and implementation preparation • Coordination of required disciplines and controls • Training of personnel • Implementation tailoring • Online implementation • New system break-in
2. Detail the major activities that need to occur to complete each phase.	Activities within the ''Analysis'' phase: • Define system requirements. • Develop a request for proposal document. • Develop evaluation criteria and evaluate alternatives. • Select a software and hardware configuration. • Develop an implementation project plan.
3. Detail all the tasks that will need to occur to complete each activity.	Tasks within the ''Define systems requirements'' activity: • Define and document business system objectives. • Document performance objectives. • Define and document anticipated benefits. • Document functional requirements. • Conduct interviews. • Document special considerations and constraints. • Assemble requirements documentation.

- Is measurable
- Has tangible results/outputs (deliverables)
- Has identifiable and readily available inputs
- Is a finite, manageable unit of work
- Requires a limited number of resources
- Fits into the natural order of work progression

A completed work breakdown structure will include the assembled detail tasks and their relationship to respective activities. A work breakdown structure may be displayed according to Figure 1 (in the figure, level 1 corresponds to ''phase,'' level 2 to ''activity,'' and level 3 to ''task'').

5.3.3. Develop a Task and Deliverables List

The different levels of the work breakdown structure should be documented in a task list that identifies each phase, activity, and task (and subtask, as appropriate). Next, the name of the person to be responsible for each task (the task ''owner'') and a description of the deliverable(s) associated with each task can be added. An example of a detailed task and deliverables list is shown in Figure 2.

When the task and deliverables list is complete, the logical order in which tasks should be performed is defined. This is done by first determining task dependencies at the lowest level of the work breakdown structure. These dependency relationships can be portrayed in the form of a project network diagram. An example of task dependencies is shown in Figure 3.

5.3.4. Assign Personnel to Tasks

Each task must be assigned personnel resources to perform the work. The steps for assigning personnel to tasks include:

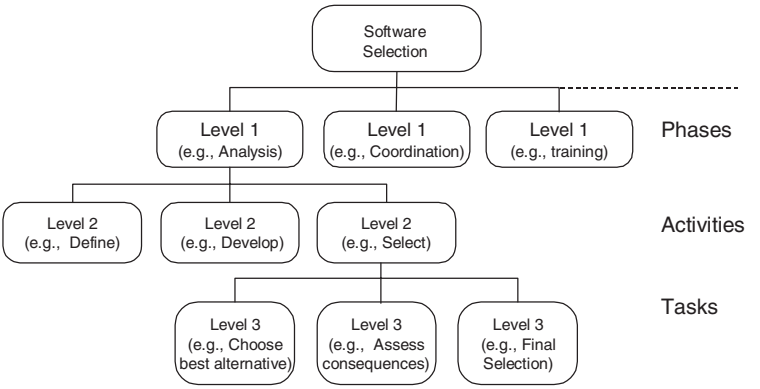

Figure 1 Partial Work Breakdown Structure.

- List the skills required to complete each task.
- Identify candidate team members whose skills meet the task requirements.
- Develop a rough estimate of the time that will be required to complete each task, based on the experience of the candidates.
- Negotiate roles and responsibilities of candidate team members relative to each task.

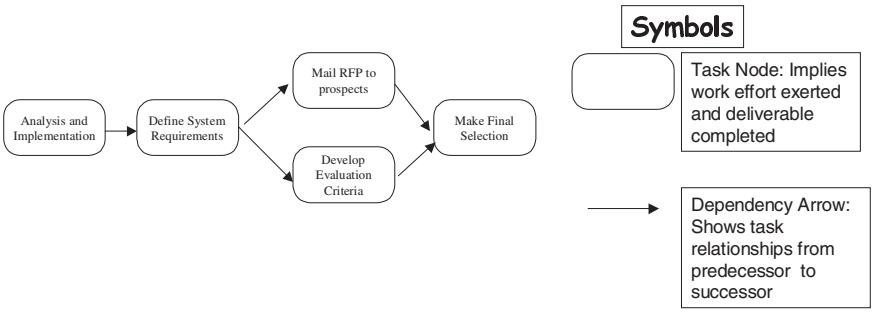

Figure 3 Task Dependencies.

- Gain commitment from the departments, performance managers, and candidates involved, particularly regarding the team members' availability to participate.
- Document the team members' project roles and responsibilities.

The project task assignments can be documented by extending the task and deliverables list (see Figure 2) to include an additional column entitled ''Task Team Members.''

5.3.5. Develop Time Estimates and Preliminary Schedule of Tasks

The next step is to develop time estimates for each task. The time estimates take two forms:

1. *Effort:* the actual work time required to complete each task, typically in terms of hours
2. *Duration:* the elapsed time between the start and finish of a task, typically in terms of days or weeks.

The effort estimates are used to determine the amount of time each team member is expected to spend on the project, as well as the related cost of their services. The task-duration estimates, when combined with the project network diagram (see Figure 4), provide the basis for setting a project schedule (i.e., task start and completion dates).

The effort and duration estimates should be developed from the bottom up, preferably by the persons responsible for their execution, in contrast to the top-down, high-level estimates prepared during the project definition phase. They should take into account past experiences with similar, standard processes, to the extent possible. As predictions, the estimates should be equally likely to be above or below the actual results rather than represent the minimum or maximum time. Figure 4 provides an example of task time estimates.

Size comparability of tasks can be achieved by applying the following rule of thumb: combine a task requiring less than seven hours of effort with another task; subdivide tasks that require more than 70 hours.

5.3.6. Determine the Critical Path

The critical path is the path in the project network diagram that consumes the longest elapsed time. It is the path in which there is no extra time available to accommodate delays. This is in contrast to other paths, where float exists and can be used to accommodate delays. A delay in the critical path will result in a delay of the entire project.

The critical path is identified for two reasons. First, if unexpected issues or changes occur to a given task after the project begins, the impact, if any, on the overall project schedule can be determined quickly. Second, knowing the critical path enables the project manager and team to consider quickly where the schedule can be compressed to accommodate project imperatives and unexpected changes.

Table 2 shows some schedule-compression options that can be considered, along with the associated caveats.

5.3.7. Balance the Workplan

Resource loading follows the critical path analysis. Resource loading specifies the resources that will be needed for each planning period (typically one week) on the project timeline. The benefit of resource loading is that it identifies conflicts in the schedule (i.e., resources assigned to different

Figure 4 Task Time Estimates.

tasks simultaneously). It may reveal resources that are overcommitted or underutilized. It helps the project manager to determine whether tasks need to be rescheduled, work reprioritized, or additional time or resources renegotiated.

The workplan is balanced when all appropriate resources are confirmed and an acceptable completion date is determined. The preliminary schedule, resource availability, and required project-completion date all need to be brought into balance.

TABLE 2 Schedule-Compression Options

Compression Option	Caveat
Overlap tasks by using partial dependencies.	• If resource loading indicates there are enough resources available • If the interim deliverable is sufficiently complete
Break dependencies and resequence tasks.	• If the associated risk is acceptable
Break tasks into subtasks that can be done in parallel.	• If resource loading indicates there are enough resources available
Reallocate resources from paths with float to the critical path.	• If the task is resource driven • If the resources have the correct skills and available time • If the noncritical path(s) have not become critical.
Authorize overtime, add shifts, increase staffing, subcontract jobs.	• If there is approval for the additional budget expense
Remove obstacles.	• If priority is high enough
Reduce project scope.	• If the project sponsor approves

5.4. Prepare the Project Budget

The primary purpose of preparing a project budget is to estimate the total cost of accomplishing the project. If the budget amount is not acceptable to the project sponsor (the client), then the project workplan will need to be reworked or the project redefined until an acceptable figure is achieved. When cast in time intervals, such as biweekly or monthly, the budget serves as one basis for project monitoring during execution of the workplan.

There are three steps to preparing a project budget:

1. Determine personnel costs.
2. Add support, overhead, and contingency factors.
3. Compile and reconcile the project budget.

This process is not necessarily linear, and some tasks related to these steps may need to be performed as part of the development of high-level cost estimates during the project-definition phase (see Section 4).

5.4.1. Determine Personnel Costs

Project personnel costs are determined by totaling the hours required by each person to perform his or her work on all the tasks to which he or she has been assigned. The person's total project hours then are multiplied by their hourly billing or compensation rate, as determined by management, to

Figure 5 Personnel Costs.

calculate his or her direct project cost. The costs for all personnel assigned to the project then are totaled to determine the project's personnel budget. Figure 5 provides an example of how personnel costs might be determined.

5.4.2. Add Support, Overhead, and Contingency Factors

Support tasks and overhead should be included in the detail workplan to account for their impact on project cost and duration. Support refers to all those tasks that facilitate production of the deliverables through better communication, performance, or management. It could be project-related training, meetings, administration, project and team management, report production, and quality assurance reviews.

Overhead is nonproductive time spent on tasks that do not support execution of the project workplan or production of the deliverables but can have considerable impact on the project schedule, the resource loading, and potentially the budget. Overhead could include travel time, holidays, vacation, professional development, or personal/sick time.

Nonpersonnel costs associated with the project are identified and estimated. Such costs may include travel expense, technology/knowledge acquisition, and contractor assistance.

Finally, contingency factors are considered to compensate for project risks and other potential project issues as well as to accommodate personnel learning curves. Contingency factors may be applied at the phase or activity level of the workplan/budget, although accuracy may be improved if applied at the detail task level.

Figure 6 extends the example from Figure 5 with nonpersonnel costs to arrive at a total project cost.

5.0	**Develop Implementation Project Plan**					$0
5.1	Meet with project team members				$16,060	$16,060
5.2	Develop detail tasks to be performed within each activity				$12,045	$12,045
	Totals	$15,385	$17,235	$14,185	$41,610	$88,415

Figure 7 Time-Phased Budget.

5.4.3. Compile and Reconcile the Project Budget

The budget is compiled by adding personnel costs and all other costs (including contingencies) to arrive at a total budget number. The budget is subdivided into time increments (weekly, biweekly, or monthly) for the expected life of the project, based on the expected allocation of resources and related costs to the time periods in the project schedule. An example of a time-phased budget is shown in Figure 7.

Because the budget is a projection of project costs, it is based on many assumptions. The compiled budget should be accompanied by a statement of the assumptions made regarding schedules, resource availability, overhead, contingency factors, nonpersonnel costs, and the like.

If the project budget is materially different from the high-level cost estimate in the project definition, a reconciliation process may need to occur. This may result in the need to rework/rebalance the project definition, the workplan, and the budget before the sponsor will approve execution of the project.

6. PHASE III: PROJECT MONITORING AND CONTROL

The project workplan and budget (see Section 5) are used as the basis for project monitoring and control. The three main purposes of project monitoring and control are to:

1. Manage the project within the constraints of budget, time, and resources
2. Manage changes that will occur
3. Manage communications and expectations

Project monitoring helps the project manager balance constraints, anticipate/identify changes, and understand expectations. A well-designed project monitoring process provides:

- Timely information regarding actual vs. planned results
- An early warning of potential project problems
- A basis for assessing the impact of changes
- An objective basis for project decision making

Project monitoring also is used to set up ongoing channels of communication among project stakeholders. The major deliverables are project progress reports and status updates; detailed workplans (updated as necessary); and cost and schedule performance reports.

6.1. Organizing for Project Implementation

An important element of project monitoring and control is the organization that is put in place to support it. Typically the project-implementation structure consists of at least two entities: the project steering committee and the project office.

6.1.1. The Project Steering Committee

The project steering committee is made up of the key stakeholders in the project. It usually is chaired by the project sponsor, and the membership is made up of individuals who are in a position to help move the project along when barriers are encountered or changes are necessary. The committee members typically are project supporters, although antagonists may also be included to ensure that their views are heard and, to the extent possible, accommodated. The project manager is often a member of the committee.

The steering committee has a number of roles. It provides direction to the project; reviews deliverables, as appropriate; receives periodic reports regarding project progress, status, difficulties, and near-future activities; helps clear roadblocks as they occur; and provides final approval that the project has been completed satisfactorily.

6.1.2. The Project Office

The project office is led by the project manager. Depending on the size and complexity of the project, the office may be staffed by appropriate technical and administrative personnel to provide assistance to the project manager.

The primary role of the project office is to ensure that the project is proceeding according to plan and that the deliverables are of acceptable quality. This is accomplished by periodic (e.g., weekly or biweekly) review of project progress with respect to plan, as well as review of deliverables as they are produced. The project office maintains and updates the master project workplan and budget and routinely reports progress and difficulties to interested stakeholders, including the steering committee.

The office also takes the lead in ensuring that any actions necessary to correct project problems are effected in a timely manner.

6.2. Project Monitoring

Project monitoring takes a number of forms, including:

- Informal monitoring
- Project workplan and budget maintenance
- Project status reporting
- Status meetings

6.2.1. Informal Monitoring

Informal project monitoring entails ''walking the project'' on a periodic basis, daily if possible. It may involve observing deliverables; holding ad hoc meetings with team members; and communicating informally and frequently with stakeholders. Much can be learned about how the project is doing simply by talking with project team members and other stakeholders.

6.2.2. Project Workplan and Budget Maintenance

Maintenance of workplans and budgets is a routine and ongoing activity. Project plans should be updated on a regular basis to reflect corrective actions and proactive strategies being implemented. Plan maintenance involves updating the detailed workplan's latest estimate to reflect current status *and* the time/cost necessary to complete the project. Plan maintenance should occur at least biweekly and should not alter the baseline workplan and budget—unless variances have become large and persistent or the scope of the project has changed. If rebaselining is necessary, it should only be done with sponsor/steering committee approval and may require approval by the person who approved the original project workplan and budget if he or she is other than the sponsor/steering committee.

6.2.3. Project Status Reporting

Status reports provide project leaders and other interested parties with an objective picture of progress, variances, and trends, as well as an audit trail and record of project progress. These reports provide leaders with an opportunity to understand and rectify variances and formulate appropriate actions to identified strengths, vulnerabilities, and risks.

Status reports may be assembled in a variety of configurations, depending on the audience being served. Typical configurations of status report packages include project team leader reports, project manager reports, and steering committee reports.

6.2.4. Status Meetings

Status report packages typically are delivered at status meetings. Team leader report packages are delivered on a regular basis to the project manager to cover completed, current, and planned work. The team leader reports are consolidated by the project office and the overall project status report is presented by the project manager to the steering committee at its regular meeting. The report to the steering committee focuses on overall project status and specific issues or roadblocks that need to be cleared. A key role of the steering committee is to take the lead in resolving issues and clearing roadblocks so the project can proceed as planned.

6.3. Project Control

Project control involves three main activities:

1. Identifying out-of-control conditions
2. Developing corrective actions
3. Following up on corrective action measures

6.3.1. Identifying Out-of-Control Conditions

An activity or task is in danger of going out of control when its schedule or budget is about to be exceeded but the deliverable(s) are not complete. Adequate monitoring of project schedule and budget will provide an early warning that a potential problem exists. An activity or task that is behind schedule and is on the critical path requires immediate attention because it will impact the overall timetable for project completion, which ultimately will adversely impact the budget for the task, the activity, the phase, and the project. Oftentimes, exceeding the budget or missing the scheduled completion date for a particular task or activity may be an early warning sign that a significant problem

is developing for the project. Either of these signs requires an immediate investigation on the part of the project manager to determine the underlying reasons.

6.3.2. Developing Corrective Actions

Once the project manager determines the cause of an overage in the budget or a slippage in the schedule, he or she must determine an appropriate response and develop a specific corrective action plan. Sometimes a problem is caused by an impediment that the project manager alone can not resolve. In these instances, the project manager should engage the help of the steering committee. One of the responsibilities of the steering committee is to provide ''air cover'' for a project manager when he or she encounters complex difficulties.

In other cases, the impediment may have been anticipated and a corrective action plan formulated as part of the project's risk-management plan. In these cases, all that may be required is to execute the corrective action specified in the plan.

6.3.3. Following up on Corrective Action Measures

To ensure that the desired outcome of the corrective action is being achieved, it is important to employ project monitoring techniques when executing a corrective action plan. The walking-the-project technique mentioned earlier is an example of an effective follow-up technique. More complex corrective actions may require a more formal status-reporting approach.

7. PHASE IV: PROJECT CLOSE

Successful completion of all the deliverables set out in the workplan does not, by itself, conclude the project. Several activities need to be accomplished before the project can be brought to a formal close, including:

- Project performance assessment and feedback
- Final status reporting
- Performance review of project team members
- Project documentation archiving
- Disbanding of the project organization

The primary purpose of the project close phase is to ensure that the expectations set throughout the project have been met.

7.1. Project Performance Assessment and Feedback

Project performance should be assessed in a structured manner, addressing the extent to which the objectives set out in the project definition and workplan have been achieved. Obtaining objectivity requires that the client's views be considered in the assessment.

7.1.1 Time, Cost, and Quality Performance

Time, cost, and quality performance are three key project parameters that should be subject to assessment. Time performance can be assessed by comparing the originally planned completion dates of deliverables, both interim and final, with the actual completion dates. Causes of any material schedule slippage should be determined and means for precluding them in future projects developed. A similar assessment of project cost can be conducted by comparing budgeted to actual expenditures and then examining any material favorable and unfavorable variances.

Quality-performance assessment, however, tends to be less quantitative than time and cost assessment. It usually relies on solicited or unsolicited input from the client and other stakeholders regarding how they view the project deliverables (e.g., did they receive what they expected?). Quality performance can also relate to how well the project team has communicated with the stakeholders and perceptions of how well the project has been managed and conducted.

7.1.2. Lessons Learned

The opportunity to identify and capture lessons learned from having done a particular project should not be missed. Lessons learned should be documented and any best practice examples relating to the project captured. Documentation of lessons learned and best practice examples should be made available to others in the organization who will be involved in future project design and execution efforts.

7.2. Final Status Reporting

A final project status report should be prepared and issued to at least the project steering committee, including the sponsor. The report does not need to be extensive, but should include:

- A statement of the project objectives and deliverables
- A recap of the approach and key elements of the workplan
- A brief discussion of any open matters that need to be addressed
- A statement that the project has (or has not) achieved its objectives
- A list of suggested next steps, if any
- Acknowledgment of any special contributions by personnel involved

Typically, the final status report is prepared by the project manager and presented at the final steering committee meeting.

7.3. Performance Review of Project Team Members

Individual performance reviews of team members should be conducted on a one-to-one basis by the project manager. Project staff should be evaluated against defined roles and expectations, with the focus on strengths and areas for improvement. Individual contributions to the project should be recognized. The information should be transmitted to each team member's performance manager in order to update developmental needs and provide helpful information for annual performance reviews. Likewise, subcontractors and vendors also should be provided with feedback on their performance.

7.4. Archiving Project Documentation

Archiving entails compilation and organization of appropriate project documentation and submitting it for filing in a designated repository. The project file should include at least the project definition, the project workplan/budget, copies of key deliverables, the final project status report, and the results of the project performance assessment.

7.5. Disbanding the Project Organization

Disbanding the project organization includes notifying the appropriate offices of the future availability of the participants who had been assigned to the project; returning the space and equipment to the issuing offices; and establishing a mechanism for following up and maintaining any deliverables, if necessary.

A project team close-out meeting should be held to reflect on the team members' interaction and identify areas for improvement in working with an extended project team. It also provides an opportunity to identify and discuss any areas of potential improvement in the project management process.

Consideration should also be given to celebrating the success of the project with the project team and extended team members. This would be a positive way to mark the end of the project, celebrate its success, and acknowledge the professional ties developed throughout the course of the work.

8. AVOIDING PROJECT MANAGEMENT PROBLEMS

8.1. When and Why Project Management Problems Occur

Project management problems typically don't manifest themselves until the project is well underway. But the basis for most problems is established early on, during the project definition and planning phases. In particular, unclear and poorly communicated statements of project objectives, scope, and deliverables will almost always result in a project workplan that, when implemented, does not fulfill the expectations of the client and other stakeholders. In the absence of clear project definition, the stakeholders will set their own expectations, which usually won't match those of the project manager and his or her team members.

During project implementation, regular and clear communication between the project participants and the project manager, as well as between the project manager and the sponsor/steering committee, will help raise issues to the surface before they become time, cost, or quality problems.

8.2. Tips for Avoiding Problems in Project Management

The following are some suggestions for avoiding problems on professional services projects:

- Invest time up front in carefully defining and communicating the project objectives, scope, and deliverables. This will save time and reduce frustration in later stages of the project.
- Know the subject matter of the project and stay within your professional skills. Seek help before you need it.
- Avoid overselling and overcommitting in the project definition. Include risk-reducing language when necessary and appropriate.
- Always be clear on project agreements and other matters. Do what you say you will do and stay within the parameters of the project definition.

- Be flexible. A project workplan documents the expected route and allows you to communicate the expected deliverables and path to the stakeholders. Make adjustments as necessary and use the plan and related expectations as the basis for explaining how the changes will affect the project.
- Effective project management is as critical as the tasks and milestones in the project. It keeps the team's efforts focused and aligned. Budget time for the project manager to perform the necessary project management tasks, including, but not limited to, frequent quality, schedule, and budget reviews.
- In large projects, consider the use of a project administrator to take responsibility for some of the crucial but time-consuming administrative tasks.
- Communicate informally and frequently with the client. Identify and communicate risks and problems as early as possible.
- Make sure the project is defined as closed at an appropriate time, typically when the objectives have been met, to avoid having the project drift on in an attempt to achieve perfection.

Manpower Resource Planning

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

CHAPTER 52
Methods Engineering*

STEPHAN KONZ
Kansas State University

1. OVERVIEW

Section 2 starts with some criteria for job design. The emphasis is on health and safety; due to progress in technology, every worker will supervise a number of slaves (machines). Section 2 then gives guidelines for organization of groups of workstations, the workstation itself, musculoskeletal disorders, fatigue, and error reduction.

Section 3 discusses gathering and organizing information. After potential projects are prioritized, the existing situation can be recorded. The big picture (between-operations analysis) or the detailed picture (within-operation analysis) can then be analyzed.

Section 4 discusses how to use the information to design.

2. GUIDELINES

This section discusses (1) criteria of job design, (2) organization of groups of workstations, (3) individual workstations, (4) musculoskeletal disorders, (5) fatigue, and (6) error reduction.

*This is a concise version of material in Konz and Johnson (2000).

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

2.1. Criteria of Job Design

Table 1 gives the six ergonomic criteria for job design:

1. Safety is first.
   A job design that endangers the worker's safety or health is not acceptable. However, life does not have infinite value. Management must take reasonable precautions. Naturally, the definition of "reasonable" is debatable. After designing for safety, design for performance, then worker comfort, and, finally, worker higher wants (social, ego, and self-actualization).
2. Make the machine user-friendly.
   Make the machine adjust to the worker, not the worker to the machine. If the system does not function well, redesign the machine or procedure rather than blame the operator.
3. Reduce the percentage excluded by the design.
   Maximize the number of people who can use the machine or procedure. As mandated by the Americans with Disabilities Act, gender, age, strength, and other personal attributes should not prevent people from using the design.
4. Design jobs to be cognitive and social.
   Physical and procedural jobs now can be done by machines—especially in the developed countries. Over 50% of all jobs in the developed countries are in offices.
5. Emphasize communication.
   We communicate with machines through controls; machines communicate to us by displays. Improved communication among people reduces errors and thus improves productivity.
6. Use machines to extend human performance.
   The choice is not whether to assign a task to a person or to a machine; it is which machine to use. Small machines (such as word processors and electric drills) tend to have costs (total of capital, maintenance, and power) of less than \$0.25/hr. Even large machines (such as lathes and automobiles) tend to cost only \$1–2/hr. Labor cost (including fringes) tends to be a minimum of \$10/hr, with \$15, \$20, or higher quite common. What is your wage rate (including fringes)/per hour?

Consider machines as "slaves." The real question then becomes how many slaves the human will supervise and how to design the system to use the output of the slaves.

2.2. Organization of Groups of Workstations

This section discusses organization of workstations (the big picture) while Section 3 discusses the workstation itself. Table 2 gives seven guidelines:

1. Use specialization even though it sacrifices versatility.
   Specialization is the key to progress. Seek the simplicity of specialization; distrust it thereafter, but first seek it. Use special-purpose equipment, material, labor, and organization.
   Special-purpose equipment does only one job but does it very well. For example, at McDonald's a special-purpose grill cooks the hamburger on both sides simultaneously.
   Special-purpose material typically trades off higher material cost vs. greater capability.
   Labor specialization improves both quality and quantity. More experience, combined with specialized tools, should yield both higher quality and higher quantity. The challenge is that this specialization gives monotonous work; with low pay, it is difficult to find workers. With high pay, finding employees is not a problem.

TABLE 1 Ergonomic Job-Design Criteria

Number	Criteria
1.	Safety is first.
2.	Make the machine user-friendly.
3.	Reduce the percentage excluded by the design.
4.	Design jobs to be cognitive and social.
5.	Emphasize communication.
6.	Use machines to extend human performance.

TABLE 2 Guidelines for Organization of Workstations

Number	Guideline
1.	Use specialization even though it sacrifices versatility.
2.	Consider both progressive and nonprogressive assembly.
3.	Minimize material-handling cost.
4.	Decouple tasks.
5.	Make several identical items at the same time.
6.	Combine operations and functions.
7.	Vary environmental stimulation inversely with task stimulation.

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

For organization specialization, we have been describing jobs that are rigidly structured, disciplined, machinelike. There is a need for a high volume of a standardized product. If you don't have the required volumes, use specialization as a goal. Use group technology to get the benefits of mass production from batch production.

2. Consider both nonprogressive and progressive assembly.

Consider an assembly with $N = 60$ elements with $m = 5$ people. Should each of the 5 workers do all 60 elements—a complete workstation, job enlargement, nonprogressive assembly? Or should each person do N/m elements—a flow line, job simplification, progressive assembly? Table 3 compares nonprogressive vs progressive assembly.

3. Minimize material-handling (MH) cost.

Material handling does not add value, just cost. Reduce this cost by analysis of its components.

- MH cost/yr = capital cost + operating cost
- Operating cost = (no. of trips/yr)(cost/trip)
- Cost/trip = fixed cost/trip + (variable cost/distance) (distance/trip)

Capital costs vary little with utilization. For low volumes, the lowest total cost may be for a system with high operating cost but low capital cost. For high volumes, the high capital-cost system may be best.

TABLE 3 Progressive (P) vs. Non-progressive (NP) Lines

Criterion	Comment
Advantages of nonprogressive	
1. Balance delay	No balance delay.
2. Scheduling flexibility	Can make multiple products at same time.
3. Shocks	Do not affect multiple stations.
4. Cumulative trauma	Less CT since greater variety in motions.
5. Satisfaction	Each worker does complete job.
Neutral	
6. Quality	NP has immediate feedback of errors vs. mixed feedback in P.
7. Material handling	Simpler in NP. But mechanization more difficult in NP.
8. Space	NP has more space/station; material handling may increase space.
9. Walking	NP has some walking; this is good.
Disadvantages	
10. Direct labor	Higher for NP (due to less specialization, cost more to learn).
11. Skill required	NP requires more skill, which may require higher pay.
12. Equipment capital cost	NP higher as equipment duplicated.
13. In-process inventory	Higher for NP as inventory at many stations.
14. Supervision	Supervision more difficult for NP (more variety, paperwork).

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

Reduce the number of trips by moving less often. Consider replacing transportation with communication (e.g., mail vs. e-mail).

Fixed cost/trip includes information transfer; thus, consider computerization. Much transportation (and communication) is distance insensitive. Twice the distance does not cost twice as much. This affects plant layout because closer (or farther) locations make little difference.

Variable cost/distance should consider energy and labor costs. Distance/trip may be irrelevant, especially if a "bus system" can replace a "taxi system."

4. Decouple tasks.

Figure 1 shows different types of flow lines. Table 4 shows some alternatives for conveyor movement, work location, and operator posture.

Assuming progressive assembly, the elements are divided among the line's stations. In most cases, the mean amount of work time allocated to each workstation is not equal. But since

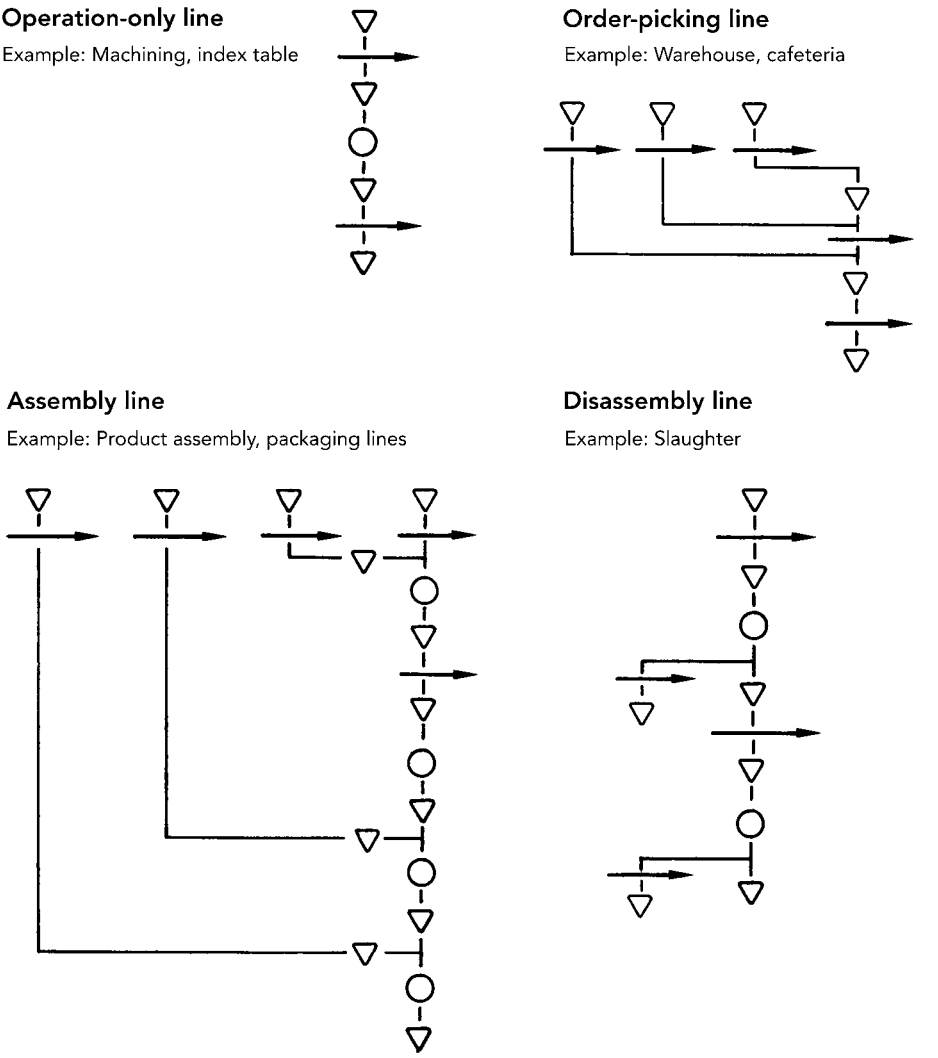

Figure 1 Flow Lines Can Be Operation-Only, Order-Picking, Assembly, or Disassembly Lines. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

TABLE 4 Alternatives for Conveyor Movement, Work Location, and Operator Posture

Conveyor Movement	Work Location	Operator Posture
Moves continuously	Removed from conveyor	Stands/sits in one spot
	Stays on conveyor	Stands/sits in one spot
	Stands/sits on moving system	
	Walks	
Starts/stops on timer	Stays on conveyor	Stands/sits in one spot
Starts/stops at operator discretion	Stays on conveyor	Stands/sits in one spot
	Removed from conveyor	Stands/sits in one spot

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

each workstation has the same cycle time, there is some idle time (cycle time − work time) at each station—this is called balance delay time.

Although it may be obvious, (1) the transport between stations need not be by conveyor (carts are a common alternative, either pushed manually or as automatically guided vehicles); (2) the transport between stations need not be at a fixed speed or time interval; and, very important, (3) there probably will be storages between the operations and transportations. This storage is known as a buffer; its purpose is to decouple the workstations (isolate stations of the line).

The two primary reasons for buffers are line balancing and shocks and disturbances.

Assume the mean times for stations A, B, C . . . are not equal. Assume A took 50 sec, B took 40 sec, and C took 60 sec. Then, without buffers, the line must be set at the speed of the slowest workstation, C. But, in addition, shocks and disturbances cause variability in the mean times. Thus, without buffers, the cycle time must be set at the slowest time of the slowest station, say 65 sec. Buffers give flexibility to the flow line.

There are two buffering techniques: change product flow and move operators. Changing product flow can be done by buffers at or between the stations, buffers due to carrier design, and buffers off-line. Moving operators can be done by (1) utility operator, (2) helping your neighbor, (3) *n* operators floating among *n* workstations, and (4) *n* operators floating among more than *n* stations. See Konz and Johnson (2000) for an extensive discussion of the various alternatives.

5. Make several identical items at the same time.

Tasks can be divided into three stages: (1) get ready, (2) do, and (3) put away. Reduce cost/unit by prorating the get-ready and put-away stages over more units.

6. Combine operations and functions.

Consider multifunction materials and equipment rather than single-function materials and equipment. For example, an invoice can be used with a window return envelope to reduce sorting the envelope when it is returned and speed processing of the bill. A farmer can combine fertilizing and plowing.

7. Vary environmental stimulation inversely with task stimulation.

For low-stimulation tasks, (1) add physical movement to the task and (2) add stimulation to the environment. The easiest environmental stimulation solution is to allow operators to talk to each other (see Figure 2). Other alternatives are windows and making the break area attractive. For high-stimulation tasks, such as in offices, reduce stimulation by improving both visual and auditory privacy.

2.3. Individual Workstations

Table 5 gives 14 guidelines for workstation design:

1. Avoid static loads and fixed work postures.

Static (isometric) load (from low variability in postures and movement) is bad for the blood supply/disposal of a specific muscle as well as the total body. We will discuss standing, sitting, head/neck, and hand/arm.

- *Standing.* The veins store the body's blood. If the legs don't move, the blood from the heart tends to go down to the legs and stay there (venous pooling). This causes more work for the heart because, for a constant blood supply, when blood per beat is lower, there are more

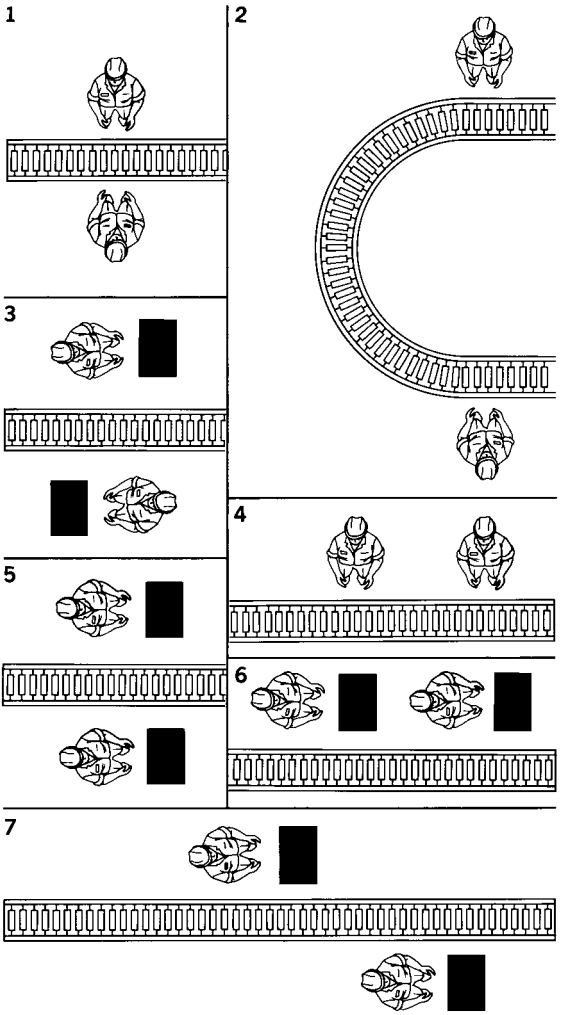

Figure 2 Vary Environmental Stimulation by Adjusting Orientation in Relation to Other People, Changing Distance, and Using Barriers Such as Equipment between Stations. The highest stimulation is 1, the lowest is 7. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

beats. Venous pooling causes swelling of the legs, edema, and varicose veins. After standing, walking about 10 steps changes ankle blood pressure to about 48 mm Hg (the same level as for sitting). Thus, standing jobs should be designed to have some leg movements. Consider a bar rail (to encourage leg movement while standing) and remote storage of supplies (to encourage walking).

- *Sitting.* Sitting is discussed in workstation guideline 4.
- *Head/neck.* The head weighs about 7.3% of body weight. For a 90 kg person, that is 6.6 kg (about the same as a bowling ball). Neck problems occur if the head leans forward or backward on the neck. Forward tilt occurs when the person reduces the distance to an object to improve visibility (inspection, fine assembly, VDT work); consider better lighting. Backward tilt may occur for people using bifocals at VDT workstations; consider single-vision glasses (work glasses). If the hands are elevated, head- or workstation-mounted magnifiers permit lowering the hands.

TABLE 5 Guidelines for Workstation Design

Number	Guideline
1.	Avoid static loads and fixed work postures.
2.	Reduce musculoskeletal disorders.
3.	Set the work height at 50 mm below the elbow.
4.	Furnish every employee with an adjustable chair.
5.	Use the feet as well as the hands.
6.	Use gravity; don't oppose it.
7.	Conserve momentum.
8.	Use two-handed motions rather than one-handed motions.
9.	Use parallel motions for eye control of two-handed motions.
10.	Use rowing motions for two-handed motions.
11.	Pivot motions about the elbow.
12.	Use the preferred hand.
13.	Keep arm motions in the normal work area.
14.	Let the small woman reach; let the large man fit.

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

- *Hand/arm.* When an operator holds a workpiece, this not only causes static load but also reduces productivity (since the person is working with one hand, not two).

  Keep the upper arm vertical. Support the arm weight by chair arms or a workstation. Pad sharp edges of workstations. Supporting the arms reduces tremor and thus permits more accurate work with the hands.

2. Reduce musculoskeletal disorders.

See Section 2.4.

3. Set the work height at 50 mm below the elbow.

For manipulative work, the optimum is about 50 mm (2 in.) below the elbow. Output does not decrease more than a couple of percent within a range from 125 mm (5 in.) below to 25 mm (1 in.) above the elbow; beyond this, the penalty is greater. If a downward force is required (polishing, sanding), the optimum is probably with the lower arm at a 45° angle.

The three solution techniques are: (1) change work surface height, (2) adjust elbow height, and (3) adjust work height on the machine.

Work surface heights (such as conveyors) often are easily adjustable. Workstation table heights often can be adjusted—perhaps even with motors.

Adjusting elbow height while sitting involves use of an adjustable-height chair. For standing, consider movable wooden platforms for short operators (for tall operators, remove the platform).

Adjusting work height may be as simple as tilting (45 or 90°) a container box. Use containers with short sides. If the part/assembly is held in a fixture, design the fixture to permit vertical and horizontal adjustment. For example, cars are now assembled in rollover frames; the frames allow the operator to work on the car while it is tilted at various angles.

4. Furnish every employee with an adjustable chair.

A chair is a low-cost tool. Chair cost is entirely a capital cost because operating cost and maintenance costs are zero. Assuming a cost of \$200/chair, a life of 11 years, and a one-shift operation of 1800 hr/yr, the cost/hour is $\$200/(11 \times 1800) = 1$ cent/hr. (Often the real comparison is between a chair without good ergonomics vs. one with ergonomic features, and the incremental cost of the good chair is less than \$100—that is, less than 0.5 cent/hr.) The cost of labor (wages plus fringes) varies with the job but will be at least \$10/hr, with \$15 or \$20 fairly common. Assuming a cost of \$10/hr, a 0.1% change in productivity (30 sec/shift) equals 1 cent/hr.

Even with an ergonomic chair, many people will have back pain if they sit continuously. The reason is that the disks of the back are nourished by movement of the back—no movement, no nourishment. Thus, encourage seating posture variability by having the person walk occasionally (to answer the phone, discuss things with others, take breaks).

5. Use the feet as well as the hands.

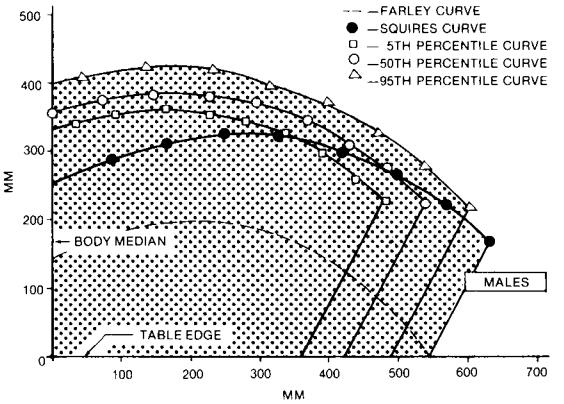

Figure 3 Normal Male Work Area for Right Hand. The left-hand area is mirrored. (From S. Konz and S. Goel, *The Shape of the Normal Work Area in the Horizontal Plane*. Reprinted with the permission of the Institute of Industrial Engineers, 25 Technology Park, Norcross, GA 30092, 770-449-0461. Copyright © 1969)

The feet can take some of the load off the hands in simple control tasks such as automobile pedals or on/off switches. For human-generated power, the legs have about three times the power of the arms.

6. Use gravity; don't oppose it.

Consider the weight of the body and the weight of the work. The weight of arm plus hand is typically about 4.9% of body weight; thus, keep arm motion horizontal or downward. Gravity also can be a "fixture"; consider painting the floor vs. the ceiling; welding below you vs. above you, and so on. Gravity also can be used for transport (chutes, wheel conveyors).

7. Conserve momentum.

Avoid the energy and time penalties of acceleration and deceleration motions. Avoid change of direction in stirring, polishing, grasping, transport, and disposal motions. For example, using the MTM predetermined time system, an 18 in. (450 mm) move to toss aside a part is an M18E and an RL1—a total of 0.63 sec. A precise placement would require an M18B, a P1SE, and an RL1—a total of 0.89 sec, an increase of 42%.

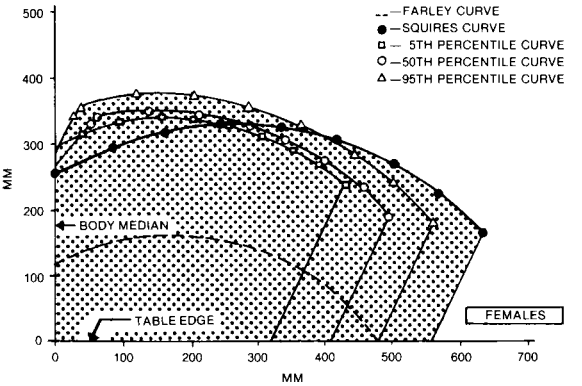

Figure 4 Normal Female Work Area for Right Hand. The left-hand area is mirrored. (From S. Konz and S. Goel, *The Shape of the Normal Work Area in the Horizontal Plane*. Figure 5 Approximate Reach Distances for Average U.S. Male and Female Workers. (From V. Putz-Anderson, Ed., *Cumulative Trauma Disorders,* copyright © 1988 Taylor & Francis Books Ltd., by permission)

8. Use two-hand motions rather than one-hand motions.

For movement of the hand/arm, two hands are better than one. Using two hands takes more time and effort, but more is produced so cost/unit is lower. When one hand (generally the left) is acting as a clamp, consider it as idle and use a mechanical clamp instead.

9. Use parallel motions for eye control of two-hand motions.

When the two hands are both moving, minimize the distance between the hands rather than making the arm motions symmetrical about the body centerline.

10. Use rowing motions for two-hand motions.
A rowing motion is superior to an alternating motion because there is less movement of the shoulder and torso.

11. Pivot motions about the elbow.
For a specific distance, minimum time is taken by pivoting about the elbow. It takes about 15% more time to reach across the body (it also takes more energy since the upper arm is moved as well as the lower arm).

12. Use the preferred hand.
The preferred hand is 5–10% faster and stronger than the nonpreferred hand. Unfortunately, since it is used more, it is more likely to have cumulative trauma. About 10% of the population uses the left hand as the preferred hand.

13. Keep arm motions in the normal work area.
Figure 3 shows the area for males; Figure 4 shows the area for females. These are the distances to the end of the thumb with no assistance from movement of the back. Closer is better. Figure 5 shows reach distance above and below the horizontal plane.

14. Let the small woman reach; let the large man fit.
The concept is to permit most of the user population to use the design. Alternative statements are ''Exclude few,'' ''Include many,'' and ''Design for the tall; accommodate the small.'' What percentage should be excluded? The Ford–UAW design guide excludes 5% of women for reach, 5% of men for clearance, and 0% of men and women for safety.

Three alternatives are (1) one size fits all, (2) multiple sizes, and (3) adjustability. Examples of one size fits all are a tall door and a big bed. An example of multiple sizes is clothing. An example of adjustability is an automobile seat.

2.4. Musculoskeletal Disorders

2.4.1. Risk Factors

Safety concerns are for short-term (time frame of seconds) effects of physical agents on the body. An example is cutting of a finger. Toxicology generally deals with long-term (years, decades) effects of chemicals on body organs. An example is exposure to acetone for 10 years, causing damage to the central nervous system. Musculoskeletal disorders concern intermediate-term (months, years) effects of body activity upon the nerves, muscles, joints, and ligaments. An example is back pain due to lifting.

Nerves supply the communication within the body. Muscles control movements of various bones. Ligaments (strong, ropelike fibers) connect bones together.

The three main occupational risk factors are repetition/duration, joint deviation, and force. Vibration is also an important risk factor. Nonoccupational risk factors can be from trauma outside work or a nonperfect body. The lack of perfection can be anatomical (weak back muscles or weak arm due to an injury) or physiological (diabetes, insufficient hormones).

Problem jobs can be identified through (1) records/statistics of the medical/safety department, (2) operator discomfort (e.g., Figure 6), (3) interviews with operators, and (4) expert opinion (perhaps using checklists such as Table 6, Table 7, and Table 8).

2.4.2. Solutions

Decrease repetition/duration, joint deviation, force, and vibration.

In general, a job is considered repetitive if the basic (fundamental) cycle time is less than 30 sec (for hand/wrist motions) and several minutes (for back/shoulder motions). However, if the job is only done for a short time (say, 15 min/shift), there is relatively low risk of cumulative trauma due to the short duration. Consider short duration as <1 hr/shift, moderate as 1 to 2 hr, and long as >2 hr. Thus, repetition really concerns the repetitions/shift. Duration also assumes weeks, months, and years of repeated activity, not just a couple of days.

Ideally the joint should operate at the neutral position—that is, minimum joint deviation.

Force on a joint typically is multiplied by a lever arm (i.e., we are really talking about a torque). Reduce (1) the magnitude of the force, (2) the lever arm, and (3) the length of time the force is applied.

Vibration typically comes from a powered handtool. Vibration increases force because operators tend to grip the vibrating tool more tightly because it vibrates.

Solutions are divided into engineering and administrative.

2.4.2.1. Engineering Solutions The first possible approach is automation—that is, eliminate the person. No person means no possible injury.

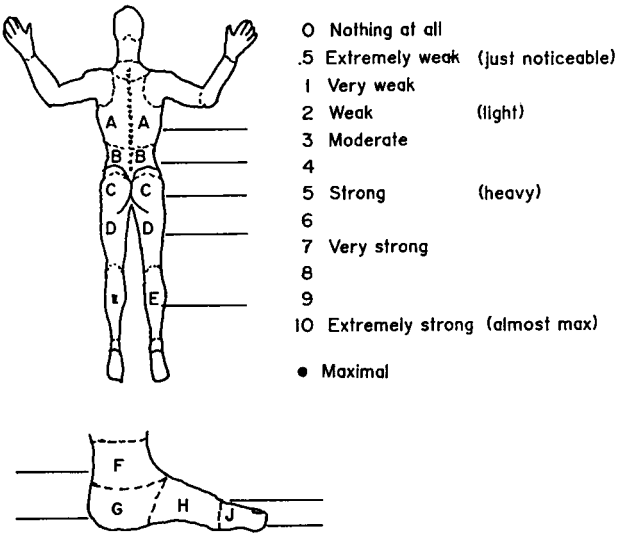

Figure 6 Body Discomfort Map. Maps can have more or less detail; this map includes the foot but other maps may emphasize the arm or hand. The worker gives the amount of discomfort at any location. One discomfort scale is the Borg category scale (CR-10) shown in the figure. The CR-10 scale gives 0.5 for "extremely weak" and 10 for "extremely strong"; people are permitted to go below 0.5 and above 10. Body discomfort maps are a popular technique of getting quantified input from operators. (From Corlett and Bishop 1976)

A second possible approach is to reduce the number of cycles or the difficulty of the cycle. Two alternatives are mechanization and job enlargement. In mechanization, the operator is still present but a machine does part of the work. Two examples are electric scissors (vs. manual scissors) and a bar code scanner (instead of information being keyed). In job enlargement, the same motions are done, but by a larger number of people. If the job takes four minutes instead of two, the repetitive motions per person per day are reduced.

The third approach is to minimize joint deviation. One guide is *Don't bend your wrist*. For example, place keyboards low to minimize backward bending of the hand. Another guide is *Don't lift your elbow*. An example was spraypainting the side of a truck by workers standing on the floor. The job was modified to have the workers stand on a platform, thus painting horizontally and downward. (This had the additional benefit of less paint settling back into the painters' faces.)

The fourth approach is to minimize force duration and amount. Consider an ergonomic pen (large grip diameter with a high-friction grip) to reduce gripping force. Can a clamp eliminate holding by a hand? Can a balancer support the tool weight? Can sliding replace lifting?

To reduce vibration, use tools that vibrate less; avoid amplified vibration (resonance). Maintain the equipment to reduce its vibration. Minimize gripping force (e.g., support the tool with a balancer or a steady rest). Keep the hands warm and dry; avoid smoking.

2.4.2.2. Administrative Solutions Administrative solutions (such as job rotation and part-time workers) seek to reduce exposure or increase operator's ability to endure stress (exercise, stress reduction, and supports).

In job rotation, people rotate jobs periodically during the shift. The concept is working rest—a specific part of the body rests while another part is working. Job rotation requires cross-trained workers (able to do more than one job), which allows more flexible scheduling; there is perceived fairness because everyone shares good and bad jobs.

Part-time workers reduce musculoskeletal disorders/person. Some other advantages are lower wage cost/hr, better fit to fluctuating demand, and (possibly) higher-quality people. (It is difficult to hire high-quality full-time people for repetitive low-paying jobs.) Some disadvantages are less time on the job (and thus less experience), possible moonlighting with other employers, and a high cost of hiring and training.

TABLE 6 General Ergonomic Checklist to Prioritize Potential Problems

After completing the effort (force), continuous effort time (duration), and efforts/min (repetition) columns, determine the priority for change.

Job Title _____ Analyst _____
Specific task _____ Phone _____
Job number _____ Dept _____ Date of analysis _____
Location _____

Body part		Effort	Continuous Effort Time	Effort/Min	Priority
Back

TABLE 7 Sample Checklist for Upper-Extremity Cumulative Trauma Disorders

No	Yes	Risk Factors
		Physical stress
_____	_____	1. Can the job be done without hand/wrist contact with sharp edges?
_____	_____	2. Is the tool operating without vibration?
_____	_____	3. Are the worker's hands exposed to temperatures >70°F (21°C)?
_____	_____	4. Can the job be done without using gloves?
		Force
_____	_____	1. Does the job require exerting less than 10 lb (4.5 kg) of force?
		2. Can the job be done without using a finger pinch grip?
		Posture
_____	_____	1. Can the job be done without wrist flexion or extension?
_____	_____	2. Can the tool be used without wrist flexion or extension?
_____	_____	3. Can the job be done without deviating the wrist from side to side?
_____	_____	4. Can the tool be used without deviating the wrist from side to side?
_____	_____	5. Can the worker be seated while performing the job?
_____	_____	6. Can the job be done without a clothes-wringing motion?
		Workstation hardware
_____	_____	1. Can the worksurface orientation be adjusted?
_____	_____	2. Can the worksurface height be adjusted?
_____	_____	3. Can the tool location be adjusted?
		Repetitiveness
_____	_____	1. Is the cycle time longer than 30 s?
		Tool design
_____	_____	1. Are the thumb and finger slightly over lapped in a closed grip?
_____	_____	2. Is the tool handle span between 2 and 2.75 in. (5 and 7 cm)?
_____	_____	3. Is the tool handle made from material other than metal?
_____	_____	4. Is the tool weight below 9 lb (4 kg)? Note exceptions to the rule.
_____	_____	5. Is the tool suspended?

Adapted from Y. Lifshitz and T. J. Armstrong, "A Design Checklist for Control and Prediction of Cumulative Trauma Disorder in Hand Intensive Manual Jobs," in *Proceedings of the Human Factors Society 30th Annual Meeting 1986.* A "no" indicates a risk factor. Checklist was tested only in an automobile final assembly plant.

Exercises should be tailored to the specific set of muscles, tendons, and ligaments that are stressed. If the work loads the muscles statically, the exercise should move them. If the work loads the muscles dynamically, the exercise should relax and stretch them.

Stress can be caused by social factors, both on and off the job. Supports for the body (armrests, back belts, wrist splints, etc.) are an appealing concept, but evidence is lacking concerning their benefits.

2.5. Fatigue

2.5.1. Background

The problem is to reduce fatigue so workers can maintain/increase productivity and have optimal stress. Fatigue can be divided into five factors:

1. Physical exertion (e.g., bicycle ergonometer work; descriptions such as "warm," "sweaty," "out of breath," "breathing heavily," "palpitations")
2. Physical discomfort (e.g., static load on small-muscle groups; descriptions such as "tense muscles," "aching," "numbness," "hurting," "stiff joints")
3. Lack of energy (mental plus physical; descriptions such as "exhausted," "spent," "overworked," "worn out," "drained")
4. Lack of motivation (mental; descriptions such as "lack of initiative," "listless," "passive," "indifferent," "uninterested")
5. Sleepiness (mental; descriptions such as "sleepy," "yawning," "drowsy," "falling asleep," "lazy").

TABLE 8 Posture Checklist for Neck, Trunk, and Legs

	Percent Time Posture Used in Job		
Job Studied	Never	<1/3	>1/3
Neck			
1. Mild forward bending (>20°)	0	0	X
2. Severe forward bending (>45°)	0	X	*
3. Backward bending (>20°)	0	X	*

Silverstien, "A Checklist for Evaluating Ergonomic Risk Factors Resulting from Awkward Postures of the Legs, Trunk, and Neck," pp. 283–301, Copyright © 1992, with permission from Elsevier Science.
A zero indicates insignificant risk. An X indicates a potential risk. An asterisk indicates a significant risk.

Jobs will have different combinations of fatigue and the combinations often will vary during the shift. Fatigue generally is overcome by rest (recovery). Rest time can be classified as off-work (evenings, holidays, weekends, vacations) and at-work. At-work is further divided into formal breaks (lunch, coffee), informal breaks (work interruptions, training), microbreaks (short pauses of a minute or less), and working rest (a different task using a different part of the body, such as answering the phone instead of keying data). From the viewpoint of financial cost, some rest time is paid and some is unpaid; from a fatigue viewpoint, a rest is a rest.

In general, weekly, annual, and lifetime working hours are decreasing and thus present fewer health/productivity problems. But daily hours may be a problem, especially for people working more than 8 hr/day and without proper sleep.

2.5.2. Fatigue Guidelines

Table 9 gives seven guidelines concerning fatigue. Guidelines 1, 2, and 3 concern fatigue prevention; guidelines 4, 5, 6, and 7 concern fatigue reduction.

TABLE 9 Guidelines for Fatigue

Number	Guideline
Fatigue prevention	
1.	Have a work-scheduling policy.
2.	Optimize stimulation during work.
3.	Minimize the fatigue dose.
Fatigue reduction	
4.	Use work breaks.
5.	Use frequent short breaks.
6.	Maximize the recovery rate.
7.	Increase the recovery/work ratio.

TABLE 10 Tips for Day Sleeping

- Develop a good sleeping environment (dark, quiet, cool, bed). Have it *dark* (e.g., use eyeshades or opaque curtains). Have it *quiet* since it is difficult to go back to sleep when daytime sleep is interrupted. Minimize noise volume. Consider earplugs, unplugging bedroom phones, turning down phone volume in other rooms, reducing TV volume in other rooms, Train your children. Have a *cool* sleeping area. The *bed* normally is OK but may be poor if the sleeper is not sleeping at home (e.g., is part of an ''augmented crew'' for trucks, aircraft). Then provide a good mattress and enough space.
- Plan your sleeping time. Tell others your schedule to minimize interruptions. Morning-to-noon bedtimes are the most unsuitable times to sleep. Consider sleeping in two periods (5–6 hr during the day and 1–2 hr in the late evening before returning to work). Less daytime sleep and some late evening sleep not only make it easier to sleep but also may give a better fit with family/social activities.
- Have a light (not zero or heavy) meal before sleep. Avoid foods that upset your stomach and thus wake you up. Avoid liquid consumption, as it increases the need to urinate (which wakes you up). Avoid caffeine. A warm drink before your bedtime (perhaps with family members starting their day) may help your social needs.
- If under emotional stress, relax before going to bed. One possibility is light exercise.

1. Have a work scheduling policy.

The problem is insufficient rest. Two aspects are (1) too many work hours, and (2) work hours at the wrong time.

Too many hours can accrue through by not counting all the hours in duty time. For example, train and flight crews have waiting and preparation time before and after the primary job. Long hours may be from overtime due to absenteeism of another person and/or moonlighting. There probably should be some organizational restriction on prolonged overtime (say over 12 hr/day and over 55 hr/week).

Lack of sleep can result from conflicts with the circadian rhythm. Table 10 gives sleeping tips; Table 11 gives shiftwork recommendations.

2. Optimize stimulation during work.

Too much stimulation causes overload; too little causes boredom. Stimulation comes from the task and the environment.

For too much stimulation, reduce environmental stimulation (see Figure 2). For example, for office tasks, increase visual and auditory privacy.

For too little stimulation, increase either task or environmental stimulation or both. Increase task stimulation by adding physical work to sedentary jobs or by job rotation. Increase environmental stimulation by (1) conversation with others, (2) varying the auditory environment

TABLE 11 Design Recommendations for Shift Systems

- Avoid permanent night work. Full entrainment of physiological functions to night work is difficult. Permanent night workers have problems due to readapting to day cycles during weekends, holidays, and vacations.
- If shifts rotate, rapid rotation is preferable to slow (weekly) rotation. Shifts should rotate forward (day, evening, night).
- Avoid starting the morning shift before 7 a.m.
- Consider distribution of leisure time. Have sufficient time to sleep between shifts (e.g., between shift changeovers). Limit the number of consecutive working days to 5–7. For every shift system, have some nonworking weekends with at least 2 successive full days off.
- Shift durations of 12 hr have disadvantages as well as advantages. Disadvantages include fatigue, covering absentees, overtime, limiting toxic exposure, and possible moonlighting when workers have large blocks of leisure time.
- Make the schedule simple and predictable. People want to be able to plan their personal lives. Make work schedules predictable. Publicly post them in advance so people can plan; 30 days in advance is a good policy.

Source: Konz and Johnson 2000, from Knauth, 1993.

(e.g., talk radio), (3) varying the visual environment (e.g., windows with a view), and (4) varying the climate (change air temperature, velocity).

3. Minimize the fatigue dose.

The problem is that the fatigue dose becomes too great to overcome easily. Two aspects are intensity and work schedule.

Reduce high intensity levels with good ergonomic practices; for example, use machines and devices to reduce hold and carry activities. Static work (holding) is especially stressful.

The effect of fatigue increases exponentially with time. Thus, it is important to get a rest before the fatigue becomes too high. Do not permit workers to skip their scheduled break. For very high-intensity work (e.g., sorting express packages), use part-time workers.

4. Use work breaks.

The problem with a conventional break is that there is no productivity during the break. A solution is to use a different part of the body to work while resting the fatigued part. If a machine is semiautomatic, the worker may be able to rest during the automatic part of the cycle (machine time). Another alternative is job rotation (worker periodically shifts tasks). Fatigue recovery is best if the alternative work uses a distinctly different part of the body—for example, loading/unloading a truck vs. driving it, word processing vs. answering a telephone.

Not quite as good, but still beneficial, is alternating similar work, as there would be differences in body posture, force requirements, mental activity, because for example, an assembly team might rotate jobs every 30 minutes. In a warehouse, for half a shift, workers might pick cases from a pallet to a conveyor, and during the second half, they would switch with the people unloading the conveyor to trucks. Job rotation also reduces the feeling of inequity because everyone shares the good and bad jobs. However, it does require cross-trained people (able to do multiple jobs). However, this in turn increases scheduling flexibility.

5. Use frequent short breaks.

The problem is how to divide break time. The key to the solution is that fatigue recovery is exponential. If recovery is complete in 30 minutes, it takes only 2 minutes to drop from 100% fatigue to 75% fatigue; it takes 21 minutes to drop from 25% fatigue to no fatigue. Thus, give break time in small segments. Some production is lost for each break. Reduce this loss by not turning the machine off and on, taking the break near the machine, and so on.

6. Maximize the recovery rate.

The problem is recovering as quickly as possible. In technical terms, reduce the fatigue half-life.

For environmental stressors, reduce contact with the stressor. Use a cool recovery area to recover from heat, a quiet area to recover from noise, no vibration to recover from vibration. For muscle stressors, it helps to have a good circulation system (to be in good shape). Active rest seems better than passive rest. The active rest may be just walking to the coffee area (blood circulation in the legs improves dramatically within <20 steps). Another technique to get active rest is to have the operator do the material handling for the workstation (obtain supplies, dispose of finished components).

7. Increase the recovery/work ratio.

The problem is insufficient time to recover. The solution is to increase recovery time or decrease work time. For example, if a specific joint is used 8 hr/day, there are 16 hr to recover; 2 hr of recovery/1 hr of work. If the work of the two arms is alternated so that one arm is used 4 hr/day, there are 20 hr to recover; 5 hr of recovery/1 hr of work. Overtime, moonlighting or 12 hr shifts can cause problems. Working 12 hr/day gives 12 hr of recovery, so there is 1 hr of recovery/1 hr of work.

2.6 Error-Reduction Guidelines

Harry and Schroeder (2000) describe the importance from a business viewpoint of joining the ''cult of perfectability.'' Table 12 gives l0 general guidelines to reduce errors. They are organized into three categories: planning, execution, and allowing for error.

1. Get enough information.

Generating enough information calls for (1) generating/collecting the relevant information and (2) ensuring that the user receives the information.

Generating the information can be aided by computerization. But the information in the computer needs to be correct! Warnings (e.g., auditory alarm when truck backs up) can generate information; unfortunately, not all warnings are followed.

Ensure information reception. Just because you put a message in a person's mailbox

TABLE 12 Guidelines for Error Reduction

Planning
1. Get enough information.
2. Ensure information is understood.
3. Have proper equipment/procedures/skill.
4. Don't forget.
5. Simplify the task.
Execution
6. Allow enough time.
7. Have sufficient motivation/attention.
Allow for errors
8. Give immediate feedback on errors.
9. Improve error detectability.
10. Minimize consequences of errors.

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

(voicemail, e-mail), doesn't mean the person accesses it! Do you know how to use all the buttons on your telephone?

2. Ensure that information is understood.

Although there is much information available on good ergonomic design of displays (instruments as well as print such as text, figures, and tables), unfortunately, not all designers seem to have paid attention to them. Communication with the general public is especially difficult due to their lack of training on your specific system as well as their diverse ages, vision, language abilities, and so on. Equipment and procedures for the general public need to have usability tests using diverse customers.

When transmitting information to others, a good technique is to have them repeat the information back to you in their words. Technically this information feedback has two steps: forward (you to them) and backward (them to you). As the number of communication nodes increases, the need for feedback increases. Critical messages thus should be written and require confirmation from the user, not only of the receipt of the message but also of the user's understanding of its message.

3. Have proper equipment/procedures/skill.

Four aspects of equipment are design, amount, arrangement, and maintenance.

With proper equipment design, the potential error is eliminated and procedures and skill are not necessary. Don't forget foreseeable use and misuse. Some examples are a ground-fault circuit interrupter to eliminate electrocution; a surge protector for computers; design of connectors so they cannot fit into the wrong plug. Equipment guards not only must be installed, they also must remain installed (and not removed by the operator). In some cases, ''antiergonomics'' is desirable—making something difficult to use. Lockout/tagout prevents equipment from being activated while it is being maintained.

Equipment amount basically involves duplication. Some examples are duplication of computer files, equipment (four engines on an airplane), and even labor (copilot).

Equipment arrangement involves the concepts of series and parallel systems as well as standby systems. Redundancy can just be duplication of the procedure, but it also can be having some information confirm the remainder—an error-checking code. For example, giving a meeting date as Thursday, February 25, lets the Thursday confirm the 25. A ZIP code confirms the names of city and state on a postal address.

Equipment maintenance typically is assumed as a given. However the Union Carbide incident at Bhopal, India, where over 2500 people were killed, demonstrates what can happen when there is an insufficient maintenance budget, for both spare parts and for labor.

Procedures describe the sequence of body motions necessary to accomplish a task. Skill is the eye/brain/hand coordination to perform the body motion.

Develop standard procedures (protocols). Then users need to be trained on the protocol. The mind seeks patterns and rules and will follow them if they are apparent. Training may require a formal procedure of (1) writing down the training procedure and training aids, (2) designating specific people as trainers, and (3) documenting that a specific person has been trained by a specific trainer on a specific date.

Skill has both mental and physical aspects. Skill or knowledge can be memorized, but an alternative is a job aid (such as information stored in a computer). Practice is important because rookies make more mistakes than old pros; that's why sports teams practice so much.

4. Don't forget.

Two approaches to avoid forgetting are to reduce the need to remember and to use memory aids.

Avoid verbal orders: they leave no reference to refresh the memory. If you receive a verbal order, write it down to create a database for future reference.

A list is a popular memory aid; the many electronic organizers being sold attest to the need for making a list. Memory aids include more than that, however. Forms not only include information but also indicate what information is needed. Patterns aid memory. For example, it is easier to remember a meeting is on the first Friday of each month than to remember the 12 individual days. At McDonald's, orders are filled in a standard sequence; next time you are there, see if you can determine the standard sequence. Other memory aids include the fuel gauge and warning lights in cars and the sticker on the windshield showing when the oil was changed.

5. Simplify the task.

Two ways to simplify tasks are to reduce the number of steps and to improve communication.

Familiar examples of reducing steps are autodialers on telephones and use of address lists for email. Many retailers now have their computers communicate point-of-sale information not only to their own central computer but also to their vendors' computers. The original concept was to speed vendors' manufacturing and shipping, but the retailers soon realized that the elimination of all the purchasing paperwork led to drastic error reductions.

Improve communication by improving controls (how people communicate to machines) and displays (how machines communicate to people); details are covered in a number of ergonomics texts. But even letters and numbers can be confused—especially the number 0 and the letter O and the number 1 and the letter l. Use all letter codes or all numeric codes, not a mixture. If a mixed code is used, omit 0, O, 1 and l. Also, do not use both a dash and an underline.

Guidelines 6 and 7 concern execution of tasks.

6. Allow enough time.

Under time stress, people make errors. Start earlier so there is more margin between the start time and the due time. Another technique to reduce time/person by putting more people on the task; this flexibility requires cross-trained people.

7. Have sufficient motivation/attention.

Motivation is not a replacement for engineering. Gamblers are motivated to win, but wanting to win is not enough. Motivation can be positive (aid performance) or negative (hinder performance).

There are many examples of superiors challenging subordinate's decisions but relatively few of subordinates challenging superior's decisions. It is difficult, though important, to require important decisions to be challenged by or justified to subordinates. Company policies and culture and openness to criticism are important factors. Even requiring superiors to explain decisions to subordinates can be valuable: when superiors try to explain the decision, they may realize it is a bad decision.

Lack of attention can occur from simple things such as distractions, but it can also be caused by people sleeping on the job or being drunk or ill. One solution technique is to have observation by other people (either personally or by TV) so sleeping, heart attacks, and so on can be observed.

Guidelines 8, 9, and 10 discuss allowing for errors.

8. Give immediate feedback on errors.

Two subdivisions of feedback are error detection and reducing delay.

Errors can be detected by people (inspection) or by machines. Machines can passively display the error (needle in the red zone) or actively display the error (audio warning, flashing light) or even make an active correction (turn on furnace when temperature in the room drops). The machine also can fail to respond (computer doesn't work when the wrong command is entered). Machines also can present possible errors for human analysis (spell-check programs). Error messages should be specific and understandable. The message ''Error'' flashing on the screen is not as useful as ''Invalid input—value too high. Permissible range is 18 to 65 years.'' Error messages should not be too irritating or people will turn them off.

Reduce the time (latency) until the error is detected. The more quickly the error is detected, the easier it is to detect why the error occurred. A quick correction may also reduce

possible damage. For example, your car may make a noise if you remove the key while the headlights are on; thus, you can turn the lights off before the battery dies.

9. Improve error detectability.

   Consider the error as a signal and the background as noise. Improve detectability by having a high signal/noise ratio—a good contrast. Amplify the signal or reduce the noise.

   One way to enhance a signal is to match it. For example, if someone gives you a message, repeat it back so he or she can see that you understand the message. A signal also can be increased. For example, putting a switch on can also trigger an indicator light. The signal should not conflict with population stereotypes (expected relationships) and thus be camouflaged. For example, don't put regular coffee in a decaf container; don't put chemicals in a refrigerator that also contains food.

   Reduce the noise by improving the background. Traffic lights are made more visible by surrounding the lights with a black background. When talking on the phone, turn down the radio.

10. Minimize consequences of errors.

    Design equipment and procedures so they are less sensitive to errors—so they are fail-safe. A well-designed system anticipates possible problems. What if an instrument light fails? the address on a letter is incorrect? the pilot has a heart attack? the air conditioning system fails? the paint drips from the brush? Some solutions are redundant instrument lights, return addresses on letters, copilots, windows that open, painting while using a dropcloth. The consequences of many errors can be reduced by guards (e.g., guards to prevent hands touching moving pulley and belts, gloves to prevent chemical burns, hard hats to prevent head injuries).

    Ease of recovery also is important. What can be done if a box jams on a conveyor turn? if a paycheck is lost? if a mistake is made on a computer input? if a car tire has a blowout? Longer time available for recovery helps. For example, a fire door with a 1 hr rating is better than one with a 0.1 hr rating.

3. GATHERING/ORGANIZING INFORMATION

This section will discuss What to study (Pareto), videotaping jobs, searching for solutions, between-operations analysis, and within-operation analysis.

3.1. What to Study (Pareto)

Engineering time is a valuable resource; don't waste time on unimportant problems. To check quickly whether a project is worth considering, calculate (1) savings/year if material cost is cut 10% and (2) savings/year if labor cost is cut 10%.

The concept of the ''insignificant many and the mighty few'' (Pareto distribution) is shown in Figure 7. Cause (x-axis) and effect (y-axis) are not related linearly. The key concept is that the bulk of the problem (opportunity) is concentrated in a few items. Pareto diagrams are a special form of a histogram of frequency counts; the key is that the categories are put into order with the largest first and smallest last; then a cumulative curve is plotted. Therefore, using the Pareto concept, if your design concerns crime, it should concentrate on the few individuals who cause most of the crimes; if it is to improve quality, it should concentrate on the few components that cause most of the problems. See Table 13. Fight the giants!

3.2. Videotaping Jobs

Videotaping is useful for task analysis and for training. Some tips are:

- Have spare batteries and a battery charger. A charger may take eight hours to recharge a battery.
- Use a camera feature that continuously displays the date on the screen; this establishes without question when the scene was shot. You may wish also to photo a card with the operator's name.
- Plan the location of camera and subject ahead of time. Use a tripod. Multiple views are best. Use some combination of a front view, a side view, a back view, ''stepladder'' views (a partial-plan view), overall views, and closeup views. Begin a scene with a full view (far shot, wide-angle view) and then zoom as desired.
- If possible, videotape multiple operators doing the same task. This permits comparisons of methods. Small differences can be detected on tape because the tape can be frozen and/or repeated. For example, how are items oriented? Is the sequence of steps the same? Does one operator deviate joints more or less than other operators?
- If the view is perpendicular to the operator front or side, the projected view can be frozen and angles determined on the screen using a protractor. These angles can then be used as input to computer models.

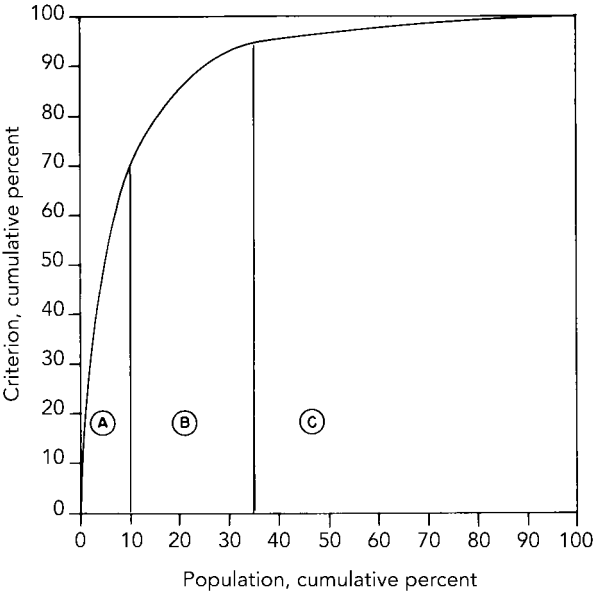

Figure 7 Pareto Distribution. Many populations have a Pareto distribution, in which a small portion of population has a large proportion of the criterion. Inventories, for example, can be classified by the ABC system. "A" items may comprise 10% of the part numbers but 70% of the inventory cost. "B" items may comprise 25% of the part numbers and 25% of the cost; the total of A + B items then comprise 35% of the part numbers and 95% of the cost. "C" items thus comprise the remaining 65% of the part numbers but only 5% of the cost. Concentrate your efforts on the "A" items. Don't use gold cannons to kill fleas! (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

- Take lots of cycles for your stock tape. Each scene should have several cycles. You can always edit, but it is expensive to go back and shoot more tape.
- For analysis of time, there are three alternatives:
  1. Put a digital clock in the scene.
  2. Use a camera–VCR system with a timecode feature, which will allow you to quickly locate any time on the tape.
  3. Count the number of frames (VHS has 30 frames/sec [0.033 sec/frame]).

TABLE 13 Items vs. Opportunities (Pareto Distribution)

Item	Opportunity
A few products	produce most of the direct labor dollars.
products	have most of the storage requirements.
products	produce most of the profit.
operations	produce most of the quality problems.
operations	produce most of the cumulative trauma.
machines	use most of the energy.
time studies	cover most of the direct labor hours.
individuals	commit most of the crimes.
individuals	have most of the money.
individuals	drink most of the beer.

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

- During taping, use audio only as a notepad. For management presentations and training, dub in a voice reading a script.
- The VCR should have both a freeze-frame and single-frame advance.
- For task analysis, have the operator as well as the engineer view the tape. The operator can point out to the engineer what is being done and why—perhaps with audio dubbing. The tape also can show the operator some problems and how other operators do the task.
- For a training or management presentation video, you will need to cut and paste your stock tape. For the script, divide a column of paper into two columns labeled audio and visual. In the audio column, enter the words to be read. In the visual column, enter the tape counter reading (start and stop) of the stock videotape. For your final tape, you also will use text shots created in the studio (title page, points you want to emphasize, conclusions, etc.), studio shots of you, and shots of still photos. Then create the final product by blending all the pieces. Perhaps you can even add music!

3.3. Searching for Solutions

Table 14 shows the general procedure for an assessment. Also see Section 4 for the steps of engineering design. The typical sequence is (1) being informed by management that there is a problem, (2), (3), (4) getting information by observation and from the operators and supervisors, and (5) making measurements. Then propose a solution. Rather than depending on inspiration for the solution, most people prefer to follow a more systematic procedure, using tried-and-true techniques established by people who have previously worked on this type of problem.

Searching for an alternative method can be done by following Kipling's ''six honest men'' (who, what, why, when, where, and how), following checklists (see examples in Section 3.5), or using the acronym SEARCH, where:

S = Simplify operations
E = Eliminate unnecessary work and material
A = Alter sequence
R = Requirements
C = Combine operations
H = How often

''Eliminate'' should be done first, then the others in any sequence.

TABLE 14 Procedure for Ergonomics and Productivity Assessment

Source of Information	Method	Data Collected
1. Management	Unstructured interview Collect statistics	Manufacturing measures of productivity, yield throughput, types of defects; job descriptions, injury and absenteeism rates
2. Plant	Ergonomics checklist walk-through	Investigator observes ergonomics and productivity, verified by operator
3. Operators	Unstructured interview Questionnaires Task analyses Videos	Comments on ergonomics, productivity; task analyses; job descriptions
4. First-line	Unstructured interviews	Current problems in manufacturing supervisors process; housekeeping
5. Field	Light, sound meters; measurements tape measures	Ambient environment; workstation dimensions

Reprinted from *International Journal of Industrial Ergonomics,* Vol. 15, M. Helander and G. Burri, ''Cost Effectiveness of Ergonomics and Quality Improvements in Electronics Manufacturing,'' pp. 137–151, copyright © 1995, with permission from Elsevier Science.
If possible, for comparison, obtain measures before and after the change.

E = Eliminate unnecessary work and material. Four subcategories are (1) eliminate unneeded work, (2) eliminate work where costs are greater than benefits, (3) use self-service, and (4) use the exception principle.

Examples of unneeded work are obsolete distribution and mailing lists. Once a year send a letter saying that unless the person completes the form and returns it, that person will no longer receive a copy. An example of costs greater than benefits is the staffing of tool cribs. Self-service at a crib is probably considerably cheaper than having an attendant get the item (consider grocery stores). Another example of self-service is replacing a single mailbox with multiple mailboxes designated ''company—this building,'' ''company—other buildings,'' and ''U.S. mail.'' An example of the exception principle is a reserved parking stall with a strange car in it. Normally the police would give a ticket. Using the exception principle, the police would give a ticket only if the stall owner complained.

S = Simplifying operations is shown by special register keys in fast-food operations. The key indicates a specific item (''Big Mac'') rather than a price. This reduces pricing errors and improves communication with the cooking area. For e-mail, the return key simplifies finding the return address and entering it.

A = Altering sequence has three subdivisions: (1) simplify other operations, (2) reduce idle/delay time, and (3) reduce material-handling cost.

Modifying when something is done may influence how it is done. For example, machining is easier before a material is hardened than after. On a car assembly line, installing a brake cylinder assembly is easier before the engine is installed. Idle/delay time often can be reduced. For example, in a restaurant, the server can bring coffee when bringing the breakfast menu instead of making two trips. Or the idle time might be used fruitfully by double tooling. Consider having two fixtures on a machine so that while the machine is processing the material on fixture 1, the operator is loading/unloading fixture 2. An example of reducing material-handling costs is using an automatic guided vehicle (bus) instead of moving items on a fork truck (taxi).

R = Requirements has two aspects (1) quality (capability) costs and (2) initial vs. continuing costs.

Costs rise exponentially (rather than linearly) vs. quality. Therefore, do not ''goldplate'' items. Indirect materials are a fruitful area to investigate because they tend not to be analyzed. For example, one firm compared the varnish applied on motor coils vs the varnish purchased; there was a 10% difference. It was found that the varnish was bought in 55-gallon drums. When the drums were being emptied, they were turned right side up when there was still considerable product inside. The solution was a stand that permitted the varnish to drip out of the drum over a period of hours.

Initial vs. continuing costs means you should focus not just on the initial capital cost of a product but on the life-cycle costs (capital cost plus operating cost plus maintenance cost).

C = Combine operations is really a discussion of general purpose vs. special purpose. For example, do you want to have a maintenance crew with one specialist doing electrical work, another doing plumbing, and another doing carpentry? Or three people, each of whom can do all three types of work? Most firms now are going for the multi-skilled operator because it is difficult to find sufficient work to keep all specialists always busy.

H = How often is a question of the proper frequency. For example, should you pick up the mail once a day or four times a day? Should solution pH be tested once an hour, once a day or once a week?

3.4. Between-Operations Analysis

This section will discuss flow diagrams, multiactivity charts, arrangement (layout) of equipment, and balancing flow lines.

3.4.1. Flow Diagrams

Flow diagrams and their associated process charts are a technique for visually organizing and structuring an overview (''mountaintop'' view) of a between-workstations problem. There are three types: single object, assembly/disassembly, and action–decision.

3.4.1.1. Single Object Figure 8 shows a single-object process chart following a housing in a machine shop; the single object also can be a person. Some examples of following a person are vacuuming an office and unloading a semitrailer.

Figure 9 shows the five standard symbols for process charts. Some people put a number inside each symbol (identifying operation 1, 2, 3) and some don't. Some people emphasize ''do'' operations by darkening those circles (but not get-ready and put-away operations) and some don't. Since a process chart is primarily a communication tool for yourself, take your choice. Most operations have scrap and rework; Figure 10 shows how to chart them. At the end of the chart, summarize the number of operations, moves (including total distance), inspections, storages and delays. Estimate times for storages (which are planned) and delays (which are unplanned storages). Since this is a big-picture analysis, detailed times for operations and inspections normally are not recorded.

FLOW CHART — Exception No. ———

Figure 8 Single-Object Process Chart. The chart follows a single object or person—in this example, an object. For good analysis, estimate distances and times. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

Figure 9 Five Standard Symbols for Process Charts. They are a circle (operation), arrow (move), square (inspect), triangle with point down (storage) and D (delay). A circle inside a square is a combined operation and inspection. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

Next you would consider possible improvements using Kipling's six honest men (who, what, where, why, when and how), SEARCH, and various checklists. This may lead to a proposed method where you would show reductions in number of operations, inspections, storages, distance moved, and so on. Because flow diagrams organize complex information and thus are a useful communication tool, you may want to make a polished copy of the flow diagrams to show to others. Since many potential improvements involve reducing movements between workstations, a map showing the movements is useful; Figure 11 shows a flow diagram of Joe College making a complex job of drinking beer in his apartment. Generally a sketch on cross-section paper is sufficient.

3.4.1.2. Assembly/Disassembly Diagrams Assembly flow diagrams (see Figure 12) tend to point out the problems of disorganized storage and movements. Figure 13 shows a disassembly diagram; another example would be in packing houses.

3.4.1.3. Action–Decision Diagrams In some cases, you may wish to study decision making; then consider an action–decision diagram (see Figure 14) or a decision structure table (see Section 3.5.2).

3.4.2. Multiactivity Charts

The purpose of a multiactivity chart is to improve utilization of multiple related activities. See Figure 15. The two or more activities (column headings) can be people or machines; they can also be parts of a person (left hand vs. right hand) or parts of a machine (cutting head vs. fixture 1 vs. fixture 2). The time axis (drawn to a convenient scale) can be seconds, minutes, or hours.

Example charts and columns might be milling a casting (operator, machine), cashing checks (cashier, customer 1, customer 2), and serving meals (customer, server, cook).

For each column, give cycles/year, cost/minute, and percent idle. Make the idle time distinctive by cross-hatching, shading, or coloring red.

Improve utilization by (1) reducing idle time in a column, (2) shifting idle time from one column to another, or (3) decreasing idle time of an expensive component (such as person) by increasing idle time of a machine. McDonald's uses this third concept when they have two dispensers of Coke in order to reduce the waiting time of the order taker (and thus the customer).

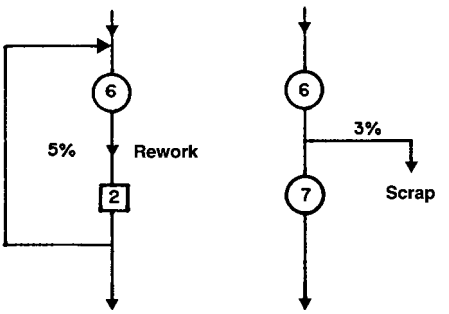

Figure 10 Rework (left) and Scrap (right) for Flow Diagrams. Rework and scrap often are more difficult to handle than good product. Even though rework is often concealed, most items have rework. Material-removal scrap occurs in machining and press operations; scrap units occur everywhere. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

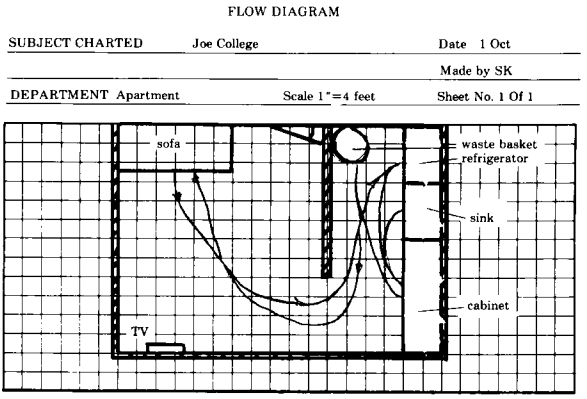

Figure 11 Flow Diagram. This is a map often used with process charts. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

Some time is considered to be free. For example, ''inside machine time'' describes the situation in which an operator is given tasks while the machine is operating. Since the operator is at the machine anyway, these tasks are ''free.'' A McDonald's example is to grasp a lid while the cup is filling.

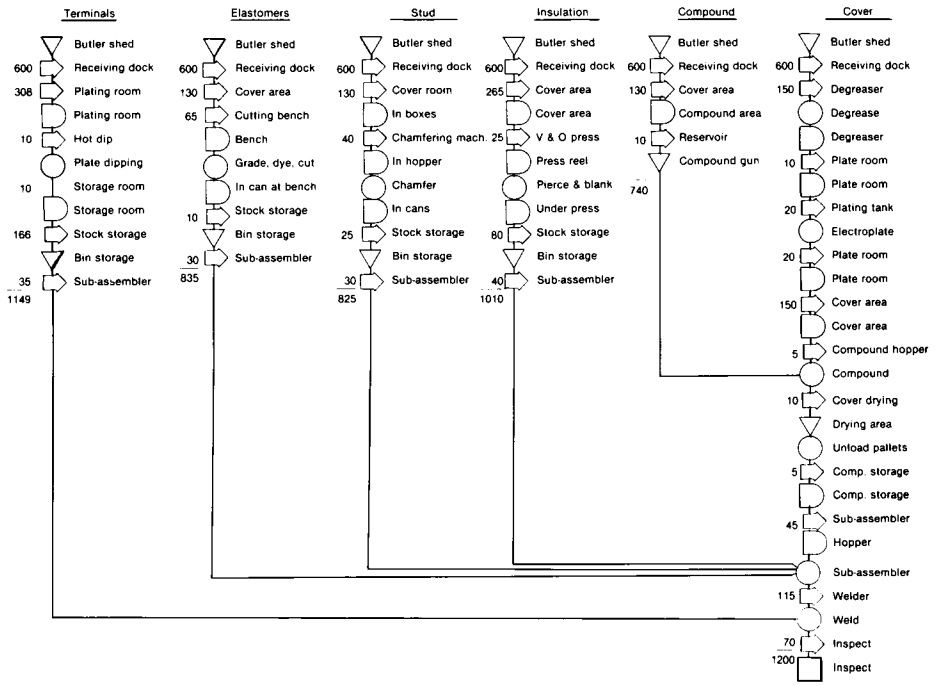

Figure 12 Assembly Process Chart. This type of chart shows relationships among components and helps emphasize storage problems. Each column is an item; the assembly is on the right. Figure 13 Disassembly Process Chart. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

1. Search items
2. Pick up item with right hand (both hands if large)
3. Is the item to be weighed? Yes/No
4. Inspect for code Yes/No
5. Inspect for identical items amongst load
6. Are number of similar items greater than 2? Yes/No
7. Inspect for positioning of code
8. Pass item to left hand
9. Pass item over scanner
10. Was scan successful? Yes/No
11. Is the item fragile or vulnerable? Yes/No
12. Place item on the second conveyor
13. Inspect—was this the last item? Yes/No
14. Does customer require a carrier bag? Yes/No
15. Press total
16. Tell customer the cost
17. Wait for payment
18. Receive payment
19. Key in amount received
20. Determine change
21. Cash money, give change
22. Obtain and give receipt
23. Transfer item to left hand
24. Put item on scales
25. Obtain price/kilo
26. Key in price/kilo with right hand
27. Inspect for price mark Yes/No
28. Press intercom button
29. Wait (continue working)
30. When buzzer sounds give the product details
31. Wait (continue working)
32. Receive price information
33. Key in price with right hand
34. Key in number of identical items
35. Place remainder of identical items on second conveyor
36. Decide whether to scan again
37. Read code? Yes/No
38. Key in code
39. Place on ledge in front of customer
40. Reach for carrier bag
41. Give bag to customer
42. Key in price of bag

Figure 14 Action–Decision Flow Diagram. This chart of a seated checkout operator in England shows use of a laser scanner. Note that in Europe the customer bags the groceries. (From Wilson and Grey 1984)

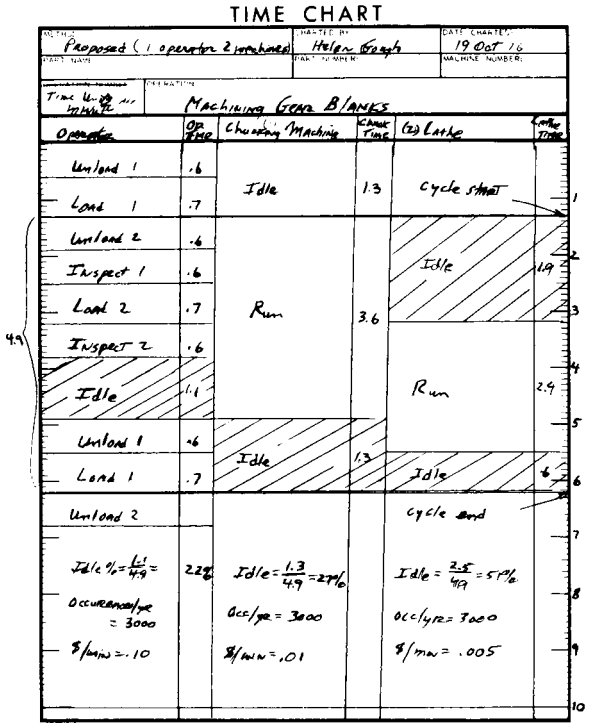

Figure 15 Multiactivity Chart. The basic concept is to have two or more activities (columns) with a common, *scaled,* time axis. The goal is to improve utilization, so emphasis is placed on idle time. For each column, calculate the percent idle time, the occurrences/year, and the cost/minute. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

As pointed out above in (3), it is possible to have more than one machine/operator—this is double tooling. For example, use two sets of load/unload fixtures on an indexing fixture to reduce idle time while waiting for the machine to cut. Or one person can service two machines (i.e., 1 operator/2 machines or 0.5 operator/machine). It is also possible to have 0.67 or 0.75 operators/machine. Do this by assigning 2 people/3 machines or 3/4, that is, having the workers work as a team, not as individuals. This will require cross-trained operators, which is very useful when someone is absent.

Kitting is the general strategy of gathering components before assembly to minimize search-and-select operations and ensure that there are no missing parts. Subassemblies also may be useful. McDonald's Big Mac has a "special sauce," which is just a mixture of relish and mayonnaise, premixed to ensure consistency.

A disadvantage of the multiactivity chart is that it requires a standardized situation. Nonstandardized situations are difficult to show. For them, use computer simulation.

3.4.3. Arrangement (Layout) of Equipment

This section describes location of one item in an existing network. Arrangement of the entire facility is covered in Chapter 55.

Problem. Table 15 shows some examples of locating one item in an existing network of customers. The item can be a person, a machine, or even a building. The network of customers can be people, machines, or buildings. The criterion minimized is usually distance moved but could be energy lost or time to reach a customer.

Typically an engineer is interested in finding the location that minimizes the distance moved—a minisum problem. An example would be locating a copy machine in an office. An alternative objec-

TABLE 15 Examples of Locating an Item in an Existing Network of Customers with Various Criteria to be Minimized

New Item	Network of Customers	Criterion Minimized
Machine tool	Machine shop	Movement of product
Tool crib	Machine shop	Walking of operators
Time clock	Factory	Walking of operators
Inspection bench	Factory	Movement of product or inspectors
Copy machine	Office	Movement of secretaries
Warehouse or store	Market	Distribution cost
Factory	Warehouses	Distribution cost
Electric substation	Motors	Power loss
Storm warning siren	City	Distance to population
IIE meeting place	Locations of IIE members	Distance traveled
Fire station	City	Time to fire

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

tive is to minimize the maximum distance—a minimax or worst-case problem. An example minimax problem would be to locate an ambulance so everyone could be reached in no more than 15 minutes. There is extensive analytical literature on this ''planar single-facility location problem''; see Francis et al. (1992, chap. 4).

The following is not elegant math but ''brute force'' calculations. The reason is that, using a hand calculator, the engineer can solve all reasonable alternatives in a short time—say 20 minutes. Then, using the calculated optimum for the criterion of distance, the designer should consider other criteria (such as capital cost, maintenance cost) before making a recommended solution.

Solution. The following example considers (1) the item to be located as a machine tool, (2) the network of customers (circles in Figure 16) as other machine tools with which the new tool will exchange product, and (3) the criterion to be minimized as distance moved by the product.

In most real problems, there are only a few possible places to put the new item; the remaining space is already filled with machines, building columns, aisles, and so forth. Assume there are only two feasible locations for the new item—the A and B rectangles in Figure 16.

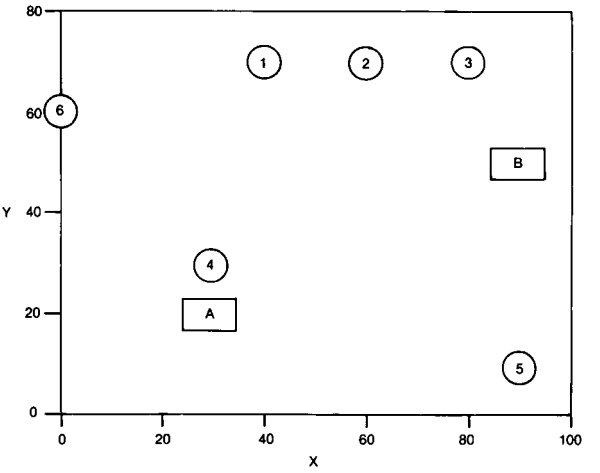

Figure 16 Information for Location of One Item. Customers (in circles) can be served from either location A or B. Table 17 gives the importance of each customer. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

Travel between a customer and A or B can be (1) straight line (e.g., conveyors), (2) rectangular (e.g., fork trucks using aisles), or (3) measured on a map (e.g., fork trucks using one-way aisles, conveyors following nondirect paths). Travel may be a mixture of the three types.

Some customers are more important than others, and thus the distance must be weighted. For a factory, an index could be pallets moved per month. For location of a fire station, the weight of a customer might depend on number of people occupying the site or the fire risk.

The movement cost of locating the new item at a specific feasible location is:

$$\text{MVCOST} = \text{WGTK (DIST)}$$

where MVCOST = index of movement cost for a feasible location
WGTK = weight (importance) of the Kth customer of N customers
DIST = distance moved

For rectangular:

$$\underset{K=1}{\overset{N}{\text{MVCOST}}} = (|X_{ij} - X_k| + |Y_{ij} - Y_k|)$$

For straight line:

$$\underset{K=1}{\overset{N}{\text{MVCOST}}} = \Sigma \sqrt{(X_{i,j} - X_k)^2 + (Y_{i,j} - Y_k)^2}$$

For the two locations given in Table 16, Table 17 shows the MVCOST. Movement cost at B is 67,954/53,581 = 126% of A.

If you wish to know the cost at locations other than A and B, calculate other locations and plot a contour map. A contour map indicates the best location is $X = 42$ and $Y = 40$ with a value of 32,000. Thus, site A is 6,000 from the minimum and site B is 13,000 from the minimum.

The previous example, however, made the gross simplification that movement cost per unit distance is constant. Figure 17 shows a more realistic relationship of cost vs. distance. Most of the cost is fixed (loading/unloading, starting/stopping, paperwork). Cost of moving is very low. Thus:

For rectangular:

$$\text{DIST} = L_k + C_k (|X_{i,j} - X_k| + |Y_{i,j} - Y_k|)$$

For straight line:

$$\text{DIST} = L_k + C_k \sqrt{(X_{i,j} - X_k)^2 + (Y_{i,j} - Y_k)^2}$$

where L_k = load + unload cost (including paperwork) per trip between the Kth customer and the feasible location

TABLE 16 Importance of Each Customer
Customers 1 to 6 can be served either from location A ($X = 30$, $Y = 20$) or from location B ($X = 90$, Y = 50). Which location minimizes movement cost?

Customer	Coordinate		Weight or Importance	Movement Type
	X	Y		
1	40	70	156	Straight line
2	60	70	179	Straight line
3	80	70	143	Straight line
4	30	30	296	Rectangular
5	90	10	94	Rectangular
6	0	60	225	Rectangular

TABLE 17 Cost of Locating a New Machine at Location A or B

		Site A		Site B	
Customer	Weight, Pallets/ Month	Distance, Meters	Cost, m-Pallets/ Month	Distance	Cost, m-Pallets/ Month
1	156	51	7,956	54	8,424
2	179	58	10,382	36	6,444
3	143	71	10,153	*22*	3,146
4	296	10	2,960	80	23,680
5	94	70	6,580	40	3,760
6	225	70	15,750	100	22,500
			53,781		67,954

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.
Since WGTK was pallets/month and DIST was in meters, MVCOST = meter-pallets/month.

$$C_k = \text{cost/unit distance (excluding } L_k)$$

Assume, for customers 1, 2, and 3, that L_k = \$0.50/trip and C_k = \$0.001/m; for customers 4, 5, and 6, L_k = \$1/trip and C_k = \$0.002/m. Then the cost for alternative A = \$854 + \$79.07 = \$933.07 while the cost for B = \$854 + \$117.89 = \$971.89. Thus, B has a movement cost of 104% of A. When making the decision where to locate the new item, use not only the movement cost but also installation cost, capital cost, and maintenance cost. Note that the product (WGTH)(DIST) (that is, the \$854) is independent of the locations; it just adds a constant value to each alternative.

Cost need not be expressed in terms of money. Consider locating a fire station where the customers are parts of the town and the weights are expected number of trips in a l0-year period. Then load might be 1 min to respond to a call, travel 1.5 min/km, and unload 1 min; the criterion is to minimize mean time/call.

The distance cost might rise by a power of 2 (the inverse square law) for problems such as location of a siren or light.

3.4.4. Balancing Flow Lines

The two most common arrangements of equipment are a job shop and a flow line (often an assembly line). The purpose of balancing a flow line is to minimize the total idle time (balance delay time). There are three givens: (1) a table of work elements with their associated times (see Table 18), (2) a precedence diagram showing the element precedence relationships (see Figure 18), and (3) required

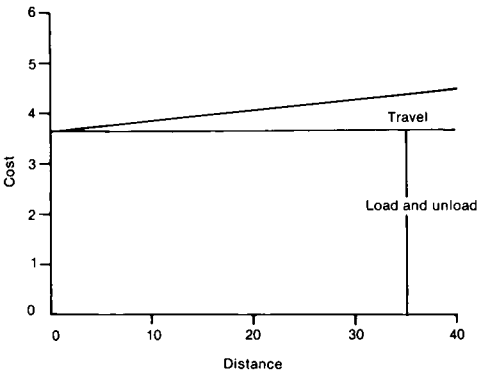

Figure 17 Relationship of Cost vs. Distance. In general, material-handling cost is almost independent of distance. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission)

TABLE 18 Elements and Work Times for the Assembly-Line Balancing Problem

Each element time is assumed constant. In practice, each element time is a distribution.

units/minute from the line. The three unknowns are (1) the number of stations, (2) the number of workers at each station, and (3) the elements to be done at each station.

1. What is the total number to be made, and in how long a time? For example, 20,000 units could be made in 1000 hr at the rate of 20/hr, 500 hr at 40/hr, or some other combination. Continuous production is only one of many alternatives; a periodic shutdown might be best. Assume we wish to make 20,000 units in 1000 hr at the rate of 20/hr. Then each station will take 1000 hr/20,000 units = 0.05 hr/unit; cycle time is .05 hr.
2. Guess an approximate number of workstations by dividing total work time by cycle time: 0.1818 hr/0.05 hr/station = 3.63 stations. Then use 4 workstations with 1 operator at each.
3. Make a trial solution as in Table 19 and Figure 19. Remembering not to violate precedence, identify each station with a cross-hatched area. Then calculate the idle percentage: 0.0182/(4 × 0.05) = 9.1%.

But this can be improved. Consider Table 20. Here stations 1 and 2 are combined into one superstation with two operators. Elemental time now totals 0.0950. Since there are two operators, the

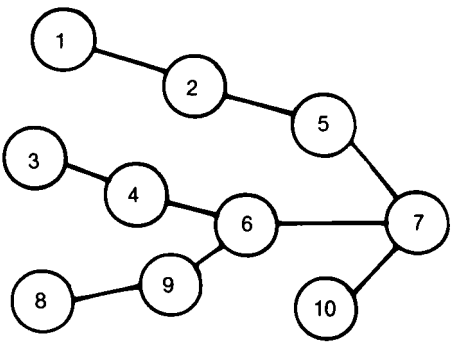

Figure 18 Precedence Diagram Showing the Sequence Required for Assembly. The lines between the circles are not drawn to scale. That is, elements 4 and 9 both must be competed before 6, but 9 could be done before or after 4. Precedence must be observed. Thus, elements 3, 4, and 9 could not be assigned to one station and elements 8 and 6 to another. However, 8, 9, and 10 could be done at one station. Cycle time = 0.0500 hr.

idle time/operator is 0.0025. So far there is no improvement over the solution of Table 19. *But there is idle time at each station.* Thus, the line cycle time can be reduced to 0.0475. The new idle time becomes $0.0083/(4 \times 0.0475) = 4.4\%$ instead of 9.1%. The point is that small changes in cycle time may have large benefits.

Small modifications of other "rigid facts" can be beneficial.

Consider element sharing. That is, operators/station need not be 1.0. One possibility is more than 1 operator/station. Two operators/station yields 2.0 operators/station. Three operators/two stations yields 1.5 operators/station. This permits a cycle time that is less than an element time. For example, with 2 operators/station, each would do every other unit.

Get fewer than 1 operator/station by having operators walk between stations or having work done off-line (i.e., using buffers). Also, operators from adjacent stations can share elements. For example, station D does half of element 16 and 17 and station E does half of element 16 and 17.

Remember that cycle times are not fixed. We assumed a cycle time of 0.05 hr (i.e., the line runs 1000 hr or $1000/8 = 125$ days). As pointed out above, it is more efficient to have cycle time of

Cycle time = 0.0475 hr; two operators at station 1.

0.0475 hr (i.e., 20,000 units × 0.0475 = 950 hr = 950/8 = 118.75 days). What is the best combination of setup cost, balance delay cost, and inventory carrying cost?

Elements can be redefined. For example, elements 16, 17, and 18 may be redefined to eliminate element 17 by allocating all of 17 to element 16 or to element 18 or to allocate a portion to element 16 or 18.

Reconsider the allocation of elements to subassemblies and assembly. For example, a nameplate might be added at a subassembly instead of at the assembly station.

3.5. Within-Operation Analysis

This section will discuss fish diagrams, decision structure tables, and checklists.

3.5.1. Fish Diagrams

Fish diagrams graphically depict a multidimensional list. See Figures 20 and 21. Professor Ishikawa developed them while on a quality control project for Kawasaki Steel; they are the ''cause'' side of cause-and-effect diagrams. The diagram gives an easily understood overview of a problem.

Start with the ''effect'' (a fishhead), a specific problem. Then add the ''cause'' (the fish body), composed of the backbone and other bones. A good diagram will have three or more levels of bones (backbone, major bones, minor bones on the major bones). There are various strategies for defining the major bones. Consider the 4 M's: manpower, machines, methods, materials. Or use the 4 P's: policies, procedures, people, plant. Or be creative.

Figures 20 and 21 were used at Bridgestone to reduce the variability of the viscosity of the splicing cement used in radial tires. Figure 21 shows the variability of the four operators before and after the quality circle studied the problem.

A very effective technique is to post the fish diagram on a wall near the problem operation. Then invite everyone to comment on possible problems and solutions; many quality problems can be reduced with better communication.

3.5.2. Decision Structure Tables

Decision structure tables are a print version of ''if, then'' statements (the ''what if'' scenario) in computer programs. They also are known as protocols or contingency tables; see Table 21 for an example. They unambiguously describe complex, multivariable, multirule decision systems. A spreadsheet is a computerized decision structure table.

Decision structure tables give better quality decisions due to (1) better decision analysis (higher-quality personnel make the decision, using complex analysis techniques if necessary) and (2) less time pressure at the time the decision is made. They are a game plan worked out in advance, not in the heat of battle. However, in addition, decision structure tables force a good methods analysis because all possibilities are considered systematically. The tables also are good training aids.

3.5.3. Checklists

Checklists allow a novice to use the distilled expertise of others. Table 6 is a checklist to prioritize potential ergonomic problems; it focuses on force, duration, and repetition for various body parts.

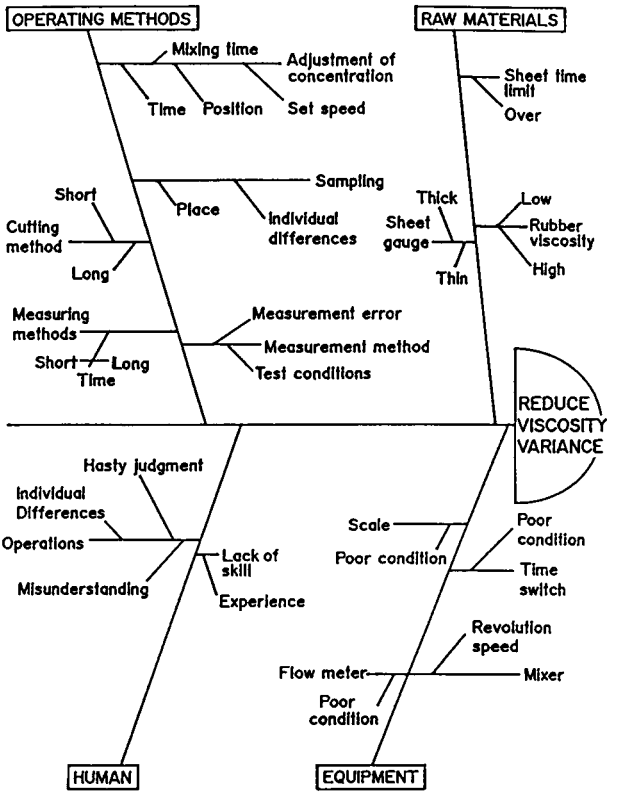

Figure 20 Fish Diagrams Used at Bridgestone Tire. The goal was to reduce viscosity variance. The four main categories were operating methods, raw materials, humans, and equipment. The variance was reduced when it was discovered that not all operators followed the standard method; those following the standard had *more* variance. See Figure 21. (From R. Cole, *Work, Mobility, and Participation: A Comparative Study of American and Japanese Industry.* Copyright © 1979 The Regents of the University of California. By permission)

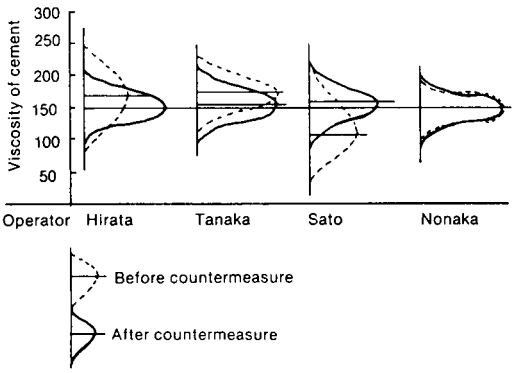

Figure 21 Distribution Curves for Viscosity Variance before and after Quality Circle Project. Reducing variance (noise) is an excellent quality-improvement technique because the effects of various changes are seen much more clearly for processes with little variability. (From R. Cole, *Work, Mobility, and Participation: A Comparative Study of American and Japanese Industry.* Copyright © 1979 The Regents of the University of California. By permission)

TABLE 21 Example of a Decision Structure Table to Select Drill Size (National Special Thread Series) before Tapping or Clearance Drill Size

If Bolt Diameter (in.) Is	And Threads Per Inch Is	Then Drill Size For 75% Thread Is	Then Clearance Drill Bit Size Is
1/16	64	3/64	51
5/64	60	1/16	45
3/32	48	49	40
7/64	48	43	32

Assume you wish a hole large enough so the drill will not touch the bolt threads.

Checklists can also focus more precisely. Table 7 is a checklist for just the upper extremity. Table 8 is a checklist to prioritize potential ergonomic problems due to posture; it focuses on force and duration for neck, trunk, and general body.

4. ENGINEERING DESIGN

After reviewing the job design guidelines from Section 2 and the information from Section 3, you can design alternatives. Remember the five steps of engineering design with the acronym DAMES: Define the problem, Analyze, Make search, Evaluate alternatives, and Specify and sell solution. See Table 22.

1. Define the problem broadly.

   Usually the designer is not given the problem but instead is confronted with the current solution. The current solution is not the problem but just one solution of among many possible solutions. The broad, detail-free problem statement should include the number of replications, the criteria, and the schedule. At this stage, putting in too much detail makes you start by defending your concept rather than opening minds (yours and your clients') to new possibilities. At this stage, the number of replications should be quite approximate (within $\pm 500\%$). Criteria (see Section 2.1) usually are multiple (capital cost, operating cost, quality) rather than just one criterion. The schedule defines priorities and allocation of resources for the project.
2. Analyze in detail.

   Now amplify step 1 (defining the problem) with more detail on replications, criteria, and schedule.

   - What are the needs of the users of the design (productivity, quality, accuracy, safety, etc.)? See Sections 2.1, 2.2, 2.3, 2.4, 2.5, and 2.6.
   - What should the design achieve?
   - What are limits (also called constraints and restrictions) to the design?
   - What are the characteristics of the population using the design? For example, for designing an office workstation, the users would be adults within certain ranges (age from 18 to 65, weight from 50 to 100 kg, etc.).

   The design should consider not only the main activities (the "do," e.g., the assembly) but also the "get-ready" and "put-away" and support activities such as setup, repairs, maintenance, material handling, utilities, product disposal, and user training.

   Since people vary, designers can follow two alternatives: (a) Make the design with fixed characteristics; the users adjust to the device. One example would be an unadjustable chair. Another example would be a machine-paced assembly line. (b) Fit the task to the worker. One example would be an adjustable chair. Another example would be a human-paced assembly line (i.e., with buffers) so all workers could work at individual paces.
3. Make search of the solution space.

   Now design a number of alternatives—not just one.

   Now use the information you gathered using the techniques of Section 3. Also get design ideas from a number of sources: workers, supervisors, staff people, other engineers, vendors, suppliers, and so on. (Benchmarking is a technique of obtaining ideas from other organizations.) The solution space will be reduced by various economic, political, aesthetic, and legal constraints. Among the feasible solutions (solutions that work), try to select the best one—the optimum solution.

TABLE 22 DAMES: The Five Steps of Engineering Design (Define, Analyze, Make search, Evaluate, Specify and sell)

Step	Comments	Example
Define the problem broadly.	Make statement broad and detail-free. Give criteria, number of replications, schedule	Design, within 5 days, a workstation for assembly of 10,000/yr of unit Y with reasonable quality and low mfg cost.
Analyze in detail.	Identify limits (constraints, restrictions). Include variability in components and users. Make machine adjust to person, not converse.	Obtain specifications of components and assembly. Obtain skills availability of people; obtain capability/availability of equipment. Get restrictions in fabrication and assembly techniques and sequence. Obtain more details on cost accounting, scheduling, and tradeoffs of criteria.
Make search of solution space.	Don't be limited by imagined constraints. Try for optimum solution, not feasible solution. Have more than one solution.	Seek a variety of assembly sequences, layouts, fixtures, units/hr, handtools, etc.
Evaluate alternatives.	Trade off multiple criteria. Calculate benefit/cost.	Alt. A: installed cost \$1000; cost/unit = \$1.10. Alt. B: installed costs \$1200; cost/unit = \$1.03.
Specify and sell solution.	Specify solution in detail. Sell solution. Accept a partial solution rather than nothing. Follow up to see that design is implemented and that design reduces the problem.	Recommend Alt. B. Install Alt. B1, a modification of B suggested by the supervisor.

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

A problem is the tendency of designers to be satisfiers rather than optimizers. That is, designers tend to stop as soon as they have one feasible solution. For example, when designing an assembly line, the designer may stop as soon as there is a solution. For an optimum solution, there must be a number of alternatives to select from. Alternatives tend to suggest further alternatives, so stopping too soon can limit solution quality and acceptance.

4. Evaluate alternatives.

To get better data for your evaluation, consider trying out your alternatives with mockups, dry runs, pilot experiments, and simulations.

You will need to trade off multiple criteria—usually without any satisfactory tradeoff values. For example, one design of an assembly line may require 0.11 min/unit while another design may require 0.10 min/unit; however, the first design gives more job satisfaction to the workers. How do you quantify job satisfaction? Even if you can put a numerical value on it, how many "satisfaction units" equal a 10% increase in assembly labor cost?

Consider a numerical ranking, using a equal interval scale for each criterion. (Method A requires 1.1 min/unit, while method B requires 1.0 min/unit; method A requires 50 m^2 of floor space, while method B requires 40 m^2.) However, managers generally want to combine the criteria. Table 23 shows one approach. After completing the evaluation, have the affected people sign off on the evaluation form. Then go back and select features from the alternatives to get an improved set of designs.

5. Specify and sell solution.

Your abstract concept must be translated into nuts and bolts—detailed specifications. Then you must convince the decision makers to accept the proposal. A key to acceptance is input

TABLE 23 Step 4 Is to Evaluate the Alternatives

Criterion	Weight	Present		Alternative 1		Alternative 2	
Minimum investment	6	A	24	B	18	A	24
Ease of supervision	10	C	20	C	20	B	30
Ease of operation	8	C	16	C	16	C	16
Ease of expansion and contraction	2	C	4	C	4	B	6
Total points			64		58		76
Relative merit (100% is best)			84%		76%		100%

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.
The criteria and weights will depend upon specific management goals. Grade each alternative (A = Excellent = 4; B = Good= 3; C = Average = 2; D = Fair = 1; F = Bad = 0). Then calculate the alternative's gradepoint (grade × weight). Defining the best as 100%, calculate the percent for each alternative.

from others (especially users and decision makers) early in the design stages (steps 1, 2, and 3). At the meeting where the final proposal is presented, there should be no surprises; the participants should feel you are presenting material they have already seen, commented on, and approved. That is, the selling is done early, not late; if they did not buy your approach then, you have modified it until it is acceptable. One common modification is partial change instead of full change; a test market approach instead of immediate national rollout; change of some of the machines in a department instead of all the machines; a partial loaf rather than a full loaf.

The installation needs to be planned in detail (who does what when). This is a relatively straightforward, though time-consuming, process. The installation plan typically is approved at a second meeting. It also should have preapproval by everyone before the decision meeting. During the installation itself, be flexible—improvements may become apparent from the suggestions of supervisors, operators, skilled-trades workers, and so on.

Finally, document the results. A documentary video and photos give opportunities to praise all the contributors (and may even reduce resistance to your next project).

CHAPTER 53
Time Standards*

STEPHAN KONZ
Kansas State University

*This chapter is a concise version of the material in Konz and Johnson (2000).

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. WHY DETERMINE TIME/JOB?

It is useful to know the direct labor cost/unit, especially when the job is repetitive. Five typical applications are:

1. Cost allocation
2. Production and inventory control
3. Evaluation of alternatives
4. Acceptable day's work
5. Incentive pay

1.1. Cost Allocation

To determine cost/unit, you need the direct material cost, the direct labor cost, and various miscellaneous costs (called overhead or burden). Direct labor cost is (direct labor time)(wage cost/hr). So you need to determine how long the job takes. But, in addition, overhead costs usually are allocated as a percentage of direct labor (e.g., overhead is 300% of direct labor cost). So again you need direct labor time. Without good estimates of the cost of production to compare vs. selling price, you don't know your profit/unit (it may even be negative!). The goal is to improve and control costs through better information.

1.2. Production and Inventory Control

Without time/unit, you can not schedule or staff (i.e., use management information systems). How many people should be assigned to the job? When should production start in order to make the due date and thus avoid stockouts?

1.3. Evaluation of Alternatives

Without time/unit, you can not compare alternatives. Should a mechanic repair a part or replace it with a new one? Is it worthwhile to use a robot that takes 10 seconds to do a task?

1.4. Acceptable Day's Work

Sam picked 1600 items from the warehouse today—is that good or bad? Supervisors would like to be able to compare actual performance to expected performance. Many applications of standards to repetitive work have shown improvement in output of 30% or more when measured daywork systems are installed in place of nonengineered standards. Output increases about 10% more when a group incentive payment is used and 20% more when an individual incentive is used.

1.5. Incentive Pay

A minority of firms use the pay-by-results (the carrot) approach. If you produce 1% more, you get paid 1% more. This works for the firm because even though direct labor cost/unit stays constant, overhead costs do not increase and thus total cost/unit decreases.

2. ESTABLISHING TIME STANDARDS

There are two basic strategies: nonengineered (subjective) standards (''did take'' times) and engineered (objective) standards (''should take'' times). The techniques to use depend upon the cost of obtaining the information and the benefits of using the information.

2.1. Nonengineered (Type 2) Estimates

''Quick and dirty'' information can be obtained at low cost. But using ''dirty'' information increases the risk of errors in decisions. Since nonengineered standards are not preceded by methods or quality analysis, they are ''did take'' times, not ''should take'' times.

There are four approaches: historical records, ask expert, time logs, and work (occurrence) sampling.

2.1.1. Historical Records

Standards from historical records tend to be very ''dirty'' (although cheap). For example, in the warehouse, how many cases can be picked per hour? From shipping records, determine the number of cases shipped in January, February, and March. From personnel, determine the number of employees in shipping in each month. Divide total cases/total hours to get cases/hr. Ignore changes in product output, product mix, absenteeism, delays, and so on.

2.1.2. Ask Expert

Here you ask a knowledgeable expert how long a job will take. For example, ask the maintenance supervisor how long it will take to paint a room. Ask the sales supervisor how many customers can be contacted per week. A serious problem is that the expert may have an interest in the answer. For example, a ''hungry'' maintenance supervisor wants work for his group and so quotes a shorter painting time; a sales supervisor may be able to hire more staff (and thus increase her prestige and power) by giving a low estimate of customers/sales representative.

2.1.3. Time Logs

It may be that a job is ''cost plus'' and so the only problem is how many hours to charge to a customer. For example, an engineer might write down, for Monday, 4.0 hr for project A, 2.5 hr for B, and 3.5 hr for C. Obviously there are many potential errors here (especially if work is done on project D, for which there no longer is any budget).

2.1.4. Work (Occurrence) Sampling

This technique is described in more detail in Chapter 54. It is especially useful when a variety of jobs are done intermittently (e.g., as in maintenance or office work). Assume that during a three-week period a maintainer spends 30% of the time doing carpentry, 40% painting, and 30% miscellaneous; this means 120 hr $\times$ 0.4 = 48 hr for painting. During the three-week period, 10,000 ft^2 of wall were painted or 10,000/48 = 208 ft^2/hr. Note that the work method used, work rate, delays, production schedule, and so on are not questioned.

2.2. Engineering (Type 1) Estimates

Engineered estimates of time must be preceded by a methods and quality analysis; the result is a ''should take'' time, not a ''did take'' time. MIL-STD-1567A requires for all individual type 1 standards (assuming the basic standards system is in place):

1. Documentation that the method was analyzed before time was determined
2. A record of the method or standard practice followed when the time standard was developed
3. A record of rating (if time study was used)
4. A record of the observed times (if time study) or predetermined time values were used
5. A record of the computations of standard time, including allowances

You would not expect a time standard established in 1960 to be valid today; things are different now, we think. But what differs? Thus, step 2 (record of method followed) is essential information for maintaining standards.

There are two basic ways of determining time/job: stopwatch time study and standard data.

2.2.1. Stopwatch Time Study

Stopwatch time study, which is described in detail in Chapter 54, requires an operator to do the operation; thus it cannot be done ahead of production. In general, it requires the operator to do the operation over and over rather than doing different tasks intermittently (such as might be done in office or maintenance work). Before the timing is done, the method must be analyzed.

In repetitive work, where detailed methods analysis is desired, a videotape of the task can be made; the analyst can study the tape instead of a live operator.

Because of learning, do not do time studies on operators who are early on the learning curve. If the study must be done early, label it temporary and restudy it in, say 30 days.

2.2.2. Standard Data

Standard data can be at the micro level or the macro level (see Chapter 54). In this approach, the analyst visualizes what the job entails (a danger is that the analyst may not think of some of the steps [elements] needed to complete the job). After determining the method, the analyst uses a table or formula to determine the amount of time for each element. The database elements are expressed in normal time (i.e., rating is included), so no additional rating is required. Then normal time is increased with allowances to obtain standard time.

Compared with time study, the standard data method has three advantages: (1) cost of determining a standard is low (assuming you have a database with standard times); (2) consistency is high because everyone using the database should get the same times; and (3) ahead-of-production standards are helpful in many planning activities. But among these three roses are two thorns: (1) you may not have the money to build the database (the databases are built from stopwatch studies and predeter-

mined times); and (2) the analyst must imagine the work method; even experienced analysts may overlook some details or low-frequency elements.

3. ADJUSTMENTS TO TIME: ALLOWANCES

3.1. Three Levels of Time

Time is reported at three levels:

1. *Observed time:* The raw (unadjusted) time taken by the worker. It does not have any rating, allowance or learning adjustment.
2. *Normal time:*

$$\text{Normal time} = (\text{observed time})(\text{rating})$$

The observer estimates the pace of the worker in relation to normal pace. Normal time is the time an experienced operator takes when working at a 100% pace. See Chapter 54 for more details.

3. *Standard time:* For allowances expressed as a percent of shift time:

$$\text{Standard time} = \text{normal time}/(1 - \text{allowances})$$

For allowances expressed as a percent of work time:

$$\text{Standard time} = \text{normal time}\ (1 + \text{allowances})$$

It is a policy decision by the firm whether to give allowances as a percent of shift or work time. Normal time needs to be increased from standard time by personal, fatigue, and delay allowances.

3.2. Personal Allowances

Personal allowances are given for such things as blowing your nose, going to the toilet, getting a drink of water, smoking, and so on. They do not vary with the task but are the same for all tasks in the firm. There is no scientific or engineering basis for the percent to give. Values of 5% (24 minutes in a 480-minute day) seem to be typical.

Most firms have standardized break periods (coffee breaks)—for example, 10 minutes in the first part of the shift and the same in the second part. It is not clear whether most firms consider this time as part of the personal allowance or in addition to it.

The midshift meal break (lunch) is another question. This 20–60-minute break obviously permits the worker to attend to personal needs and recover from fatigue. Yet lunch usually is not considered as part of allowances—even if the lunch period is paid.

Some firms give an additional break if work is over 8 hours. For example, if a shift is over 10 hours, there is an additional break of 10 minutes after the 9th hour.

In addition, some firms give an additional allowance to all workers for cleanup (either of the person or the machine), putting on and taking off of protective clothing, or travel. In mines, the travel allowance is called portal-to-portal pay; pay begins when the worker crosses the mine portal, even though the worker will not arrive at the working surface until some time later.

3.3. Fatigue Allowances

The rationale of fatigue allowances is to compensate the person for the time lost due to fatigue. In contrast to personal allowances, which are given to everyone, fatigue allowances are given only for cause—for fatigue. No fatigue? Then no fatigue allowance!

Another challenge is the concept of machine time. With the increasing capabilities of servomechanisms and computers, many machines operate semiautomatically (operator is required only to load/unload the machine) or automatically (machine loads, processes, and unloads). During the machine time of the work cycle, the operator may be able to drink coffee (personal allowance) or talk to the supervisor (delay allowance) or recover from fatigue. Thus, as a general principle, give a fatigue allowance only for the portion of the work cycle outside the machine time.

The following will discuss the fatigue allowances developed by the International Labor Organization (ILO 1992). They were supplied by a British consulting firm. Use of the ILO values is complex. Remembering that fatigue allowances are given for work time only (not machine time), sum the

applicable fatigue allowance points. Then, using Table 1, convert points to percent time. For a more detailed discussion of allowances, see Konz and Johnson (2000, chap. 32).

The fatigue factors are grouped into three categories: physical, mental, and environmental.

3.3.1. Physical: Physical Fatigue

Table 2 shows how the ILO makes a distinction among carrying loads, lifting loads, and force applied. In the NIOSH lifting guideline, the lift origin and destination, frequency of move, angle, and container are considered as well as load.

3.3.2. Physical: Short Cycle

Table 3 gives the fatigue allowance to allow time for the muscles to recover.

3.3.3. Physical: Static Load (Body Posture)

Table 4 gives the allowance for poor posture.

3.3.4. Physical: Restrictive Clothing

Table 5 gives the allowance for restrictive clothing.

3.3.5. Mental: Concentration/Anxiety

Table 6 gives the allowance for concentration/anxiety.

3.3.6. Mental: Monotony

Table 7 gives the allowance for monotony. In the author's opinion, allowances for monotony, boredom, lack of a feeling of accomplishment, and the like are questionable. These factors are unlikely to cause fatigue and thus increase time/cycle. These factors primarily reflect unpleasantness and thus should be reflected in the wage rate/hr rather than the time/unit.

3.3.7. Environmental: Climate

Table 8 gives the allowance for climate.

3.3.8. Environmental: Dust, Dirt, and Fumes

Table 9 gives the allowance for dust, dirt and fumes.

TABLE 1 Conversion from Points Allowance to Percent Allowance for ILO

Points	0	1	2	3	4	5	6	7	8	9
0	10	10	10	10	10	10	10	11	11	11

TABLE 4 Posture Allowances

Points	Activity
0	Sitting easily
2	Sitting awkwardly or mixed sitting and standing
4	Standing or walking freely
5	Ascending or descending stairs, unladen
6	Standing with a load; walking with a load
8	Climbing up or down ladders; some bending, lifting, stretching, or throwing
10	Awkward lifting; shoveling ballast to container
12	Constant bending, lifting, stretching, or throwing
16	Coal mining with pickaxes; lying in low seam

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

TABLE 5 Restrictive Clothing Allowances

Points	Clothing
1	Thin rubber (surgeon's) gloves
2	Household rubber gloves; rubber boots
3	Grinder's goggles
5	Industrial rubber or leather gloves
8	Face mask (e.g., for paint spraying)
15	Asbestos suit or tarpaulin coat
20	Restrictive protective clothing and respirator

ILO (1979) considers clothing weight in relation to effort and movement. Also consider whether it affects ventilation and breathing.

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

TABLE 6 Concentration/Anxiety Allowances

Allowance Points	Degree
0	Routine, simple assembly; shoveling ballast
1	Routine packing, washing vehicles, wheeling trolley down clear gangway
2	Feed press tool (hand clear of press); topping up battery
3	Painting walls
4	Assembling small and simple batches (performed without much thinking); sewing machine work (automatically guided)
5	Assembling warehouse orders by trolley; simple inspection
6	Load/unload press tool; hand feed into machine; spraypainting metalwork
7	Adding up figures; inspecting detailed components
8	Buffing and polishing
10	Guiding work by hand on sewing machine; packing assorted chocolates (memorizing patterns and selecting accordingly); assembly work too complex to become automatic; welding parts held in jig
15	Driving a bus in heavy traffic or fog; marking out in detail with high accuracy

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

ILO (1979) considers what would happen if the operator were to relax attention, responsibility, need for exact timing, and accuracy or precision required.

TABLE 7 Monotony Allowances

Allowance Points	Degree
0	Two people on jobbing work
3	Cleaning own shoes for 0.5 hr on one's own
5	Operator on repetitive work; operator working alone on nonrepetitive work
6	Routine inspection
8	Adding similar columns of figures
11	One operator working alone on highly repetitive work

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

ILO (1979) considers the degree of mental stimulation and whether there is companionship, competitive spirit, music, and so on.

TABLE 8 Climate Allowances

Points for Temperature/Humidity			
	Temperature, °C		
Humidity, %	Up to 24	24–32	Over 32
Up to 75	0	6–9	12–16
76–85	1–3	8–12	15–26
Over 85	4–6	12–17	20–36

Points Wet	
0	Normal factory operations
1	Outdoor workers (e.g., postman)
2	Working continuously in the damp
4	Rubbing down walls with wet pumice block
5	Continuous handling of wet articles
10	Laundry washhouse, wet work, steamy, floor running with water, hands wet

Points Ventilation	
0	Offices; factories with office-type conditions
1	Workshop with reasonable ventilation but some drafts
3	Drafty workshops
14	Working in sewer

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

ILO (1979) considers temperature/humidity, wet, and ventilation. For temperature/humidity, use the average environmental temperature. For wet, consider the cumulative effect over a long period. For ventilation, consider quality/freshness of air and its circulation by air conditioning or natural movement.

3.3.9. Environmental: Noise and Vibration

Table 10 gives the allowance for noise and vibration.

3.3.10. Environmental: Eye Strain

Table 11 gives the allowance for eye strain.

3.3.11. Overview of Fatigue Allowances

In general, the fatigue allowances seem to have inadequate range. In addition, note from Table 1 that points are not converted one for one to percent. A person with 0 points for fatigue gets a 10% fatigue allowance. A person with 30 points gets a 15% fatigue allowance—an increase of only 5%.

In addition, neither the length of the workday nor the number of days/week is specified. Presumably it is 8 hr/day and 5 days/week. The author does not recommend changing the allowance for working a shorter or longer time period. Any adjustment should be in the discipline level (see Section 5.2.2).

3.4. Delay Allowances

Delay allowances should vary with the task but not the operator. They compensate for machine breakdowns, interrupted material flow, conversations with supervisors, machine maintenance and cleaning, and so on. If the delay is long (e.g., 30 minutes), the operator clocks out (records the start and stop time of the delay on a form) and works on something else during the clocked-out time. Delays usually permit the operator to take some personal time and reduce fatigue; that is, they also serve as personal allowances and fatigue allowances.

How do you set a delay allowance? One possibility is to record the delays during a work sampling study or time study. For example, if there were 4 minutes of delay during 100 minutes of time study, then 4% could be used for the delay allowance.

Errors in delay allowances can occur from poor sampling or changing conditions.

To obtain a valid sample of delays, the sample must represent the total shift, not just the middle of the shift. That is, the delays must be observed at the start and stop of the shift and just before and after lunch and coffee breaks, in addition to the middle of the shift. Also observe delays on the second and third shifts.

TABLE 9 Dust, Dirt, and Fumes Allowances

Points	Dust
0	Office, normal light assembly, press shop
1	Grinding or buffing with good extraction
2	Sawing wood
4	Emptying ashes
6	Finishing weld
10	Running coke from hoppers into skips or trucks
11	Unloading cement
12	Demolishing building
Points	**Dirt**
0	Office work, normal assembly operations
1	Office duplicators
2	Dustman (garbage collector)
4	Stripping internal combustion engine
5	Working under old motor vehicle
7	Unloading bags of cement
10	Coal miner; chimneysweep with brushes
Points	**Fumes**
0	Lathe tuning with coolants
1	Emulsion paint, gas cutting, soldering with resin
5	Motor vehicle exhaust in small commercial garage
6	Cellulose painting
10	Molder procuring metal and filling mold

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

For dust, consider both volume and nature of the dust. The dirt allowance covers ''washing time'' where this is paid for (e.g., 3 min for washing). Do not allow both time and points. For fumes, consider the nature and concentration; whether toxic or injurious to the health; irritating to eyes, nose, throat, or skin; odor.

TABLE 10 Noise and Vibration Allowances

Points	Noise Category
0	Working in a quiet office, no distracting noise; light assembly work
1	Work in a city office with continual traffic noise outside
2	Light machine shop; office or assembly shop where noise is a distraction
4	Woodworking machine shop
5	Operating steam hammer in forge
9	Riveting in a shipyard
10	Road drilling
Points	**Vibration Category**
1	Shoveling light materials
2	Power sewing machine; power press or guillotine if operator is holding the material; cross-cut sawing
4	Shoveling ballast; portable power drill operated by one hand
6	Pickaxing
8	Power drill (2 hands)
15	Road drill on concrete

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

ILO (1979) considers whether the noise affects concentration, is a steady hum or a background noise, is regular or occurs unexpectedly, is irritating or soothing. Consider the impact of the vibration on the body, limbs, or hands and the addition to mental effort as a result, or to a series of jars or shocks.

TABLE 11 Eye Strain Allowances

Points	Eye Strain Category
0	Normal factory work
2	Inspection of easily visible faults; sorting distinctively colored articles by color; factory work in poor lighting
4	Intermittent inspection for detailed faults; grading apples
8	Reading a newspaper in a bus
10	Continuous visual inspection (cloth from a loom)
14	Engraving using an eyeglass

From International Labour Office, *Introduction to Work Study,* 4th (Rev.) Ed., pp. 491–498. Copyright © International Labour Organization 1992.

ILO (1979) considers the lighting conditions, glare, flicker, illumination, color, and closeness of work and for how long strain is endured.

Conditions change over time. A reasonable procedure is to give delay allowances an expiration date, for example, two years after being set. After two years, they must be redetermined.

4. ADJUSTMENTS TO TIME: LEARNING

4.1. Learning

Failure to adjust standard time for learning is the primary cause of incorrect times. Learning occurs both in the individual and in the organization.

4.1.1. Individual Learning

Individual learning is improvement in time/unit even though neither the product design nor the tools and equipment change. The improvement is due to better eye–hand coordination, fewer mistakes, and reduced decision time.

4.1.2. Organization Learning (Manufacturing Progress)

This is improvement with changing product design, changing tools and equipment, and changing work methods; it also includes individual learning. Often it is called manufacturing progress.

Consider the server Maureen serving breakfast. During the individual learning period, she learned where the coffeepot and cups were, the prices of each product, and so on. The amount of time she took declined to a plateau. Then management set a policy to serve coffee in cups without saucers and furnish cream in sealed, one-serving containers so the container need not be carried upright. These changes in product design reduced time for the task. Other possible changes might include a coffeepot at each end of the counter. A different coffeepot might have a better handle so less care is needed to prevent burns. The organization might decide to have the server leave the bill when the last food item is served. Organization progress comes from three factors: operator learning with existing technology, new technology, and substitution of capital for labor.

Point 1 was just discussed. Examples of new technology are the subsurface bulblike nose on the front of tankers (which increased tanker speed at very low cost) and solid-state electronics. Moore's law states that the number of transistors on a given chip size (roughly a gauge of chip performance) doubles every 1.5–2 years. Some example numbers are 3,500 transistors/chip in 1972, 134,000 in 1982, 3,100,000 in 1993, and 7,500,000 in 1997.

Use of two coffee pots by Maureen is an example of substituting capital for labor. Another example is the use of the computer in the office, permitting automation of many office functions. The ratio of capital/labor also can be improved by economies of scale. This occurs when equipment with twice the capacity costs less than twice as much. Then capital cost/unit is reduced and fewer work hours are needed/unit of output.

4.1.3. Quantifying Improvement

"Practice makes perfect" has been known for a long time. Wright (1936) took a key step when he published manufacturing progress curves for the aircraft industry. Wright made two major contributions. First, he quantified the amount of manufacturing progress for a specific product. The equation was of the form Cost = a (number of airplanes)^b; (see Figure 1). But the second step was probably even more important: he made the data a straight line (by putting the curve in the axis!) (see Figure 2). That is, the data is on a log–log scale.

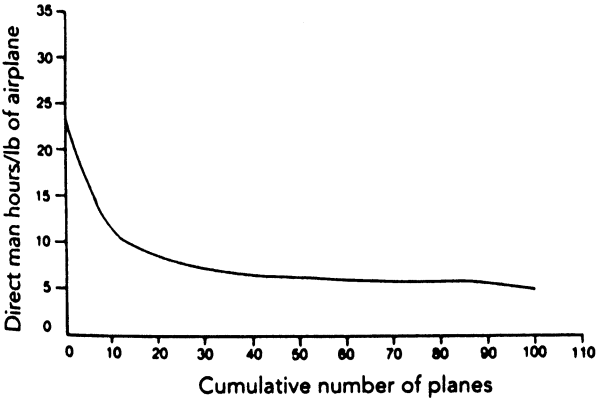

Figure 1 Practice Makes Perfect. As more and more units are produced, the fixed cost is divided by more and more units, so fixed cost/unit declines. In addition, variable cost/unit declines because fewer mistakes are made, less time is spent looking up instructions, better tooling is used, and so on. The variable cost data usually can be fitted with an equation of the form $y = ax^b$. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.)

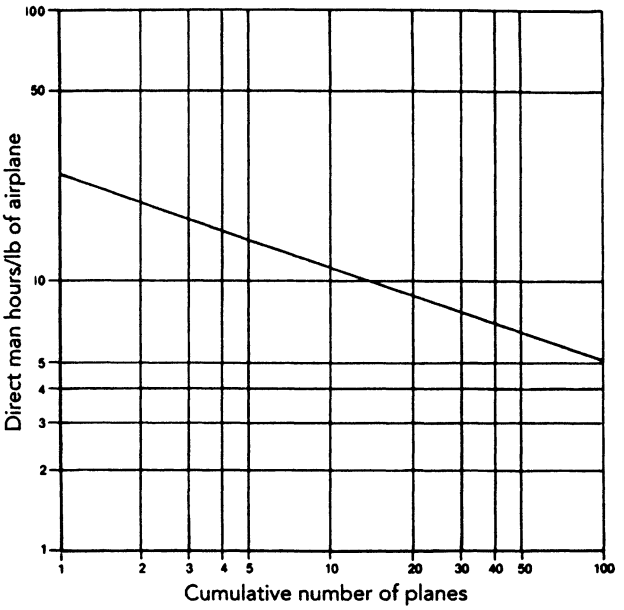

Figure 2 Log–Log Scale. Supervisors like straight lines. Plotting $y = ax^b$ on log–log paper gives a straight line. The key piece of information supervisors desire is the rate of improvement—the slope of the line. The convention is to refer to reduction with doubled quantities. If quantity $x_1 = 8$, the quantity $x_2 = 16$. Then if cost at x_1 is $y_1 = 100$ and cost at x_2 is $y_2 = 80$, this is an 80% curve. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.)

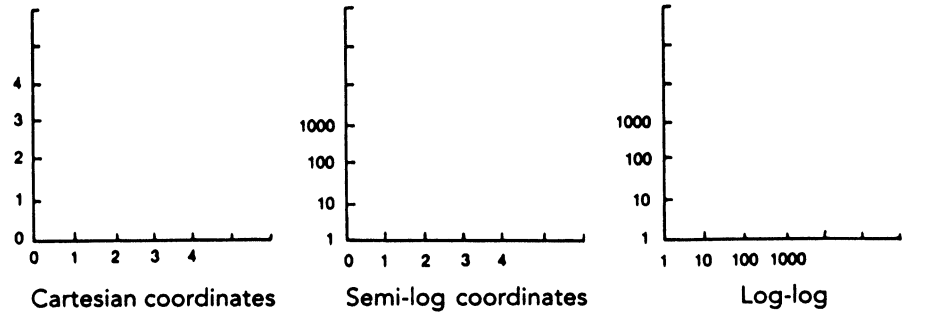

Figure 3 Cartesian Coordinates, Semi-Log Coordinates, and Log–Log Coordinates. Cartesian coordinates have equal distances for equal numerical differences; that is, the linear difference from 1 to 3 is the same as from 8 to 10. On a log scale, the same distance represents a constant *ratio*; that is, the distance from 2 to 4 is the same as from 30 to 60 or 1000 to 2000. Semi-log paper has one axis Cartesian and one axis log. Log–log (double log) paper has a log scale on both axes. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.)

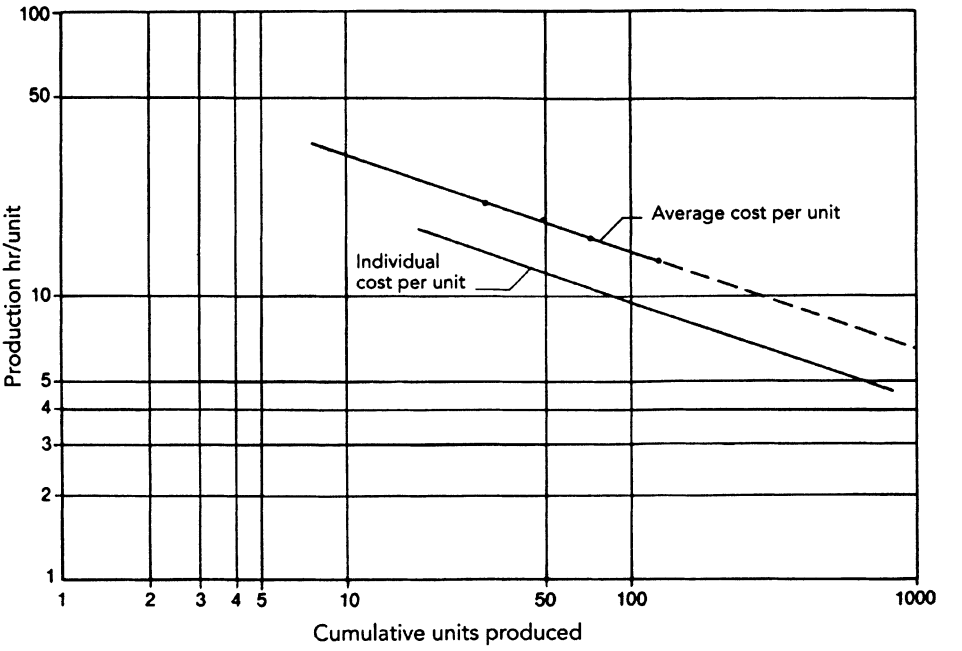

Figure 4 Average Cost/Unit from Table 12. Table 12 gives a 79% curve. Cost/unit is the cost of the nth unit; average cost/unit is the sum of the unit costs/n. Cost/unit can be estimated by multiplying average cost/unit by the factor from Table 12. The average cost of the first 20 units is estimated as 25.9 from the fitted line; the cost of the 20th unit is 25.9(0.658) = 17.0 hr. (From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.)

TABLE 12 Factors for Various Improvement Curves

Improvement Curve, % Between Doubled Quantities	Learning Factor, b, For Curve $y = ax^b$	Multiplier to Determine Unit Cost if Average Cost Is Known	Multiplier to Determine Average Cost if Unit Cost Is Known
70	−0.515	0.485	2.06
72	−0.474	0.524	1.91
74	−0.434	0.565	1.77
76	−0.396	0.606	1.65
78	−0.358	0.641	1.56
80	−0.322	0.676	1.48
82	−0.286	0.709	1.41
84	−0.252	0.746	1.34
85	−0.234	0.763	1.31
86	−0.218	0.781	1.28
88	−0.184	0.813	1.23
90	−0.152	0.847	1.18
92	−0.120	0.877	1.14
94	−0.089	0.909	1.10
95	−0.074	0.926	1.08
96	−0.059	0.943	1.06
98	−0.029	0.971	1.03

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

The multipliers in columns 3 and 4 are large-quantity approximations. For example, for a 90% curve, the table value in column 4 is 1.18. A more precise value at a quantity of 10 = 1.07, at 50 = 1.13, and at 100 = 1.17. A more precise value for an 85% curve at a quantity of 100 = 1.29; a more precise value for a 95% curve at a quantity of 100 = 1.077.

TABLE 13 Time and Completed Units as They Might Be Reported for a Product

Month	Units Completed (Pass Final Inspection)	Month's Direct Labor Hours Charged To Project	Cumulative Units Completed	Cumulative Work Hours Charged to Project	Average Work hr/unit
March	14	410	14	410	29.3
April	9	191	23	601	26.1
May	16	244	39	845	21.7
June	21	284	60	1129	18.8
June	24	238	84	1367	16.3
August	43	401	127	1708	13.4

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

On a log scale, the physical distance between doubled quantities is constant (i.e., 8 to 16 is the same distance as 16 to 32 or 25 to 50) (see Figure 4). Wright gave the new cost as a percent of the original cost when the production quantity had doubled. If cost at unit 10 was 100 hr and cost at unit 20 was 85 hr, then this was an 85/100 = 85% curve. Since the curve was a straight line, it was easy to calculate the cost of the 15th or the 50th unit. If you wish to solve the $Y = ax^b$ equation instead of using a graph (calculators are much better now than in 1935), see Table 12.

For example, assume the time for a (i.e., cycle 1)= 10 min and there is a 90% curve (i.e., $b = -0.152$), then the time for the 50th unit is: $Y = 10\ (50)^{-0.152} = 10/(50)^{0.152} = 5.52$ min.

Table 13 shows how data might be obtained for fitting a curve. During the month of March, various people wrote down on charge slips a total of 410 hours against this project charge number.

The average work hours/unit during March then becomes 29.3. The average x-coordinate is $(1 + 14)/2 = 7.5$. Because the curve shape is changing so rapidly in the early units, some authors recommend plotting the first lot at the 1/3 point[$(1 + 14)/3$] and points for all subsequent lots at the midpoint.

During April, 9 units passed final inspection and 191 hours were charged against the project. Cumulative hours of 601 divided by cumulative completed output of 23 gives average hr/unit of 26.1. The 26.1 is plotted at $(15 + 23)/2 = 19$. As you can see from the example data, there are many possible errors in the data, so a curve more complex than a straight line on log–log paper is not justified. Figure 4 shows the resulting curve.

Although average cost/unit is what is usually used, you may wish to calculate cost at a specific unit. Conversely, the data may be for specific units and you may want average cost. Table 12 gives the multiplier for various slopes. The multipliers are based on the fact that the average cost curve and the unit cost curve are parallel after an initial transient. Initial transient usually is 20 units, although it could be as few as 3. The multiplier for a 79% slope is $(0.641 + 0.676)/2 = 0.658$. Thus, if we wish to estimate the cost of the 20th unit, it is $(24.9 \text{ hr})(0.658) = 16.4$ hr.

Cost/unit is especially useful in scheduling. For example, if 50 units are scheduled for September, then work-hr/unit (for a 79% curve) at unit $127 = (13.4)(0.656) = 8.8$ and at unit $177 = 7.8$. Therefore between 390 and 440 hours should be scheduled.

Looking at Figure 4, you can see that the extrapolated line predicts cost/unit at 200 to be 11.4 hr, at 500 to be 8.3, and at 1,000 to be 6.6. If we add more cycles on the paper, the line eventually reaches a cost of zero at cumulative production of 200,000 units. Can cost go to zero? Can a tree grow to the sky? No.

The log–log plot increases understanding of improvement, but it also deceives. Note that cost/unit for unit 20 was 24.9 hr. When output was doubled to 40 units, cost dropped to 19.7; doubling to 80 dropped cost to 15.5; doubling to 160 dropped cost to 12.1; doubling to 320 dropped cost to 9.6; doubling to 640 dropped cost to 7.6. Now consider the improvement for each doubling. For the first doubling from 20 to 40 units, cost dropped 5.20 hr or 0.260 hr/unit of extra experience. For the next doubling from 40 to 80, cost dropped 4.2 hr or 0.105 hr/unit of extra experience. For the doubling from 320 to 640, cost dropped 2.0 hr or 0.006 hr/unit of extra experience. In summary, the more experience, the more difficult it is to show additional improvement.

Yet the figures would predict zero cost at 200,000 units, and products just aren't made in zero time. One explanation is that total output of the product, in its present design, is stopped before 200,000 units are produced. In other words, if we no longer produce Model T's and start to produce Model A's, we start on a new improvement curve at zero experience. A second explanation is that the effect of improvement in hours is masked by changes in labor wages/hr. The Model T Ford had a manufacturing progress rate of 86%. In 1910, when 12,300 Model T Fords had been built, the price was $950. When it went out of production in 1926 after a cumulative output of 15,000,000, the price was $270; $200 in constant prices plus inflation of $70.

The third explanation is that straight lines on log–log paper are not perfect fits over large ranges of cycles. If output is going to go to 1,000,000 cumulative units over a 10-year period, you really shouldn't expect to predict the cost of the 1,000,000th unit (which will be built 10 years from the start) from the data of the first 6 months. There is too much change in economic conditions, managers, unions, technology and other factors. Anyone who expects the future to be perfectly predicted by a formula has not yet lost money in the stock market.

4.1.4. Typical Values for Organization Progress

The rate of improvement depends on the amount that can be learned. The more that can be learned, the more will be learned. The amount that can be learned depends upon two factors: (1) amount of previous experience with the product and (2) extent of mechanization. Table 14 gives manufacturing progress as a function of the manual/machine ratio. Allemang (1977) estimates percent progress from

TABLE 14 Prediction of Manufacturing Progress

Percent of Task Time		
Manual	Machine	Manufacturing Progress, %
25	75	90
50	50	85
75	25	80

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

product design stability, a product characteristics table (complexity, accessability, close tolerances, test specifications, and delicate parts), parts shortage, and operator learning.

Konz and Johnson (2000) have two detailed tables giving about 75 manufacturing progress rates reported in the literature.

4.1.5. Typical Values for Learning

Assume learning has two components: (1) cognitive learning and (2) motor learning (Dar-El et al. 1995a, b). Cognitive learning has a greater improvement (say 70% curve), while motor learning is slower (say 90% curve). For a task with both types, initially the cognitive dominates and then the motor learning dominates. Use values of 70% for ''pure cognitive,'' 72.5% for ''high cognitive,'' 77.5% for ''more cognitive than motor,'' 82.5% for ''more motor than cognitive,'' and 90% for ''pure motor.'' Konz and Johnson (2000) give a table of 43 tasks for which learning curves have been reported.

The improvement takes place through reduction of fumbles and delays rather than greater movement speed. Stationary motions such as position and grasp improve the most while reach and move improve little. It is reduced information-processing time rather than faster hand speed that affects the reduction.

The range of times and the minimum time of elements show little change with practice. The reduction is due to a shift in the distribution of times; the shorter times are achieved more often and the slower times less often—''going slowly less often'' (Salvendy and Seymour 1973).

The initial time for a cognitive task might be 13–15 times the standard time; the initial time for a manual task might be 2.5 times the standard time.

4.1.6. Example Applications of Learning

Table 15 shows the effect of learning/manufacturing progress on time standards. The fact that labor hr/unit declines as output increases makes computations using the applications of standard time more complicated. Ah, for the simple life!

4.1.6.1. Cost Allocation Knowing what your costs are is especially important if you have a make–buy decision or are bidding on new contracts. If a component is used on more than one product (standardization), it can progress much faster on the curve since its sales come from multiple sources. Manufacturing progress also means that standard costs quickly become obsolete.

Note that small lots (say due to a customer emergency) can have very high costs. For example, if a standard lot size is 100 and labor cost is 1 hr/unit and there is a 95% curve, a lot of 6 would have a labor cost about 23% higher (1.23 hr/unit). Consider charging more for special orders!

4.1.6.2. Scheduling Knowing how many people are needed and when is obviously an important decision. Also, learning/manufacturing progress calculations will emphasize the penalties of small lots.

4.1.6.3. Evaluation of Alternatives When alternatives are being compared, a pilot project might be run. Data might be obtained for 50–100 cycles. Note that the times after the pilot study should be substantially shorter due to learning. In addition, the learning/manufacturing progress rate for alternatives A and B might differ so that what initially is best will not be best in the long run.

TABLE 15 Demonstration of the Learning Effect on Time Standards

Learning Curve, %	Time/Unit at			Percent of Standard at		
	2X	4X	32X	2X	4X	32X
98	0.98	0.96	0.90	102	104	111
95	0.95	0.90	0.77	105	111	129
90	0.90	0.81	0.59	111	124	169
85	0.85	0.72	0.44	118	138	225

From *Work Design: Industrial Ergonomics,* 5th Ed., by S. Konz and S. Johnson. Copyright © 2000 by Holcomb Hathaway, Pub., Scottsdale, AZ. Reprinted with permission.

Even a small learning rate can have a major effect on performance. X = experience level of the operator when time study was taken, for example, 50, 100, or 500 cycles. The table gives time/unit based on a time standard of 1.0 min/unit; therefore, if actual time standard were 5.0 min/unit, then time/unit at 98% and 2X would be 0.98 (5.0) = 4.9.

4.1.6.4. Acceptable Day's Work Assume a time standard y is set at an experience level x. Assume further, for ease of understanding, that $y = 1.0$ min and $x = 100$ units. A time study technician, Bill, made a time study of the first 100 units produced by Sally, calculated the average time, and then left. Sally continued working. Let's assume a 95% rate is appropriate. Sally completes the 200th piece shortly before lunch and the 400th by the end of the shift. The average time/unit for the first day is about 0.9 min (111% of standard). The second day, Sally completes the 800th unit early in the afternoon. She will complete the 3200th unit by the end of the week. The average time of 0.77 min/unit during the week yields 129% of standard!

Point. If none of the operators in your plant ever turns in a time that improves as they gain experience, do you have stupid operators or stupid supervisors?

Next point. The magnitude of the learning effect dwarfs potential errors in rating. You might be off 5% or 10% in rating but this effect is trivial compared versus the errors in using a time standard without considering learning/mfg. progress.

Third point. Any time standard that does not consider learning/manufacturing progress will become less and less accurate with the passage of time.

Final point. Since learning and manufacturing progress are occurring, output and number of work hours should not both be constant. Either the same number of people should produce more or fewer people can produce a constant output.

5. DOCUMENTING, USING, AND MAINTAINING STANDARDS

5.1. Documenting Standards

Standards are part of a goal-setting system, and control is essential to any goal-setting system.

The more detailed the data, the more detailed the possible analysis; you can always consolidate data after they is gathered, but you can't break the data down if they are consolidated before they are gathered. Computerization permits detailed recording and thus analysis of downtime, machine breakdown, setup time, and so on. With bar coding of parts and computer terminals at workstations, it is feasible to record times for each individual part. For example, for product Y, operator 24 completed operation 7 on part 1 at 10:05, part 2 at 10.08, and so on. More commonly, however, you would just record that for product Y, operator 24 started operation 7 at 10:00 and completed the 25 units at 11:50. Least useful would be recording, for product Y, that all operations on 25 units were completed on Tuesday. Companies tend to develop elaborate codes for types of downtime, quality problems, and so on. Be careful about downtime reporting: it is easy to abuse.

5.2. Using Standards

5.2.1. Reports

Variance is the difference between standard performance and actual performance. Generally, attention is focused on large negative variances so that impediments to productivity can be corrected. Performance should be fed back to both workers and management at least weekly. Daily reports highlight delays and production problems; monthly reports smooth the fluctuations and show long-term trends.

5.2.2. Consequences of Not Making Standard

If the standard is used to determine an acceptable day's work or pay incentive wages, the question arises, What if a person doesn't produce at a standard rate?

For a typical low-task standard such as methods time measurement (MTM), over 99% of the population should be able to achieve standard, especially after allowances are added. The relevant question is not what workers are able to do but what they actually do.

Comparisons of performance vs. standard should be over a longer time period (such as a week) rather than a short period (such as a day).

The first possibility to consider is learning. As noted above, for cognitive work, the first cycle time may be as much as 13 times MTM standard and, for motor work, 2.5 times MTM standard. If a new operator's performance is plotted vs. the typical learning curve for that job, you can see whether the operator is making satisfactory progress. For example, Jane might be expected to achieve 50% of standard the first week, 80% the second week, 90% the third week, 95% the fourth week, and 100% the fifth week. Lack of satisfactory progress implies a need for training (i.e., the operator may not be using a good method).

If Jane is a permanent, experienced worker, the below-standard performance could be considered ''excused'' or ''nonexcused.'' Excused failure is for temporary situations—bad parts from the supplier, back injuries, pregnancy for females, and so forth. For example, ''Employees returning to work from Worker's Compensation due to a loss-of-time accident in excess of 30 days will be given consideration based upon the medical circumstances of each individual case.''

Nonexcused performances are those for which the worker is considered capable of achieving the standard but did not make it.

Table 16 shows some example penalties. Most firms have a ''forget'' feature; for example, one month of acceptable performance drops you down a step. The use of an established discipline procedure allows workers to self-select themselves for a job. The firm can have only minimal preemployment screening and thus not be subject to discrimination charges.

Standards are based on an eight-hour day, but people work longer and shorter shifts. Because most standards tend to be loose, people can pace themselves and output/hr tends to be constant over the shift. I do not recommend changing the standard for shifts other than eight hours.

The level at which discipline takes place is negotiable between the firm and the union. For example, it might be 95% of standard—that is, as long as workers perform above 95% of standard, they are considered satisfactory. However, this tends to get overall performance slightly higher—say 98%. The best long-range strategy probably is to set discipline at 100% of standard. Anything less will give a long-term loss in production, especially if a measured daywork system is used instead of incentives.

Firms can use several strategies to improve the group's performance and reduce output restrictions. Basically, they allow the employees as well as the firm to benefit from output over 100%.

The primary technique is to give money for output over 100%. A 1% increase in pay for a 1% increase in output is the prevalent system.

Another alternative is to give the worker time off for output over 100%. For example, allow individuals to ''bank'' weekly hours earned over 100%. Most people will soon run up a positive balance to use as ''insurance.'' This can be combined with a plan in which all hours in the bank over (say) 20 hr are given as scheduled paid time off. This tends to drop absenteeism because workers can use the paid time off for personal reasons.

5.3. Maintaining Standards (Auditing)

A standard can *restrict* productivity if it has not been updated because workers will produce only to the obsolete standard and not to their capabilities.

What to audit? To keep the work-measurement system up to date, accurate, and useful, MIL-STD-1567A says the audit should determine (1) the validity of the prescribed coverage, (2) the percentage of type I and II coverage, (3) use of labor standards, (4) accuracy of reporting, (5) attainment of goals, and (6) results of corrective actions regarding variance analysis.

How often to audit? Auditing should be on a periodic schedule. A good procedure is to set an expiration date on each standard at the time it is set; MIL-STD-1567 says annually. A rule of thumb is to have it expire at 24 months if the application is <50 hr/year, at 12 months if between 50 and 600 hr/year, and at 6 months if over 600 hr/year. Then, when the standard expires, and if it is still an active job, an audit is made. If it is not active, the standard will be converted from permanent to temporary. Then, if the job is resumed, the temporary can be used for a short period (e.g., 30 days) until a new permanent standard is set. An advantage of a known expiration date is that if a standard is audited (and perhaps tightened), the operator will not feel picked on.

If the resources for auditing are not sufficient for doing all the audits required, use the Pareto principle. Audit the ''mighty few'' and don't audit the ''insignificant many.'' However, when the standard on one of the insignificant many passes the expiration date, convert the permanent standard to temporary.

TABLE 16 Example Discipline Levels for Not Producing Enough

Step	Description
0	Normal operator, acceptable performance
1	Oral warning
2	Oral warning; detailed review of method with supervisor or trainer
3	Written warning; additional training
4	Written warning; some loss of pay
5	Written warning; larger loss of pay
6	Discharge from job

A published set of rules ensures that everyone is treated fairly. Most organizations have a similar set of rules for tardiness and absenteeism.

CHAPTER 54

Work Measurement: Principles and Techniques

AURA CASTILLO MATIAS
University of the Philippines Diliman

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. WORK MEASUREMENT: AN OVERVIEW

Work measurement, as the name suggests, provides management with a means of measuring the time taken in the performance of an operation or series of operations. Work measurement is the application of techniques designed to establish standard times for a qualified worker to carry out a specified job at a defined level of performance. With today's increasing global competition among producers of products or providers of service, there has been an increasing effort to establish standards based on facts and scientific methods rather than the use of estimates based on judgment or experience (Niebel and Freivalds 1999). Sound standards have many applications that can mean the difference between the success or failure of a business. Accurately established time standards make it possible to produce more within a given plant, thus increasing the efficiency of the equipment and the optimal utilization of personnel. Poorly established standards, although better than no standards at all, lead to high costs, low productivity, and labor unrest.

Common uses of work measurement include the following:

- To compare the efficiency of alternative methods. Other conditions being equal, the method that takes the least time will be the best method.
- To balance the work of members of teams, in association with multiple activity charts, so that, as nearly as possible, each member has tasks taking an equal time to perform.
- To determine, in association with man and machine multiple activity charts, the number of machines an operator can run.
- To provide information on which the planning and scheduling of production can be based, including plant and labor requirements for carrying out the program of work, the utilization of available machine and labor capacity, and delivery promises.
- To provide information for labor cost control and to enable standard costs to be fixed and maintained.
- To provide information on which incentive plans can be based.

Time standards are always based on a specific method and working conditions. As time passes, improvements may be introduced, whether by the supervisor, the methods engineer, management, or the operator. Regardless of who introduced the method changes, they will directly affect the time standard being applied. This should signal the need for the method to be restudied and reevaluated. The time study analyst should be advised of such changes so that the portion of the operation that is affected by the change can be reviewed and the time standard recalculated.

To ensure that the methods applied when the time study was conducted are still being employed, regular audits should be scheduled by the time study analysts. The more frequently a standard is applied, the more frequent the audits should be. Time study audits do not necessarily lead to conducting a time study of the entire method. If, however, a major modification in the method is observed (e.g., change in tools used, different sequence in operations, change in materials processed, change in process or approach), then a new detailed study must be performed.

1.1. Basic Procedure of Work Measurement

In general, the basic procedure of work measurement uses the following steps:

1. *Select* the work to be studied.
2. *Record* all the relevant data relating to the circumstances in which the work is being done, the methods, and the elements of activity in them.
3. *Examine* the recorded data and the detailed breakdown critically to ensure that the most effective method and motions are being used and that unproductive and foreign elements are separated from productive elements.

4. *Measure* the quantity of work involved in each element in terms of time using the appropriate work-measurement technique.
5. *Calculate* the standard time for the operation, which in the case of stopwatch time study will include time allowances to cover relaxation, personal needs, etc.
6. *Define* precisely the series of activities and method of operation for which the time has been compiled and issue the time as standard for the activities and methods specified.

1.2. Work Measurement Techniques

Operations managers and engineering staff need to be aware of the many different work measurement techniques that are available so that they can make appropriate choices as operating conditions change. Successful installation of any of the work-measurement techniques needs the full support of management to commit the time and financial resources necessary on a continuing basis. The objective of this chapter is to discuss these different alternatives, compare their advantages and disadvantages, and offer some guidelines for proper selection and application.

There are four types of work measurement techniques: time study, predetermined time standards (PTS), standard data, and work sampling. All of these techniques are based on facts and consider each detail of work. The first three techniques measure the normal time required to perform the entire work cycle. Work sampling measures the proportion of time of various work activities that constitute a job. Table 1 describes these techniques and where each is appropriately used. Table 2 provides a further comparison among work measurement techniques in terms of their advantages and disadvantages.

2. TIME STUDY

Time study is a work measurement technique for recording the times and rates of working for the elements of a specified job carried out under specified conditions and for analyzing the data so as to obtain the time necessary for carrying out the job at a defined level of performance. The objective of time study is to determine reliable time standards for all work, both direct and indirect, with due allowance for fatigue and for personal and unavoidable delays, for the efficient and effective management of operations.

The establishment of reliable and accurate time standards makes it possible for companies to define their capacity or output, thus increasing the efficient use of equipment and obtaining optimum utilization of personnel. Because time is a common measure for all jobs, time standards can be used to investigate the difference between actual and standard performance and take appropriate action where necessary. It can also be used to facilitate job design as a basis for comparing various methods of doing the job, purchasing the most productive new equipment, introducing sound production controls, designing an efficient workplace layout, and balancing between work schedules and available manpower. Other benefits of establishing reliable time standards include budgetary control, development of incentive plans, and ensuring that quality specifications are met.

2.1. A Fair Day's Work

Time study is often referred to, among industry practitioners, as a method of determining a "fair day's work." In general, that means fair to both the company and the employee. Employees are expected to give the full day's work that they get paid for, with reasonable allowances for personal delays, unavoidable delays, and fatigue. Employees are expected to perform the prescribed method at a pace, neither fast nor slow, that may be considered representative of a full day's output by a well-trained, experienced, and cooperative operator.

2.2. Time Study Equipment

The equipment needed to develop reliable standards is minimal, easy to use and often inexpensive. Only four basic items are needed: an accurate and reliable stopwatch, a time study board, a well-designed time study form, and a calculator to compute the recorded observations. Videotape equipment can also be very useful.

2.2.1. Time-Recording Equipment

Several types of time-recording equipment are available today. The most common are decimal minute stopwatches, computer-assisted electronic stopwatches, and videotape cameras.

Two types of stopwatches are used today, the mechanical decimal minute watch and the electronic stopwatch. The mechanical decimal minute watch has 100 divisions on its face, each division equal to 0.01 min. One minute requires one revolution of the long hand. The small dial on the watch face has 30 divisions, each representing 1 min. For every full revolution of the long hand, the small hand moves 1 division, or 1 min.

Electronic stopwatches provide resolution to 0.001 sec and an accuracy of $\pm 0.002\%$. They are lightweight and have a digital display. They permit the timing of any number of individual elements

TABLE 1 Techniques of Work Measurement

Method	Definition and Where Used
Time study	Technique for recording the times of performing a certain job or its elements carried out under specified conditions and for analyzing the data so as to obtain the time necessary for an operator to carry it out at a defined rate of performance. • Where there are repetitive work cycles of short to long duration OR • Where wide variety of dissimilar work is performed OR • Where process control elements constitute a part of the cycle
Predetermined time standards (PTS)	Technique whereby times established for basic human motions (classified according to the nature of the motion and the conditions under which it is made) are used to build up the time for a job at a defined level of performance. • Where work is predominantly operator controlled OR • Where there are repetitive cycles of short to medium duration OR • Where it is necessary to plan work methods in advance of production OR • Where there has been controversy over time study results OR • Where there has been controversy over consistency of existing standards
Standard data	Technique that refers to all the tabulated elemental standards, curves, alignment charts, and tables that are compiled from time studies and predetermined time standards (PTS) to allow the measurement of a specific job without the use of a timing device. Formula construction represents a simplification of standard data. It involves design of algebraic expression or a system of curves that establishes a time standard in advance of production by substitution of known values peculiar to the job for the variable elements. • Where there are similar work of short to long duration OR • Where there has been controversy over time study results OR • Where there has been controversy over consistency of existing standards
Work sampling	Technique used to investigate the proportions of total time devoted to the various activities that constitute a job or work situation. • Where there are considerable differences in work content from cycle to cycle, as in shipping, materials handling, and clerical activities, OR • Where activity studies are needed to show machine or space utilization, or the percentage of time spent on various activities OR • Where there is an objection to stopwatch time studies

while also measuring the total elapsed time. Thus, they can be conveniently used for both continuous and snapback timing (see Section 2.4.4). Electronic watches have become increasingly more affordable than mechanical stopwatches, and it is expected that mechanical watches will quickly disappear from use.

Three types of computer-assisted electronic stopwatches are now on the market: the DataMyte 1010, the COMPU-RATE, and the OS-3 Plus Event Recorder. The DataMyte 1010 all-solid-state battery-operated data collector, developed by the Electro/General Corporation in 1971, is a practical alternative to both mechanical and electronic stopwatches. Observed data are keyed in and recorded in a solid-state memory in computer language. Elapsed time readings are recorded and computed automatically. Data recordings may be directly downloaded from the DataMyte to most personal computers through an output cable. The instrument is self-contained and can be carried around the workplace. The rechargeable battery power provides approximately 12 hr of continuous operation. It takes 40–50% less time to conduct time studies with the DataMyte and a computer than with a stopwatch and a hand calculator.

TABLE 2 Comparison of Different Work-Measurement Techniques

Time Study	Predetermined Time Standards	Standard Data	Work Sampling
Advantages:			
1. Enables analysts to observe the complete cycle, providing an opportunity to suggest and initiate methods improvement. 2. The only method that actually measures and records the actual time taken by an operator. 3. More likely to provide coverage of those elements that occur less than one per cycle. 4. Quickly provides accurate values for machine-controlled elements 5. Relatively simple to learn and explain.	1. Forces detailed and accurate descriptions of the workplace layout; motion patterns; and shape, size, and fit of components and tools. 2. Encourages work simplification to reduce standard times. 3. Eliminates performance rating. 4. Permits establishing methods and standards in advance of actual production. 5. Permits easy and accurate adjustments of time standards to accommodate minor changes in method 6. Provides more consistent standards.	1. Averages performance rating. 2. Establishes consistent standards. 3. Permits establishing methods and standards in advance of actual production. 4. Allows standards to be established rapidly and inexpensively. 5. Permits easy adjustment of time standards to accommodate minor changes in method.	1. Eliminates tension caused by constant observation of the worker. 2. Does not require continuous observations over a long period of time. 3. Represents typical or average conditions over a period of time where conditions change from hour to hour or day to day. 4. Permits simultaneous development of standards from different operations. 5. Ideally suited to studies of machine utilization, activity analyses, and delays. 6. Can be used with performance rating to determine standard times.
Disadvantages:			
1. Requires the performance rating of a worker's skill and effort. 2. Requires continuous observation of the worker over repeated work cycles. 3. May not provide accurate evaluation of noncyclic elements. 4. Requires work to be performed by an operator.	1. Depends on complete and accurate descriptions of the required methods for the accuracy of the time standard. 2. Requires more time for the training of competent analysts. 3. More difficult to explain to workers and supervisors. 4. May require more work-hours to establish standards for long-cycle operations. 5. Must use stopwatch or standard data for process-controlled and machine-controlled elements.	1. Involves significant costs in setting up the standard data. Once these costs are incurred, additional costs are needed to maintain the system. 2. May not accommodate small variations in method. 3. May require more skilled analysts for complex formulas. 4. More difficult to explain to workers and supervisors. 5. May result to significant inaccuracies if extended beyond the scope of the data used in their development.	1. Assumes that the worker uses an acceptable and standard method. 2. Requires that the observer to identify and classify a wide range of work activities and delays. 3. Should be confined to constant populations. 4. Makes it more difficult to apply a correct performance rating factor than does time study.

The COMPU-RATE, developed by Faehr Electronic Timers, Inc., is a portable device using batteries, which provide about 120 hr of running time. Manual entries are required only for the element column and the top four lines of the form. This allows the analyst to concentrate on observing the work and the operator performance. Time can be in thousandths of a minute or one hundred-thousandths of an hour. The COMPU-RATE software system computes the mean and median element values, adjustment of mean times to normal time after inputting the performance rating, and allowed times in minutes and/or hours per piece and pieces per hour. Errors can be corrected through an edit function.

The GageTalker Corporation (formerly Observational Systems) markets the OS-3 Plus Event Recorder. This versatile recorder is useful for setting and updating standard times, machine downtime studies, and work sampling. The device allows the analyst to select the time units appropriate for the study—0.001 min, 0.0001 hr, or 0.1 sec. The total time, frequency, mean times, performance ratings, normal times, allowances, standard times, and pieces per hour may be printed through printer interface devices. In addition, the standard deviation, the maximum and minimum element values and frequencies are also available.

Videotape cameras are an excellent means for recording operator's methods and elapsed time to facilitate performance rating. By recording exact details of the method used, analysts can study the operation frame by frame and assign normal time values. Projecting the tape at the same speed at which the pictures were taken and then rating the performance of the operator can also be used. For example, a half minute to deal 52 cards into a four-hand bridge deck is considered by many to be typical of normal performance. An operator carrying a 9 kg (20 lb) load a distance of 7.6 m (25 ft) may be expected to take 0.095 min when working at a normal pace (Niebel 1992).

Observing the videotape is a fair and accurate way to rate performance because all the facts are documented. Also, the videotape can be used to uncover potential methods improvements that otherwise would have not been observed using a stopwatch procedure. Videotapes are also excellent training material for novice time study analysts, particularly in acquiring consistency in conducting performance rating.

2.2.2. Time Study Board

It is often convenient for time study analysts to have a suitable board to hold the time study form and the stopwatch. The board should be light but made of sufficiently hard material. Suitable materials include ¼ in. plywood and smooth plastic. The board should have both arm and body contacts for comfortable fit and ease of writing while being held. A clip holds the time study form. The stopwatch should be mounted in the upper right-hand corner of the board for right-handed observers. Standing in the proper position, the analyst should be able to look over the top of the watch to the workstation and follow the operator's movements while keeping both the watch and time study form in the immediate field of vision.

2.2.3. Time Study Forms

It is important that a well-designed form be used for recording elapsed time and working up the study. The time study form is used to record all the details of the time study. It should be designed so that the analyst can conveniently record watch readings, foreign elements (see Section 2.4.2), and rating factors and calculate the allowed time. It should also provide space to record all pertinent information concerning the operator being observed, method studied, tools and equipment used, department where the operation is being performed, and prevailing working conditions. Figures 1 and 2 illustrates a time study form (Niebel 1992) that is sufficiently flexible to be used for practically any type of operation. Various elements of the operation are recorded horizontally across the top of the sheet, and the cycles studied are entered vertically row-wise. The four columns under each element are R for ratings, W for watch reading, OT for observed time, and NT for normal time. At the back of the time study form, a sketch of the workstation layout is drawn and a detailed description is given of the work elements, tools and equipment utilized, and work conditions. Computed results of the time study can also be summarized next to each work element defined.

2.3. Requirements for Effective Time Study

Certain fundamental requirements must be met before the time study can be undertaken. First, all details of the method to be followed and working conditions must be standardized at all points where it is to be used before the operation is studied. Furthermore, the operator should be thoroughly acquainted with the prescribed method to be followed before the study begins. Without standardization, the time standards will have little value and will continually be a source of distrust, grievances, and internal friction. Reasons for selecting a particular job may be any of the following:

1. The job in question is a new one, not previously carried out (new product, component, operation, or set of activities)
2. A change in material or method of working has been made and a new time standard is required.

Figure 2 Back of Time Study Form. (From Niebel 1992)

3. A complaint has been received from a worker or worker's representative about the time standard for an operation.
4. A particular operation appears to be a bottleneck holding up subsequent operations and possibly (through accumulations of work in process behind it) previous operations.
5. Standard times are required before an incentive plan is introduced.
6. A piece of equipment appears to be idle for an excessive time or its output is low, and it therefore becomes necessary to investigate the method of its use.
7. The job needs studying as a preliminary to making a methods study or to compare the efficiency of two proposed methods.
8. The cost of a particular job appears to be excessive.

Second, analysts should inform the union steward, the department supervisor, and the operator that the job is to be studied. Each of these parties can then make specific preparations to allow a smooth and coordinated study. The operator should verify that he or she is performing the correct method and should become acquainted with all details of that operation. The supervisor should check the method in advance to ensure that feeds, speeds, cutting tools, lubricants, and so forth conform to standard practice (as established by the methods department) and that sufficient material is available on hand. If several operators are available for the study, the time study analyst and the supervisor should select the operator that represents the average or above-average performance within the group (Niebel 1992). This type of operator will give the most satisfactory results than either a low-skilled or highly superior operator (see Section 2.4.1 for choosing an operator). The union steward should then make sure that only trained, competent operators are selected for the study, explain to the operator why the study is being undertaken, and answer any pertinent questions raised by the operator on the study.

Because of many human interests and reactions associated with the time study technique, a full understanding among the supervisor, employee, union steward, and time study analyst is essential. Since time standards directly affect both the employee and company financially, time study results must be completely dependable and accurate. Inaccuracies and poor judgment may result in loss of confidence by the operator and the union, which may ultimately undo harmonious labor relations between the union and management. To achieve and maintain good human relations, the time study analyst should ensure that the correct method is being used, accurately record the times taken, honestly evaluate the performance of the operator, and conduct himself or herself in a manner that will gain and hold the respect and confidence of both labor and management.

2.4. Conducting the Study

To ensure success, the actual conduct of a time study must be systematic and apply a scientific approach. The following elements should be included:

1. Obtaining and recording all the information available about the job, the operator, and surrounding conditions that is likely to affect the carrying out of the work
2. Recording a complete description of the method, breaking down the operation into elements (see Section 2.4.2)
3. Examining the detailed breakdown to ensure that the most effective method and motions are being used and determining the number of cycles to study
4. Measuring with a timing device (usually a stopwatch) and recording the time taken by the operative to perform each element of the operation
5. At the same time, assessing the effective speed of work of the operator relative to the observer's concept of the rate corresponding to standard rating
6. Extending the observed times to basic times
7. Determining the allowances for the operation
8. Determining the standard time for the operation

2.4.1. Choosing an Operator

After reviewing the job in operation, both the supervisor and the analyst should agree that the job is ready to be studied. If more than one person is performing the job, several criteria should be considered when selecting a qualified operator for the study. In general, a qualified operator is one who has acquired the skill, knowledge, and other attributes to carry out the work to satisfactory standards of quantity, physical specifications, and safety. Normal pace is neither fast nor slow and gives due consideration to the physical, mental, and visual requirements of a specific job.

The qualified operator usually performs the work consistently and systematically, thereby making it easier for the analyst to apply a correct performance factor. The operator should be completely

trained in the method and should demonstrate motivation in doing a good job. The operator should have confidence in both time study methods and the analyst, be cooperative, and willingly follow suggestions made by the supervisor or the analyst.

In cases where only one operator performs the operation, the analyst needs to be especially careful in establishing the performance rating. It is possible that the operator may be performing either fast or slow.

Once the qualified operator has been selected, the analyst should approach the operator in a friendly manner and demonstrate understanding of the operation to be studied to obtain full cooperation. The operator should have the opportunity to ask questions and be encouraged to offer suggestions in improving the job. The analyst, in return, should answer all queries frankly and patiently and willingly receive the operator's suggestions. Winning the respect and goodwill of the operators helps establish a fair and acceptable time standard.

2.4.2. Breaking the Job into Elements

For ease of measurement, the operation should be divided into groups of motions known as elements. An element is a distinct part of a specified job selected for convenience of observation. It is a division of work that can be easily measured with a stopwatch and that has readily identifiable breakpoints. To divide the operation into individual elements, the analyst should carefully observe the operator over several cycles. A work cycle is the sequence of elements that are required to perform a job or yield a unit of production. The sequence may include elements that do not occur every cycle.

It is desirable to determine, prior to conducting the time study, the elements into which the operation is divided. Breaking down the operation into elements improves method description and provides good internal consistency during the time study. Elements also make it possible to reuse the data and permit different ratings for the work cycle.

Elements are classified into the following types:

1. Repetitive element: an element that occurs in every work cycle of the job
2. Occasional element: an element that does not occur in every work cycle of the job but that may occur at regular or irregular intervals
3. Constant element: an element for which the basic time remains constant whenever it is performed (e.g., stop machine)
4. Variable element: an element for which the basic time varies in relation to some characteristics of the product, equipment, or process (e.g., walk ''X'' meters)
5. Manual element: an element performed by a worker
6. Machine element: an element automatically performed by a power-driven machine or process
7. Governing element: an element occupying a longer time than that of any other element being performed concurrently
8. Foreign element: an element observed during a study that after analysis is not found to be a necessary part of the job

Each element should be recorded in proper sequence, including a definition of its breakpoints or terminal points. The analyst should follow some basic guidelines when dividing the job into elements:

1. Ascertain that all elements being performed are necessary. If some are unnecessary and the objective is to come up with a standard time, the time study should be discontinued and a method study should be conducted.
2. Elements should be easily identifiable (with clear start and break-off points) so that once established, they can be repeatedly recognized. Sounds (such as machine motor starts and stops) and change in motion of hand (putting down tool, reaching for material) are good breakpoints.
3. Elements should be as short in duration as possible to be timed accurately. The minimum practical units for timing are generally considered to be 0.04 min or 2.4 sec (Niebel and Freivalds 1999). For less-trained observers, it may be 0.07–0.10 minutes. Very short cycles should, if possible, be next to long elements.
4. Elements should be chosen so that they represent naturally unified and recognizably distinct segments of the operation. To illustrate, reaching for a tool can be detailed as reaching, grasping, moving, and positioning. This can be better treated as a whole and describe as ''obtaining and positioning of wrench.''
5. Irregular elements should be separated from regular elements.
6. Machine-paced elements should be separated from operator-controlled elements; the division helps recognize true delays.

7. Constant elements should be separated from variable elements.
8. Foreign or accidental elements should be identified.
9. End points should be defined (break-off points).

2.4.3. Number of Cycles to Study

Since time study is a sampling procedure, it is important that an adequately sized sample of data be collected to ensure that the resulting standard is reasonably accurate. From an economic standpoint, the activity of the job and the duration of the cycle influence the number of cycles that can be studied. The General Electric Company has established Table 3 as an approximate guide to the number of cycles to observe.

A more accurate sample size can be established using statistical methods. It is known that averages of samples $\bar{x}$ drawn from a normal distribution of observations are distributed normally about the population mean μ. The variance about the population mean μ equals σ^2/n, where n equals the sample size and σ^2 equals the population variance. Normal curve theory leads to the following confidence interval:

$$\bar{x} \pm z\frac{\sigma}{\sqrt{n}}$$

The preceding equation assumes that the standard deviation of the population is known. In general, this is not true, but the population standard deviation may be estimated by the sample standard deviation s, where:

$$s = \sqrt{\frac{\Sigma^2 x_i^2}{n-1} - \frac{(\Sigma x_i)^2}{n(n-1)}}$$

However, since pilot time studies involve only small samples ($n < 30$) of a population; a t-distribution must be used. The confidence interval equation is then:

$$\bar{x} \pm t\frac{s}{\sqrt{n}}$$

The $\pm$ term can be considered an error term expressed as a fraction of $\bar{x}$:

$$k\bar{x} = \frac{ts}{\sqrt{n}}$$

where k = an acceptable percentage of $\bar{x}$. If we let N be the number of observations for the actual time study, solving for N yields:

TABLE 3 Recommended Number of Observation Cycles

Cycle Time, min	Recommended Number of Cycles
0.01	200
0.25	100
0.50	60
0.75	40
1.00	30
2.00	20
2.00–5.00	15
5.00–10.00	10
10.00–20.00	8
20.00–40.00	5
40.00–above	3

From B. Niebel and A. Freivalds, *Methods, Standards, and Work Design,* 10th Ed. © 1999 McGraw-Hill Companies, Inc. Reprinted by permission.

$$N = \left\{\frac{st}{k\bar{x}}\right\}^2$$

For example, a pilot study of 30 readings for a given element showed that $\bar{x} = 0.25$ and $s = 0.08$. A 5% probability of error for 29 DOF (30 − 1 DOF) yields $t = 2.045$ (see Table 4 for values of t). Solving for N yields (rounded up):

$$N = \left[\frac{(0.08)(2.045)}{(0.05)(0.25)}\right]^2 = 171.3 \approx 172 \text{ observations}$$

Thus, a total of 172 observations need to be taken for the pilot sample $\bar{x}$ to be within ±5% of the population mean μ.

2.4.4. Principal Methods of Timing

There are two techniques of recording the elemental times during a time study: the continuous method and the snapback method. Each technique has its advantages and disadvantages, which are described as follows.

2.4.4.1. Continuous Timing The watch runs continuously throughout the study. It is started at the beginning of the first element of the first cycle to be timed and is not stopped until the whole study is completed. At the end of each element, the watch reading is recorded. The purpose of this procedure is to ensure that all the time during which the job is observed is recorded in the study.

The continuous method is often preferred over the snapback method for several reasons. The principal advantage is that the resulting study presents a complete record of the entire observation period. Consequently, this type of study is more appealing to the operator and the union because no time is left out of the study, and that all delays and foreign elements have been recorded. The continuous method is also more suited for measuring and recording short elements. Since no time is lost in snapping the hand back to zero, accurate values are obtained on successive short elements.

More clerical work is involved when using the continuous method. The individual element time values are obtained on successive subtractions after the study is completed to determine the elapsed elemental times.

2.4.4.2. Snapback Timing The hands of the stopwatch are returned to zero at the end of each element and are allowed to start immediately. The time for each element is obtained directly. The mechanism of the watch is never stopped and the hand immediately starts to record the time of the next element. It requires less clerical work than the continuous method because time recorded is already time of elements. Elements observed out of order by the operator can also be readily recorded without special notation.

Among the disadvantages of the snapback method are:

1. If the stopwatch is analog, time is lost in snapping back to zero and cumulative error is introduced into the study. However, this error becomes insignificant when using a digital stopwatch because only the delay is in the display but internally it does not lag.
2. Short elements are difficult to time (0.04 min and less).
3. No verification of overall time with the sum of elemental watch readings is given.
4. A record of complete study is not always given in the snapback method. Delays and foreign elements may not be recorded.

2.4.5. Recording Difficulties Encountered

During the course of the study, the analyst may occasionally encounter variations in the sequence of elements originally established. First, the analyst may miss reading an element. Second, the analyst may observe elements performed out of sequence. A third variation is the introduction of foreign elements during the course of the study.

2.4.5.1. Missed Readings When missing a reading, analysts should in no circumstance approximate or endeavor to record the missed value. Put a mark M on the W column (referring to Figure 1) or the area where the time should have been logged. Occasionally, the operator omits an element. This is handled by drawing a horizontal line through the space in the W column. This occurrence should happen infrequently; it usually indicates an inexperienced operator or a lack of a standard method. Should elements be omitted repeatedly, the analyst should stop the study and investigate the necessity of performing the omitted elements in cooperation with the supervisor and the operator.

From R. A. Fisher and F. Yates, *Statistical Tables for Biological, Agricultural, and Medical Research,* 6th Ed., Oliver & Boyd, Ltd., Edinburgh, by permission of the authors and publishers.

[a] Probabilities refer to the sum of the two tail areas; for single tail, divide the probability by 2.

2.4.5.2. Variations from Expected Sequence of Work This happens frequently when observing new and inexperienced workers or on a long-cycle job made of many elements. If using snapback timing, just note the jump from one element to another by putting arrows. For continuous timing:

1. Draw a horizontal line in the box where the time is to be logged.
2. Below the line, log the time operator began the element, and above, record the time it ended.
3. Continue logging in this format until the next element observed is the normal element in the sequence.

2.4.5.3. Foreign Elements Foreign elements are unavoidable delays such as talk with the supervisor, tool breakage, material replenishment, etc. or personal delays such as drinking, resting, etc. A separate area should be assigned where details of the delay can be recorded (letter code A, B, C . . . , start and end time, description). Put the code in the box of the element done upon resumption.

2.4.5.4. Short Foreign Elements Occasionally, foreign elements can be of a short duration that makes it impossible to time. Delays like dropping and retrieving of tools, wiping of brows, or short answers to supervisor's inquiries are example of such situations. In these situations, continue timing the elements but encircle the time and put in the remarks column the foreign element encountered.

2.5. Rating the Operator's Performance

The purpose of performance rating is to determine, from the time actually taken by the operator being observed, the standard time that can be maintained by the average qualified worker and that can be used as a realistic basis for planning, control, and incentive plans. The speed of accomplishment must be related to an idea of a normal speed for the same type of work. This is an important reason for doing a proper method study on a job before attempting to set a time standard. It enables the analyst to gain a clear understanding of the nature of the work and often enables him or her to eliminate excessive effort or judgment and so bring the rating process nearer to a simple assessment of speed.

Standard performance is the rate of output that qualified workers will naturally achieve without undue fatigue or overexertion during a typical working day or shift, provided that they know and adhere to the specified method and are motivated to apply themselves to their work. This performance is denoted as 100 on the standard rating and performance scales. Depending on the skill and effort of the operator, it may be necessary to adjust upwards to normal the time of a good operator and adjust downwards to normal the time of a poor operator.

In principle, performance rating adjusts the mean observed time (OT) for each element performed during the study to the normal time (NT) that would be required by a qualified operator to perform the same work:

$$\mathrm{NT} = (\mathrm{OT})\left(\frac{R}{100}\right)$$

where R is expressed as a percentage. If the analyst decides that the operation being observed is being performed with less effective speed than the concept of standard, the analyst will use a factor of less than 100 (e.g., 75 or 90). If, on the other hand, the analyst decides that the effective rate of working is above standard, it has a factor greater than 100 (e.g., 115 or 120).

Unfortunately, there is no universally accepted method of performance rating, nor is there a universal concept of normal performance. The majority of rating systems used are largely dependent on the judgment of the time study analyst. It is primarily for this reason that the analyst reflects high personal qualifications.

To define normal performance, it is desirable for a company to identify benchmark examples so that various time study analysts can develop consistency in performance rating. The benchmark examples should be supplemented by a clear description of the characteristics of an employee carrying out a normal performance.

To do a fair job of rating, the time study analyst must evaluate the job in terms of the factors that affect the rate of working. Factors outside and within the worker's control include:

- *Outside the worker's control:*
  1. Variations in the quality or other characteristics of the material used, although they may be within the prescribed tolerance limits
  2. Changes in the operating efficiency of equipment within the useful life
  3. Minor and unavoidable changes in methods or conditions of operations
  4. Variations in the mental attention necessary for the performance of certain elements
  5. Changes in climatic and other surrounding conditions such as light and temperature.

- *Within the worker's control:*
  1. Acceptable variations in the quality of the product
  2. Variations due to his or her ability
  3. Variations due to attitude of mind, especially the operator's attitude to the organization

2.5.1. Scales of Rating

For a comparison between the observed rate of working and the standard rate to be made effectively, it is necessary to have a numerical scale against which to make the assessment. The rating can then be used as a factor by which the observed time can be multiplied to give the basic time, which is the time it would take the qualified worker, motivated to apply himself or herself, to carry out the element at standard rating.

There are several scales of rating in use, the most common of which are the following:

2.5.1.1. Westinghouse System Developed by Westinghouse Electric Corporation, this is one of the oldest rating systems. It has had wide application, especially on short-cycle, repetitive operation where performance rating of the entire study takes place (Niebel 1992). This method considers four factors in evaluating performance: skill, effort, environmental condition, and consistency. The overall performance factor rating is obtained by adding the sum of the equivalent numerical values of the four factors to unity. It must be noted that the performance factor is applicable only for manually performed elements. All machine-controlled elements are rated 100. Table 5 summarizes the ratings for each factor.

In 1949, Westinghouse Electric Corporation developed a new rating method called the performance rating plan (Niebel and Freivalds 1999). In addition to using the operator-related physical attributes, the company attempted to evaluate the relationship between those physical attributes and the basic divisions of work.

The characteristics and attributes that the Westinghouse performance-rating plan considers are dexterity, effectiveness, and physical application. These three major classifications are assigned nine attributes that carry numerical weights: three are related to dexterity, four to effectiveness, and two to physical application. Table 6 provides values for each of these attributes at various levels of performance.

Westinghouse rating procedures are appropriate for either cycle rating or overall study rating. Both of the Westinghouse rating techniques demand considerable training to differentiate the levels of each attribute.

2.5.1.2. Synthetic Rating Morrow (1946) developed a procedure known as the synthetic method to eliminate judgment of the time study observer, therefore giving more consistent results. The procedure determines a performance factor for representative effort elements of the work cycle by comparing actual elemental observed times and fundamental motion data (see Section 3). This factor would then be applied to the remainder of the manually controlled elements comprising the study. The ratio is given by:

$$P = \frac{\text{fundamental motion time}}{\text{observed mean element time}}$$

For example, the observed average time of work element 2 is 0.08 min and the corresponding fundamental motion time is 0.096. In addition, the observed average time of work element 5 is 0.22 with corresponding fundamental motion time of 0.278. The performance factor of element 2 and element 5 are computed as

$$P_2 = \frac{0.096}{0.08} = 1.2 \qquad P_5 = \frac{0.278}{0.22} = 1.26$$

The mean of the performance factors of elements 2 and 5 is

$$\overline{P} = \frac{1.2 + 1.26}{2} = 1.23 \text{ or } 123\%$$

This rating factor is then used for all other effort elements of the method.

2.5.1.3. Speed Rating Today, speed rating is probably the most widely used rating system (Niebel 1992). Speed rating is a performance evaluation that considers only the rate of accomplishment of the work per unit time. In this method, observers measure the effectiveness of operator against concept of a normal operator and then assign a percentage to indicate the ratio of the observed

performance to standard performance. A rating of 100% is considered normal. A rating of 125% means a slow operator and a rating of 90% means a fast operator.

To be consistently accurate in using speed rating, the analyst must be familiar with the work being studied. The analyst first appraises the operator as whether performance is above or below the concept of normal rate. Then the precise position in the rating scale is determined. Benchmarks of various activities can be used for comparing with the performance being observed. It is recommended that analysts undergo a comprehensive training program prior to conducting independent studies (Niebel 1992).

2.5.1.4 Objective Rating The objective rating method developed by Mundel and Danner (1994) eliminates the difficulty of establishing normal speed criteria for every type of work by establishing a single work assignment to which the pace of all other jobs are compared. After the pace is judged, a second factor indicating its relative difficulty is assigned. The performance rating is expressed as the product of the pace rating factor and the job difficulty adjustment factor.

Factors influencing the difficulty adjustment that have been assigned numerical values for a range of degrees are: (1) amount of body used, (2) foot pedals, (3) bimanualness, (4) eye–hand coordination,

Attentiveness			0	−0.02	−0.04

From Niebel 1992.

(5) handling or sensory requirements, and (6) weight handled or resistance encountered. The sum of the numerical values for each of the factors constitute the difficulty factor. Hence performance rating would be

$$P = (\text{pace rating})(\text{difficulty adjustment})$$

Tables of percentage values for the effects of various difficulties in operation performed can be found in Mundel and Danner (1994).

2.5.2. Selecting a Rating System

From a practical-standpoint, the performance-rating technique that is easiest to understand, apply, and explain is speed rating when augmented by standard data benchmarks (see Section 4). As is true of all procedures requiring the exercise of judgment, the simpler and more concise the technique, the easier it is to use and, in general, the more valid the results. Five criteria are used to ensure the success of the speed rating procedure (Niebel 1992):

1. *Experience by the time study analyst in the class of work being performed:* The analyst should be sufficiently familiar with the details of the work being observed as well as have experience as an observer.
2. *Use of standard data benchmarks on at least two of the elements performed:* The accuracy of the analyst's ratings can be validated using standard data elements. Standard data are a helpful guide to establishing performance factors.
3. *Regular training in speed rating:* It is important that time study analysts receive regular training in performance rating. Training may involve observation of films or videotape illustrating a variety of operations characteristic of the company's operations.
4. *Selection of an operator who has adequate experience:* As much as possible, the analyst should select an operator who has had sufficient experience on the job. It is desirable to select a cooperative operator who in the past has performed regularly at normal or above normal pace.
5. *Use of the mean value of three or more independent studies:* It is good practice to conduct more than one study before arriving at the standard time. These can be made on the same operator at different times, or on different operators. The total error due to both the performance rating and the measurement of the elemental times is reduced when the averages of several independent studies are used in computing standards.

2.6. Allowances

The fundamental purpose of all allowances is to add enough time to normal production time to enable the average worker to meet the standard when performing at standard performance. Even when the most practical, economical, and effective method has been developed, the job will still require the expenditure of human effort, and some allowance must therefore be made for recovery from fatigue and for unavoidable delays. Allowance must also be made to enable a worker to attend to his personal needs. Other special allowances may also have to be added to the basic time in order to arrive at a fair standard.

Fatigue and personal needs allowances are in addition to the basic time intended to provide the worker with the opportunity to recover from the physiological and psychological effects of carrying out specified work under specified conditions and to allow attention to personal needs. The amount of allowance will depend on the nature of the job, the work environment, and individual characteristics of the operator (e.g., age, physical condition, and working habits). Usually a 5% allowance for personal delays is appropriate in the majority of work environments nowadays. It is also considered good practice to provide an allowance for fatigue on the effort elements of the time study.

Special allowances include many different factors related to the process, equipment, materials, and so on and are further classified into unavoidable delays and policy allowances. Unavoidable delays are a small allowance of time that may be included in a standard time to meet legitimate and expected items of work or delays, such as due to power outages, defective materials, waiting lines, late deliveries, and other events beyond the control of the operator. Precise measurement of such occurrences is uneconomical because of their infrequent or irregular occurrence.

Policy allowance (ILO 1979) is an increment, other than bonus increment, applied to standard time (or to some constituent part of it) to provide a satisfactory level of earnings for a specified level of performance under exceptional circumstances (e.g. new employees, differently abled, workers on light duty, elderly). Special allowances may also be given for any activities that are not normally part of the operation cycle but that are essential to the satisfactory performance of the work. Such allowances may be permanent or temporary and are typically decided by management with possible union negotiations (Niebel and Freivalds 1999). Policy allowances should be used with utmost caution and only in clearly defined circumstances. The usual reason for making a policy allowance is to line up standard times with requirements of wage agreements between employers and trade unions.

Whenever possible, these allowances should be determined by a time study. Two methods are frequently used for developing standard allowance data. A production study, which requires analysts to study two to three operations over a long period, records the duration and reason for each idle interval. After a reasonably representative sample is established, the percent allowance for each applicable characteristic is determined. The other method involves work sampling studies. This method requires taking a large number of random observations. (See Chapter 53 for more information on allowances.)

The allowance is typically given as a percentage and is used as a multiplier, so that normal time (NT) can be readily adjusted to the standard time (ST):

$$ST = NT + NT(\text{allowance}) = NT(1 + \text{allowance})$$

The total allowance is determined by adding individual allowance percentages applicable to a job. For example, total allowance is computed as the sum of personal needs (5%), fatigue (4%), and unavoidable delays (1%), equal to 10%. Normal time would then be multiplied by 1.1 to determine standard time.

2.7. Calculating the Standard Time

The standard time for the operation under study is obtained by the sum of the elemental standard times. Standard times may be expressed in minutes per piece or hours per hundred pieces for oper-

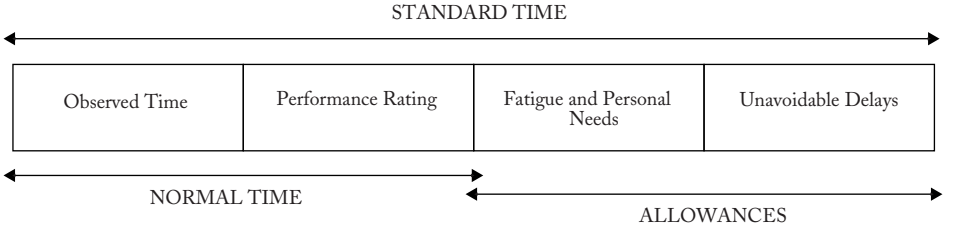

Figure 3 Breakdown of Standard Time.

ations with short cycles. In this form, it is convenient to compute the operator's efficiency and daily earnings if an incentive plan is applied. The percent efficiency of the operator can be expressed as:

$$E = 100\left(\frac{H_e}{H_c}\right)$$

where E = percent efficiency
H_e = earned standard hours
H_c = clock hours on the job

For example, the work standard for an operation is 11.5 min/piece. In an 8-hour shift, an operator produced 50 pieces in a given working day. The standard hours earned would be:

$$H_e = \frac{50 \text{ pieces} \times 11.50 \text{ min/piece}}{60 \text{ min/hr}} = 9.58 \text{ hr}$$

The operator's efficiency would be computed as:

$$\text{Efficiency} = \frac{100 \times 9.58 \text{ hr}}{8 \text{ hr}} = 119.7\%$$

2.7.1. Temporary Standards

In many cases, time study analysts establish a standard on a relatively new operation wherein there is insufficient volume for the operator to reach his long-term efficiency. Employees require time to become proficient in any new or different operation. If the analyst rates the operator based on the usual concept of output (i.e., rating the operator below 100), the resulting standard may be unduly tight and make it difficult to achieve any incentive earnings. On the other hand, if a liberal standard is established, this may cause an increase in labor expense and other related production costs.

The most satisfactory solution to such situations would be the establishment of temporary standards. The analyst establishes the standard based on the difficulty of the job and the number of pieces to be produced. Then, by using a learning curve (see Chapter 53 on learning curves) for the work, as well as existing standard data, an equitable temporary standard for the work can be established. When released to the production floor, the standard should be clearly identified as temporary and applicable to only to a fixed quantity or fixed duration. Upon expiration, temporary standards should be immediately replaced by permanent standards.

2.7.2. Setup Standards

Setup standards are for those elements that involve all events that take place between completion of the previous job and the start of the present job. Setup standards also include teardown or put-away elements, such as clocking in on the job, getting tools from the tool crib, getting drawings from the dispatcher, setting up the machine, removing tools from the machine, returning tools to the tool crib, and clocking out from the job. The analysts need to use the same care and precision in studying the setup time because only one cycle, if not a few, can be observed and recorded in one day. Because setup elements are of long duration, there is a reasonable amount of time to break the job down, record the time, and evaluate the performance as the operator proceeds from one work element to the next.

3. PREDETERMINED TIME STANDARDS

Predetermined time standards (PTS) are techniques that aim at defining the time needed for the performance of various operations by derivation from preset standards of time for various motions and not by direct observation and measurement. PTS is a work measurement technique whereby times established for basic human motions (classified according to the nature of the motion and the conditions under which it is made) are used to build up the time for a job at defined levels of performance. They are derived as a result of studying a large sample of diversified operations.

There are a number of different PTS systems, and it will be useful to present the main ways in which the systems vary. The differences are with respect to the levels and scope of application of data, motion classification, and time units. Essentially, these predetermined time systems are sets of motion–time tables with explanatory rules and instructions on the use of the motion–time values. Most companies require considerable training in the practical application of these techniques to earn certification before analysts are allowed to apply the Work-Factor, MTM, or MOST systems. Figure 4 illustrates the derivation of all of these predetermined time systems.

No two PTS systems have the same set of time values. This is partly due to the fact that different systems have different motion classes and the time data therefore refer to different things. Variations

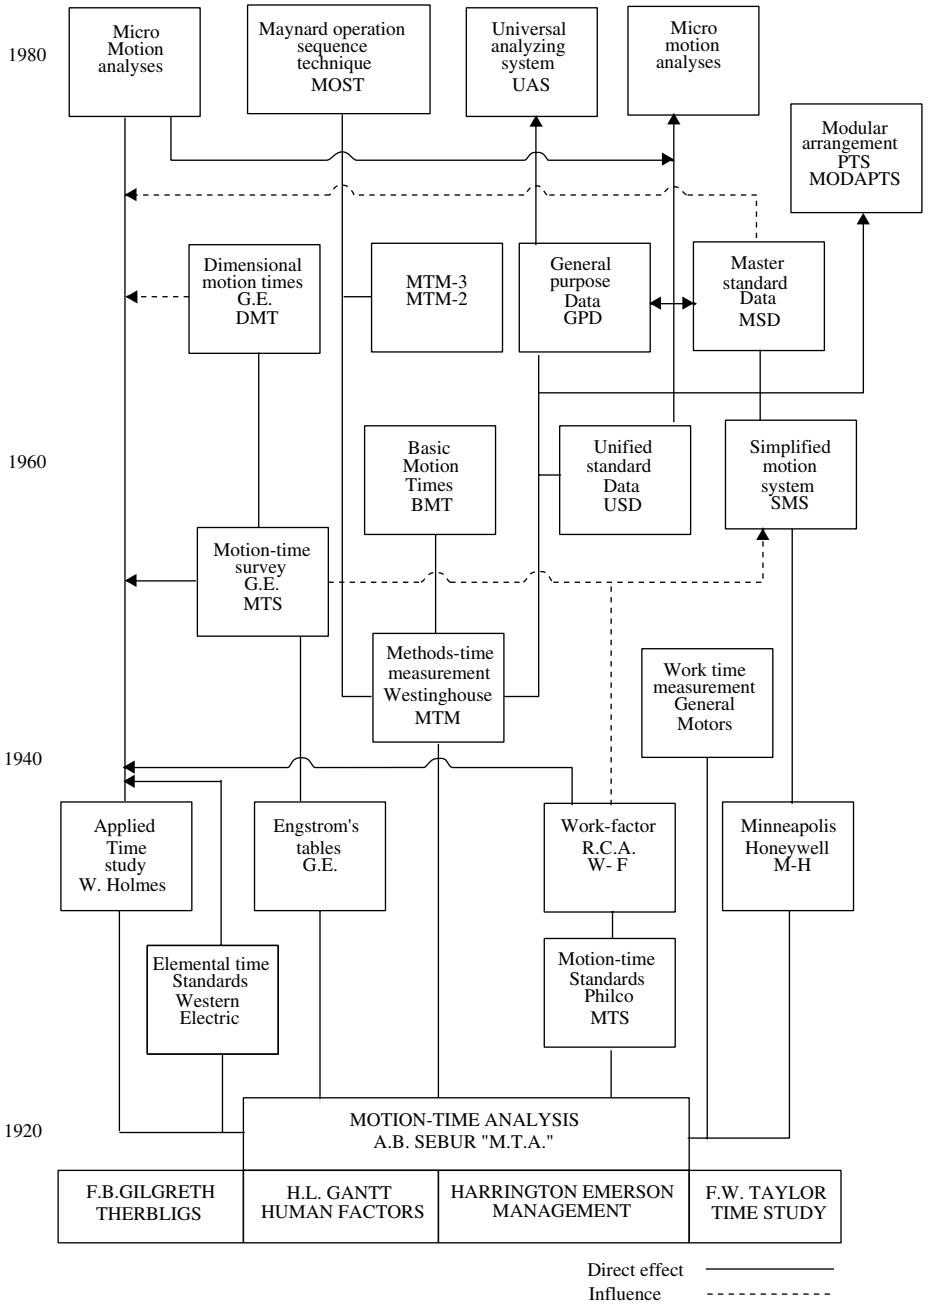

Figure 4 Family Tree of Predetermined Times. (From Sellie 1992)

in time units are due to differences in the methods adopted for standardizing the motion times, the choice of the basic unit (seconds, minutes, hours, or fractions of a minute), and the practice of adding contingency allowances or not.

The scope of application of a PTS system can be universal or generic, functional, or specific. A universal system is one that is designed for body members in general. Its application is not restricted

to any specific type of work. The motion descriptions only identify the body member being used. Examples of generic terms are REACH, TRANSPORT, GRASP, WALK. Examples of universal systems are MTM-1 to MTM-3, Work-Factor, MOST, and MODAPTS.

A functional system defines motion element times for a particular type of activity, such as clerical work (MTM-C), uses of microscopes (MTM-M), and so on. The element names indicate the function for which the system was developed. For example, FILE is a common element name in office work environments.

A specific system is one where the motion–time tables were constructed for specific operations or work areas. Examples are standard motion–time tables developed for electronic tests (MTM-TE), to measure one-of-a-kind and small-lot production (MTM-MEK).

The approach in applying PTS systems uses the following general procedure:

1. Summarize all left- and right-hand motions required to perform the job properly (e.g., SIMO chart).
2. Determine governing or limiting elements for elements done simultaneously.
3. Eliminate or delete nonlimiting elements.
4. Summarize only the limiting or governing elements.
5. Determine from the PTS table the basic time to perform the elements.
6. Add up the basic elemental times of limiting elements obtained from time tables.

3.1. Methods–Time Measurement (MTM)

Methods–Time Measurement systems were first developed by Harold B. Maynard in 1946 at the Westinghouse Electric Corporation in collaboration with Gustave J. Stegemerten and John L. Schwab. Maynard was commissioned by Westinghouse to develop a system for describing and evaluating operations methods.

MTM became the first widely used predetermined time system. In the United States, it is administered, advanced, and controlled by the MTM Association for Standards and Research. This nonprofit association is one of 12 associations comprising the International MTM Directorate. The success of the MTM systems is attributed to the active committee structure made up of members of the association.

The original MTM system is now known as MTM-1. Subsequent modifications were later developed to provide easier and quicker systems by condensing and reducing the number of motion options and time values. MTM-2 and MTM-3 are examples of second-level and third-level MTM data. In addition, the MTM family of systems include MTM-V, MTM-C, MTM-M, MTM-TE, MTM-MEK, and MTM-UAS.

3.1.1. MTM-1

MTM-1 data are the result of frame-by-frame analyses of motion picture films of different types of work. The film was analyzed for the motion content of the operation in question, rated by the Westinghouse technique, evaluated to determine the degree of difficulty caused by the characteristics of the motion and frame counts measured to yield normal motion times. The first set of predetermined time standards defined time values for the seven fundamental motions of: REACH, MOVE, TURN, GRASP, POSITION, DISENGAGE, and RELEASE.

Further analyses categorized some fundamental motions into different distinct cases. Five cases of REACH, 3 cases of MOVE, 2 cases of RELEASE, and 18 cases of POSITION were established based on factors that affect motion times, such as distance, weight of the object, and type of motion.

Table 7 summarizes the MTM-1 values. Time values are expressed in terms of a new time unit known as the time-measurement unit (TMU), and assigned a unit value of 0.00001 hr, equal to 1 TMU. The tabulated values do not include any allowances. Proponents of the MTM-1 system state that fatigue allowance in not needed in most applications because the time values are based on a work rate that can be sustained at steady state for the working life of a healthy employee.

In using this system, first all left-hand and right-hand motions required to perform a job properly are summarized and tabulated. Then the rated times in TMU for each motion are determined from the MTM-1 tables. The time required for a normal performance of the task is obtained by adding only the limiting motions (the longer time between two simultaneous motions predominates). The nonlimiting motion values are then either circled or deleted. Figure 5 illustrates the use of MTM-1 in analyzing a simple operation.

3.1.2. MTM-2

MTM-2 is a system of synthesized MTM data and is the second general level of MTM data. It consists of single basic MTM motions and certain combinations of basic MTM motions. MTM-2

recognizes 11 classes of actions. The motion times range from 3 to 61 TMU. The 11 categories and their symbols are:

Category	Code(s)
GET	GA, GB, GC
PUT	PA, PB, PC
GET WEIGHT	GW
PUT WEIGHT	PW
REGRASP	R
APPLY PRESSURE	A
EYE ACTION	E
FOOT ACTION	F
STEP	S
BEND & ARISE	B
CRANK	C

GET and PUT categories are affected by the distance traveled by the knuckle at the base of the index finger for hand motions and the path traveled by the fingertips, if only the fingers move. Five distance classes are defined (see Table 8).

GET is a composite of REACH, GRASP, and RELEASE. The time required to perform a GET motion is affected by the case involved (distinguished by the grasping action involved), the distance reached, and the weight of the object handled. The three cases A, B, and C of GET are judged using the decision model in Figure 6.

PUT is considered a combination of MOVE and POSITION. It involves moving an object to a destination with the hand or fingers. It starts with the object grasped and under control at the initial place and includes all transporting and correcting motions necessary to place the object. The motion

TABLE 8 Summary of MTM-2 Data

	14	6	7	15	18	9	61

Courtesy: MTM Association.

ends with the object still under control at the intended place. Similarly, the time required to perform a PUT motion is affected by distance and weight variables. Three cases of PUT are likewise distinguished based on the number of correcting motions required. A correcting motion is an unintentional stop, hesitation, or change in direction at the terminal point. Identification of the cases of PUT can be made using the decision model shown in Figure 7. When there is engagement of parts following a correction, an additional PUT motion is allowed when the distance exceeds 2.5 cm (1 in.).

A further consideration is that a PUT motion can be accomplished either as an insertion or an alignment. An insertion involves placing one object into another while an alignment involves orienting a part on a surface. Table 9 assists the analyst in better identifying the appropriate case.

GET WEIGHT (GW) is the action required for the hand and arm to take up the weight of the object. It occurs after the fingers have closed on the object in the preceding GET motion and is accomplished before any actual movement takes place. The time value for a GW is 1 TMU per kilogram (2.2 lb). For instance, a 4 kg (8.8 lb) load handled by both hands will be assigned a time value of 2 TMU since the effective weight per hand will be 2 kg (4.4 lb). When the weight is less than 1 kg (2.2 lb) per hand, no GW is assigned.

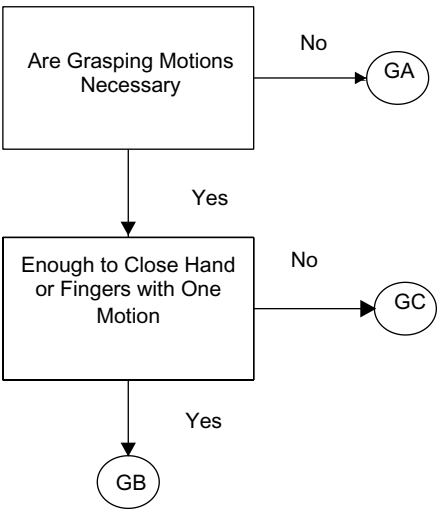

Figure 6 Algorithm for Determining Case of GET. (MTM Association)

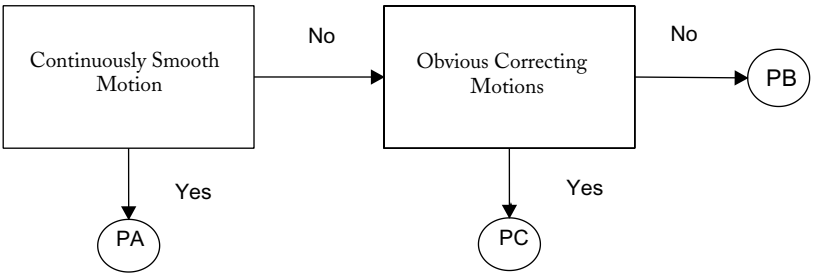

Figure 7 Algorithm for Determining Case of PUT. (MTM Association)

PUT WEIGHT (PW) is an addition to a PUT motion due to the weight of the object moved. Additions are 1 TMU per 5 kg (11 lb) of effective weight, up to a maximum of 20 kg (44 lb).

The category REGRASP (R) is a hand action with the purpose of changing the grasp on an object with the hand maintaining control. It is assigned a time of 6 TMU.

APPLY PRESSURE (A) applies to the action of exerting muscular force on an object to achieve control, restrain, or overcome resistance to motion. It can be performed by any body member and the object is not displaced more than 6.4 mm (0.25 in.) during the action. It is assigned a time of 14 TMU. An example of A is the final tightening action made with a screwdriver.

EYE ACTION (E) is an action that involves either recognizing a readily distinguishable characteristic of an object or shifting the aim of the axis of vision to a new viewing area. A single eye focus is defined as moving beyond a 10 cm (3.94 in.) diameter circle at a typical viewing distance of 40 cm (15.75 in.). Recognition time considered is sufficient only for simple binary decisions. The estimated value of E is 7 TMU. The value of E is allowed only when E is independent of hand or body motions.

FOOT movements are 9 TMU and STEP movements are 18 TMU. The time for STEP movement is based on an 85 cm (34 in.) pace. The decision model shown in Figure 8 helps differentiate a STEP movement from a FOOT movement.

BEND & ARISE (B) occurs when the body changes its vertical position. Examples include sitting down, standing up, and kneeling. B is assigned a time value of 61 TMU.

CRANK (C) is the motion of moving an object in a circular path of more than half a revolution with the hand or finger. For less than half a revolution, a PUT is used instead. Two variables are considered in applying the C motion: the number of revolutions and the weight of the object. A time of 15 TMU is allotted for each complete revolution. Where weight is significant, PW is applied to each revolution. The number of revolutions should be rounded to the nearest whole number.

In performing MTM-2 analysis, the principle of limiting motion or combined motions applied in MTM-1 is also used. That is, for two simultaneous motions, the longer time predominates.

3.1.3. MTM-3

The third-level MTM system is MTM-3. This level was developed to supplement MTM-1 and MTM-2. The system is helpful in work situations where saving time takes preference over accuracy. The accuracy of MTM-3 is within $\pm 5\%$, with a 95% confidence level compared to MTM-1 analyses for cycles of approximately 4 min (Niebel and Freivalds 1999). MTM-3, however, cannot be applied to operations that require eye focus or eye travel time because the MTM-3 data do not include these motions.

TABLE 9 Comparison of Insertion and Alignment PUT Cases (mm/in.)

	PA	PB	PC
Insertion	Clearance $>$ 10.2 mm (0.4 in.)	Clearance $<$ 10.2 mm (0.4 in.)	Tight fit
Alignment	Tolerance $>$6.3 mm (0.25 in.)	1.6 mm (0.06 in.) $<$ Tolerance $<$ 6.3 mm (0.25 in.)	Tolerance $<$ 1.6 mm (0.06 in.)

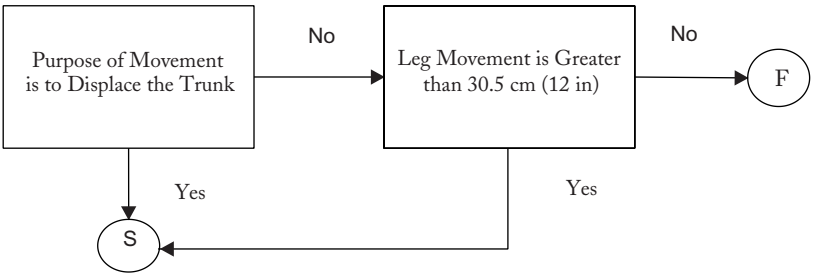

Figure 8 Algorithm for Differentiating between STEP (S) and FOOT (F) Motion. (MTM Association)

The MTM-3 consists of only four categories of manual motions:

1. *Handle:* getting control of an object with the hand or fingers and placing the object in a new location
2. *Transport:* moving an object to a new location with the hand or fingers
3. *Step and foot motions:* step movement based on an 85 cm (34 in.) pace and foot movements
4. *Bend and arise:* a motion where the body changes its vertical position

Table 10 presents a summary of MTM-3 data. It consists of 10 time values, ranging from 7–61 TMU.

3.1.4. MTM-V

This functional PTS system was developed by Svenka MTM Grupen, the Swedish MTM Association, for use in metal-cutting operations. The MTM-V system is of the fourth level and contains time values for handling and adjusting workpieces of any weight and size, including machine tool setup, attaching crane hooks, and other mechanical handling equipment. The system does not include process-controlled activities. The system's 12 elements are of two types: those that can be accomplished by the hand and finger alone and those that require the use of a hand tool to accomplish the objective. This technique is said to be about 23 times faster to apply than MTM-1 (Niebel and Freivalds 1999).

3.1.5. MTM-C

MTM-C is a functional work-measurement system used to establish time standards for clerical-related work tasks at two levels of job description, precision, and speed of analysis. This system was developed by a consortium of banking and service industries.

Level 1 data categories cover nine areas. A six-digit numeric coding system (similar to MTM-V) is used to provide a detailed description of the operation being studied, each of which is documented with a specific MTM-1 motion pattern. Level 2 data are directly traceable to Level 1 and to MTM-1, which covers the same activities at a combined motion level. Distance ranges are reduced to one, and elements use simplified alphanumeric and mnemonic codes.

Calculating standard time using MTM-C takes less time to perform than with MTM-1 because the number of elements used to describe the clerical operation is reduced significantly. MTM-C Level

1 can be calculated faster than MTM-2 and MTM-C Level 2 is faster than MTM-3. Comparing the standards for replacing a page in a three-ring binder, developed first using MTM-1, then using MTM-C Level 1 (see Table 11), and finally using MTM-C Level 2 (see Table 12), exhibits how closely these three standards agree (see Table 13).

3.1.6. MTM-M

MTM-M is a functional, basic-level system specifically designed for evaluating work using a stereoscopic microscope. The data used were original data developed through the efforts of the United States/Canada MTM Association. In general, MTM-M is a higher-level system, similar to MTM-2.

This system is contained in four major tables and one subtable. Four variables when selecting the appropriate data must be considered: (1) type of tool; (2) condition of the tool; (3) terminating characteristic of the motion; and (4) distance/tolerance ratio. Additional factors that have impact on motion performance include the tool load state (empty or loaded), microscopic power, distance moved, positioning tolerance, purpose of the motion, and simultaneous motions.

3.1.7. Specialized MTM Systems

There are three other specialized MTM systems: MTM-TE, MTM-MEK, and MTM-UAS. MTM-TE was developed for electronic tests and uses two levels of data derived from MTM-1. Level 1 includes

TABLE 13 Comparison of MTM-1, MTM-C (1), and MTM-C (2)

Techniques	Number of Elements	Standard (TMU)
MTM-1	57	577.8
MTM-C Level 1	21	577
MTM-C Level 2	11	575

From B. Niebel and A. Freivalds, *Methods, Standards, and Work Design,* 10th Ed. © 1999 McGraw-Hill Companies, Inc. Reprinted by permission.

the elements get, move, body motions, identify, adjust, and miscellaneous data. Level 2 includes get and place, read and identify, adjust, body motions, and writing.

The second specialized system, MTM-MEK, was designed to measure one-of-a-kind and small-lot production. It also is a two-level system developed from MTM-1 and can analyze all manual activities as long as certain requirements are met. MTM-MEK can be used provided that the operation is not highly repetitive; the method used to perform a given operation typically varies from cycle to cycle; the task is complex and requires employee training; and the workplace, tools, and equipment used are universal in nature. The data in MTM-MEK consist of 51 time values classified into the following eight categories: get and place, handle tool, place, operate, motion cycles, fasten or loose, body motions, and visual control. In addition, standard data for a wide range of assembly tasks in one-of-a-kind and small-lot production are also available. These data consist of 290 time values in the following categories: fasten, clamp and unclamp, clean and/or apply lubricant/adhesive, assemble standard parts, inspect and measure, mark, and transport.

The third specialized system, MTM-UAS, is a third-level system. It was developed to provide a process description as well as to determine the allowed times for activities related to batch production. MTM-UAS can be applied to batch production activities that have the following characteristics: similar tasks, customized workplace, good levels of work organization, detailed instructions, and well-trained operators. The system consists of 77 time values in seven of the eight categories used in MTM-MEK: get and place, place, handle tool, operate, motion cycles, body motions, and visual control. MTM-UAS is about eight times faster to apply than MTM-1. At cycle times greater than 4.6 min, the standard calculated using MTM-UAS is within $\pm 5\%$ of that calculated from MTM-1, with a 95% confidence level (Niebel and Freivalds 1999).

3.2. Maynard Operations Sequence Technique (MOST)

The Swedish Division of H.B. Maynard and Company, Inc. developed Maynard Operation Sequence Technique (MOST) from 1967 to 1972. An outgrowth of MTM, MOST is a simplified system developed by Zandin (1980) as a result of an extensive review of MTM data. With MOST, analysts can establish standards at least five times faster than with MTM-1 without compromising accuracy.

The MOST system is based on the structure and theory of MTM-1 and MTM-2, and its systems can be applied to direct productive work as well as material handling, distribution, maintenance, and clerical activities. It is applicable for any cycle length and repetitiveness for as long as there are variations in the motion pattern from one cycle to another.

MOST utilizes larger blocks of fundamental motions than MTM-2. In contrast to MTM-2, which is built around 37 time values for describing manual work, MOST utilizes only 16 time fragments. MOST identifies three basic sequence models: general move, controlled move, and tool use.

- *General move:* The general move sequence is defined as the spatial free movement of an object through the air. This can account for as much as 35% of the work of a machine operator and even more for an assembly worker. A specific move sequence consists of three phases, each with a subset of parameters: get (A, B, G), put (A, B, P), and return (A). Thus, this activity is represented by the following sequence of seven letters or subactivities:

A B G A B P A

where A = action distance (primarily horizontal distance of hand or body motions)
B = bend (mainly vertical body motions)
G = grasp or gain control
P = position or place

The variations for each subactivity are indicated by a time-related index number to the applicable parameter. MOST uses index numbers of 0, 1, 3, 6, 10, and 16, corresponding to the relative difficulty of the parameter as shown in Table 14. Simply adding the index numbers and multiplying the sum by a scaled factor of 10 to yield the appropriate TMUs obtains the time value for the sequence. For instance, a move sequence is indicated by the index figure:

$$A_1B_0G_1A_1B_0P_1A_1$$

where A_1 = reach to washer with 12.7 cm (5 in.) travel
B_0 = no body motion
G_1 = grasp washer
A_1 = place washer with 12.7 cm (5 in.) travel
B_0 = no body motion
P_1 = place washer with a loose fit
A_1 = return to original position with 12.7 cm (5 in.) travel

1 TMU = .00001 hour	1 hour = 100,000 TMU
= .0006 minute	1 minute = 1,667 TMU
= .036 second	1 second = 27.8 TMU

The standard time for this sequence is $(1 + 0 + 1 + 1 + 0 + 1 + 1) \times 10 = 50$ TMUs.

- *Controlled move:* The controlled move sequence describe the movement of an object when it either remains in contact with a surface or remains attached to another object during the movement. It covers manual operations such as cranking, pulling a starting lever, turning a steering wheel, and engaging a starting switch. In controlled move sequences, the following parameters are considered: the previously defined action distance (A), body motion (B), gain control (G); and the new parameters move controlled (M), process time (X), and align (I). The controlled move parameters are further defined in Table 14.
- *Tool use:* The tool-use sequence covers the use of common hand tools. Cutting, gauging, fastening, and writing with tools are all covered by this sequence. The tool-use sequence embraces a combination of general move and controlled move activities. Additional parameters unique to

this activity are: fasten (F), loosen (L), cut (C), surface treat (S), record (R), think (T), and measure (M). These are further defined also in Table 14.

Two adaptations to the MOST work-measurement system are also in use: mini MOST and maxi MOST. Mini MOST measures identical, short-cycle operations, while maxi MOST measures long-cycle operations with significant variations in actual method from one cycle to another.

MOST is now available in a computer-aided format. This computerized version allows the analyst to retrieve suboperation data and perform the numerical operations to determine the standard of performance for the input characteristics of the method being analyzed. Another relatively new computerized version, ErgoMOST, enables the analyst to examine ergonomic problems in the workplace. ErgoMOST uses a biomechanical model to calculate stresses of push/pull and lifts, highlight awkward postures and repetitive body movements, and quantify the relative risk of the job using ergonomic stress indices. The computer software provides a utility function for identifying ergonomic recommendations and generating reports. The advantages of using a computerized system vs. manual applications are faster speed at which application can be made, minimized errors, and facilitation of numerical operations.

3.3. Macromotion Analyses

Standards International, Inc. has developed two specialized predetermined time systems: MICRO Motion Analyses and MACRO Motion Analyses. MICRO Motion Analyses is used for precise methods specifications and time standards, while MACRO Motion Analyses is for general-purpose data. They were developed to provide improvements over MTM and Work-Factor with much input from several of Standards International's clientele. Specifically, MTM and Work-Factor systems were not found to be adequate for some special types of motions, which entailed describing these motions and assigning appropriate time values using the individual user's judgement. Also, some analysts found difficulty in using the tables. These systems have been proven to be valid in thousands of applications,

having been used by Standards International for several years in conjunction with their consulting activities. The MACRO Motion tables are provided in Table 15.

3.4. Guidelines for System Selection

The choice of PTS system to use is generally characterized by the following:

1. *Terminology:* PTS terminology is primarily verbs that are used to denote the action taken by body members. Each system defines its own set of action words for the body motions covered by its time values. A term used in one system may or may not mean the same in another system. Therefore, in order to properly use any PTS system, one needs to have a clear understanding of the rules in the use of the system.
2. *Work pace:* Performance rating is not necessary when using predetermined motion times because motion–time values have been established in advance. For example, MTM data were leveled to represent a 100% or ''normal'' performance level.
3. *Methods description required:* The extent of methods description provided by the analyst is usually determined by the detail required by the system. Although a more detailed description can be provided, it is typical for the analyst to provide only the minimum required. Condensed systems tend to have a lesser degree of methods description than basic-level systems. The more methods description is required, the longer the time needed for analysis.
4. *Accuracy desired:* Some operations need very precise time values for manual operations. Precise measurement is possible with several of the detailed PTS systems where the work motions are well structured and predictable. On other operations, the work motions are unpredictable and it is impractical to make a detailed analyses. Tables are available that provide quick approximate time values.

Chicago, Illinois

5. *Speed and ease of application:* The length of the individual motion time or element time shown on the PTS tables determines the speed of application. The shorter the average element time, the greater the number of elements that need to be recorded and the longer it will take to perform the analysis. The ease of application is influenced by the clarity of the terminology and rules for the motions to be used. If the motion–time rules are unclear or inexact, a great deal of time may be lost in selecting the right time value from the PTS tables and the chances of errors will increase.

Exact understanding and correct application of predetermined motion times require careful training in the system employed. Guidance from a thoroughly trained practitioner in the system is preferable. Other major considerations include the type of work to be measured and the purpose of the measurement. Analysts must pick the system to fit the work and the need.

The ultimate guideline on the system to be used depends on management's objectives and beliefs. If management requires accurate performance measures, the system selected should be one that will give accurate values for the type of work to be measured. On the other hand, if management desires only approximate results, it is unnecessary to spend much time and effort in developing precise measurements.

4. STANDARD DATA

Many operations in a given system have several common elements. The element "walking," for example, is a component of many different jobs. When these jobs are timed, the same common

element is timed again and again. The function of the analyst would therefore be made much easier if the analyst had a set of data from which he or she could readily derive standard times for these common work elements without necessarily going into the process of timing each one. If, for instance, a standard time would be derived for the particular element "walking" and could be read directly from a table, this would not only reduce effort and cost but also lead to greater consistency in time estimations.

It is however, difficult to visualize a situation where all the possible elements making up a job could be timed and stored for future retrieval. We may therefore conclude that in practice it is better to restrict the number of jobs for which standard data are derived.

The reliability of the data can be increased if as many common elements as possible that are performed in the same way are grouped together from analysis and if a sufficient amount of accumulated or collected data on each element has been analyzed by a trained analyst. Making sure that all the factors affecting a certain element have been taken into consideration can further increase reliability.

Standard data refers to all the tabulated elemental standards, curves, alignment charts, and tables that are compiled to allow the measurement of a specific job without the use of a timing device.

These are element time standards, from time studies, that have been proven to be accurate and reliable. There are three levels of detail: MOTION, ELEMENTAL, and TASKS. The more refined the standard data element, the broader is its range of application. Although it has the widest usage, it takes longer to develop.

Motion-level systems are typified by MTM, MODAPTS, or other PTS systems. It involves times of the smallest component range from about 0.01 to 1 sec (e.g., reach, grasp, move, position, release). Elemental level system components vary from about 1 to 1000 sec. Components come from either PTS systems or time study (e.g., get equipment, polish shoes, put equipment away). Task-level component times range upward. Components come from elemental combinations, from time study, from occurrence sampling, or even from employee activity logs (e.g., loading of truck, driving truck 200 km [124 mi], unloading truck).

Components can either be constant or variable. It is critical in developing standard data to model variable components. Example of variable elements are include in Table 16, illustrating the levels of detail for standard time systems (Konz 1990).

The advantages of the standard data approach include the following:

1. Provides a catalog of facts, therefore saving time, effort, and money
2. Permits analysts to concentrate on methods improvement
3. Provides a quick and reliable tool for methods and standards evaluation
4. Allows standards to be determined prior to production
5. Results in more consistent standards among jobs, departments, and plants
6. Eliminates the subjective rating of the operator's speed performance

4.1. Developing Standard Time Data

The general approach in developing standard time data is as follows:

1. *Decide on the coverage:* The coverage should be restricted to one or more departments or work areas or to a limited range of processes within the system in which several similar elements, performed by the same method, are involved in carrying out the jobs.
2. *Break the jobs into elements:* In this case, try to identify as many elements as possible that are common to the various jobs.

TABLE 16 Levels of Detail for Standard Time Systems

Motions (Typical time range from 0.1 to 1 sec)			
Element	Code	Time, TMU	
Reach	R10C	12.9	
Grasp	G4B	9.1	1 sec = 27.8 TMU
Move	M10B	12.2	
Position	P1SE	5.6	1 TMU = 0.036 sec

Pack box	40

Variable elements (Typical time range 1 sec to 1000 sec)	
Element	Parameters
Walk	F(distance traveled, load carried)
Assemble bracket	F(number of holes, type of fastener)
Pack box	F(type of component packed, number packed)
Repair TV set	F(manufacturing of set, type of defect)

From S. Konz, *Work Design: Industrial Ergonomics,* 3d Ed. Copyright © 1990 Publishing Horizons, Inc. Reprinted by permission.

3. *Decide on the type of reading:* Decide whether to use readings based on stopwatch time studies or derived from PTS systems such as MTM.
4. *Determine the relevant factors:* There are factors that are likely to affect the time for each element. Classify them into major and minor factors.
5. To validate the standard time data, measure the time taken to perform the activity from actual observation.

4.2. Uses of Standard Data

For easy reference, standard data should be classified as either constant or variable data elements. Constant standard data elements should be tabulated. Variable data can either be tabulated or expressed as a curve or equation through formula construction.

Formula construction represents a simplification of standard data. It involves the design of an algebraic expression or a system of curves that establishes a time standard in advance of production by substitution of known values peculiar to the job for the variable element.

In this age of computers, standard data can be stored, retrieved, and accumulated. Several software systems have fundamental motion databases. The software can select, retrieve, and modify the appropriate motion or elements to generate a time standard. When properly applied, standard data allow the establishment of accurate time standards prior to actual production quickly and consistently. This is especially useful for estimating the cost of new products or work, preparing quotations and for subcontracting purposes and for establishing standards for indirect labor. In addition, this technique provides management with fair and proven satisfactory standards that help alleviate labor–management conflicts.

5. WORK SAMPLING

Among work measurement techniques, work sampling is one of the simplest available to time study analysts, yet it can be adapted to analyze complex and sophisticated patterns of work. Work sampling is a method of finding the proportions of total time devoted to various activities that constitute a job or work situation by random sampling. It is called by other names, including activity sampling, ratio-delay study, random observation method, snap-reading method, and observation ratio study.

The results of work sampling are effective for determining machine and personnel utilization, allowances applicable to the job and production standards. They are also particularly useful for analyzing nonrepetitive or irregularly occurring activities where no complete methods or frequency descriptions are available. Although the same information can be obtained using time study procedures, work sampling often provides this information faster and at considerably less cost.

Work sampling studies normally extend over a long period (two- to four-week period) to enable a comparatively large number of observations at random intervals to be taken. The percentage of time that a process is in a certain activity is obtained by the ratio of observations of the given activity to the total number of observations. Consider an analyst who takes 100 observations of the shop floor at random intervals over several weeks. It was observed that a certain machine was idle in 30 instances for miscellaneous reasons. The estimated idle time of this machine would then be 30% of the working day.

L. H. C. Tippett first applied work sampling in the British textile industry during the early 1930s. The technique was later introduced in the United States by Morrow (1941) under the name ''ratio-delay study.'' The technique did not gain wide acceptance at the outset. It gained attention when the name ''work sampling'' was coined by Brisley (1952) and Waddell (1952) at the time when increased attention was being paid to indirect labor. Also, the increasing number of able practitioners brought more discriminating use of the technique.

The accuracy of the data determined using work sampling depends mainly on the number of observations made, the length of the period under which the study was undertaken, and the conditions under which the study was conducted. Reliability and accuracy of information can only be obtained by using a sufficiently large sample size and a sampling period representing typical conditions.

5.1. Definitions and Objectives of Work Sampling Studies

Work is defined in work sampling studies as the specific activity being studied. It is further broken down into mutually exclusive categories of work. Exhaustive descriptions of the activity are defined so that an observation can be readily classified as belonging to one and only one category. Work sampling studies are not necessarily confined to studying work environments but can also be applied to other activities or events. They can be used to estimate, for example, the percentage of TV commercials that are about beer, percentage of people wearing glasses, and the like.

The theory of work sampling is based on the fundamental law of probability. That is, an event can either be present or absent at any given instant. This concept is presented in the following expression:

$$(p + q)^n = 1$$

where p = probability of a single occurrence
$q = (1 - p)$ = probability of an absence of an occurrence
n = number of observations

If the above expression is expanded according to the binomial theorem, the distribution of the probabilities obtained from the expansion is known as the binomial distribution. According to elementary statistics, as n becomes larger, the binomial distribution approaches the normal distribution. Since work sampling studies involve large sample sizes, the normal distribution is a satisfactory approximation of the binomial distribution. Rather than use the binomial distribution, it is more convenient to use the distribution of a proportion, with a mean p and a standard deviation of $\sqrt{pq/n}$ as the approximately normally distributed random variable.

The immediate goal of work sampling is to produce an estimate of the proportion of total time of each category of work a job has been subdivided. To establish a good estimate, two qualities must be taken into consideration: absence of bias and low variance.

A biased estimate is one that is apt to be too high or too low because of the procedure used to determine it. For example, if one work category is ''clean up'' and the analyst always leaves before the end of the shift, the estimate for this category will probably be too low because the observer may miss some occurrences that take place after he or she leaves the work area. Similarly, if workers are able to anticipate the times when observations are taken, the results of the study may be biased by the workers themselves. It is expected that workers will engage in productive activity as soon as the analyst is seen taking observations.

Work sampling studies are undertaken for various purposes, including obtaining general information, justifying proposed changes, and setting standards. Implicitly, obtaining general information allows management to achieve cost reduction through improved utilization of equipment or manpower and the identification of areas that need additional facilities. General information studies are also used to establish and monitor standards for indirect labor, in which case pace rating is done at the time of observation and some unit (or units) of output must be collected.

Work sampling studies are also frequently used to substantiate a subjective opinion. For example, the cost of installing a new materials-handling system may need to be justified with a reputable estimate of the amount of time currently being spent on materials-handling activities. Although the design of such a special-purpose study is easier than of a general information study, problems may arise with the objectivity of the analysts. The attempt to prove that the suggestion is justified may introduce bias into the estimates.

Stopwatch time studies and predetermined time standards are generally superior to work sampling for setting time standards on any well-defined job. However, work sampling can be used if other systems are not appropriate, such as for determining the unavoidable delay allowances. Because work sampling studies extend over several weeks, many different causes of delay can be captured and hence the information obtained can be very useful in establishing allowances.

Work sampling is frequently used to set job standards for jobs having irregular components that vary in the amount of time devoted to any one unit of output. For example, time for reconditioning and repairs on machines varies depending on the severity of the damage or cause of the breakdown. When a large sample population of jobs, representative of the population of future jobs, is observed, the established standard is expected to fit the mean of that population.

5.2. Work Sampling Methodology

Before any actual observations for work sampling study can be made, detailed planning must be done. Because work sampling is a flexible tool adaptable to both very simple and very complex studies, it is impossible to provide a single step-by-step procedure for designing and conducting a study that will fit all uses of work sampling. Hence, the following list of steps is presented as an example procedure rather than a comprehensive guide.

1. *Determine the scope of the study:* It is important to decide on the objective of the work sampling. Select the area to be studied and determine the method of measuring output. Make sure that the work sampling technique is indeed appropriate for the concern area.
2. *Brief personnel involved in the study:* Before beginning a work sampling program, the analyst must explain and solicit the cooperation of all the members of the organization who will be affected by the results of the study. Labor–management disputes are minimized by a careful explanation of the study's objective(s), methodology and deliverables and the possible effects the study will have on the members and their work.
3. *Determine the general method to be used to record data:* In general, this is easily determined by the available equipment. For example, electronic work-measurement machines with op-

tional work sampling software (see Section 2.2.1) can be extremely helpful in scheduling random observations, performance rating individual readings, and producing summary statistics. On the other hand, the purchase of a new computer system for a specific study can cause unreasonable delay.

4. *Classify the activity into work categories:* It is essential from the outset that the analyst be clear in his or her own mind about what he or she wants to achieve and why. Avoid ambiguity when classifying activities. Categories should be consistent with the end use of the study, initially recognizable by sight. Categories should be carefully defined so as to be mutually exclusive or nonoverlapping.
5. *Design the appropriate forms to be used for recording data:* An observation form to record the data to be gathered during the work sampling study should be designed. Because each work sampling study is unique from the standpoint of the total observations needed, the random times that the observations are made, and the information being sought, a standard form is not usually accepted. The best form is tailored to the study objectives. Figure 9 is an example of a work sampling study form.
6. *Carefully plan the frequency and interval of sampling:*
   (a) *Conduct preliminary sampling:* Make a small random observation (about 30 samples) to generate the approximate values of p and q for key categories of the activity.
   (b) *Determine confidence level and margin of error preferred for the study:* Confidence level is commonly pegged at 95%, 99%, and 99.9% with equivalent Z-values of 1.96, 2.56 and 3.3 respectively.
   (c) *Determine the sample size* n *and the time period of the study:* Determine the approximate number of observations that will be required and divide this by the number of days of the study and by the number of observations per round. This should give you the number of observation rounds per day that are needed. If this figure is unreasonably large, then either the number of days or the desired precision must be evaluated. It is better if the study period is long. This would better show normal fluctuations in production or work (e.g., if you need to make 300 observations, you should not make all 300 observations in one day but spread it over several observation days.).
   (d) *Select the necessary random times:* Using tables, calculators, or computers, establish the necessary random times when observations are to be taken. Although it is not necessary

to generate all predetermined times of observations for the entire study, the times for the first few days should be established to make the sampling method clear to the analyst. For example, random number generators built into most scientific calculators can be used to identify random observation times during which observations are taken.

7. *Take a short test study:* The first day's data, and possibly the second or third if they are recognized to contain bias, will need to be discarded (Pape 1992). Individual circumstances such as familiarity of the workforce with the work sampling and the cost of data collection will determine the length of the test study. Familiarity with the activity and the work sampling scheme should be established by the analyst.
8. *Make and record observations:* Adhere to the work sampling scheme. Gather and record data so that it can be used in multiple ways. Take note of other identifiers or qualifiers of work categories such as day of the week, location, shift, and the like. As the study progresses, control charts (see Section 5.3.4) can be set up to plot the daily estimates of event/activity occurrences to monitor one ore more of the p values for key categories.
9. *Process the results and reevaluate the precision of estimates:* The analysis of results can be calculated readily in the record sheet. It is possible to find out the percentage of effective time compared with that of delays, analyze the reasons for ineffective time, and ascertain the percentage of time spent by a worker, groups of workers, or a machine in a given work element. As the study progresses, confidence intervals can be calculated periodically. Results of this reevaluation may permit terminating the study early or may suggest that it be extended beyond the original planned length.
10. *Write up and file results:* The form of the report will depend on the objectives of the study. The report should contain the estimates of the proportion of time allocated to the various categories, the precision of these estimates, and the computed standard times. Reports should be retained for future reference in similar or follow-up studies.

5.3. Work Sampling Study Plans

Detailed planning must be done prior to taking actual observations. The plans start with a preliminary estimate of the activities on which information is sought. This estimate can frequently be made from historical data. However, if a reasonable estimate cannot be made, preliminary sampling of the work area for two or three days can be used as basis for these estimates.

Once preliminary estimates have been made, the analyst can determine the desired accuracy of the results expressed as a tolerance, or limit error, within a stated confidence level. Next, the analyst must estimate the number of observations to be made and determine the frequency of observations. Finally, the work sampling form on which to tabulate the data is designed, as well as the control charts used in conjunction with the study.

5.3.1. Determining the Observations Needed

To determine the number of observations needed or sample size, the analyst must set the desired accuracy of the results. The more observations made, the more valid the final results will be. Three thousand observations give considerably more reliable results than 300. However, because of the cost of obtaining so many observations and the marginal improvement in accuracy, 300 observations may be ample.

The size of the sample is therefore important, and we can express our confidence in whether or not the sample is representative by using a desired confidence level. It is customary to estimate precision by assuming a normal distribution for each of the p's and claiming $(1 - \alpha)$ confidence interval that

$$p - [Z_{\alpha/2}(\sigma_p)] < p' < p + [Z_{\alpha/2}(\sigma_p)]$$

The quantity σ_p is the standard deviation of the estimate p. The true variance of p depends on the manner in which observations are made. Hence,

$$p - Z_{\alpha/2}\sqrt{\frac{pq}{n}} < p' < p + Z_{\alpha/2}\sqrt{\frac{pq}{n}}$$

The quantity $Z_{\alpha/2}$ is a constant associated with the normal distribution such that the probability of any one normally distributed quantity being more than $Z_{\alpha/2}$ from its true value is less than α. The 95% confidence obtainable by using 1.96 and the 90% confidence obtainable by using 1.645 are the most frequently used in practice (see Table 17).

For example, a preliminary study estimates that a machine is in set up 25 times out of 100 observations. The interval with approximately a 95% of containing p' is then

TABLE 17 Confidence Levels and $Z_{\alpha/2}$ Values

Desired Confidence Level $1 - \alpha$	$Z_{\alpha/2}$
0.90	1.645
0.95	1.96
0.98	2.326
0.99	2.576

$$0.25 - 1.96\sqrt{\frac{(0.25)(0.75)}{100}} < p' < 0.25 + 1.96\sqrt{\frac{(0.25)(0.75)}{100}}$$

$$0.165 < p' < 0.335$$

There are two methods of determining the sample size: the statistical method and the nomogram method:

5.3.1.1. Statistical Method The formula used for this method is,

$$n = \frac{p(1 - p)(Z_{\alpha/2})^2}{e^2}$$

where p = percentage occurrence of the element being sought, expressed as a decimal
n = total number of random observations upon which p is based
e = precision (accuracy desired)
$Z_{\alpha/2}$ = constant associated with the normal distribution

Before we can use this formula, however, we need to have at least an idea of the value of p. The first step is therefore to carry out a number of random observations in the working area. Let us assume that some 100 random observations were carried out as a preliminary study and that these showed the machine to be operational 90% of the time. We thus use this approximate value as the estimate of p.

Choosing a confidence level of 95% with a 2% precision, the sample size is computed as:

$$n = \frac{(0.9)(0.1)(1.96)^2}{(0.02)^2} = 865 \text{ observations}$$

If the analyst does not have the time or capability to collect 865 observations but can only collect 500 data points, the above equation can be inverted to solve for the resulting error limit:

$$e = Z_{\alpha/2}\sqrt{\frac{p(1 - p)}{n}}$$

$$e = 1.96\sqrt{\frac{0.9(0.1)}{500}} = 0.0263$$

With 500 observations, the accuracy of the study is reduced to $\pm 2.63\%$. Thus, there is a direct trade-off between the error or accuracy of the study and the number of observations collected.

Alternatively, some practitioners find it easier to specify the *relative* precision of estimate desired in a study. Instead of setting $p \pm e$, a relative precision range of $p \pm Rp$. The proportion R is termed the relative precision in contrast to the precision e, which, for clarity, can be:

$$n_R = \frac{(1 - p)(Z_{\alpha/2})^2}{pR^2}$$

referred to as the absolute precision. Since $R = e/p$, substituting in the sample size formula yields:

$$R = Z_{\alpha/2}\sqrt{\frac{(1-p)}{pn}}$$

If a precision limit within 10% of e is desired (R = 0.10), the required sample size for the above example is:

$$n_R = \frac{(0.1)(1.96)^2}{(0.9)(0.10)^2} = 43 \text{ observations}$$

The determination of the sample size can be improved as data are gathered, and p can be estimated from the initial observations taken. After a study has been take for I days, the new sample size is determined by,

$$N(I) = \frac{p(1-p)(Z_{\alpha/2})^2}{e^2}$$

But n observations have already been obtained. Hence the additional number of observations necessary to produce the absolute precision e will be:

$$N(I) - n = n\left\{\left(\frac{p(1-p)}{n}\right)\frac{Z_{\alpha/2}{}^2}{e^2} - 1\right\} = n\left(V\frac{Z_{\alpha/2}{}^2}{e^2} - 1\right)$$

If observations are taken at an average rate of n/I observations per day, the additional days required to produce the absolute precision e will be equal to:

$$\text{Additional days} = I\left(V\frac{(Z_{\alpha/2})^2}{e^2} - 1\right)$$

For example, 5 days of data have produce 125 observations of a particular category during 500 total worker observations so that $p = 125/500 = 0.25$. If a precision of 0.02 with 95% confidence is desired, a total of 1801 (i.e., $n = [(0.25)(0.75)(1.96)^2]/(0.02)^2$) observations will be needed. Since 500 observations have already been taken, an additional 1301 observations will still be needed. Because it has taken 5 days to get the first 500 observations (or 100 observations/day), it is reasonable to expect that the study will require an additional 1301/100 = 13.01 days.

The above equation yields this figure immediately as:

$$5\left(\frac{(0.25)(0.75)(1.96)^2}{500(0.02)^2} - 1\right) = 13.01$$

Software for determining the observations required for work sampling study is readily available today. These programs perform all the statistical calculations required to determine sample sizes and confidence intervals. For example, calculations for 90%, 95%, and 99% confidence intervals for a sample can be calculated. They can also provide the number of samples necessary to achieve the desired confidence for a specified degree of accuracy.

5.3.1.2. Nomogram Method An easier way to determine sample size is to read off the number of observations needed directly from a nomogram developed by Moskowitz (1965) such as the one shown in Figure 10. To use the nomogram, we draw a line from the *element percentage occurrence* ordinate p (e.g., $p = 20\%$) to intercept the *precision interval* (accuracy required) ordinate D (e.g., $D = 0.04$ or 4%) and extend it until it meets the vertical line in the center of the exhibit. This intersection identifies the pivot point. Connecting that pivot point by a new line with the desired confidence level on the short scale, for example 95%, and extending this new line to the right-most scale yields the necessary sample size, which for this example is $n = 384$ observations. By a similar procedure, the nomograph can also be used to solve for precision or for confidence level, given the other three quantities.

5.3.2. Determining Observation Frequency

Two important principles are important in selecting observation times: randomization and stratification. Randomization is used to reduce the possible bias of periodic observations times introduced by worker anticipation of observation times. Observations must be taken at random times within a day and the total number of observations stratified by the number of days of the study period. Stratification is undertaken to reduce the variance of the estimates. It is also applied to obtain representativeness

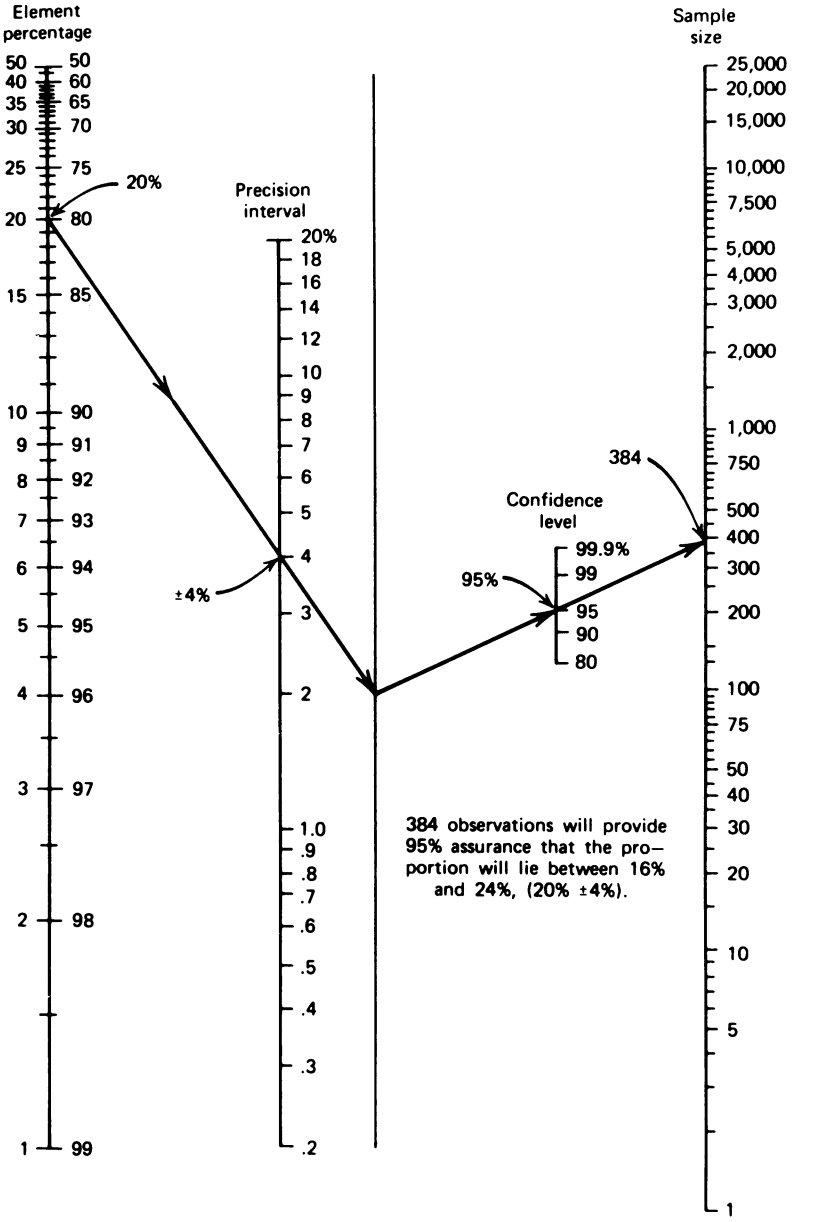

Figure 10 Nomograph. (Reprinted by permission from Moskowitz 1965)

of the sample based on various attributes. Spreading out the observations will give better estimates and a more representative result. It also allows the use of the data in multiple ways, such as identifying seasonal activities and reasons for unavoidable delays.

The frequency of the observations depends, for the most part, on the sample size and the time available to develop the data. If 3600 observations need to be completed in 20 calendar days, the analyst will need to obtain approximately $3600/20 = 180$ observations per day. Other factors that determine observation frequency include:

- Nature of work being observed
- Length of work cycle: short work (small assembly) or long work (major machining process)
- Pattern of work: repetitive or irregular; peak and slump season; cyclical work
- Number of analysts (or other constraining resources) available

Determining a target length for a work sampling study requires rational judgment on the part of the analyst. The study should be long enough to include normal fluctuations in production. The longer the overall study, the better the chance of observing average conditions. However, extending the study over an infinitely long time span may prove useless and costly. Usually, work sampling studies are made over a period ranging from two to four weeks.

After determining the number of observations per day, the analyst must select the actual time needed to record the observations. To obtain a representative sample, observations should be taken at all times of the day. There are many ways of randomizing the occurrence of the observations. One method is to use tables of random numbers published in many handbooks and textbooks or the simple random number generators programmed in many hand-held scientific calculators.

Any type of watch can be used to identify the predetermined times of observations. Computers can also be used to determine the schedule of daily observations. Another alternative to help analysts decide when to make daily observations is a random reminder. A pocket-sized instrument beeps at random times, letting analysts know when to make the next observation. Electronic clipboards with optional work sampling software can also be extremely helpful. For example, the OS-3 Plus recorder (see Section 2.2) is available with a work sampling program that permits the scheduling of random observations and the performance rating of individual readings. It also produces a summary statistics and formatted printed reports.

In one approach, the analyst may select numbers from the statistical table of random numbers, ranging from 1 to 480. If each number carries a value, in minutes, the numbers selected can then set the time, in minutes, from the beginning of the day to the time for taking the observations. For example, the random numbers 25 and 152 would mean that the analyst should make a series of observations 25 minutes and 152 minutes after the beginning of the shift. If the day begins at 8 a.m., then at 8:25 a.m., an inspection of the work area would begin, followed by an observation made at 10:32 a.m.

Another approach considers four adjacent digits in the random number table. The first digit is the day identifier, with numbers 1 to 5 identifying the workday Monday through Friday. The second digit is the hour identifier, with numbers 0 to 8 added to the starting time of work (e.g., 7:00 a.m.). The third and fourth digits are the minutes identifiers, with numbers between 0 and 60 acceptable.

Computers can also be used to determine the schedule of daily observations. For example, work sampling programs for the DataMyte collecter described in Section 2.2 can print random time schedules.

Moder and Kahn (1980) propose a decision process for selecting a sampling procedure for each day of a work sampling study (see Figure 11). They assume that observations will be stratified by days under all plans. They define four sampling strategies: systematic random sampling (SyRS), stratified continuous random sampling (StCRS), stratified noncontinuous random sampling (StNCRS), and restricted random sampling (RRS).

Systematic random sampling is practiced if, when r observations per worker are to be taken during a day of t min duration, a time is selected at random during the first t/r min of the day. Subsequent observations are made at intervals of exactly t/r min.

In stratified, continuous random sampling, the use of the word "continuous" implies that the observer is assigned 100% to work sampling and thus works "continuously" at work sampling. The observations are still snap observations, and no continuous time study is implied. Randomization is achieved by (1) random selection of the starting point of each observation round (numbers can be assigned to each station and a number selected at random), (2) random selection of several different routes (assign numbers to various feasible routes), and (3) coin flip determination of the direction of route will be taken (clockwise or counterclockwise). The degree of randomization needed to deter worker bias can be decided by those who are familiar with the job process being studied.

Although Moder and Kahn (1980) use the notation "stratified, noncontinuous random sampling" for the procedure when a single random time is selected during each t/r min interval during the day, it could also apply to the practice of selecting 3 random times in each hour when 24 times are desired during an 8 hr day. If observation rounds are being made, routes can be randomized as with StCRS.

In restricted random sampling, "random sampling" implies selection of r times at random from the total time period of duration t. When an observer is making a full observation round and two times are selected to close together to allow completion of the earlier round, the restriction implies that the second time *selected* is rejected and replaced with another random time. Since this procedure is adopted at the beginning, no bias is induced by the method, and variance may be slightly decreased.

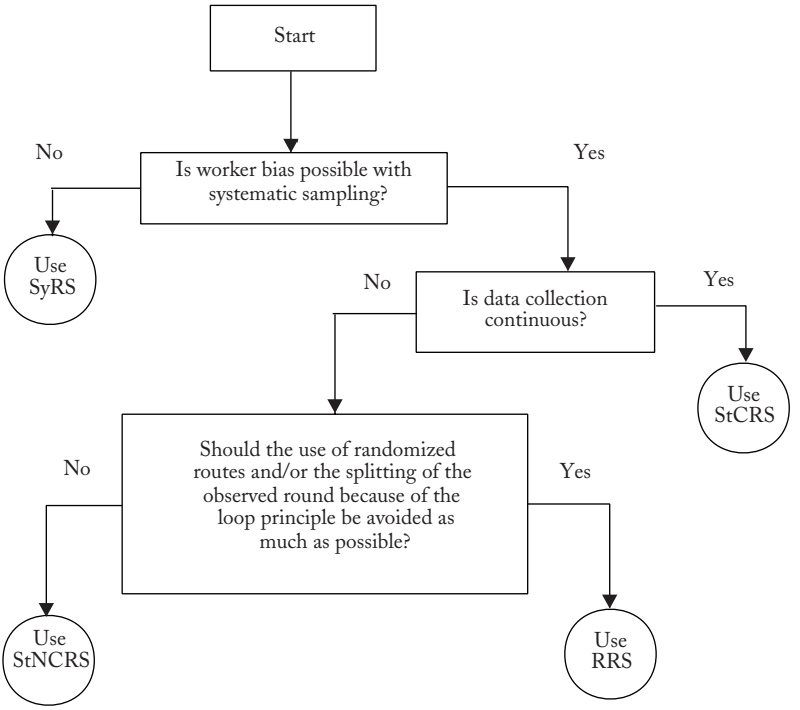

Figure 11 Decision Tree for the Selection of a Sampling Procedure for Work Sampling Studies. (From Pape 1992)

5.3.2.1. Loop Principle When observation rounds of approximately 5 min or more are being made, some bias will be incurred if the loop principle is not recognized. A time selected by any of the preceding procedures is customarily taken to be the starting point of an observation round to be made during a specific period (a day for RRS and SyRS, t/r min or hr for StNCRS). However, to keep the round within the specific period, that round cannot be observed during the first few minutes of the period. Thus, biases can be induced when end and beginning activity differs from midperiod activity.

To reduce this source of bias, consider the last observation round of the period as extending into the first few minutes of the same day. That is, if a round takes 10 min, and if the last observation time of the day is 3 min before closing, the last 70% of the round is conducted during the first 7 min of the workday and before the ''first'' round of the day begins.

If a work sampling study is being conducted of only a few workers or machines, the loop principle can usually be ignored.

5.3.3. Observations and Data Recording

The methods of collecting work sampling data vary with the size and the purpose of the study. Work sampling data can be collected by one of three methods: self-observation, observation by a trained analyst or the supervisor, and use of video camera equipment.

5.3.3.1. Self-observation If the purpose of a work sampling study can be achieved simply by having the workers who are being studied become aware of their own work, self-observation can be effective. The time for an observation can be signaled by a auditory signal (buzzer or beeper). The operator records on a simple ledger what he or she was doing opposite the number of the observation at the time the signal was heard. Although operators are expected to know exactly the work categories of their jobs, estimates produced by this method are subject to a great deal of bias. Instead, this technique is used more effectively among semiprofessional personnel, who are more conscientious about the effectiveness of their time usage.

5.3.3.2. Observation by a Trained Analyst or Supervisor In making the observations, the analyst must anticipate the expected recording. The observation should be made at the same point a given distance from the work area. If the operator is observed to be idle, the analyst must determine the reason for the idleness.

Recording consists of simply making a stroke in the form of the appropriate work element at the proper and predetermined time. No stopwatches are used. The analyst should avoid recording what has just happened or what will be happening. Rather, the analyst should record what is actually happening at the exact moment of the observation.

5.3.3.3. Observations from a Video Camera Unbiased work sampling studies involving only people can be performed using a video camera (Niebel and Freivalds 1999). The arrival of an observer at the work area may influence the activity of the operator. The operator becomes productively engaged as soon as the analyst is seen approaching the work area. However, it is essential that the analyst reviewing the film be familiar with the process being studied. Despite the advantage of replay, it is possible that in some instances some observations can be ambiguous or omitted.

5.3.4. Using Control Charts

Control chart techniques used in statistical quality control activities can be applied to work sampling studies. In particular, the *p*-chart can be used by time study analysts because work sampling studies deal with percentages or proportions (see Chapter 69 for more information on control charts). A control chart similar to Figure 12 (Niebel and Freivalds 1999) can be constructed by plotting the p' values for each day of observation.

In statistical process control, *p*-charts are used to indicate whether or not the process is control. In general, analysts use the $\pm 3\sigma$ limits as control limits on the *p*-chart. In a similar manner, time study analysts can use this chart to indicate whether work sampling data fall within the $\pm 3\alpha$ limits of the estimate p. In other words, if a sample has a value that falls outside the $\pm 3\sigma$ limits, the sample is said to be out of control.

As in statistical control work, points that fall outside the upper or lower control limits may be of statistical significance. For example, two successive out-of-control points may indicate that the population being observed has changed. That is, conditions in the work environment may have changed or process/work improvement been realized. Control charts can show the progressive improvement work, thus triggering the need to change the standards applied.

5.4. Establishing Standard Times

The computational requirements of a work sampling study are very simple. First, the observed time (OT) for a given work category or element is calculated from the working time divided by the number of units produced during that time:

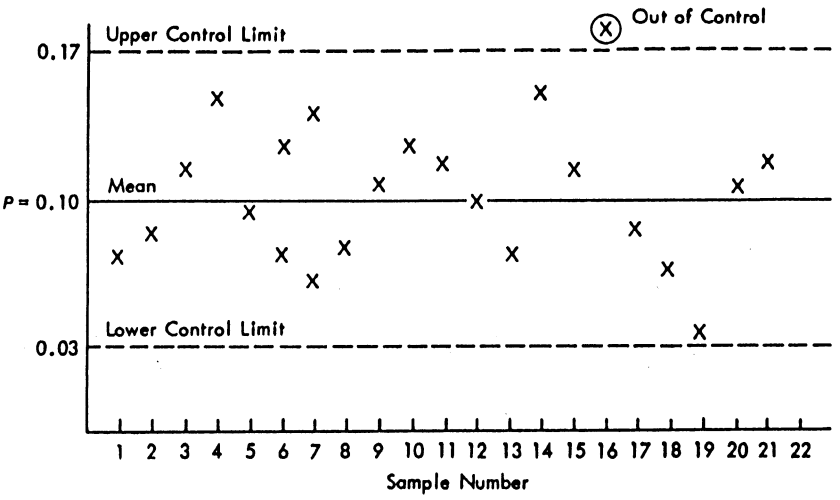

Figure 12 Sample Control Chart. (From B. Niebel and A. Freivalds, Methods, Standards, and Work Design, 10th Ed. © 1999 McGraw-Hill Companies, Inc. Reprinted by permission.)

$$\text{OT} = \frac{Tn_i}{Pn}$$

where T = total time
n_i = number of occurrences for element I
n = total number of observations
P = total production for period studied

The normal time (NT) is obtained by multiplying the observed time by the average rating:

$$\text{NT} = (\text{OT})\frac{R}{100}$$

where R = average rating = $\sum \frac{R}{n_i}$

Finally, the standard time (ST) is found by adding allowances to the normal time:

$$\text{ST} = \text{NT}\ (1 + \text{allowance})$$

To illustrate, a drill press operator was observed to have drilled 350 units during an 8 hr workshift. The work sampling study recorded that this represented 92% of her total working day (working + idle) with an average rating of 110%. Applying an allowance of 15%, the standard time for the drilling process is obtained by:

$$\text{ST} = \text{OT}\left(\frac{R}{100}\right)(1 + \text{allowance})$$

$$\text{ST} = \left[\frac{480}{350} \times 0.92\right]\left[\frac{110}{100}\right](1.15) = 1.596 \text{ min}$$

5.5. Computerized Work Sampling

With the aid of a computer, the total cost of work sampling studies can be reduced by approximately 35% because of the high percentage of clerical effort relative to actual observation time (Niebel and Freivalds 1999). The majority of the clerical effort involved in summarizing work sampling data is significantly reduced. Computer software can be applied to determine the sample size and sampling scheme (number of daily observations required, number of trips and the time of day for each trip, etc.), calculate percentages and accuracy, plot data on control charts, and summarize daily and cumulative results.

One such computer software is the mechanized activity sampling technique (MAST), developed to automate the clerical work and mathematical calculations involved in work sampling studies. MAST also assists the analyst in computing the element, developing performance ratings, checking statistical accuracies, preparing and maintaining control charts, and extrapolating the data into equivalent staffing needs and/or machines and annual costs.

Users of MAST claim the following benefits of the automated system (Niebel and Freivalds 1999):

1. Reduction of clerical routines
2. Results of the study are achieved more rapidly and presented in a professional format
3. Reduction in the cost of conducting the work sampling study
4. Improved accuracy in computations
5. Fewer errors committed by analysts
6. Incentive to make greater use of the work sampling technique

6. MEASUREMENT OF INDIRECT LABOR OPERATIONS

Most of the advances in work measurement have dealt mainly in the measurement of direct labor. The emphasis during the first half of the 20th century was on controlling costs due to direct labor. Because the indirect components of cost were highly variable and difficult to trace, the quantitative skills needed to analyze many problems associated with the indirect components were not available.

Employees classified under indirect labor include shipping and receiving, trucking, inventory, inspection, material handling, toolroom, and janitorial and maintenance. Expense labor positions are found in office operations such as clerical, accounting, sales, management, and engineering.

The rapid growth in the numbers of office workers, maintenance workers, and other indirect and expense employees is due to several factors. First, the increased mechanization of industry and the

complete automation of many processes, including the use of robots, have decreased the need for craftsmen and operators. This trend toward increased mechanization has resulted in a huge demand for electronics specialists, electricians, technicians, and other service personnel. The design of complicated machines and controls has also resulted in greater demand for engineers, designers and draftsmen.

Second, the tremendous increase in paperwork brought about by legislation is responsible to a large extent for an increasing need for clerical personnel.

Third, office and maintenance work has not been subjected to the methods study and technical advances that have been applied so effectively to direct labor in industrial processes. With a large share of most payrolls earmarked for indirect and expense labor, progressive management is beginning to realize the opportunities for the application of methods and standards in this area.

6.1. Indirect and Expense Work Standards

The tools used for establishing time standards for indirect and expense work are the same as those used for direct work: time study, PTS systems, and standard data and work sampling. However, because of the high degree of variability characteristic of most indirect and expense work, time would not permit using stopwatch time studies for each and every standard developed. Standards will usually be established using a combination of techniques depending on the nature of the work. Other methods such as queuing theory and Monte Carlo simulation (see Chapter 100 for more on queuing models) are frequently used to determine delays due to waiting time in service facilities such as the stockroom or tool crib.

As for other work, methods analysis should precede work measurement in all indirect work operations. After completion of a thorough methods program, development of standards can be performed. Once standards have been developed for most of the common elements used in indirect work, time standards for specific tasks can be calculated quickly and economically.

All indirect and expense work is considered a combination of four divisions: (1) direct work, (2) transportation, (3) indirect work, and (4) unnecessary work and delays.

Direct work is that segment of the operation that discernibly advances the progress of work. For example, in operating a fax machine, the direct work elements may include insert document into paper feed, locate and dial telephone number, press send button. Such direct work can be measured using conventional techniques such as stopwatch time study, standard data, and fundamental motion data. Fundamental motion data systems such as Work-Factor, MTM-2, and MOST have been widely applied in establishing standards.

Transportation is the work performed by movements during the course of the job or from one task to another. Typical transportation elements include walk, carry load, ride elevator, push cart, and ride on motor truck. Transportation elements can be measured using standard data and work sampling.

The indirect work portion of indirect or expense labor is activities that cannot be evaluated by physical evidence in the completed job. It can be further classified into three categories: (1) tooling, (2) material, and (3) planning.

Tooling work elements include the acquisition, disposition, and maintenance of all tools needed to perform an operation. Typical elements under this category include getting and checking tools and equipment, cleaning tools, repairing and calibrating tools, and returning tools to the tool crib. Tooling elements can be measured using work sampling or standard data.

Material work elements involve acquiring and checking the material used in an operation and disposing of scrap. Examples of material work elements are getting materials, making minor repairs to materials, and picking up and disposing of scrap. Like tooling elements, material work elements can be measured. Use historical data to determine their frequency.

The planning elements represent the most difficult area in which to establish standards. Consulting with the supervisor, planning work program, inspecting, checking, and testing are common examples. In this case, work sampling is the most practical technique to provide a basis for determining the time required to perform the planning elements.

Unnecessary work and delay encountered in indirect and expense work are mainly due to queues. Workers need to stand in line at the tool crib, the stockroom, or the fax machine, photocopy machine, or some other equipment. Through the application of queuing theory, analysts may be able to determine the waiting time incurred in such activities as well as determine the optimum number of service facilities to improve service quality.

Where maintenance and other indirect operations are numerous and diversified, efforts have been made to reduce the number of time standards for indirect operations through universal indirect labor standards (UILS). The principle behind UILS is the assignment of the major proportion of indirect operations to appropriate groups (Niebel and Freivalds 1999). Each group has its own standard, which is the average time for all indirect operations assigned to the group. For example, the following indirect operations replacing defective part, replacing limit switch, and repairing door may represent group A. The standard time for any indirect operation performed in group A may be set at 45 minutes.

This time represents the mean ($\bar{x}$) of all jobs within the group and the dispersion of the jobs within the group for $\pm 2\sigma$ is some predetermined percentage of $\bar{x}$.

Three principal steps in introducing a universal indirect labor system, called time slotting, are:

1. Determine the number of standards (groups or slots) to do a satisfactory job. (20 slots should be used when the range is up to 40 hours).
2. Determine the numerical standard representative of each group of operations contained in each slot.
3. Assigning the standard to the appropriate slot of indirect labor work as it occurs.

The first step is to determine good benchmark standards, based on measurements of an adequate sample of the indirect labor for which the UILS system is being developed. A relatively large number of standards (200 or more) that is representative of the entire population of indirect needs to be established. Competent analysts can develop these measured benchmarks using work measurement techniques.

After the benchmarks are established, they are then arranged in decreasing order (from shortest to longest time). If there are 20 slots, and if a uniform distribution is used, the time standard for the first slot (UILS one) is computed by calculating the mean of the first 10 benchmark standards. Similarly, the value of UILS two is taken by the mean of benchmark standards 11–20. Succeeding UILS slots will be calculated on the successive 10 benchmark standards. Hence, the UILS 20 would be equal to the mean of benchmark standards 191 through 200. Engineers have used this procedure extensively in the development of UILS.

Another approach to designing a UILS system is cluster analysis (Knott 1992). Here, given a distribution of job times, the time boundaries and slot times can be determined to give a priori criterion. This might be, for example, absolute percent error calculated over a time period of one week.

$$\text{Absolute percent error} = \frac{\text{actual standard time} - \text{universal standard time}}{\text{actual standard time}} \times 100$$

More reliable UILS result from using the normal distribution rather than the uniform distribution. For 20 slots, the 200 standards would not be assigned as 10 per slot. Rather, the standard normal variable would be divided into 20 equal intervals. For example, the standard normal variable may have a truncated range of:

$$-3.0 \leq z \leq 3.0$$

which accounts for 99.87% of the area under the normal curve. The range of each interval would be 0.3. The benchmark standards used in the compilation of the mean of each of the 20 slots would equal:

$$\frac{P(z \in \text{interval})(200)}{0.9987}$$

Slot number 1 and 20 would have:

$$\frac{P(-3.0 \leq z \leq -2.7)(200)}{0.9987} = \frac{P(2.7 \leq z \leq 3.0)(200)}{0.9987}$$

Investigations have shown that the distribution of job times in practice is not normal but has a "positive skew" (Knott 1992). A typical distribution of job times is shown in Figure 13. A simple slotting scale has been constructed into this distribution.

To establish standards on indirect and expense work, Table 18 is presented as a guide for choosing the appropriate method.

6.2. Advantages of Indirect Work Standards

Applying standards on indirect work offer distinct advantages to both the employer and the employee. Some of these advantages are:

1. Installation of standards leads to many operating improvements.
2. Establishment of standards results in better performance.
3. Indirect labor costs are related to the workload, regardless of fluctuations in the overall workload.

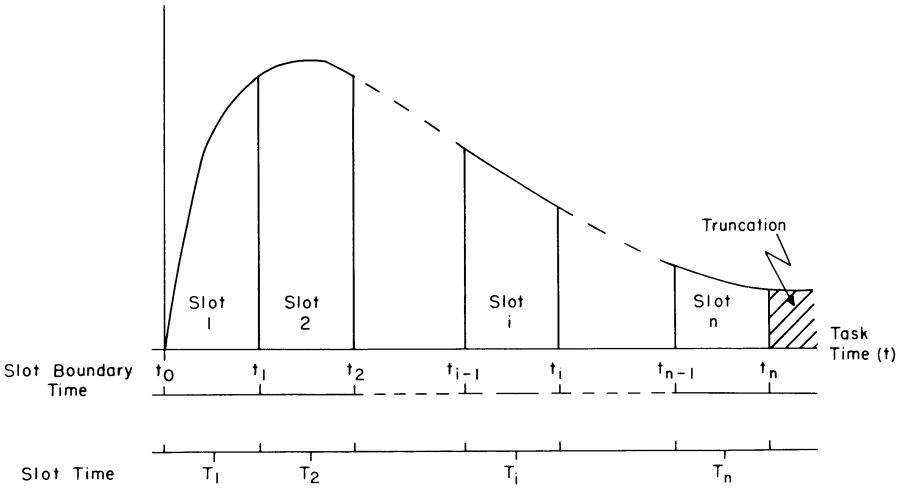

Figure 13 Elements of a Time-Slotting Scale. (From Knott 1992)

4. Labor loads can be budgeted.
5. The efficiency of various indirect labor departments can be determined.
6. The costs of such items as specific repairs, reports, and documents are allocated.
7. System improvements can be evaluated prior to installation.
8. The establishment of incentive wage-payment plans on indirect work is allowed.
9. Accurate planning and scheduling of indirect labor leads to timely performance.
10. Employees require less supervision with the establishment of standard measures of performance.

TABLE 18 Guide to Establishing Indirect Labor and Expense Standard

Indirect and Expense-Type Work	Recommended Method of Establishing Standards
Routine maintenance. Work standards 0.5 to 3 hr	Standard data, MTM-2, MTM-3, Work-Factor, MOST, macromotion analyses
Complicated maintenance, standards 3–40 hr	Slotting based on universal indirect labor (UIL) standards
Shipping and receiving	Standard data, MTM-2, MTM-3, Work-Factor, MOST, macromotion analyses
Tool room	Slotting based on UIL standards
Inspection	Standard data, MTM-2, Work-Factor, MOST, macromotion analyses
Tool design	Slotting based on UIL standards
Buying	Standards based on historical records, analysis, and work sampling
Accounting	Standards based on historical records, analysis, and work sampling
Plant engineering	Standards based on historical records, analysis, and work sampling
Clerical	Standard data, MTM-2, Work-Factor, MOST, micro- and macromotion analyses
Janitorial	Standard data, slotting based on UIL standards
General management	Standards based on historical records, analysis, and work sampling

From B. Niebel and A. Freivalds, *Methods, Standards, and Work Design,* 10th Ed. © 1999 McGraw-Hill Companies, Inc. Reprinted by permission.

Since indirect labor operations are difficult to standardize by virtue of their nonrepetitive characteristic, they are infrequently subjected to methods analysis. Consequently, this area usually offers a greater potential for cost reduction and increasing profitability through methods and time study than shop-floor operations. Methods improvement, along with employee training, makes it possible and practical to establish standards on indirect labor operations.

Systems and Facilities Design

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

CHAPTER 55
Facilities Size, Location, and Layout

JAMES A. TOMPKINS
Tompkins Associates

1. INTRODUCTION

Site selection for a new factory or distribution center is a complicated and arduous process and must be based on the strategic vision of the organization, the requirements of the supply chain, and the needs of the customer. Determined both quantitatively and qualitatively, proper site selection usually involves upper management, since the level of success of the new facility will have a major impact on the bottom line of the organization.

The purposes for site selection are relocation, expansion, and/or decentralization. Motivations for selecting a site can vary depending on the purpose (e.g., the urgency of the matter may eliminate some complex quantitative assessment or some site research), but we will treat the process in the aggregate, touching on generic steps taken to make a good decision.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

Many stakeholders will give different reasons for selecting a site for a new industrial facility. When the word gets out that your organization is in the market, several individuals and companies eager to help you find the right location will be in contact. The Chamber of Commerce, realtors, local and state governments, and developers will offer substantial incentive packages to locate in their location.

The objective of all site selections is to turn a property or an existing facility into a weapon of competitive advantage. As Figure 1 indicates, an organization must transition from a big-picture analysis of its strategies and mission (macro analysis), to an assessment of addressable locations (micro analysis), to the construction phase. Though construction can happen without the comprehensive analysis discussed in this chapter, competitive advantage is rare when the upfront evaluation work is not done completely.

Among the more common mistakes made by corporations when selecting a site are:

- *Proceeding with a site search without a plan for the new facility:* Do not start looking until you know what you are looking for. You must establish criteria for the site's requirements. This will tell you what size warehouse your organization needs, what its footprint should look like, what the column spacing should be, dock and road requirements, etc. From this information, the site selection process can be narrowed to those properties that will accommodate the footprint of the original building design, as well as any planned expansions. Do not try to fit a round peg into a square hole. Immediately eliminate sites that do not accommodate the facility as designed.
- *Allowing premature publicity:* There are advantages and disadvantages to keeping your search for a site confidential as long as possible. Announcing your plan to the public may result in free publicity, support from local communities, and a head start on employee recruiting. On the other hand, announcing your intentions may drive up land prices, open the door to an onslaught of people and organizations hoping to influence your decisions, and feed the rumor mill in a way that might be detrimental to the company.
- *Failure to use a good criteria checklist:* The only way to find a site that fits your specific needs is through the use of a detailed customized criteria checklist. If you are using a one-page document, you've left out a lot of important details. To be an effective tool, the checklist must be as comprehensive as you can make it, and should include both long-and short-term economical, community, and quality of life factors.
- *Failure to align project plans with future requirements and technological trends:* Do not build for today or tomorrow; build for 2, 5, or even 10 years from now. How will the new facility accommodate increased sales, need for crossdocking, and different product lines? These are questions to be answered before you move, rather than after occupying the building.
- *Failure to accurately estimate the true cost of doing business at each proposed location:* The lowest cost site may not be the most economical place to do business. Your comparison of sites must include a thorough and detailed analysis of projected production costs. Do not let yourself be surprised by the cost of services and utilities like water, electricity, waste disposal, local special taxes, or site security. These factors can have a dramatic long-term cost impact on the bottom line.
- *Giving consideration to intangibles at the wrong time:* The purpose of the macro analysis is to precisely determine how best to utilize the site for competitive advantage. Allowing personal preferences about location and style only serves to shift the emphasis of the process from strategic and organizational requirements.
- *Failure to use consultants to supplement staff skills:* Collecting data on possible sites, accurately projecting operating costs, and evaluating incentive packages is a time-consuming process that cannot be rushed. Few owners have the time or in-house resources to do this job correctly. Facilities-planning consultants can collect the data and provide an unbiased source of advice on each facet of the site-selection process. With a wide breadth of knowledge and accessibility to time-saving planning tools, consultants make for an efficient and effective means of moving the process forward.

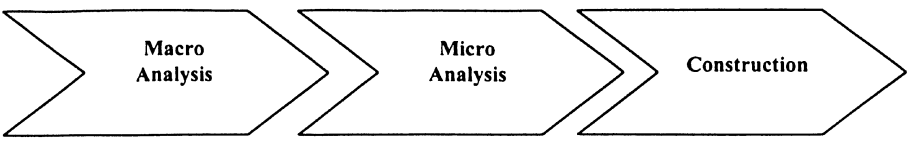

Figure 1 The Progression from Concept to Reality.

2. PROCEDURE—THE MACRO ANALYSIS (LSMP)

As Figure 2 illustrates, the macro analysis methodology is comprised of five parts:

- Organizations must envision themselves as an element of a supply chain that requires continuous improvements among all of its links, as opposed to the siloism of the past. Future competititve advantage hinges on examining the continuous improvement process as it relates to the aggregate supply chain.
- Customer satisfaction is the understanding that customers' perceptions and expectations rather than the organization's idea of what the customer wants, are key to profit maximization.
- Network analysis is the determination of the distribution plan that will provide the customer with the right goods in the right quantity at the right time and place while minimizing distribution costs through the correct balance of warehouses and transportation costs.
- The strategic master plan is the expression of future space, labor, and equipment requirements in order to analyze and justify alternative plans.
- Team selection is the establishment of a cross-functional group of people, internal and external to the organization, who bring their talents to the process.

2.1. Supply Chain Needs

The vision for the future of the site and for the aggregate supply chain must address the concepts of change and integration. Customer requirements, commerce structures, and market demands fluctuate faster than organizations can adapt to them. By understanding the impacts of change and integration and designing facilities around these concepts, organizations can improve chances for competitive advantage.

- *Total integration:* An ultimate customer focus where material and information flow will be designed into the system and the supply chain will be fully optimized.
- *Blurred boundaries:* Traditional customer/supplier and manufacturing/warehousing boundaries will be shifted to simplify, add value, and increase responsiveness.
- *Consolidation:* Efficient and effective transportation infrastructures will allow for high levels of customer satisfaction from fewer points along and throughout the supply chain.
- *Reliability:* Robust, redundant, and fault-tolerant systems will enable organizations to increase up time.
- *Maintainability:* A 24/7 schedule will mandate increased predictive maintenance and self-assessment.

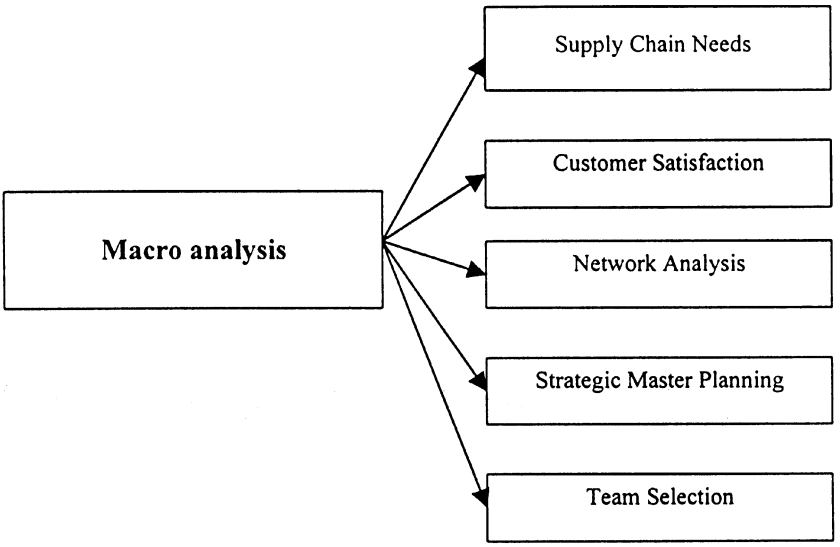

Figure 2 The Macro Analysis.

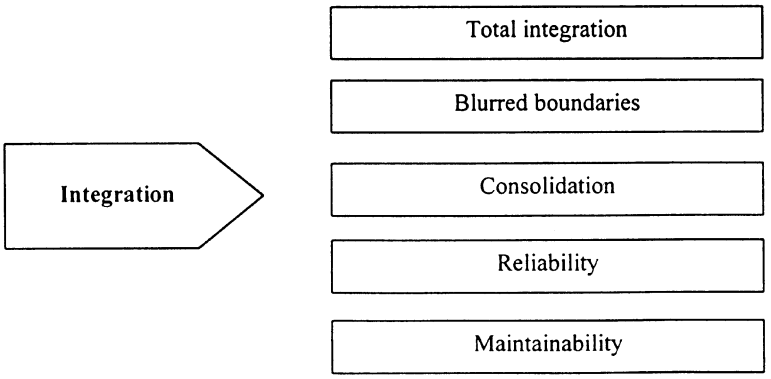

Figure 3 The Challenges of Integration.

- *Flexibility:* Addressing change in product variety and rate of new product introductions through soft, friendly systems that handle products of different sizes and weights.
- *Modularity:* Accommodating the change in product volumes through systems that operate at a variety of rates.
- *Upgradeability:* Gracefully incorporating technology, process, and methodology changes into current systems.
- *Adaptability:* Responding to systems requirements on the fly.
- *Selective operability:* Operating in segments without degradation of the overall supply chain.
- *Supportability:* Maintaining the system while automated and nonautomated elements are brought online.

2.2. Customer Satisfaction Standards

Customer requirements are changing constantly, and the one-size-fits-all philosophy is obsolete. The growth of e-commerce has affected the size (decreasing) and frequency (increasing) of orders. In the end, customer perception of quality, which may or may not be an accurate depiction of organizational quality, drives the success of the business. The needs of the customer must be the focus.

Customer satisfaction is a means by which companies attempt to differentiate their products, keep customers loyal, improve profits, increase sales, and thus become the supplier of choice. Customer satisfaction is not based on what the supplier does; rather, it is based on what customers think the supplier does. Since customer satisfaction is an ongoing process of meeting and exceeding expectations, organizations must embrace continuous improvement and always look toward the consumer for affirmation.

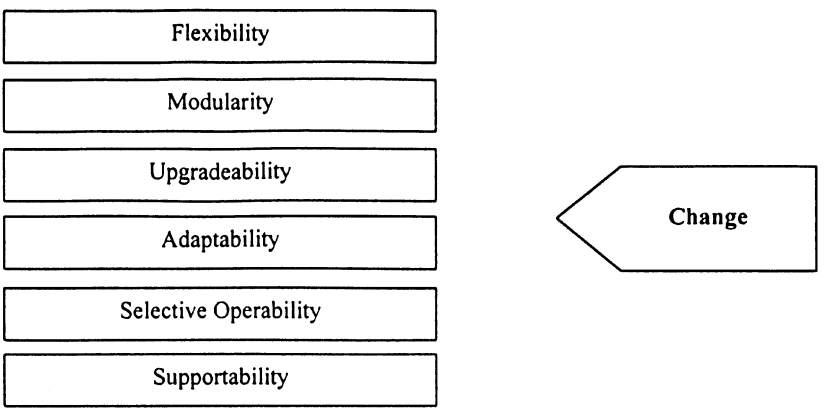

Figure 4 The Challenges of Change.

How does customer satisfaction factor into the macro analysis stage of site selection? Beyond product quality and price, it impacts such processes and methodologies as:

- On-time delivery: From where is the customer order originating? Is the network configuration such that the customer is receiving a shipment as quickly as possible?
- High fill-rate percentage: Is the site large enough to accommodate a distribution/warehousing/manufacturing center that promptly produces, stores, and ships merchandise?
- Ability to adapt: Does the site have the potential to adapt to peak/seasonal shifts?

Customer satisfaction is achieved through an understanding of requirements and expectations. Organizations should ask themselves the following questions when defining their strategic master plan:

- What are the pipeline requirements and expectations?
- What is the organization's impact on achieving customer satisfaction in the supply chain?
- How do the customers perceive current operations, processes, and resources?
- Are there gaps between what is currently possible and what is currently being done for customer satisfaction?
- What service offerings can be created based on pipeline requirements?
- How will the organization measure, track, and improve performance?

2.3. The Strategic Master Plan and Establishing a Baseline

The strategic master plan (SMP) is a seven-step process from which a baseline, or foundation on which costs are analyzed, is developed. Without a baseline, site selection is based on ''crystal ball'' methodology, and crystal balls are known to give wrong answers from time to time.

Step 1: *Document the existing operation:*
- What are your operations costing you now?
- What are your current throughput and storage requirements?
- How much safety stocks does your operation keep now?
- What are the documented standard operating procedures? How do they compare with what actually happens in the warehouse?
- What policies are in place to govern the acquisition, the utilization, and the disposal of resources?
- Establish a baseline against which recommendations for improvements can be measured.

Step 2: *Determine facility requirements for a specified planning horizon:*
- What will your operations cost in the next three years? Five years?
- What will be your processing, material handling, and storage requirements in the next three years? Five years?
- Is there sufficient safety stock to meet the forecasted demand?
- What are your firm's objectives? What resources are needed to meet those objectives?
- How do your firm's objectives take into account the dynamic, global business world?
- What is the impact of customer ordering changes on order picking requirements?

Step 3: *Identify deficiencies in current operations:*
- Are your firm's customers requiring faster delivery, more variety, and more adaptability?
- Does your firm succeed in delivering on-time?
- Are existing facilities, methods, equipment, and/or labor the most efficient and effective means for handling capacity requirements and forecasts?

Step 4: *Identify alternative plans:*
- What alternate sites and operation methods can be considered? What are the quantitative and qualitative issues connected with these alternatives?
- How do these alternate sites and methods reduce or eliminate the deficiencies in the current operation?

Step 5: *Evaluate alternative plans:*

- What are the after-tax costs of the alternatives? The returns on investment?

Step 6: *Select and specify the recommended plan:*

- What are the space, equipment, personnel, and standard operating procedure requirements of the facility over the planning horizon?

Step 7: *Update the SMP:*

- How will changes in the business climate affect the first six steps of the SMP?

Note: The process of developing a SMP is continuous; completion of the first six steps is no cause for celebration, since your business continues to evolve. Recognize that a static plan is as good as no plan at all.

2.4. Network Analysis

Basically, a distribution network is a series of nodes and transportation links. Distribution networks can range from direct shipments from the source to demand points for job shop items to complex multisite networks. The design of a distribution network is dependent on factors such as the type of products, range and volume of products, geographic spread of service area, the level of service required, and the number and type of customers. However, since distribution is a dynamic environment, it is challenged by business issues such as the global marketplace, the level of government involvement, the environment, and energy. At the same time, the customer requirements of increased pace, variety, and adaptability while reducing costs must be understood. Of course, these issues impact the internal pressures of distribution requirements to centralize, utilize third parties, improve information systems, increase productivity, and more fully utilize people. Therefore, the only way to enhance distribution excellence is to pursue the integration of distribution by applying strategic planning.

Strategic planning is the process of deciding on objectives of the firm; changes in the objectives; resources to attain these objectives; and policies to govern the acquisition, use, and disposition of resources. The objective of strategic planning is to define the overall approach to stocking points, transportation, inventory management, customer service, and information systems and the way they relate in order to provide the maximum return on investment.

Strategic planning is an offensive tool designed to guard against a predictable change in requirements, the timing of which can be anticipated. Strategic planning is directed at forecasting future needs far enough in advance of the actual requirements to allow sufficient lead time to meet those needs efficiently. Granted, forecasting with a long planning horizon is a risky business and distribution plans based on such forecasts often prove unworkable. Nevertheless, the forecast is the best available information concerning the future, and it is foolish not to use that information to one's advantage. In fact, the only way to survive the rapidly changing distribution environment today is to have good strategic plans that address the future needs of distribution and the factors influencing distribution. These factors are:

- **Global marketplace:** The global marketplace is a distribution issue. In fact, in today's world there is no choice but to understand the global strategy implications on all distribution decisions. As shifts occur in the world's trading patterns, this changes the distribution requirements, alters the location and number of warehouses, increases pipeline inventories, and creates new transportation opportunities and problems.
- **Government involvement:** A global trend is for governments to deregulate many activities, most notably transportation. It is important that distribution professionals understand that just as government involvement has an impact on distribution, distribution leadership has an obligation to have an impact on government on behalf of distribution.
- **Reverse distribution:** An issue that is closely tied to the issue of government involvement is the issue of reverse distribution. Reverse distribution is the task of recovering packaging and shipping materials and backhauling them to a central collection point for recycling. Handling the mechanics of reverse distribution will require significant attention by distribution professionals. Not only will they need to understand a diverse set of state and federal laws, but they will have to deal with backhauls, handling the waste packaging in their warehouses, and the customer satisfaction issue of recycling.
- **Off-highway vehicles:** The EPA is pushing to regulate off-highway vehicles; this effort will include lift trucks and will further push warehouses in the direction of electric vehicles. The internal combustion lift trucks that will be sold in the future will need to meet much stricter emission standards, but in many applications these vehicles will be replaced by electric vehicles.

- **Energy:** Another issue, like the environment, that has not been a major topic of consideration by distribution professionals is the issue of energy. Nevertheless, the cost of energy is a major concern to transportation companies. In the United States, 60% of all energy consumption is for transportation. Although these costs tend to be buried in the overall cost of transportation, any significant shift in the cost of energy could have an impact on the costs of transportation and therefore on distribution. It is therefore important that, at least as a sensitivity issue, the issue of energy costs be viewed in making all distribution decisions.
- **Pace:** There exists an accelerating rate of change in all aspects of human endeavor: social, political, economic, technological, ecological and psychological. It is not surprising, then, that the reduction of lead times, shorter product lives, and increases in inventory turnover are resulting in significant increases in the pace of change in distribution. Distribution must be more responsive because the demands being placed upon it by customers.
- **Variety:** The variety of tasks to be handled by distribution will continue to increase. Special packaging, unitizing, pricing, labeling, kitting, and delivery requirements will become the norm. Distribution will be required to perform operations that traditionally have been viewed as manufacturing operations. Systems and procedures will be put in place to handle information consistent with the desires of the customers.
- **Flexibility:** The most important aspect of flexible distribution is *versatility*—in equipment, systems, and workers. The design, specification, and implementation of versatile equipment is required to achieve flexible distribution. Warehouse storage rack and material-handling equipment, as well as transportation equipment, should be selected with sufficient versatility to handle today's distribution requirements and, when justifiable, future requirements. Similarly, versatile systems have an impact on adapting customer labeling, automatic identification, communications, and documentation requirements. We never want to find ourselves saying to a customer, ''I am sorry, our system does not allow us to accommodate your request.'' Lastly, we must have multiskilled personnel to achieve flexible distribution. Overly restrictive work rules, excessive job classifications and labor grades, and insufficient training have often resulted in a lack of flexibility in distribution. Multiskilling eliminates barriers between tasks, and workers can better understand the implications of their performance. Throughout distribution organizations, there is a need to destroy the traditional barriers between tasks.
- **Modularity:** The three most important aspects of modular distribution are modular distribution assets, modular work assignments, and time modularity. The issue of modular distribution assets has to do with the expansion and contraction of warehouse space and the increase or decrease of transportation equipment. Similarly, for transportation equipment, purchase and lease decisions, as well as contract terms, should be evaluated while considering both the long-term and short-term fluctuations in traffic. The challenge of modular work assignments has to do with the daily balance of work within a warehouse. Once people have been given multiple skills, it is important to be certain that people are assigned in such a way to allow for a continuous flow of materials through distribution. Lastly, to provide modular distribution is the issue of time modularity. Creativity in employee work schedules can have a significant impact on an operation's output. Many distribution operations have been significantly improved by adjusting work schedules so that there is a balance between the staff on hand and the tasks to be performed. Not addressing the issue of time modularity often results in distribution operations having very low productivity.
- **Price:** A prerequisite for the success of free enterprise is efficient, effective, and low-cost distribution. Although the cost of distribution is less than 10% of the price that the customer must pay, it is of the utmost importance to the customer that even this price be reduced. As a percentage of Gross National Product, distribution costs are down from a high of almost 15% to 11%, and as a percentage of Gross Domestic Product, they are down from a high of almost 18% to below 12%. Thus, it is very important that the cost of distribution be even further reduced.
- **Centralization:** There will be fewer large centralized warehouses in the future to replace the more numerous, smaller, decentralized warehouses of the past. There will be fewer managers and administrative people involved with distribution as integrated distribution is pursued and distribution staffs are centralized. Along with the centralization of warehouses and staffs will come the centralization of order entry, customer service, and data processing. The increased responsiveness of transportation at lower costs, the focus on the total cost of distribution, the realities of customer satisfaction, pace, variety, and adaptability—all are pointed toward the centralization theme. The trend toward centralized distribution will result in higher inventory turnover, which will in turn lead to new opportunities for automation and sophisticated information systems.

- **Third-party logistics:** Third-party logistics (3PL) is the utilization of an outside firm to perform some or all of the distribution functions presently performed internally. As companies better understand integrated distribution and as distribution leadership better understands the costs of distribution, there will be an increasing trend toward the outsourcing of portions of the distribution function.
- **Information systems:** Information technology is impacting everything from business to education to entertainment. It is not surprising, therefore, that information technology is having, and will continue to have, a major impact on distribution. It has become clear that all distribution documentation must be electronically transmitted and not mailed. All distribution paperwork needs to be scrutinized and eliminated whenever possible. It is important for distribution leadership to realize that paperwork means delays, errors, additional work, and therefore wasted time and money. Distribution information systems must be real-time and paperless and standardized throughout the distribution supply chain.
- **Productivity:** Accountability for performance in distribution must be increased. Distribution management must establish standards, identify opportunities for improvement, measure performance, and take action to ensure continuous distribution improvement. The entire distribution function must realize that productivity must be increased. The option of maintaining the status quo is totally unacceptable. The improvement of distribution productivity includes labor productivity, but it goes well beyond labor productivity.
- **People:** Customers drive the business of distribution, but performance depends upon distribution people. Customer satisfaction results from contact with distribution people, and so an important, ongoing distribution issue remains in people. In the past, distribution people were narrowly focused, having a specialized skill or technical strength. These distribution people do not conform to today's distribution needs. The people needed in distribution today must adopt a broader view of distribution, a more integrated understanding of distribution, a team-based, participative organization culture, and a total dedication to the supply chain and to customer satisfaction.

2.4.1. Strategic Distribution Network Planning

Distribution network planning is one of the main areas to which strategic planning is applied. A strategic distribution network plan is developed to meet a specific set of requirements over a given planning horizon. A good plan will determine the best network that will provide the customer with the right goods, in the right quantity, at the right place, at the right time, and minimize the total distribution cost. As the number of warehouses increases, delivery costs decrease and warehouse costs increase. The opposite is also true: as the number of warehouses decreases, the delivery cost increases. Therefore, to minimize total distribution cost it is important to find the best balance of these costs.

The objective of strategic distribution network planning is to determine a plan that indicates the most economical way to ship and receive product while maintaining or increasing customer satisfaction, or simply put, to maximize profits and optimize service. Strategic distribution network planning typically answers the following:

1. How many distribution centers should exist?
2. Where should the distribution center(s) be located?
3. How much inventory should be stocked at each distribution center?
4. What customers should be serviced by each distribution center?
5. How should the customers order from the distribution center?
6. How should the distribution centers order from vendors?
7. How frequently should shipments be made to each customer?
8. What should the service levels be?
9. What transportation methods should be utilized?

Planning a distribution network is a sequential process that continually needs updating. Some companies run into the pitfall of performing steps 3 through 6 before collecting and understanding the most important steps, which are 1 and 2. The answer to distribution network planning is only as good as the data put into the analysis. The steps taken in distribution design are listed below:

1. Document distribution network.
2. Identify delivery requirements.
3. Establish database.
4. Develop alternative networks.
5. Model annual operating costs.

6. Evaluate alternatives.
7. Specify the plan.

2.4.1.1. Document Distribution Network The steps for documenting the distribution network, identifying delivery requirements, and establishing the database can be done simultaneously. The main goal of these steps is to gain an understanding of the current system and define the requirements of the future system. In order to document the existing systems, information must be collected on the distribution centers and the transportation system. In gathering information on the distribution centers, it is critical to collect from all existing sites considered, since the study could result in making recommendations on closing, moving or expanding the facilities. The following information needs to be collected for each site:

- *Space utilizations:* Determine the utilization of the distribution center. This will allow you to determine the amount of physical inventory space that will be required if this facility is to be closed when the analysis is complete. It also identifies how much more inventory can be combined into this location.
- *Layout and equipment:* List the equipment and layout of each facility. If you have a list of equipment available, it will be easier to determine the investment requirements of a new or expanded facility.
- *Warehouse operating procedure:* Understand the order picking and shipping procedures. If there are two product lines in one location, are they picked and shipped together? Understand the differences in operating methods between facilities. This may explain why one facility achieves a higher throughput efficiency per person. Understand how replenishment orders are placed or pushed to the distribution center.
- *Staffing levels:* Document levels by position. Understand which jobs could be consolidated. Collect labor rates by level, including fringe benefits.
- *Receiving and shipping volumes:* Understand the number of incoming and outgoing trucks and the number of docks. This will be important if the facility is required to increase throughput.
- *Building characteristics:* Collect building characteristics such as clear height, lighting levels, column spacing, etc. Collect this for the same reason as layout information, but keep in mind to review expansion capabilities.
- *Access to location:* Review the access to main highways. Determine whether this will have an effect on freight cost.
- *Annual operating cost:* Collect lease cost, taxes, insurance, maintenance, energy cost, and other facility cost.
- *Inventory:* Collect information on inventory turns and levels, fill rates, safety stock levels, and ABC analysis. By having this information, the savings of consolidating facilities can be determined. Also collect which, and how much, stock is slow moving or seasonal to help determine if it should be centralized in one location or whether public warehouse space should be used. Get future inventory goals.
- *Performance reporting:* Understand the performance measures for service requirements, order completeness, shipping accuracy, etc.

The following information should be collected for the transportation system:

- *Freight classes and discounts:* Collect the freight classes and rates used. In addition to freight classes, get the discounts by carrier or location. It is also important to understand where the discounts apply (under which parameters, i.e. routes, minimum weights).
- *Transportation operating procedures:* Understand how a certain mode of transport is selected and how a carrier is selected.
- *Delivery requirements:* What are the delivery requirements (days of delivery) to the customer in days, and how is carrier performance measured? Is order completeness measured?
- *Replenishment weight/cube:* At what weight is a trailer cubed out? Get this information from each replenishment point and for a typical load of general merchandise.

At the end of the site visits, a project team meeting should be held that summarizes the data collected and the assessment of each site. This assessment will give the team insight into its operation, and more than likely they will discover information unknown to management that will be useful in developing alternatives.

To document the future distribution network requirements, it is not only important to understand the factors influencing distribution but also to understand the marketing strategies and sales forecast. The following list identifies questions that should be answered by marketing and sales:

- Are there any new products coming out? From where are they sourced? What is the target market area (geographically)?
- What are the ordering parameters right now? For example, what is the minimum order size? Are they changing any terms of order (i.e., charging for expedite service)?
- What is the direction of the market? (Packaging changes, wholesalers, mass merchants having more volume.)
- Are sales increasing each year?
- Are customer shifts becoming apparent? Are fewer customers handling more volume?
- Have geographic shifts emerged? Have sales increased by geographic regions?

2.4.1.2. Identify Delivery Requirements One of the key data requirements in analyzing a distribution network is that of the delivery requirements (time order placement to receipt of the shipment). If the requirements are not identifiable, a customer satisfaction gap analysis must be undertaken. The gap analysis is a series of questions directed at internal staff and customers. The purpose is to identify discrepancies between customer perception of satisfaction and satisfaction requirements. At some point, the sales sharply decline because competition exceeds both your delivery and your cost (assuming equal product quality). The key is to find the best customer satisfaction that maximizes profits.

2.4.1.3. Establish Database The database of orders that are to be modeled can be established while the existing network is being documented. This information should include ship-to locations, weight of the shipments, products ordered, and the quantity ordered. Once the data are established, the next step should be to validate the data. In order to ensure that the information was transferred properly, print out a few records of invoices and compare these to hard copies. Also, it is a good idea to prepare a summary report (sales, cases sold, weight shipped) for a sanity check to ensure all the data in the files were transferred. Once the data are valid, various analyses such as ABC analysis by picks, location (geographical), volumes, and product volumes by regions of the country should be run. These reports should be used to help determine alternatives.

2.4.1.4. Develop Alternatives Once the data have been collected, the next step consists of developing alternative site locations and operating methods. The input used to determine alternatives consists of site visits, future requirements, database analysis, and customer service surveys. The methods used for the selection of each site will vary.

Sites are not the only option to consider as alternatives. Operating methods must also be considered. Consideration must also be given to criteria such as consolidating vendor shipments, centralizing slow-moving items in one place, keeping company divisions separate, and direct shipment by vendors. Once alternative sites are determined, data must be collected on freight rates, warehouse cost, and labor cost for the alternative sites.

2.4.1.5. Model Annual Operating Cost Modeling software doesn't guarantee the right answer. Modeling should only be used as a tool to aid in the decision process. The real value in distribution planning is the knowledge gained from understanding the working of a company's distribution system, knowledge on distribution planning, and the imagination to use the model in ways to really benefit the distribution network. Alternatives can be close in cost but have a wide range in number of facilities; therefore, it is important to have some other criteria to judge the modeling runs, such as:

1. *Central administrative costs and order processing cost:* Typically, these costs increase with the number of warehouses. It takes more effort to coordinate and manage a larger network of facilities.
2. *Cycle and safety stock carrying costs:* More warehouses means more total system inventory. Inventory theory supports that safety stocks will increase with the number of facilities.
3. *Customer order size effects:* Customers who are close to a warehouse generally tend to order more frequently and in smaller quantity than customers who are farther away. This implies that delivery costs tend to increase on a \$/cwt basis as the number of facilities increases.
4. *Interwarehouse transfer cost:* The more distribution centers there are, the greater the coordination problems and the more likely the tendency to transfer inventory between facilities due to imbalanced inventory availability.
5. *Negotiated reduction in warehousing and delivery costs:* The fewer facilities, the greater their individual volume, and hence the more opportunity there is to negotiate more favorable arrangements for warehousing and delivery service.

No matter what modeling method is used, the overall approach should closely resemble the following steps:

- *Validate the existing network:* Run computer model to simulate the existing cost. Compare this cost to actual cost.
- *Run alternative networks:* Once the model is valid, alternative networks should be run for present volumes and forecasted volumes.
- *Summarize runs and rank:* Create a table to summarize cost by alternative. The table should list distribution center cost individually.
- *Summarize all annual costs and satisfaction factors:* Create a table that indicates by alternative all the cost and service factors.
- *Perform a sensitivity analysis:* Sensitivity analysis is based on the idea of setting up runs that fluctuate some components of the data. This could be a cost that is uncertain or has potential to change. By modifying this single parameter, the effect on the run can be determined.
- *Determine all investment costs associated with each alternative:* Such as cost of new warehouse equipment required to save space, expansion, and construction cost or any building modifications such as adding dock doors. This information will be of use in the next step.

2.4.1.6. Evaluate Alternatives The economic analysis compares the recommended network plan to all alternatives. To do this analysis, you must determine all the investments and savings associated with each alternative. Costs such as new warehouse equipment, construction cost, and any building modification should be included. Additionally, the following information must be identified: personnel relocation, severance, stock relocation, computer relocation, taxes, equipment relocation, and the sale of existing land and buildings.

The result of this step should be a return on investment of each alternative compared to the baseline. Once this step is completed, a sensitivity analysis that fluctuates various costs and savings to see which alternatives are the most stable should be performed. To round out the analysis, a qualitative analysis should be performed, looking at such factors as customer service and ease of implementation. Once a conclusion has been reached, a time-phased implementation schedule should be drawn up listing the major steps involved in transferring the distribution network from the existing system to the future system.

2.4.1.7. Specify the Plan The final step in the distribution network planning process is selling the results to top management. This must be expressed so that management can understand the impact of the strategy on the total business. This communication should express not only the finances relating to transportation and warehouse costs, but overall sales and customer satisfaction.

2.4.2. Do Not Underestimate the Importance of Distribution

Distribution is the management of inventory to achieve customer satisfaction. Today, many companies have realized that distribution is a major frontier for both customer satisfaction enhancement and cost reduction. It is important to remember that a good strategic distribution network plan is a requirement of success and that it should not be composed simply of ideas, thoughts, or possibilities whose validity has not been researched. The distribution network plan is based upon a set of premises concerning future sales volumes, inventory levels, transportation cost, and warehouse cost. Requirements should be defined, analyzed, and evaluated and should result in the development of a specific set of strategic requirements. A good distribution network plan is action oriented and time phased and keeps the ultimate customer's requirements at the forefront at all times.

2.5. Team Selection

Once the need to identify a site is realized, an in-house selection team should be established. Facility management can make the site-selection process easier by also establishing alliances with external resources such as:

- Brokers
- Economic developers
- Government agencies
- Utilities
- Consultants

Once a prime geographical area for the new facility has been settled on and management has approved the SMP, the job of selecting the best community and site begins. This is the most difficult and time-consuming part of the process; support from outside sources will help the in-house team narrow down the list of potential candidates.

2.5.1. Real Estate Brokers

Real estate brokers are typically tied into a multiple-listing service that lists all available property in an area. Many agencies also employ state-of-the-art technology so prospective buyers can see many views of a particular site without leaving the broker's office. Be careful to select a broker comfortable with industrial site searches; many advertise commercial expertise, but industrial requirements are different from generic commercial ones, especially insofar as environmental regulations. Remember that brokers are compensated only for successful transactions, and hard-sell approaches may or may not create pressure for the selection team.

2.5.2. Government Agencies

State and local government development agencies, as well as chambers of commerce, are reliable information sources. Economic developers are sometimes hired employees of a city or county to promote area growth; they can also be commercial real estate brokers. A good economic developer will be able to save you time by showing you only properties that meet your needs; they will also steer you away from properties that may have watershed or zoning restrictions that would prohibit locating your facility. An economic developer most likely will have important political connections that can help cut through ''red tape'' and therefore speed up the process of site selection. Since government staff is motivated to attract new industry to its area, make certain that the area is compatible with company objectives before relying on this information source. A plus is that economic developers are usually aware of all incentive possibilities.

2.5.3. Utilities

Once a general area has been chosen, gas and electric companies can provide useful information on specific sites. Utilities are unbiased sources of advice and often work with brokers on specific land and building details.

2.5.4. Consultants

Facilities planning consultants provide an unbiased source of advice on each facet of the site selection process. With a wide breadth of knowledge and accessibility to time-saving planning tools, consultants make for an efficient and effective means of establishing important quantitative information such as the baseline and for ''flushing out'' all possible and feasible alternatives.

3. PROCEDURE—THE MICRO ANALYSIS (SITE SELECTION)

Once the ''big picture'' has been analyzed and a macro analysis developed, the microlevel work, in which a specific site must be chosen, begins. This is illustrated in Figure 5.

3.1. Community Selection

Once the general area for site selection has been determined by means of the macro analysis, the selection team should identify specific communities within that area for serious consideration. Since each community will interpret and administer legislation and government mandated/funded programs differently, the site-selection team must take special care to assess each community against company criteria and objectives. The team must therefore view and evaluate communities as they are likely to exist when the proposed facility comes on-line.

A checklist is an ideal method for measuring community attitudes and trends. The following presents some general subjects against which a community might be evaluated:

1. Are attitudes of government favorable to industry and progress?
2. How acceptable are the educational and training systems, from daycare through university?
3. Are municipal services operating on a level acceptable for community progress?
4. How is the quality of life as far as shopping, entertainment, and medical facilities?
5. Are there accessible support services for industry, such as maintenance and machine shops?
6. What are the residential neighborhoods like?
7. Can a labor force be built without compromising skill and productivity requirements?
8. Are construction and contracting services sufficient to build a facility?
9. What economic incentives are being offered?

One important economic factor is the local tax on inventories, primarily because this cost can vary significantly from one location to another. States or other taxing authorities have used the presence of inventory in storage as a basis for levying franchise, income, or other taxes on the owner of the property. Rates of taxation within states, or even within counties or towns, can also show

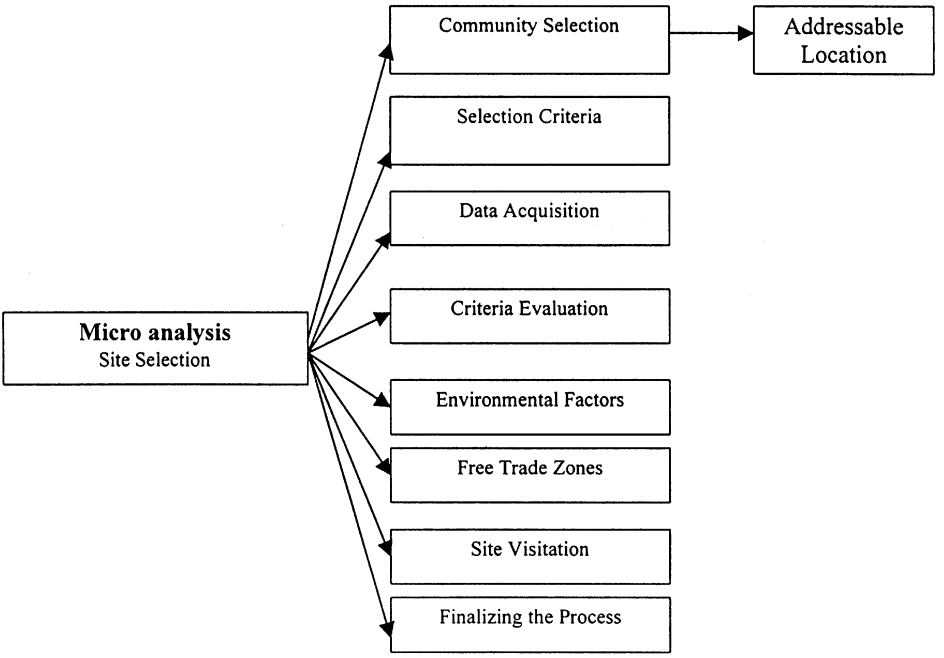

Figure 5 The Micro Analysis.

significant differences. Because state and local tax situations change frequently, expert advice should be sought when comparing tax policies of different communities.

3.2. A Site-Selection Checklist

One must utilize a comprehensive site selection checklist as part of an assessment of a particular location. A sample checklist is provided below. Checklists such as the one below are useful when establishing contacts in prospective site areas. It is not recommended that site-selection teams solicit information "cold"; in other words, observation, rather than someone else's perception, will provide an accurate depiction of the site and its advantages and disadvantages.

Site Factors

1. General Information
   - Site location
     City _____
     County _____
     State _____
   - Total acreage
   - Approximate cost per acre
   - Approximate dimension of site
     Width _____
     Length _____
2. Zoning
   - Current _____Residential _____Light _____Medium _____Heavy Industry _____Commercial _____Other
   - Can zoning be changed? _____Yes _____No
   - Check which, if any, is required: _____Rezoning _____Variance _____Special Exception
   - Probability for success: _____Excellent _____Good _____Fair _____Poor

- Applicable zoning regulations (attach copy)
- Parking/loading regulations
- Open space requirements
  Office/portion
  Maximum building allowed
  Warehouse/DC portion
  Percent of lot occupancy allowed
  Setbacks if required
- On-site waste treatment required
- Height restrictions
- Noise limits
- Odor limits
- Are neighboring uses compatible with proposed use? _____Yes _____No
- Can a good title be secured? _____Yes _____No
- Can protective easements, protective covenants, or mineral rights be tolerated? _____Yes _____No
- Is expansion allowed? _____Yes _____No
  If yes, how much?

3. Topography

- Grade of slope _____level _____ rolling _____ mostly level _____ steep
  Lowest elevation _____
  Highest elevation _____
- Drainage _____Excellent _____Good _____Fair _____Poor
- Are there any: _____Marshlands _____Ponds _____Streams _____Brooks _____Ditches _____Lakes
- Are they: _____On site _____Adjacent to Site _____Bordering Site
- What is the 100-year flood plan?
- Is any part of the site subject to flooding?
- What is the groundwater level? _____feet
- Describe surface soil:
- Does site have any fill? _____Yes _____No
- Soil percolation rate: _____Good _____ Fair
- Load-bearing capacity of soil: _____ lb/ft^2
- Is site wooded? _____Yes _____No
  How much?
- Cost of removal
- Cost of grading
- Storm water discharged: _____ storm sewer _____ other
- Roof drainage discharged: _____ storm sewer _____ other
  Collection required _____Yes _____No

4. Landscaping requirements

- Building and parking lot
- Access road
- Loading zones
- Site buffer

5. Access to site

Is site visible from the highway? _____Yes _____No

Describe access including distance from site to:

Interstate highways

Major local roads

Central business district

Rail
Water
Airport
Describe availability of public transportation
Will access road need to be built? _____Yes _____No
If yes, who will build?
Who will maintain?
Cost of maintenance?
Is rail extended to site? _____Yes _____No
Name of railroad(s)
If no, how far?
Cost of extension to site
Who will maintain extension?

6. Sanitary sewage
- Is sanitary sewage on site? _____Yes _____No
- Reserve capacity in treatment plant _____GPD
- Tap charges
- Special regulations
- Anticipated long-range plans for permanent disposal of sewage

7. Water
- Is water line on site? _____Yes _____No
- Location of water main
- Size of main
- Static pressure _____PSI
- Residual pressure at 1000 GPM flow _____PSI
- Hardness of water
- Is supply adequate? _____Yes _____No
- Capacity of water plant _____ gallons
- Are fire hydrants metered? _____Yes _____No
- If water and sewer not on site:

What is distance to nearest line
Water
Sewer
Line size
Water
Sewer
Cost to extend line
Water
Sewer

8. Sprinklers
- What type of sprinkler system does code permit?
- Is there sufficient water pressure for sprinkler system? _____Yes _____No
- Is water for sprinkler metered? _____Yes _____No
- Is separate water supply required for sprinkler system? _____Yes _____No
- Where can sprinkler drainage be discharged?

9. Electric power
- Is adequate electric power available to site? _____Yes _____No

Capacity available to site
- Describe high-voltage lines on site
- Service is _____ underground _____overhead
- Is submetering permitted? _____Yes _____No

- Indicate if reduced rates are available for:
  Heat pumps _____Yes _____No
  Electric heating _____Yes _____No
  Insulation _____Yes _____No
- Rates

10. Gas
- Type of gas available _____natural _____LP
- Capacity
- Line size _____inches
- Pressure of gas _____ PSI
- Is submetering permitted? _____Yes _____No
  If not, cost of extension
- Rates

11. Other utilities
- Coal
  Source of supply
  Reserves
  Quality
  Cost per million BTU delivered
  Method of delivery
- Oil
  Source of supply
  Volume
  Quality
  Cost per million BTU delivered
  Method of delivery

12. Taxes
- Date of most recent appraisal
- Real estate tax history, last five years
- History of tax assessments, last five years
- Proposed
  Increases
  Assessments
  Tax rates
- Are abatement programs in effect? _____Yes _____No
  If yes, describe
- Is site in an Enterprise Zone? _____Yes _____No
- Are industrial revenue bonds available? _____Yes _____No
- Services provided for taxes paid

Community Factors

1. Labor history
- Does labor force have deep community roots?
- Do most workers own their own homes?
- Is labor force largely transient?
- Can you determine prospects of future favor tranquillity as evidence by labor turnover or absenteeism?
- Has labor group maintained a good reputation for accepting technological change?
- Do employees have a good reputation for housekeeping practices and care of equipment?
- Labor availability survey
- Population at last census
- Population density per square mile

- Percent agriculture
- Total employed in manufacturing
- Total employed in nonmanufacturing
- Percent men in labor force
- County-wide potential employment
- Unemployed available workers
- Shift willingness
- Distribution of available labor
  Skilled
  Semiskilled
  Unskilled
- For women: average family income and whether basic need exists for supplemental income
- Do farm areas serve as good labor pool?
- Is there high degree of farm mechanization?
- Does community have increasing supply of women seeking industrial jobs?
- Can you complement rather than compete with existing industry?
- Will seasonal jobs in nearby resort areas affect labor availability?
- Is community subject to other seasonal labor variations?
- Does adequate labor pool exist within reasonable radius?
- Are young people taking jobs elsewhere?
- Would better opportunities keep young people at home?
- Influence of local industry on labor
- Principle community factors
- Wage rates, by skill
- Working hours
- Shift patterns
- Hourly or piece rates
- Fringe benefits
- Degree of competition for skills
- Pattern of productivity
- Seniority provisions
- Layoff provisions
- Grievance
- Presence of any unusual or radical tendencies
- Does industrial accident rate for community compare favorably with national averages?
- Will you be direct (or indirect) competition with an industrial pace-setter?

2. Maturity of citizens

- Do local civic and religious leaders have enlightened and progressive attitude toward business and industry?
- Do people of community display political awareness?
- How many voters went to the polls in the last municipal election?
- How many voters went to the polls in the last national election?
- Do local people understand how business operates in the American economy?
- Are there community educational programs directed at young people?
- Do social and economic backgrounds of community point toward maturity?
- Is standard of living at or above normal average?

3. Management potential

- Can prospective workers be expected to grow into added responsibilities?
- Can you translate evaluation into estimates for potential supervisors and executives?
- Can you expect to recruit certain management echelons locally?
- Are specialized skills available such as specific and technical manpower?
- Have local people responded well to in-plant training?

4. Water pollution
   - Will you have waste disposal problems?
   - Can streams nearby accommodate waste water?
   - Will good business practice plus local or state ordinances call for waste treatment?
5. Transportation
   - Rail

     On a rate-blanketing basis, are rates to principle markets satisfactory?

     Has pattern of differential freight rate increases been relatively favorable for your proposed area?

     Area?

     Are there amply freight forwarders for LCL

     Does railroad give transit or stop-off privileges for partial unloading and loading enroute?

     Are there adequate truck handling facilities at freight terminals?

     Is pick-up and deliver service available?

     Which of these principal rail considerations are important?

     Branch or mail line

     Freight schedules

     Switching per day

     Yard limits

     Direction of turnout to private siding from yard

     Orientation of site to roadbed

     Relative elevation of site and roadbed

     Potential construction difficulties such as culvert, fill, bridge, cut

     Does prospective rail carrier favor the use of technologically improved equipment to meet shipper needs?
   - Truck

     Are there state laws re: truck size and weight restrictions Is site near a trucking gateway in order to reduce in-transit times?

     Are state gasoline taxes in line with alternate sites?

     Is the pattern of recent truck freight rate increased reasonable?

     Will the new Federal Highway Program help solve trucking problems?

     Is there good access to bridges and culverts?

     Which of these factors are important?

     Natural traffic flow

     Specific routes

     Schedules

     Rates

     Transfers

     Common, contract, or private carrier
   - Air

     Is site near a good airport?

     Are rates and schedules or scheduled airlines satisfactory for hire shipment?

     Are there good air-freight forwarders nearby?

     Is airport service convenient for transport of personnel?

     Is there helicopter shuttle service?
   - Ocean

     Is proximity to inland water transport important?

     Is proximity to overseas shipping important?

     Does area have alert and progressive port authority?

     Are port facilities closed in winter?

     Is ample lighterage available?

     Is access to port convenient and economical?

     Are water transport rates and schedules competitive?

- Other
  Is railway express service available?
  Are pipelines used as common carriers?
  Does community have desirable level of passenger transportation facilities?
  Are there toll roads or bridges?
  Do winter conditions adversely affect transport?
  Does community have public or private warehouse available to help out witht short-range inventory storage problems?

6. Raw material supply
- Are raw material sources reliable? Close enough?
- Are the raw materials committed to others?
- Are terms of sale and delivery right?
- Are multiple supply areas available?

7. Residential housing
- Are there plentiful rental properties?
- Are houses available in several costs brackets?
- Does extent of home ownership among hourly employees indicate stability and community pride?
- Are residential property values increasing?
- Are attractive suburbs within convenient distance of selected community?
- Is community saddled with submarginal or slum areas? Is rehabilitation in progress?

8. Education
- Assess the number and sufficiency of
  Public schools
  Vocational colleges, trade schools, and apprenticeships
  Foremanship courses
  Adult education, degree programs
- Is school growth keeping up with community growth?
- What is the overall education picture?
  Expense to public
  Teacher salaries
  PTA enthusiasm
  Building program

9. Health and welfare
- Are there satisfactory
  Hospitals
  General practitioners
  Dentists
  Clinics
  Nurses
  Public health facilities
- Do hospitals have adequate ratings by State Board of Health?
- How large an area is served by hospitals?
- Are Blue Cross and allied plans available?
- Does community have a workable disaster plan?
- Are there reasonable state industrial safety and health laws?
- Does the community have adequate and well-enforced sanitary laws?

10. General community aspects
- How sufficient is the community recreation system insofar as:
  Family recreation (e.g. parks and playgrounds)
  Outdoor activities (e.g. golf and tennis)
  Libraries

Civic attractions (e.g. museums)
Fraternal organizations
- Sufficiency of public buildings

Gyms
Churches
Auditoriums
- Is the physical center of town attractive?
- Are there good hotels, motels, and restaurants?
- Is banking adequate?
- Are shopping and commercial districts well laid out?

11. Commercial services
- Evaluate quantity and quality of commercial services typically required by industry

Major repair shops
Industrial distributors
Lumber and allied materials
Stationery
Local trucking
Air freight services
Blueprint services
HVAC repair
Testing labs
Electric motor maintenance
Lubricants
Engineering department supplies
Food and sundry vending
Railway express
Postal service
Industrial repair
Janitorial service
- Evaluate quantity and quality of construction services and facilities in or near the community

Architects
Prime contractors
Mechanics
Engineers
Subcontractors
Electricians
Piping
Construction labor
Special equipment
Plasterer
Painting
Paving
Carpentry
Rigger
Mason
Tiling
Landscape

12. Police
- Does police department have high standards of personnel, equipment, training, and morale?
- Is police patrol provided for industrial properties?
- Are private watchmen or uniformed detective services available?

- Is incidence of crime as low or lower than in surrounding area?
- Does community have disproportionate number of bars?
- Is judiciary system well organized?

13. Fire department
- Does fire department have high standards of personnel, equipment, training, and morale?
- Is community fire insurance classification up near the top?
- Is site within fire hydrant limits?
- Are adjacent communities near enough to send apparatus in case of serious fire?

14. Infrastructure
- Does quality of construction and maintenance indicate an efficient highway department?
- Are roads kept free of ice and snow?
- Is there a satisfactory highway improvement program in place?
- How adequate is garbage collection?
- Does the sewage department have realistic plans for expansion and improvement?

15. Planning and zoning
- Is the city planning commission active and progressive?
- Are smoke, noise, and odors controlled?
- Can facilities expect protection from undesirables?
- Do building inspectors have a reputation for honesty and integrity?

16. Community financial picture
- Does community indebtedness present a healthy picture?
- Is community taxation well balanced between residential, commercial, and industrial sources?
- Is pattern of community expenditures well balanced between needs and income?
- Is total community tax picture in line with services received?
- Are community tax inducements offered to prospective industries?

17. Community business climate
- Is attitude of local officials sympathetic and enthusiastic toward existing and new industry?
- Is record of local government good insofar as honesty, efficiency, and principles?
- Does community have business-sponsored civic organizations dedicated to improving business climate? Have results been achieved?
- Is community industrially well diversified?
- Have any manufacturers migrated from the community recently?
- Are the industries dynamic and growing?

18. Community employer evaluation
- Have most employers demonstrated enlightened management policies?
- Have employers kept pace with rising wage standards voluntarily?
- How do you rate employee/employer communications within the manufacturing community?

19. State taxes
- What is the existing gross debt of the state?
- Do state corporate taxes compare favorably with those of competition elsewhere?
- Is there a state individual income tax?
- Does the state levy property taxes?
- Is there a state sales tax?
- Does the state grant permission to deduct Federal Income Tax?

20. State business climate
- Are state legislative, executive, and judiciary branches performing as well as counterparts in other states?
- Are state salaries attractive enough to get and keep good people?
- Are state wage and hour laws fairly written and administered?
- Is state workman's compensation satisfactory?
- Is state unemployment compensation equitable?

- Does state have an active and progressive development commission?
- What are state laws regarding:
  Unreasonable union acts?
  Secondary boycotts?
  Illegal strikes and picketing?
- Have other industries been asked whether there are hidden restrictive laws?

3.2.1. Comparing Specific Sites Based on Organization-Specific Criteria

The following example shows how specific sites can be compared. The matrix established is based on weighted criteria deemed important to the client; both qualitative and quantitative factors are included in the assessment. Information is gathered from a variety of sources, including:

- U.S. government agencies
- State economic developers
- County development agencies
- City governments
- Trade groups
- Commercial real estate agents

3.2.2. Evaluation of Addressable Locations

Step 1 is the establishment of criteria and the respective weights each criterion holds. Company X has determined that the following general categories are significant in the determination of the best site for their new warehouse. Further specification of each criterion is noted in step 2.

• Customer service	15%
• Cost	15%
• Infrastructure	15%
• Suppliers	15%
• Labor	20%
• Community	5%
• Incentives	13%
• Climate	2%
	100%

Step 2 is the information-gathering stage. Information is taken from government and community sources.

Criteria	Location X—Greenfield	Location Y—Greenfield
	Customer Satisfaction	
1. Number of days to market		
Boston	4	3
Chicago	3	3
Miami	3	3
New York	4	2
Dallas	3	3
2. Distance to market (mi)		
Boston	971	1118
Chicago	411	542
Miami	839	681
New York	986	899
Dallas	776	894
3. Carriers available	2 terminals, 21 carriers	1 terminal, 9 carriers
4. Parcel service	All	All
5. Interstate access	18 miles to interstate	6 miles to interstate
6. Freight rates—outbound	$2.09M	$1.98M
7. Freight rates—inbound	$570K	$680K

Criteria	Location X—Greenfield	Location Y—Greenfield
Cost		
1. Land cost		
Per acre	$20K	–[a]
Total land cost	$440K	–[a]
2. Construction cost		
Distribution	$30/ft^2	$28/ft^2
Manufacturing	$45/ft^2	$40/ft^2
3. Incentives	LEDA	KEA Land $75,000
[a]Financial incentive offered by economic developers was the ''donation'' of a Greenfield site.		
Infrastructure		
1. Fire main supply	2400 GPM	1286 GPM
2. Fire department rating	4	3
3. Power source	LA Utility	KY Authority
4. Sewer	X	Y
5. Service roads	45 ft.	30 ft.
6. Park lighting	Installed	Add
7. Security	Fence optional	Fence optional
8. Data transmission lines	56 KB $941/mon	56 KB $856/mon
9. Telephone lines	Fiberoptic	Fiberoptic
10. Commercial airport (distance)	96 mi	30 mi
11. Local airport runway length	5000 ft	5000 ft
Suppliers		
1. Tool and die	3	4
2. Corrugated	1	2
3. Material-handling vendors	2	2
4. Pallets	2	2
Labor		
1. Major employers	XeronTech—300 Tachion Inc.—220	CirrinePlex—500 Handle Tire—350 Goodson Snacks—110
2. Labor Pool	87,400	15,540
Employed	81,500	13,396
Unemployed	5,900	2,144
Rate of unemployment	7%	14%
3. New employers	XeronTech—300 Duplexus Packaging—86	Goodson Snacks—110
4. Industry leaving	None	Nechcon Laminate—200 Abernathy Textiles—640
5. Right to work	No	Yes
6. Union activity	ACTW LIU UFCW	IAM BCTW UGWA
Community		
1. Local government	Mayor 5 Council members	Mayor Alderman
2. Population	11,295	7,056
3. Schools		
Enrollment	7,000	4,500
Student:teacher ratio	17:1	18:1
Post-secondary schools	(1) Community college (1) Technical school (1) 25,000-student university	(2) Community colleges (1) 4,500-student liberal arts college

Criteria	Location X—Greenfield	Location Y—Greenfield
	Community	
4. Hospitals		
Beds	227	91
Doctors	90	16
Dentists	22	2
5. Recreation		
Parks	10	4

<$125,000	166	45
>$125,000	71	23
7. Closest metropolitan area	75 mi	25 mi
	Financial Incentives	
1. Economic developer	LEDA	KEA
2. Fire protection	$60,000	$230,000
3. Site preparation	$75,000	$75,000
4. Tax abatements	$150,000	$300,000
5. Other		Land—$300,000
	Climate	
1. Average annual temperature (F)	57.6	60
2. Average annual rainfall (in.)	47	52
3. Average annual snowfall (in.)	12	9
4. Prevailing winds	NE	S

Step 3 is the development of a matrix for each constituent. Each constituent of each criterion is further weighted within its category and ranked on a 0–10 scale, with 10 representing an ''ideal.'' One example is provided in Chart 2. The process will be conducted for all of the criteria.

		Location X—Greenfield		Location Y—Greenfield	
Criterion	Weight	Value	Weighted	Value	Weighted
	Customer Service				
Number of days to primary market	25%	5	1.25	5	1.25
Number of days to secondary markets	10%	4	0.40	6	0.60
Carriers available	15%	7	1.05	5	0.75
Parcel service	15%	10	1.50	10	1.50
Interstate access	15%	5	0.75	5	0.75
Freight rates (outbound)	10%	5	0.50	5	0.50
Freight rates (inbound)	10%	6	0.60	5	0.50
Totals	100%		6.05		5.85

Step 4 is the development of a matrix showing each general category, its values and weights. A final recommendation is based on this matrix.

		Location X—Greenfield		Location Y—Greenfield	
Criterion	**Weight**	**Value**	**Weighted**	**Value**	**Weighted**
Customer service	15%	6.05	0.91	5.85	0.88
Cost	15%	3.50	0.53	9.60	1.44
Infrastructure	15%	7.67	1.15	5.00	0.75
Suppliers	15%	5.61	0.84	4.87	0.73
Labor	20%	6.22	1.24	7.15	1.43
Community	5%	6.45	0.32	4.33	0.22
Incentives	13%	4.00	0.52	9.75	1.27
Climate	2%	5.22	0.10	5.85	0.12
Totals	100%		5.61		6.84

The methodology by which information is gathered is to establish an open, fruitful dialogue with these sources; this can be through a phone call, fax transmission, e-mail, or postal correspondence. It is vital to the success of any site-selection process that the information be shared on an immediate basis and follow-up (including questions) be timely and constructive.

The deliverable of this comprehensive study of sites is the recommendation of the best fit for expansion or location/relocation.

3.3. Environmental Factors

Even "clean" facilities need to be cognizant of the many regulations protecting the environment. Site-selection teams should be aware that cases can be cited of companies buying sites at low prices but having "to eat" prohibitive cleanup costs, a legacy left by the previous tenant. Even though firms that have potential pollution problems are supposed to notify the United States Environmental Protection Agency (U.S. EPA) of these problems, site-selection teams need to be alert to certain red flags when considering previously inhabited sites.

- Landfills and other solid waste depositories should be excluded from the selection process. Remediation costs normally exceed land value.
- Any site with underground storage tanks (USTs) should be thoroughly assessed. Older tanks need to be checked for rust and leaks, and all USTs must be evaluated and maintained regularly. Underground gasoline tanks must, by law in many states, be noncorrosive; replacement of old, corrosive tanks is an expensive process.
- Any facility with asbestos will require abatement or encapsulation, which is a costly procedure.
- Sites with potential for soil and groundwater contamination, due to inadequately treated sewage, discharge of manufactured or agricultural wastes, the dumping of toxic wastes, or even runoff from nearby golf courses, should be considered problematic.
- Storm water is considered one of the three leading causes of pollution in U.S. waters. Permits are required for storm water discharge, and contingencies must be made for storm water to be separated from sanitary sewer systems.
- Sites where solid waste disposal is necessary must be located near a licensed outlet. Burning of waste materials is not permitted in most locales.

Site-selection teams must learn all about pertinent regulations that govern the use of a site for specific operations. Teams should never assume the site is "clean"; this is an expensive assumption to make.

3.4. Free Trade Zones

One of the considerations in selecting a site is whether or not the site is in a free trade zone (FTZ) and whether or not the FTZ meets the company's needs. FTZs are secured areas within the United States but they are legally considered outside the company's territory. The purpose is to attract and promote international trade and commerce. Foreign and domestic goods may be stored, manufactured, and processed duty-free in the FTZ, which is typically a fenced-in area with warehouse facilities and industrial park space and access to all modes of transportation. Subzones, which fall beyond the perimeter of the public zone, are set up to accommodate industries that satisfy specific government criteria (e.g. ability to generate public benefit through employment).

Companies that intend to import products for manufacture or sale should research the feasibility of the FTZ. The advantages are:

- Customs duty and internal revenue tax, if applicable, are paid only when merchandise is transferred from a foreign trade zone to a custom territory for consumption.
- Goods may be exported from a zone free of duty and tax.
- Merchandise may remain in a zone indefinitely, whether or not subject to duty.

Companies should note that certain commodities and industries are excluded from zone consideration: alcoholic beverages, tobacco, firearms, white phosphorous material, sugar, and material operations that may prove to be a detriment to public health and welfare. No retail trade is allowed in FTZs.

3.5. Site Visitation

The team should visit the final round of site candidates. Items either misrepresented or unrepresented in previous information can be determined, and the final assessment may be based on this new information. Extensive research should be done at each site visitation, including in-depth interviews with managers of similar businesses. The project team should keep in mind labor market dynamics, business costs, and support infrastructure.

3.6. Finalizing the Process

Once the site has been selected, productivity should be maintained; in other words, a ''business as usual'' atmosphere must be generated so as to meet supply chain and customer requirements as seamlessly as possible. The following steps should be taken to ensure that the relocation or expansion plans of the company move forward smoothly:

- Identify and communicate with employees.
- Address training and recruitment issues for the new facility.
- Schedule all official announcements with discretion—premature public disclosure may alienate and demoralize employees.
- Assign either an individual or a team to monitor all aspects of the new facility, not just the construction or the move (taxes, regulations, human resources, and telecommunications all play major roles in successful site accommodation, so these must be considered and handled as diligently as the building or the relocating itself).

Site selection is the next logical step after the strategic distribution network planning, which analyzes the company's distribution network and develops facilities requirements and customer service requirements based on the warehouse strategic master plan. Site selection is the microanalysis of the company's needs, and through the use of a structured approach, where criteria are identified, sourced, quantified, weighted, and evaluated, it enables the company to see what the best choice is for expansion or relocation.

The team must be fully cognizant of restrictions and limitations (e.g., pollution controls or energy consumption) placed on parcels of land by governmental bodies before making lasting decisions. Through the careful processes of distribution network analysis, site evaluation and negotiation, companies can select a site that offers flexibility, versatility, and utility for many years.

4. MOVING FROM SITE SELECTION TO CONSTRUCTION

As if site selection is not difficult enough, then comes the actual construction of the facility. On a blueprint, the requirements have little more than conceptual meaning; once brought into reality with bricks and mortar, the structure will either prove immensely effective and efficient or be a capitally intensive reminder of an organization not fully comprehending its strategy.

Building an industrial facility such as a manufacturing plant or distribution center is an arduous undertaking, taking up to two years from start to finish. There should not be a question about why something is being done, who is doing it, or how much more efficient it will make your operations. Unfortunately, many projects are overwrought with conflict, unexpected changes and delays, and ultimately a realization that the building doesn't reflect, much less satisfy, the needs of the company: today, tomorrow, or next year.

The following will provide an overview of project methodologies and make suggestions on how to choose the right architect/engineering firm and contractors. Construction is not a ''let your fingers do the walking through the Yellow Pages'' type of endeavor. In order to make a concept a reality, careful planning and implementation of the four major elements of construction, as illustrated in

Figure 6, must be in order. Know what you want out of your manufacturing plant, warehouse, or DC and stick to the plan.

The construction or expansion of a DC or manufacturing facility is a complex undertaking that, if not properly managed, can overwhelm an organization, delay the occupancy of a much-needed facility, and adversely affect a corporation's bottom line. Effective facilities construction requires a balancing act among expectations, cost, scope, schedule, quality, and ongoing operations.

A typical distribution facility can cost over 10 million dollars, take six months to plan, nine months to build, three months for fit-up, and two months to bring on line. It can include the participation of consultants, architects, engineers, realtors, bankers, lawyers, economic developers, state, local, and federal officials, general contractors, subcontractors, and suppliers. During design, construction and start-up, many employees are called on to assume additional responsibilities related to the new facility while continuing to perform their normal jobs. Day-to-day operations must continue, and customer service must not suffer.

No wonder the building process is often viewed by participants as a painful interruption of business as usual rather than as a celebration of growth and financial success for the corporate team.

With proper planning and with use of internal and external resources, the building process can be managed. Projects can be brought in on time, budgets can be maintained, and quality can be achieved. The process will not be painless, but the pain can be reduced if the following steps are taken:

- Establish realistic criteria for site selection.
- Select the contracting or project delivery method that best fits your needs.
- Select the best construction team for your project.
- Vigorously manage the project.

As the site-selection process proceeds, it is easy to lose sight of the ultimate goal: to locate and build a facility in accordance with your strategic master plan. This is the only way that strategic master plan forecast results can be achieved. Resist the temptation to make compromises to the site criteria that will change the building's functionality. Your objective should be to build around the process, from the inside out. Stick to your plan.

4.1. Methods of Project Delivery

With the conceptual design in hand and with a suitable site selected, it is time to decide what contracting method you will use to turn concepts into detail design and detail design into concrete and steel.

There are several methods of project delivery commonly used in today's market. Each method has advantages and disadvantages. Before deciding which method to use for your project, answer the following questions:

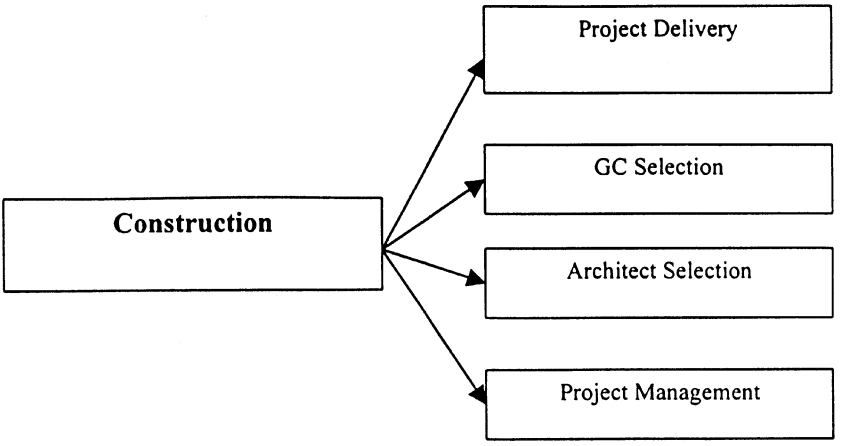

Figure 6 Construction Process.

- *How involved in the details do you want to be?* Different methods of project delivery require different degrees of owner involvement. You must be clear about what your role and responsibilities will be. After the project starts, delays caused by the owner can be costly.
- *What schedule requirements and constraints do you have?* Different contracting methods support different schedule requirements. Make sure that you understand the typical time line for each project delivery method.
- *What budget constraints do you have?* What contracting method best fits your budget?
- *What resources do you have in-house to devote to the project?* Do you have qualified people on staff that can act as your representative, or should you assign this role to a consultant?
- *What are your priorities—scope, schedule, budget, aesthetics, quality?* Each project-delivery method has advantages and disadvantages in these areas. Only through a thorough understanding of the methods can the correct selection be made.

The success of a project is often directly related to the delivery method used. The following section outlines four commonly used methods of project delivery. Once the above questions are answered, the appropriate method for your project can be selected.

4.1.1. Design-Bid-Build (Traditional Method)

The conventional fixed bid method of delivery project approach is characterized by a clear separation between the design phase and the construction phase. The owner hires an architect/engineering firm (A&E) that turns the functional requirements of the building into a detailed set of construction drawings and specifications. These drawings and specifications, as well as schedule requirements and special conditions, become the basis of a request for proposal (RFP) that is issued to general contractors (GC) for bids. Bids are received and evaluated and a fixed price or lump sum contract is awarded to a GC. The GC purchases materials and awards subcontracts as required to satisfy his obligations as detailed in the contract documents.

The GC assumes the entrepreneurial risk of completing the work in accordance with the plans and specifications for the lump sum amount agreed to in the contract. The owner's liability in theory is limited because he has a firm price to do the work. The key thing to remember here is that the contractor has given a lump sum price to perform the scope of work that is detailed in the bid documents; he has not given a lump sum price to do "whatever it takes."

As in any method of project delivery, changes in the scope are grounds for additional compensation. Likewise, changes in the schedule (e.g., delays caused by someone other than the GC or their subcontractor) can be grounds for requesting an extension time and additional compensation. Generally, delays caused by weather are covered under an excusable delay clause in the contract. In this case, the contractor would not be eligible for additional compensation to cover his extended presence on the job but would receive an extension of time equal to the time lost.

This is still the most common method of contracting in today's commercial market. Most public projects, both state and federal, use this traditional method. It is well suited to projects where aesthetics are important and elaborate or very specialized design is required. Examples would be churches, government buildings, schools, hospitals, and multistory office buildings. Figure 8 is a typical organizational chart for a design–bid–build project.

- *Advantages of design–bid–build:*
- Construction drawings and specifications are very complete and depict in detail how the project is to be constructed prior to breaking ground.
- The A&E is retained directly by the owner and represents his interest throughout the project.
- Owner has a good estimate of the final project cost before construction begins.
- A&E and GC are retained separately by the owner with clear divisions of responsibility.
- *Disadvantages of design–bid–build:*
- The entire process takes longer than other methods.
- It generally costs more than other methods.

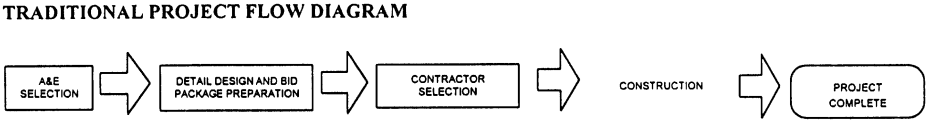

Figure 7 Design–Bid–Build Method.

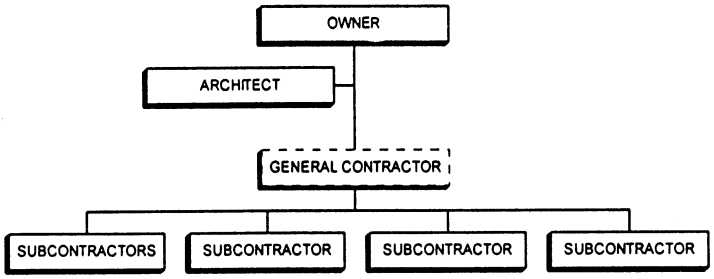

Figure 8 Organization Chart for Design-Bid-Build.

- The A&E and GC may develop an adversarial relationship, with the owner caught in the middle.
- It requires extensive owner involvement on an ongoing basis throughout the project.

4.1.2. Construction Management (CM method)

In the past 20 years, the technique known as construction management (CM) has evolved, flourished, and to some degree lost favor. It was touted as a method of speeding the construction process through fast tracking while giving the owner additional control of the project by eliminating the general contractor. Instead of awarding the project to a GC through a competitive bidding process or through negotiations, the owner hires a construction manager just as he hires an architect. The GC system is eliminated in favor of a system designed to have the architect and CM both work for the owner on a fee basis. A typical organizational chart for a CM project is shown in Figure 9.

The CM provides managerial services and acts as the owner's agent in construction matters. Rather than the owner contracting with a single GC, he contracts directly with multiple prime contractors and specialty subcontractors. The construction manager schedules, coordinates, and directs the day-to-day activities of these contractors. He generally does not perform any work himself, but he may provide essential services normally included in a GC's overhead cost, such as temporary facilities, utilities, cleanup, and security. These services are provided on a cost-reimbursement basis and are not part of the CM's fee.

The construction management system, which is depicted in Figure 10, is best suited to large, complex projects requiring substantial full-time, on-site support staffs. A typical CM staff for a major industrial or public works project might include engineers, accountants, purchasing agents, safety representatives, inspectors, and construction specialist. Extensive owner representation is also required.

In theory, the overall schedule is reduced by maximizing the fast-track approach. As drawings are completed, contracts are awarded and work begins. There is no doubt that the project duration can be reduced by overlapping design and construction. However, in a case where multiple contractors are proceeding simultaneously at breakneck speeds, disputes between contractors and the CM/owner are common. This gives rise to an unnecessarily formal, and often adversarial, project climate. The owner becomes an arbitrator of disputes in a no-win situation. No matter what he does, it will ultimately cost him money. This type of project is typically characterized by disgruntled contractors, continuous change order requests, claims for additional compensation, and sometimes litigation.

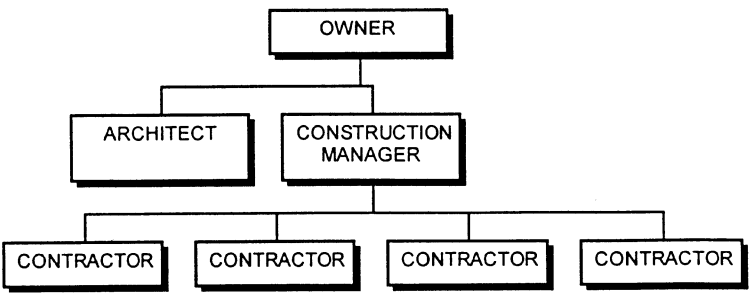

Figure 9 Construction Management Method.

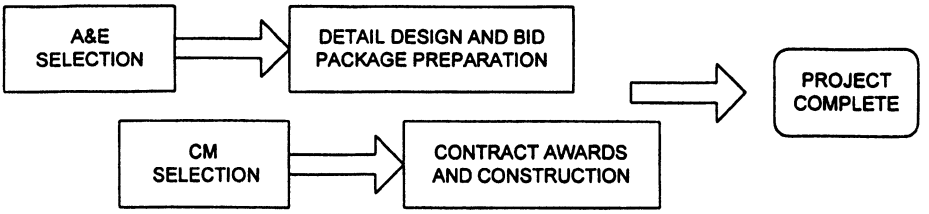

Figure 10 Organization Chart for Construction Management.

Because the construction manager is retained on a fee basis, he does not warrant or guarantee results, and may have little incentive to keep the cost down. In contrast to a fixed price contract with a GC, here the owner must assume ultimate liability for the final cost of the project no matter what the circumstances.

- *Advantages of a CM system:*
- Total project duration is reduced by fast tracking.
- Reduces owner's staffing requirements for large or complicated projects.
- Architect and construction manager both work directly for the owner.
- *Disadvantages of a CM system:*
- Often leads to disputes between multiple prime contractors.
- Final cost of the project is not known until late in the process.
- Owner's exposure is increased since CM is retained on a fee basis.

4.1.3. Design–Build

The design–build method of project delivery, which is illustrated in Figure 11, has become increasingly popular as an alternative to the traditional (design–bid–build) process. Here the owner contracts with a single source for both the design and construction of the facility. The single source is usually a contractor who specializes in this type of construction. He may have design capabilities in-house or may subcontract this phase to an A&E firm. In either case, the design–build contractor assumes full responsibility for the adequacy of the design and its constructability.

The design–build project begins with the owner (or owner's agent) developing a RFP, including a functional bid specification. This document will include:

- Layout drawings
- Project overview
- Summary of key building characteristics
- Construction completion date requirements

The RFP package is issued to a group of prequalified design–build contractors. Bids are received and evaluated by the owner/agent, and a contract is issued to the successful contractor.

The design–build contractor begins the development of detailed building specifications that are submitted to the owner for approval. The detailed building specifications are completed in sequential packages, phased with the construction sequence. This allows construction to begin prior to completion of the total design process, reducing the total project lead time. A typical design-build project organizational chart is shown in Figure 12.

The most important advantage of design–build is that it can significantly shorten the total project duration by overlapping or fast-tracking design and construction without exposing the owner to change order requests, claims and litigation due to errors, omissions, or ambiguities in the plans or

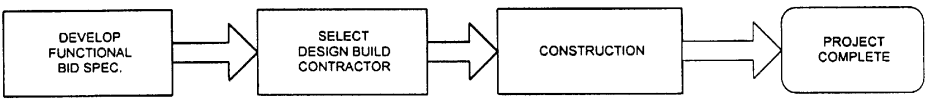

Figure 11 Design-Build Method.

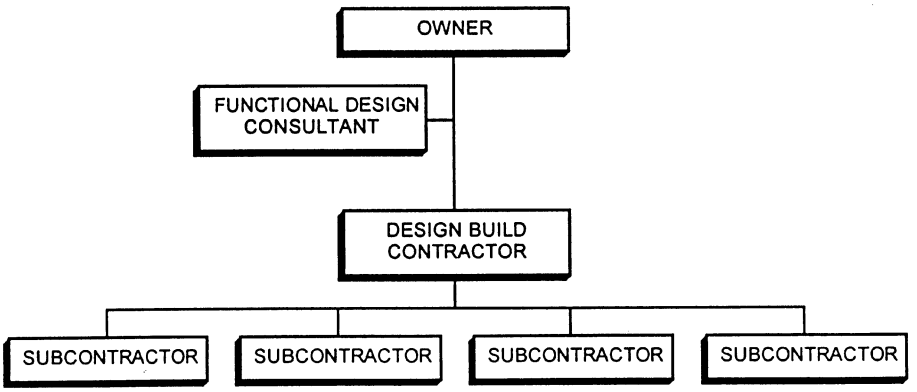

Figure 12 Organization Chart for Design-Build Method.

specifications. Likewise, the owner will not have to referee disputes between his architect and general contractor.

Design–build gives the owner a single source of responsibility and a single point of communications for all project-related issues, including schedule, budget, quality, and warranties.

A disadvantage of the system is that the owner loses the benefits of having an independent architect working directly for him. The designer now works for the contractor. His selection may have been based on price rather than qualifications and experience, and his primary objective may be to turn out a generic design quickly rather than interpret the owners needs and expectations. Drawings prepared by design–build contractors are typically intended for field use rather than owner review and are characterized by a lack of detail and much standardization. It can be difficult for an owner to visualize the details of the finished facility based on these drawings. It can also be difficult to coordinate the purchase, detail design, and installation of owner-furnished equipment and materials, using the information provided by the design–build contractor.

Since the owner does not communicate directly with the designer on a regular basis, his influence is diminished and his control of the details is lost. He also loses the advantages of having the architect act as an unbiased quality control auditor who inspects the work for compliance with plans and specifications.

- *Advantages of design–build:*
  - Gives the owner a single point of responsibility.
  - Minimizes change order request.
  - Promotes continuity between design and construction.
- *Disadvamtages of design–build:*
  - Less owner control—designer is working for contractor.
  - Loss of checks and balances.
  - Drawings may lack details.

4.1.4. Team Design/Construct

The team design/construct project approach, as depicted in Figure 13, is set up with separate contracts between the owner and the A&E and GC, like the design–bid–build process, but the detail design is completed in sequential steps like the design–build process.

The process begins with the owner/agent developing an A&E RFP that is submitted to qualified firms. The RFP can request either a fixed cost bid throughout the project or a fee for time plus expenses. After evaluating the bids and interviewing candidates, an A&E firm is selected and a contract is signed.

Next, the owner/agent and the A&E develop an RFP for the selection of a GC. The request for propsal includes:

- Layout drawings
- Project overview
- Summary of key building characteristics

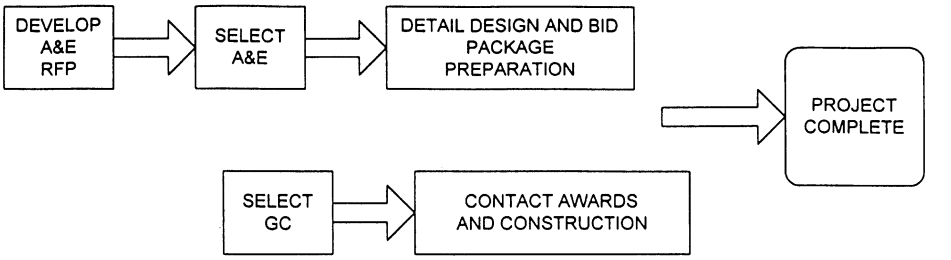

Figure 13 Team Design/Construct Method.

- Construction completion date requirements
- The general conditions governing the project
- The general requirement specifications
- The project bid form

The bid form requests the GC to state the fee to cover the project's general conditions and requirements (this is essentially the project overhead) and a fixed profit percentage for the cost of the work. This essentially creates a cost structure of time and materials with an agreed-upon profit margin for the contractor.

Once all bids are received, the owner/agent and A&E evaluate the bids and select a GC to become a member of the project team. While the selection process is taking place for the GC, the A&E is concurrently developing the building construction documents. Six different performance specification bid packages are developed and released at different points in time in order to expedite construction of the project. Each of the packages is reviewed by the entire project team, including the GC. Once all parties agree on a performance specification bid package, the GC solicits fixed bids from appropriate subcontractors.

All subcontractor bids are evaluated and summarized by the GC and reviewed with the owner/agent and A&E. The team mutually selects the subcontractor that will be used. With this process, the owner still receives the cost advantage of a competitive bid and is directly passed all project costs. Once contracts have been awarded for all six packages, a guaranteed maximum price (GMP) is established. Generally, the contract with the GC is structured such that any savings between the GMP and the actual final cost is shared, 75% returned to the owner and 25% to the GC. This keeps the GC aggressively seeking ways to save the owner money. A typical project organizational chart for the team design construct process is presented in Figure 14.

- *Advantages of team design/construct:*
  - All primary team members are on board from the outset of the project.
  - The GC is involved in the design process, allowing valuable cost savings input early on.
  - Reduces project lead time by facilitating a fast-track approach.
  - All project costs are available to owner.
- *Disadvantages of team design/construct:*
  - Total project costs are not established at start of construction.
  - Advantages of the competitive bidding process are lost.

Owners must familiarize themselves with the pros and cons of the various methods of project delivery. Ultimately, he should choose the method that best meets his needs and that he feels the most comfortable with. After contracts are signed and long-term commitments are made, is not the time to discover that you have selected the wrong contracting method for your project. In summary, the four methods are listed in Table 1.

4.2. Selecting an Architect

A&E firms come in all sizes with varying areas of specialties. One may concentrate on retail facilities like shopping centers and department stores; others may specialize in low-rise office complexes, public school facilities, or industrial complexes. Staffs can range from 2 or 3, to more than 100. Large firms typically have in-house engineering specialty capabilities such as civil/site, structural,

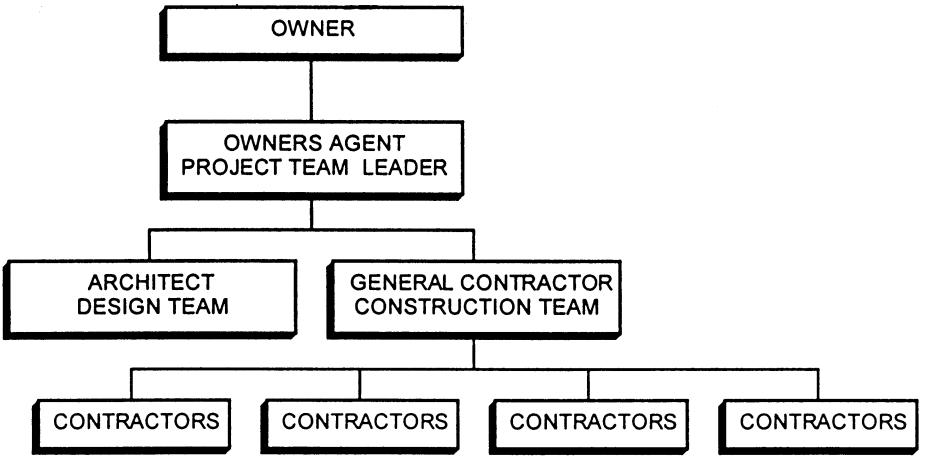

Figure 14 Organization Chart for Team Design/Construct Method.

mechanical, electrical, and so on, while smaller firms usually subcontract these phases to an outside consulting firm.

It is important that you find the right size and type of firm for your project. A very small firm is not capable of delivering the kind of service that a large or complex project requires. While the quality of the design work may be comparable, small firms just can't be as responsive as firms that keep the majority of the work in-house and have a large enough staff to work on multiple tasks at

TABLE 1 Methods for Project Delivery

	Design–Bid–Build	Construction Management	Design–Build	Team Design/Construct
Owner involvement	High throughout process	High throughout process since construction manager is retained on fee basis	Diminished influence since designer works for the contractor	Reduced because owner is represented by third party consultant or agent
Costs	Generally highest among the methods	High with no incentive to keep costs down	Reduced due to fewer change order requests; designs often generic or standard	Though not known up front, costs are managed through GMP process
Schedule	Generally longer than other three methods	Reduced by fast tracking	Reduced by fast tracking or overlapping	Reduced by fast tracking
Scope	Typically used in highly elaborate, aesthetic projects such as schools, churches, and hospitals	Seen in major public works or industrial projects	Not typical in projects requiring very specific, elaborate design	Seen in all types of projects

the same time. When the project gets started, any delay in completing design drawings on time, reviewing and returning contractor and supplier submittals, or responding to questions by any of the project participants can delay the progress of the work and have financial consequences for the owner. Likewise, if a firm has never designed a modern manufacturing or distribution center, it is unlikely that it will have the expertise that your project needs. Large firms may have the advantages of big staffs, but because of their size, workload, and number of clients, they may be unable to give your project the personal attention that a smaller firm can.

Start your selection process by compiling a list of potential candidates. Contact your local branch of the American Institute of Architects (AIA) to obtain a list of firms in your area who specialize in industrial facility design. Ask friends and business associates who have been through the process for their recommendations. Visit facilities in your area that you admire and find out who designed them. If there are firms in your area that specialize in the type of structure that you are planning, add them to your list.

From this initial list, interview only those firms that you think might be able to meet your needs. Consider the following when selecting finalists:

- Experience with similar projects (size, site conditions, functional complexity)
- Size of firm (is it the appropriate size for your project?)
- In-house capabilities (are they sufficient for your project?)
- Length of time in business (financial stability—will they be around next year?)
- Staff experience (experience of those assigned to your project)
- References (check references thoroughly)

Consider Company X: they're hoping to build a new, 1 million ft^2 facility to accommodate their distribution needs. Current management has never contracted out for an A&E firm, so they choose N Enterprises, basically out of the phone book. They're an A&E firm after all! Unfortunately, they have two architects and one structural engineer, each with three years of experience. They're working on two 2000 ft^2 residences currently. Company X fails to call but one reference: the engineer's mother, for whom they built an addition on her home. What's wrong with this picture?

Consider Company Y: they're hoping to expand their existing facility by 50,000 ft^2 to accommodate new manufacturing equipment. Their management wants "only the best," so they hire the leading architect in the country. Although the firm is large and well known throughout the world, its reputation was built on design of large, high-profile office complexes, not industrial facilities. This firm will essentially have to start from scratch. With little previous experience in designing industrial facilities to draw from, the process is likely to take longer and be more costly. The final design is adequate but lacks imagination and shows that the firm really didn't have an understanding of company Y's operation and requirements. The firm is so large and has so many projects going on that company Y's project doesn't get the attention it deserves.

These are extreme examples of poor A&E selection. Keep in mind, though, that it is better to err on the side of caution and do your homework slowly. RFPs and selection matrices will help this process.

From the information gathered, develop a short list of three to five firms to send RFPs. In order to be able to compare responses, the RFP must clearly define the scope of services that the architect is to provide. Basic services include information gathering, preparation of preliminary schematics designs, detailed design development, construction document preparation, assistance in awarding contracts, and contract administrative services during the construction phase.

The RFP should also include:

- A description of the project approach (organization, methods and procedures)
- An overview of the project's objectives (why the facility is being built)
- Design criteria and constraints (what must be included to achieve objectives)
- Schedule requirements and constraints (must start and/or must complete dates)
- Budget parameters (accurate estimate of the intended budget)

Generally, the more relevant and detailed information you can include in your RFP, the more responsive the A&E proposals will be.

The RFP can request either a fixed cost bid, an hourly rate plus reimbursable expenses, or a combination of the two. Whatever method of compensation you choose, make sure you clearly understand the agreement and have an accurate estimate of the final cost of services.

The final selection of an architect should be based not only on technical competence, experience, organization, cost, and schedule, but also on your personal confidence in the firm's ability to meet your expectations. An example of an A&E selection matrix is included in Table 2; each firm is ranked

TABLE 2 A & E Selection Matrix

	Company A	Company B	Company C	Company D	Company E
1. Project understanding	5	5	3	5	5
2. Scope of services	5	4	2	4	4
3. Scope of qualifications	5	5	3	4	4
4. Experience with similar projects	5	3	3	5	3
5. Cost not to exceed	$352,000	$497,000	$430,000	$370,000	$295,000
6. Hourly rate	$65/hr	$70/hr	$89/hr	$53/hr	$61/hr
7. Project staffing	5	4	5	5	3
8. In-house staffing	5	5	5	5	2
9. Schedule	3	2	5	4	3
Total	33	28	26	32	24

on a 1 (poor) to 5 (excellent) scale on a predetermined set of criteria. Results of interviews and written proposals are considered in these assessments. Based on the numbers below, Company A and Company D were in a dead heat for the project. In the end, however, Company A was chosen due to its stronger showing in services, deliverables, and staffing. Price alone should never be the motivating factor in an A&E selection.

Make sure that you have met and feel comfortable with the people who will actually be working on your project. Finally, select a firm whose style, personality, and project approach are compatible with yours.

4.3. Selecting a Contractor

The traditional way of selecting contractors is through the competitive bidding process. This may result in an initial low price, but it does not necessarily result in selection of the best contractor for the project. Price is an important consideration, but other factors, such as experience with similar projects, financial stability and strength, number of years in business, reputation, annual volume, and safety record, must be considered before entering into a long-term binding agreement with a contractor.

For this reason, RFPs should only be issued to a short list of prequalified contractors that meet acceptable standards in all categories, any of which you would be willing to award the project to. Below is an example of a prequalification form that can be used to screen prospective contractors. Here again, we are using a rating system of from 1 to 5, with 5 being the highest possible score. This is only an example; you will need to evaluate what categories to include on your form and what weights to assign to each factor. However, at this stage in the selection process, emphasis should be placed on financial strength, experience, and reputation.

The role of the GC has changed significantly over the years. Where once the GC employed his own tradesmen to perform the work, today most work is done by specialty subcontractors: electrical, plumbing, roofing, and so on. The GC is predominantly a supervisor. He assembles a group of specialists, generally through the competitive bidding process, and then has the responsibility of scheduling and coordinating their activities to ensure that the work is performed correctly and completed on time. Subcontractor administration is the GC's primary concern once construction begins. GCs may subcontract more than 98% of the work to be performed on a project. For this reason, the owner must reserve the right of final approval of all major subcontractor and material suppliers. During final negotiations with GCs, the owner should review the credentials of all proposed subcontractors (e.g., electrical, HVAC, fire protection, etc.) and critical material suppliers such as structural steel fabricators. If there is any question about the ability of any of these participants to perform, the owner should insist that they be replaced.

Obviously, selecting the right contractor is essential to the success of your building project. The right contractor is the one that has the appropriate balance between stability, technical competence, experience, organization, cost and that intangible element: your personal confidence.

4.4. Project Management

Having decided what to build, where to build it and who will do the work, you might be ready to wash your hands of the whole thing and let the process run its natural course. This approach can be disastrous. Construction projects are dynamic creatures requiring constant monitoring and guidance. If left to its own device, the project can take a wrong turn before you realize what has happened.

TABLE 3 GC Selection Matrix

Item	Description	Weight	Rating	Score
1	Number of years in business under present name		3	0.15
2	Annual volume	8%	3	0.24
3	Bondable for this size project (prerequisite)[a]	10%	5	0.50
4	Financial strength	10%	3	0.30
5	Overall experience	10%	3	0.42
6	Experience with similar projects	16%	5	0.80
7	Home office location	5%	1	0.05
8	Qualifications of key employees	8%	3	0.24
9	Safety record	12%	4	0.48
10	Reputation and references	12%	3	0.36
	Total	100%		3.54

[a] *Eliminates contractor:* A performance bond is a guarantee by a surety to the owner that the contractor will complete the work in accordance with the plans and specifications. If the contractor defaults under the terms of the contract, the surety becomes responsible for the contractor's obligations and must complete the work in accordance with the terms of the contract.

Generally, performance bonds can only be obtained by contractors who have a documented history of financial stability and satisfactory performance.

Whether or not a bond is required from the successful bidder, requiring all potential contractors to furnish letters from a surety that they are bondable ensures that only financially sound companies will participate in the process.

Lost time or money spent is rarely fully recoverable. To avoid surprises, cost, schedule, and quality must be constantly monitored.

The nature of the construction process leads to natural differences of opinion among the participants. Everyday issues must be identified and resolved before they develop into problems. Timely decisions must be made so that the project can move forward as scheduled. Placing an activity on hold because approval drawings have not been returned or because the person who needs to make a decision is on vacation can disrupt the flow of a project and prove to be costly to the owner.

The secret to a successful project is effective project management. The individual who has the responsibility to represent the owner has more at stake than meets the eye. He must coordinate, facilitate and take responsibility for the successful completion of the project. No matter which method of project delivery has been chosen, the owner will have ongoing responsibilities, and must assume an active role throughout the building process. The owner must:

- Be represented at all planning and progress meetings
- Develop and maintain a master project milestone schedule
- Provide timely information to the A&E, contractor, or suppliers
- Develop and implement procedures for budget tracking and cost control
- Review payment requests and make recommendation for disposition
- Coordinate and expedite delivery and installation of owner-furnished materials and equipment
- Review drawings, submittals, and product samples as required
- Maintain documents, records, and logs as required to protect the owners interest
- Prepare and submit progress reports and schedule updates to top management
- Review and approve all change order requests

Completing a major project on time and within budget requires an extraordinary amount of time and effort on the part of the owner. Those with limited resources, who do not have experienced construction professionals on staff who can be assigned to the project, should consider securing the services of an outside consultant to act as their agent. An experienced consultant who is familiar with the strategic master plan and understands the role of the facility as a production tool rather than a structural box can be invaluable to the owner. Working as the owner's designated representative, he can move the project along smoothly from one phase to the next without interruption or delay while protecting the integrity of the functional design at each step. This ensures that contractors, suppliers, or other project participants do not make changes to the structure that will affect the process that the building has been designed to house.

For example, the placement of light fixtures, conduits, ductwork, or fire-protection lines below the designated clear height of the building can dramatically affect the designed manufacturing or warehousing process by restricting the travel of material handling equipment. Relocating utilities or other obstructions after the fact can be costly to the owner. Having a qualified representative on site during critical construction phases is a case of spending a penny to save a dollar.

The planning, design, site selection, construction, and start-up of a new or expanded distribution center or manufacturing facility is a linear process that follows logical steps from concept to completion. It is easy to understand the steps; it is not easy to manage the process effectively.

Do not underestimate the difficulties that will arise between concept and completion. Typically, millions of dollars of construction money are at stake, as well as the potential loss of revenues should the facility not be operational as scheduled, not perform as anticipated, or prove to be in the wrong location.

4.5. Summary Points for Construction

Let's review the steps to project success:

- *Establish realistic criteria for site selection:* When we say "realistic," we mean according to the needs identified in a strategic master plan (SMP). The SMP will identify and prioritize facility requirements for a given planning horizon, based on historical data and objective analytical projections. Establish needs and stick to the plan.
- *Select the contracting or project-delivery method that best fits your needs:* The generalized definitions of the four methods described in this monograph are intended only to introduce the reader to the process. Before committing to any method, the owner should have a clear understanding of the rules of the game and the roles and responsibilities of each player. Knowledge is power. Do research. Have unbiased consultants or third parties help you.
- *Select the best construction team for your project:* Your project is only as great as the skills and dedication of its team members. Do not get involved with unnecessary conflict and politics. Be careful; use quantitative and qualitative evaluations. Weight each criterion based on its unique importance to you. Your cautious diligence will pay off.
- *Vigorously manage the project:* You've done a lot of work up to this point; Do not let success slip away by neglecting the bricks-and-mortar phase. Allocate qualified staff to oversee the process, or select third-party agents or consultants to represent your interest during this critical stage. Wiping your hands of the construction process now is guaranteed to create difficulties down the road.

5. CONCLUSION

Developing a comprehensive plan that encompasses site selection and construction ensures that the organizational mission and goals will be addressed in the concept to reality process. Through a combination of awareness, research, reflection, and leadership, organizations can be assured that the property they choose and facility they ultimately build will increase return on assets, enhance competitive advantage, and provide the supply chain with the resources, processes, and methodologies that provide a true competitive advantage.

CHAPTER 56
Material-Handling Systems

YAVUZ A. BOZER
University of Michigan

1. OVERVIEW

At a basic level, material handling is primarily concerned with the storage and movement of material (in various forms) in/through production and service systems such as factories, warehouses, distribution centers, cross-docks, container terminals, airports, hospitals, and similar mission-oriented facilities. Although the physical movement of material is perhaps the most visible aspect of material handling, as suggested by the following ''right definition,'' material handling goes beyond that. Material handling is ''providing the right amount of the right material, in the right condition, at the right place, at the right time, in the right position, in the right sequence, and for the right cost, by using the right method(s)'' (Tompkins et al. 1996). Note that using the ''right method(s)'' includes safety and ergonomic considerations, especially when humans are involved directly or indirectly in the handling system.

It is interesting to note that some publications have used a similar definition (i.e., providing the right amount of the right material at the right time and place) in referring to the just-in-time philosophy of the Toyota Production System, which is now generally known as lean manufacturing. This overlap suggests that providing the right amount of the right material at the right time and place must occur at two levels. One is at a planning level, where decisions such as lot sizes, shipment frequencies, reorder quantities, production or delivery schedules, and so on are made, while the other is at an execution level, where actual product (or parcel) movement and tracking/control takes place. The former would generally fall under production and inventory control for manufacturing facilities (or scheduling and planning for service facilities), while the latter would fall under material handling for either type of facility.

Another interesting aspect of material handling is the fact that, in the context of lean manufacturing, material handling is viewed uniformly as waste. A driving force in lean manufacturing is the elimination of waste. If this is interpreted strictly as the elimination of all material handling, it becomes immediately obvious that no goods would be shipped from factories (in fact, all the incoming raw material and purchased components would accumulate at the receiving dock of a factory), all incoming and outgoing ships would wait indefinitely at container terminals, no trucks would be loaded or unloaded at cross-docks, and so on. Clearly, the intent is to eliminate waste by eliminating all movement and inventories that are not essential for completing the mission of a production or service system. Therefore, planning, engineering, and the successful day-to-day operation of the material-handling system is absolutely necessary to achieve efficiency while meeting the goals of a mission-oriented facility. Significant cost-savings and performance improvements can be realized by eliminating and/or simplifying material handling functions, implementing methods changes, selecting proper handling equipment, and eliminating unnecessary handling operations and inventories.

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

With the increasing availability and use of automatic identification technologies (such as bar coding), many people have come to recognize that material and information flow together, or that material flow generates information and vice versa. Clearly, the two flows occur in different forms over different channels. Material flow involves movement of physical objects, while information flow involves movement of bytes or packets; material flow is handled via people, conveyors, lift trucks, hand trucks, and so on while information flow is handled through copper or fiber networks. However, as one type of flow occurs, it changes the state of the other or it triggers certain ''events'' for the other, and the two flows are in many ways intertwined.

Before automatic identification technologies became widely available, information flow was slow relative to material flow. Material would be moved (typically in large batches and/or over a period of time) before the information system was updated. This resulted in delays and in information that was too old, highly clustered, and often inaccurate to be useful, except for accounting or off-line, limited tracking purposes. Today, with the aid of automatic identification technologies (such as bar coding and voice recognition), used in conjunction with computer networks and communications technologies (such as radio frequency), information systems are often updated on a real-time (or near-real-time) basis and hence have become more accurate and more prominent/useful to a wider range of users, from decision makers to operations managers and end customers. This has also resulted in a higher degree of parallelism between information flow and material flow.

Due to rapid advances in computing technology, the information system has, at the same time, moved from a batch-oriented, centralized mainframe environment to a real-time-oriented, decentralized microprocessor environment, which makes it possible to store/retrieve larger amounts of information at multiple locations while developing more advanced logic to guide, optimize, or interpret material flow. (Despite an occasional misplaced parcel or lost luggage, most readers can readily identify with excellent examples of real-time information and material-flow systems used by overnight delivery providers and major airports.) While information technology and the hardware/software considerations for material-handling systems are well beyond the scope of this chapter, reference will be made to information flow/handling and its implications when appropriate.

2. CONTAINERIZATION AND UNIT LOADS

Perhaps one of the least understood, yet critical, aspects of material handling is the notion of containerization and unit loads. Many design drivers in materials handling, such as frequency of flow, load dimensions and weight, type of equipment that can or cannot be used, are often dictated by the type of container(s) and unit load(s) handled by the system. However, there is no clear-cut definition of a container or a unit load; a container in one application may very well be a unit load in another. Generally speaking, a container serves as a receptacle to keep individual/loose parts or packages together, confined in the same physical space, such as a cardboard box, a wire basket, or a tote box, among others. A unit load, on the other hand, is generally defined as the unit to be moved or stored at one time; it may consist of a single part or a bundle of parts/products, or it may consist of one or more containers. Also, the unit load includes the carrier or support needed to store or move the load. For example, a group of cardboard boxes (i.e., containers) stacked on top of a pallet would constitute a unit load, which includes the pallet itself and, say, stretch wrapping to stabilize the individual boxes.

Another example would be a 6-pack of soft drink cans. The container is the can and the bundle of six cans may be the unit load. Many people would find it difficult or awkward to carry six (loose) cans at one time. When the cans are held together with the white plastic holder, however, it becomes much easier to handle them. This underlines the significance of the unit load concept and the inclusion of support structures in its definition. Of course, a 12-pack carton is another example of a unit load. Multiple 12-pack cartons stacked on a pallet (as one might see in a grocery store) would be yet another example of a unit load. Clearly, multiple types of unit loads may flow through one or more systems as cans are bundled into 6-pack or 12-pack loads, which are then stacked on pallets.

The size and configuration of the unit load often determines how it can be moved and stored. For example, a forklift truck will typically be used if the unit load is palletized. If the unit load is chained, strapped, or stringed, however, a hook or similar lifting device, attached to a crane/hoist, may be used to lift and move the load. The configuration as well as the dimensions and weight of the unit load will dictate or rule out certain types of material handling equipment. Since it is not possible to treat the subject of unit loads and handling equipment in a comprehensive manner due to limited space, here we will show only some of the basic type of equipment typically used with palletized loads or with containers that have smooth surfaces, such as tote boxes, cardboard boxes, and the like. For more information, the interested reader may refer to Chapter 6 in Tompkins et al. (1996), among others.

The size and configuration of the unit load also determines how often it must be moved and stored. For example, if 100 boxes must be moved per hour from point A to point B, and a trip-based material-handling system is used (i.e., devices such as lift trucks must perform trips to move the

loads), then 100 trips/hr would be required to move the boxes one at a time. However, if the boxes are palletized, for example, and moved in batches of 20 (i.e., a unit load consists of 20 boxes), then 5 trips/hr would be performed from point A to point B. In many cases, the speed of the handling device would not show a significant difference, whether it is moving 1 box or 20 boxes, as long as the unit load is within the weight/volume capacity of the device and standard safety precautions are followed.

Hence, from a material-handling perspective, it may appear that moving the boxes in batches of 20 is the preferred approach since the device(s) would have to perform only 5 trips/hr instead of 100 trips/hr. However, moving the boxes in batches of 20 also leads to a phenomenon known as transfer lot delay. That is, if the transfer lot size is 20 boxes, the first box at point A must wait for the remaining 19 boxes, the second box at point A must wait for the remaining 18 boxes, and so on, before they can be moved to point B. In many systems (including manufacturing systems), such a delay increases the time required to move the boxes through the system even if the throughput (i.e., the rate at which the boxes are moved through the system—in our case 100 per hour) remains the same. Such an increase in time is also accompanied by a proportional increase in the number of boxes in the system at any one time, which would be work-in-process, WIP, or work-in-progress, depending on the application.

The average time to move a box through the system (say, the cycle time per box) and the average level of WIP would be minimized if the boxes are moved one at a time, *provided there is enough material-handling capacity to move the boxes one at a time.* Whether there is sufficient capacity to achieve one-piece flow or not depends on the volume of flow, as well as the distance, from point A to point B. If the flow volume is high and the distance from A to B nonnegligible, then we may have no choice but to use a conveyor to achieve one-piece flow.

However, conveyors require a large initial investment, and once they are installed, they are difficult to modify or relocate. Hence, as is the case in lean manufacturing, one-piece flow is often achieved by reducing the distance from A to B to such a short distance that the material-handling function is essentially eliminated. That is, no handling device or conveyor is required; instead, either the human operator moves the part with him or her over a very short distance or simple slide/roll mechanisms are used to slide or roll the parts from A to B. This approach is generally known as setting up manufacturing cells to put machines A and B within very close proximity of one another, which works reasonably well for manufacturing applications. In other applications, such as warehouses and airports, however, there are cases where the cell analogy does not apply and the ideal solution may indeed be a conveyor or a trip-based handling system. Furthermore, in facilities such as warehouses and airports, the handling system is also often used to sort the loads, and for high-volume, high-speed sortation, conveyors may be the best solution.

Thus, material-handling decisions are often complex decisions that involve the configuration and size of the unit load(s), the determination of transfer lot size(s), the type of handling systems available (trip-based, conveyors, or robots), the volume of flow, the frequency of flow, and the distances involved. In the next section, some basic handling equipment is presented. We note that the material presented here applies largely to discrete-parts material flow systems, where there is a discrete unit of flow. In some applications, such as oil refineries and sugar-processing plants, the flow is a continuous flow and until the product is unitized (by putting it in, say, a barrel or package), there is no discrete unit of flow. Such systems generally fall under bulk material-handling systems, where flow is often measured as gallons/hr, tons/shift, and so on.

The reader may refer to Fruchtbaum (1988), Shamlou (1988), and Woodcock and Mason (1987), among others, for bulk material-handling. It is interesting to note that some systems may be a combination of bulk and discrete-parts flow. For example, in a soft drink bottling plant, the preparation or mixing of the drink may be in bulk form, but once the drink is filled into cans or bottles via the filling machines, the flow will be a discrete flow. Likewise, in a pasta factory, the preparation of the durum wheat would typically involve bulk handling, but once the dough is mixed and pressed into various forms and shapes through the dies, the remainder of the flow will be in discrete units. (Of course, individual pieces of pasta may still be treated as bulk flow until they are packaged.) Both of the above examples happen to involve food handling and preparation, which is often subject to more strict and specialized handling standards.

3. BASIC MATERIAL-HANDLING EQUIPMENT

In this section, we will present some basic equipment used in various material-handling applications. It is by no means a comprehensive list. Material handling is a dynamic world; new technologies, new equipment, and creative applications of the two continue to change the face of material handling. The reader is, therefore, encouraged to take advantage of the Web to get up-to-date information on material-handling technology, equipment, applications, and vendors. Today, most vendors in the United States have Web pages to describe their capabilities and display their equipment/systems. Many of them include material on information/computer systems, especially in those cases where automated equipment/systems are involved. The reader is encouraged to check, among others, the

Figure 1 Pallet Jack. (Courtesy of Blue Giant Equipment Corporation)

website of Modern Materials Handling (a trade publication at www.mmh.com/info) and websites such as forkz.com (see www.forkz.com/Business/Industries/Industrial_Supply/Materials_Handling/ for a list of material-handling vendors under various categories).

4. INDUSTRIAL TRUCKS

There is a wide range of industrial trucks available. Going from simple to sophisticated and from wide-aisle to narrow-aisle trucks, a possible list would be as follows: (1) hand truck/cart, (2) pallet jack, (3) walkie stacker, (4) pallet/platform truck, (5) counterbalanced lift truck, (6) straddle truck, (7) reach truck, (8) sideloader, (9) turret truck, (10) storage/retrieval truck, and (11) order picker truck, among others. Examples of 2, 3, 5, 6, 8, 9, and 11 are shown in Figures 1, 2, 3, 4, 5, 6, and

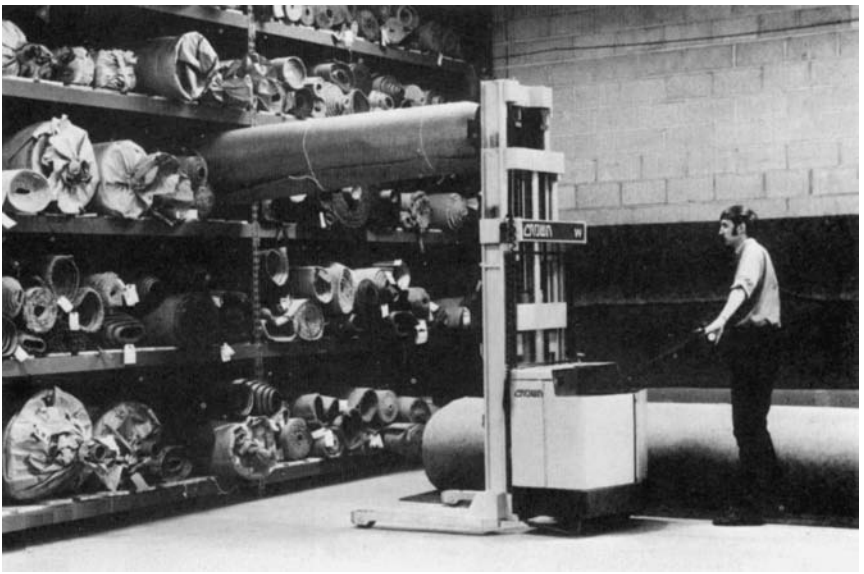

Figure 2 Walkie Stacker. (Courtesy of Crown Lift Trucks)

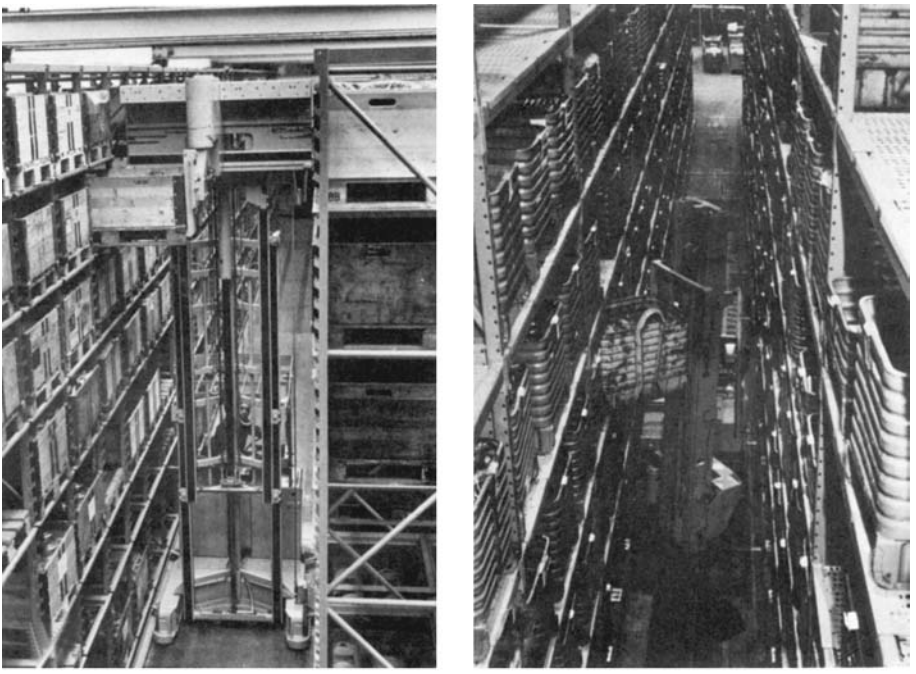
Figure 5 Sideloader Trucks. (Courtesy of The Raymond Corporation. Raymond is a registered trademark of The Raymond Corporation.)



(a) (b)

Figure 6 Turret Trucks. (Courtesy of Lansing Bagnall and Drexel Industries, Inc.)

7, respectively. The simplest truck with a mast (which allows the load to be raised and lowered) is a walkie stacker. The most common truck found in industry, however, is the counterbalanced lift truck, which still requires wide aisles due to its turning radius, and the fact that the truck must face the rack to store or retrieve the load.

Due to its shorter size, the straddle truck has a smaller turning radius than the counterbalanced lift truck; however, outriggers (''long feet'') are added to compensate for load weight. Also, the straddle truck still has to face the rack to store/retrieve a load, which results in wide aisles. A reach truck is very similar to a straddle truck except that it is has relatively shorter outriggers and it is equipped with a pantograph mechanism that allows the truck to insert/remove a load into/from the rack without moving the truck back and forth; the truck still has to face the rack, however.

To further reduce aisle width, the sideloader truck was introduced. This truck faces only one side of the aisle; aisle width is reduced by eliminating any turns inside the aisle. It is also especially suited for handling long stock such as lumber or bar stock. Its primary drawback, of course, is the fact that in order to serve the opposite side of the aisle, the truck must leave the aisle, turn around, and reenter facing the opposite side. Serving both sides of the aisle at the same time, while requiring no turns inside the aisle, became possible with the turret truck, which resembles a counterbalanced lift truck but is able to store/retrieve loads without facing the rack. This is accomplished by giving the turret truck a swing mast or swing forks: the body of the truck remains stationary (facing forward in the aisle) while the load is turned to face the rack and the operator remains at ground level. As rack heights increased to better utilize land and cubic space, it became necessary to raise the operator along with the load, which led to the storage/retrieval truck.

Another truck that raises the operator with the load is the order picker truck. However, unlike the above trucks which are designed primarily for unit load in and unit load out, an order picker truck allows the operator to start with an empty pallet (or magazine) and stack various containers or parts on it as he/she picks the appropriate parts/products from unit loads stored in the rack.

A summary of basic features of various industrial trucks, including cost, is presented in Table 1, adapted from (Tompkins et al. 1996). The reader should keep in mind that truck prices and features change over time; nevertheless, the information provided in Table 1 is useful for comparison purposes.

An industrial truck is basically used for moving loads in and out of storage (i.e., they perform a storage/retrieval function) and/or moving loads from one point to other point(s). Counterbalanced lift trucks, and similar low-mast trucks, are also used for loading/unloading trailers at shipping/receiving docks. In the first case, a fundamental question that arises is the throughput capacity of a truck; that is, how many storages and retrievals per hour can a particular truck perform? In the second case, a similar question posed in a slightly different fashion would be: given the throughput requirement (the number of loads that must be moved per time unit), how many trucks do we need? Both questions may appear simple on the surface, but they are not straightforward to answer.

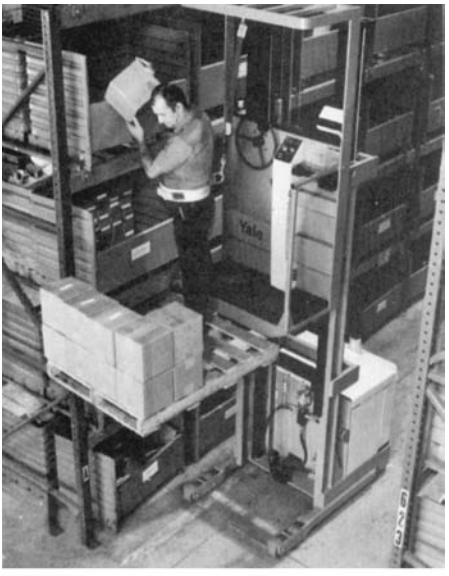


Figure 7 Order Picker Truck. (Courtesy of Yale Industrial Trucks)

TABLE 1 Features of Various Industrial Trucks

	Cost	Lift Height	Aisle Width	Weight Capacity	Lift Speed	Travel Speed
Counter balance	$30,000	22 ft	10–13 ft	2–10K lb	80 fpm	550 fpm
Straddle	$35,000	21 ft	7–9 ft	2–6K lb	60 fpm	470 fpm
Straddle reach	$40,000	30 ft	6–8 ft	2–5K lb	50 fpm	490 fpm
Sideload	$75,000	30 ft	5–7 ft	2–10K lb	50 fpm	440 fpm
Turret	$95,000	40 ft	5–7 ft	3–4K lb	75 fpm	490 fpm

Consider first the storage/retrieval case. The throughput capacity of the truck depends on the rack size, the storage policy, the travel speed and type of truck, and the load pick-up/deposit times. Assuming a unit load in, unit load out operation, a truck will handle a load either on a single command (SC) or dual command (DC) basis. With SC operation, the truck starts at the input/output (I/O) point, which is typically located at the lower left-hand corner of the rack, travels to the appropriate rack opening, deposits (or picks up) the load, and returns to the I/O point. With SC storage, the truck picks up the load from the I/O point and returns empty to the I/O point. With SC retrieval, the truck travels empty from the I/O point to the rack, picks up the load, and brings it to the I/O point, where it is deposited.

To avoid empty travel to/from the I/O point, a truck can perform a DC cycle, provided that a storage request and a retrieval request are present at the same time. To perform a DC cycle, the truck starts at the I/O point, picks up the load to be stored, travels to an empty rack opening to deposit the load, then travels directly to the rack opening where the load to be retrieved is located, picks up that load, travels to the I/O point and deposits the load. Hence, two loads are handled on each DC cycle and empty travel occurs only from the storage point to the retrieval point.

The throughput capacity of a truck (operating within an aisle) depends on the expected time it takes to perform a SC and a DC cycle; it also depends on what fraction of time the truck performs a SC or DC cycle. Suppose the storage rack is H ft high and L ft long. Further suppose the truck's lift speed (or vertical speed) is v fpm and its travel speed (or horizontal speed) is h fpm. If the truck is capable of concurrent (i.e., simultaneous) travel in the horizontal and vertical directions, Bozer and White (1984) have shown that the expected SC travel time, say *E(SC),* and the expected DC travel time, say *E(DC),* can be computed from the following equations, assuming that randomized storage is used (i.e., a load is equally likely to be stored in or retrieved from any location in the rack) and the I/O point is located at the lower left-hand corner of the rack:

$$E(SC) = \left(1 + \frac{b^2}{3}\right) T \tag{1}$$

$$E(DC) = (40 + 15b^2 - b^3) \left(\frac{T}{30}\right) \tag{2}$$

where b is the shape factor and T is the scaling factor for the rack. Expressions for alternative I/O point locations can be easily obtained from Eqs. (1) and (2); the reader may refer to Bozer and White (1984).

The shape factor and scaling factor are computed as follows. Let t_h designate the horizontal travel time from the I/O point to the farthest end of the aisle, that is, $t_h = L/h$. Likewise, let t_v designate the vertical travel time from the I/O point to the top of the rack; that is, $t_v = H/v$. Note that $t_h(t_v)$ simply represents the length (height) of the rack in time. We then have:

$$T = \max[t_h, t_v], \tag{3}$$

and

$$b = \min\left(\frac{t_h}{T}, \frac{t_v}{T}\right). \tag{4}$$

In other words, T simply represents the longer (in time) side of the rack, and b is the shorter (in time) side of the rack divided by the longer (in time) side. Note that $0 < b \leq 1$, by definition. If $b = 1$, the rack is said to be square-in-time (SIT).

The above results are based on randomized storage, which is as an approximation of the closest-open-location (COL) rule used in industry. (Under COL, an incoming load is simply stored in the

open location closest in time to the I/O point.) If the average rack utilization is high, the above expected travel times are reasonably accurate (not considering acceleration/deceleration of the truck). If the average rack utilization falls below 90% or so, however, the above expected travel times are likely to overestimate the actual expected travel times since the COL rule tends to favor rack openings close to the I/O point, while randomized storage always picks each opening in the rack with equal probability.

Concurrent travel is possible whenever the lift motor (vertical motor) is separate from the travel motor (horizontal motor). While concurrent travel is often limited when the forks are raised (due to safety considerations), most trucks follow a combination of concurrent and sequential travel while operating. A conservative approach would be to assume 100% sequential travel; that is, the truck first moves horizontally down the aisle, once it stops, then the forks are raised (for vertical travel).

With sequential travel, $E(SC)$ and $E(DC)$ can be computed from the following equations assuming randomized storage:

$$E(SC) = (1 + b)T \tag{5}$$

$$E(DC) = (1 + b)(1.333T) \tag{6}$$

where T is the scaling factor [Eq. (3)] and b is the shape factor [Eq. (4)] as before.

The total cycle time for a SC cycle (say T_{SC}) or a DC cycle (say, T_{SC}) is obtained by adding the load pick-up time (P) and the load deposit time (D) to the expected travel time. That is,

$$T_{SC} = E(SC) + P + D \tag{7}$$

and

$$T_{DC} = E(DC) + 2P + 2D \tag{8}$$

Often the load pick-up/deposit time is constant and $P = D$.

As an example, consider a rack 20 ft tall ($H = 20$) and 100 ft long ($L = 100$). The I/O point is assumed to be located at the lower left-hand corner of the rack. Suppose the truck's lift speed is 80 fpm ($v = 80$) and travel speed is 250 fpm ($h = 250$). The load pick-up or deposit time is equal to 0.15 min ($P = D = 0.15$). Using Eqs. (3) and (4), we obtain $T = 0.40$ and $b = 0.625$. That is, the rack's longer side is 0.40 min long and its shape factor is equal to 0.625. Assuming randomized storage and *concurrent* travel, we obtain $E(SC) = 0.4521$ min and $E(DC) = 0.6082$ min from Eqs. (1) and (2), respectively. Hence, for the expected cycle times we obtain $T_{SC} = 0.7521$ min and $T_{DC} = 1.2082$ min. Although the expected DC cycle time is longer than the expected SC cycle time, two loads (one storage and one retrieval) are handled on each DC cycle.

The throughput capacity of the truck (operating in one aisle) depends on the fraction of SC vs. DC cycles it performs. If an operation is defined as a storage or a retrieval, the throughput capacity can be measured in operations performed per hour. Suppose 50% of the operations in the above example are storages and 50% are retrievals. (In the long-term, of course, the two percentages would be equal; however, during certain shifts or segments of the day, the truck may perform more operations of one type.) Further suppose that 30% of the storages are performed on a DC basis (i.e., 30% of the storages are matched with a retrieval and the rest are performed on a SC basis).

If the throughput capacity is denoted by z operations/hr, we have $(2 \times 0.15z)(1.2082 \div 2) + (0.35z + 0.35z)(0.7521) = 60(0.90) = 54$ min/hr, assuming a 90% truck utilization. Note that 30% of 50% yields $0.15z$, which is the fraction of storage operations performed per hour on a DC basis; each storage operation takes $1.2082 \div 2 = 0.6041$ min when performed as part of a DC cycle. Also, each such storage operation is matched with a retrieval operation, which explains the multiplication of $0.15z$ by two. Likewise, 70% of 50% yields $0.35z$, which is the fraction of storage operations performed per hour on a SC basis. The same holds true for SC retrievals. Solving the above equation for z, we obtain $z = 76.30$ operations/hr as the throughput capacity of the truck at 90% utilization. A smaller value for truck utilization may be used to allow for downtime or maintenance, battery recharge or replacement, time for the truck to change aisles, and so on.

For comparison purposes, the reader may verify that, with *sequential* travel, assuming no other changes, the throughput capacity of the truck drops to 61.02 operations/hr. That is, in this particular example, the truck performs approximately 25% more operations per hour with concurrent travel. The number of trucks needed depends on the overall throughput requirement of the system. For example, if the system needs to perform 220 operations/hr, $220/76.30 = 2.88$, or 3 trucks, would be required if concurrent travel is assumed. With sequential travel, 3.61, or 4 trucks, would be required. An additional allowance may be required for congestion if the trucks serve a small number of aisles and interfere with each other. Also, we assumed that all the loads are delivered to (and removed from) the I/O point (located at the end of each aisle) via another handling system. Additional

truck travel time required can be easily computed if a single, central I/O point is used to serve all the aisles.

Consider next the case where trucks are used for moving loads from one point to other point(s). Given the throughput requirement (i.e., the number of loads that must be moved per time unit), and the layout/configuration of the points served by the trucks, we would like to know how many trucks are needed. It is assumed that one load is moved on each trip.

To determine the number of trucks needed, in addition to the throughput requirement and the location of the points, we need to specify a "dispatching policy," which basically determines which truck moves which load and when. There are a number of centralized and decentralized dispatching rules one can adopt. Centralized rules require a central dispatcher (or computer) to keep track of each load in the system waiting to be moved; such loads are also known as move requests. They also require a means of communication between the dispatcher and each device so that the appropriate device can be dispatched to the appropriate load. Decentralized rules tend to be less efficient but simpler and less expensive. With decentralized rules, each device generally follows a set of fixed instructions (or preprogrammed instructions) to decide which load to move next.

Specifying a dispatching rule is important because the dispatching rule often affects how much empty travel (or "deadheading") each device performs in serving the move requests. Depending on the flow patterns and the location of the points served by the devices, each device may have to perform a nontrivial amount of empty travel. The model we present below assumes first-come-first-served (FCFS) dispatching, which is a simple, centralized dispatching rule used in industry. Under FCFS dispatching, when a device becomes available (i.e., it delivers a load and becomes empty), it is assigned to the oldest move request in the system, regardless of the location of the oldest move request relative to the location of the device. If there are no move requests in the system when the device becomes available, then it idles at its last delivery point and waits for the next move request to arrive. When a move request arrives, if there is an idle device, it is assigned to the move request; if there are two or more idle devices, one of them is randomly picked and assigned to the move request. If there are no idle devices when a move request arrives, then it must wait until it becomes the oldest move request in the system and a device becomes available.

If the device becomes available at point i (or station i) and the oldest move request is located at point j (or station j), the device travels empty from station i to station j. Hence, when a device is assigned to a move request (i.e., when a device is serving a move request), the service time includes the empty travel time needed for the device to reach the move request. Obviously, there are several possible improvements to the FCFS dispatching rule. For example, when a device becomes available at station i, instead of the oldest move request, it could be assigned to the move request closest to station i. Such a rule, known as the shortest-travel-time-first (STTF) rule, is also used in industry, and it tends to reduce empty device travel relative to FCFS dispatching. However, STTF dispatching does not lend itself well to analytical modeling and therefore its use often requires simulation. In contrast, FCFS dispatching can be modeled analytically, and the results obtained with it would at least serve as a benchmark.

Assuming FCFS dispatching, suppose the flow data are given as a from-to chart, where f_{ij} represents the number of loads that must be moved per hour from station i to station j. (Recall that one load is moved on each trip.) Let $t^e_{ij}(t^f_{ij})$ be the empty (loaded) device travel time in minutes from station i to station j. Assuming that it takes P mins to pick-up and D mins to deposit the load, for simplicity we will assume that $t^f_{ij} = t^e_{ij} + (P + D)$. (The model we show below works with any user-defined t^e_{ij} and t^f_{ij} values.)

With FCFS dispatching, using the results presented by Chow (1986), the number of empty trips performed per hour from station i to j, say, e_{ij}, can be shown to be given by the following equation:

$$e_{ij} = \sum_k f_{ki} \left(\sum_k f_{jk}/F \right) \tag{9}$$

where F is the total loaded trips performed per hour, that is, $F = \Sigma_i \Sigma_j f_{ij}$. Note that the empty trips performed per hour from station i to j is proportional to the number loaded trips/hr ending at station i and the number of loaded trips/hr originating at station j. Each time the device completes a loaded trip, it becomes empty by definition. Hence, if more loaded trips end at station i, the device becomes empty more often at station i. Likewise, if more loaded trips originate at station j, more empty devices must be dispatched to station j. Equation (9) is also presented by (Egbelu 1987); however, no dispatching rule is specified. We note that the two terms shown in Eq. (9) can be multiplied to obtain e_{ij} only when the next load to be served by an empty device is independent of the current location of the device, which holds true under FCFS dispatching.

In Eq. (9), we allow the case where j is equal to i; that is, an empty trip may be performed from station i to station i, which implies that when a device delivers a load at station i, it is possible that the oldest move request in the system is located at station i. Depending on the exact locations of the

pick-up and deposit points associated with station i, such an empty trip may or may not require a nonnegligible travel time.

Let $\alpha_f(\alpha_e)$ denote the total loaded (empty) device travel required (in min/hr). It is straightforward to obtain α_f and α_e as follows:

$$\alpha_f = \sum_i \sum_j f_{ij} t_{ij}^f \quad \text{and} \quad \alpha_e = \sum_i \sum_j e_{ij} t_{ij}^e \tag{10}$$

where e_{ij} is obtained from Eq. (9) and f_{ij} is user specified. Given the values of α_f and α_e, the number of trucks required, say, N, can be obtained as follows:

$$N = \frac{(\alpha_f + \alpha_e)}{(60 - t)u} \tag{11}$$

where t is the device unavailable time (expressed in min/hr) due to, say, battery replacement or scheduled breaks for lift truck drivers, and so on, and u is the target device utilization during the time that it is available. Of course, N is rounded up to the closest integer value.

The following example will demonstrate the use of the above model. Suppose four stations are to be served by a fleet of lift trucks. Suppose the from-to chart, that is the loads moved per hour, and the empty travel times (in min/trip) are given as follows:

From/to (loaded trips/hr)

	1	2	3	4
1	–	8	4	12
2		–	4	2
3			–	
4				–

Empty travel time (min/trip)

	1	2	3	4
1	0.0	1.0	0.8	1.5
2	1.0	0.0	1.2	0.5
3	0.8	1.2	0.0	1.0
4	1.5	0.5	1.0	0.0

Load pick-up and deposit are each assumed to require 0.50 min. For simplicity, loaded travel times are obtained by adding the pick-up and deposit times to the empty travel times.

The total number of loaded trips performed per hour (F) is equal to 30. Using Eq. (9), we obtain the following matrix for the number of empty trips performed per hour under FCFS dispatching:

From/to (Empty trips/hr)

	1	2	3	4
1	0.0	0.0	0.0	0.0
2	6.4	1.6	0.0	0.0
3	6.4	1.6	0.0	0.0
4	11.2	2.8	0.0	0.0

The reader may verify that the entries in the above matrix sum up to 30 trips/hr as expected. (Recall that each loaded trip is followed by an empty trip, although the duration of an empty trip may be negligible.) Also, we note that no empty trips are performed out of station 1 because no loads are delivered into station 1. (A device becomes empty only after it has delivered a load.) Likewise, no empty devices are dispatched to stations 3 and 4 because these two stations do not send any loads, which means they never request an empty device.

Using the loaded and empty trips performed per hour, from Eq. (10) we obtain $\alpha_f = 65$ min/hr and $\alpha_e = 31.64$ min/hr. That is, the total (loaded plus empty) travel time requirement comes to 96.64 min/hr. Of course, there are only 60 min/hr; hence the preceding result simply implies that we are going to need more than one lift truck. Assuming $t = 5$ min/hr and $u = 0.90$, from Eq. (11) we obtain $N = 1.952$, that is, two lift trucks are needed.

During its available time (i.e., during the 55-minute portion of an hour), the expected state of each lift truck can be broken down as follows: $(65/2)/55 = 59.09\%$ of the time traveling loaded (including load pick-up/deposit); $(31.64/2)/55 = 28.76\%$ of the time traveling empty; and the remaining portion of the time (12.15%) waiting idle for the next move request. The expected device utilization during a 55-minute period comes to $59.09\% + 28.76\% = 87.85\%$, which is less than the target utilization of 90% because two lift trucks are provided when the exact mathematical requirement was 1.952 trucks. Note that each device travels empty almost one-third of the time that it is busy ($28.76/87.85 = 0.3273$).

One possible approach to reduce empty travel time (or deadheading) is to change the dispatching rule from FCFS to STTF. Generally speaking, STTF reduces empty device travel, and a system that meets throughput under FCFS will continue to meet throughput under STTF. However, with STTF, even if the system meets throughput and all the move requests are eventually served, some move requests placed by certain stations may have to wait longer than usual depending on the layout of the stations. This may occur especially if the stations are clustered. Note that under STTF, a device will continue to serve all the move requests in a cluster of stations, including those that arrive while it is busy, before it is dispatched to a move request placed by a station outside the cluster.

Another possible approach to reduce empty device travel is to eliminate dispatching and run each device according to a predetermined schedule. If there is little or no variance in the system, that is, if the arrival of the move requests can be predicted with reasonable certainty, then running the devices according to a schedule may be the best approach. In fact, in some systems, such as lean manufacturing systems, since each cell or station operates to takt time, the device routes, and each move they make, can be set up ahead of time. With shrinking unit load sizes, this approach has led to what is known as a ''milk run,'' where each device, on each trip, makes a preplanned number of deliveries to a particular set of stations at specific times. In many instances, ''tuggers'' with carts attached perform the milk runs. Such handling systems are known as tractor-trailer systems, which were the forerunners to automated guided vehicle (AGV) systems discussed in Section 7.

5. CONVEYORS

Conveyors are perhaps the oldest means of handling material. As is the case with industrial trucks, there is a wide range of conveyors available for different applications. They may take the form of a simple gravity chute (where a load placed at point A simply slides down to point B with gravity) or a sophisticated high-speed sortation conveyor that can sort hundreds of thousands of items per hour. Virtually any type of conveyor, in any type of industry/application, can be designed to handle virtually any type of material, including bulk materials (coal, sugar, etc.), loose items (nuts, bolts, screws, etc.), packaged goods (such as a men's shirt or lady's blouse), individual products (such as a light bulb or an engine block in a fixture), and palletized or containerized loads.

Due to limited space and extensive variations in design, only a basic set of conveyors are presented in this chapter. Such a list would include: (1) chute conveyor (Figure 8), (2) belt conveyor (Figure 9), (3) roller conveyor (Figure 10), (4) wheel conveyor (Figure 11), (5) slat conveyor (Figure 12), (6) Chain conveyor (Figure 13), (7) tow-line conveyor (Figure 14), (8) trolley conveyor (Figure 15), and (9) power-and-free conveyor (Figure 16).

Belt conveyors come in a wide variety of forms. The simplest form is a flat belt conveyor, which is often roller supported (i.e., there is a series of rollers placed underneath the belt). Belt conveyors are typically driven by a drive pulley/roller connected to an electric motor. For conveying items that may not be containerized, however, belt conveyors can also be of the slider-bed-supported type, where a flat metal surface is placed underneath the belt. An everyday example of the slider-bed supported belt conveyor can be found at the check-out lanes of most grocery stores.

An important characteristic of belt conveyors is that items or containers placed on such conveyors retain their relative position as they are conveyed, unless, of course, one of the items is intentionally

stopped or removed. Belt conveyors can also be used for moving loads between floors; this may be done with a belt incline or a spiral belt conveyor, which consists of sections of powered belt conveyors spiraling up or down. Depending on the application, there is a large variety of plastic belts one may use for horizontal conveying and belt inclines.

Telescoping belt conveyors have been used successfully at shipping/receiving docks to load/unload trailers. (The belt conveyor telescopes into the trailer to minimize walking distances during manual load/unload operations.) In addition, (troughed) belt conveyors are used extensively in handling bulk materials horizontally as well as up/down an incline.

Roller conveyors also come in a wide variety of forms and are used in wide ranging applications. Typically, a roller conveyor is driven either by a belt (placed underneath the rollers), a drive shaft (that runs along the conveyor underneath the rollers, the rollers are connected to the drive shaft with industrial-grade rubber bands), a chain-and-sprocket mechanism (a sprocket is attached to the end of each roller, the chain runs along one end of the conveyor), or an electric motor placed inside the rollers themselves.

Roller conveyors are most useful when the load to be conveyed has a smooth conveying surface. (Loads with irregular conveying surfaces would be better suited for belt or slat conveyors.) As a rule of thumb, for load stability, the roller spacing on the conveyor should be such that the smallest load conveyed is supported by at least three rollers at all times. Otherwise, the load may rock back-and-forth as it travels on the conveyor. In addition to conveying containerized loads, roller conveyors can be used for accumulation, which is a critical function required in some conveyor systems. Zero-pressure-accumulation is a type of technique often used with roller conveyors to accumulate many loads without buckling (i.e., without loads falling off the conveyor as more loads arrive at the accumulation point).

Wheel conveyors (or skate wheel conveyors) are relatively inexpensive because they are not powered (i.e., gravity or a human's push is often used to move the loads). They are quite cost effective in moving light to medium-weight loads over short distances. A collapsing variety, which can collapse and expand and has legs with adjustable height, has been used at shipping/receiving docks to load/

Figure 14 In-floor Tow-Line Conveyor.

unload trailers. The conveyor is stretched into the trailer to minimize walking distances during manual load/unload operations.

A slat conveyor consists of individual slats attached to a chain (or other driving mechanism) that runs underneath the conveyor. Often the slats are made of wood or steel. Slat conveyors, similar to belt conveyors, provide a smooth conveying surface to move heavy and/or irregularly shaped loads that may or may not be containerized. Most conveyors used in the baggage claim areas of airports can be classified as slat conveyors.

Chain conveyors are often used for moving medium-weight to heavy loads over short distances. They are also used for performing 90° transfers, where a set of chain conveyors pops up (or moves up) from underneath the load to lift it an inch or so, moves it laterally off of one conveyor and onto another one, and then moves back down to release the load.

Tow-line conveyors consist of a drive mechanism (often a chain) that may be buried in the floor (in-floor tow line conveyor) or supported by an overhead track (overhead tow-line conveyor). Hooks or dogs attached to the chain move the load forward when the chain is powered. Such motion can also be described as synchronized motion because all the loads attached to the conveyor move at the same time and at the same speed.

Tow-line conveyors generally offer a cost-effective means of moving loads (often placed on carts with nonpowered wheels) over long distances with no human operators. Each cart being pulled by the conveyor can be preprogrammed manually to be diverted off the conveyor automatically at specific points (marked on the floor, often by magnets). Hence, a cart manually hooked onto the conveyor at point A can be diverted off the conveyor at point B or point C with no human intervention. Tow-line conveyors, especially the in-floor variety, are also used in automotive manufacturing, where the automobile bodies are moved through the paint and assembly areas. Such tow-line conveyors are also known as ''drag chain'' conveyors.

Trolley conveyors, which are often used for moving loads overhead, are very similar to tow-line conveyors. A chain is placed inside an overhead track, which may be I-shaped or U-shaped. The carriers are attached to the chain via trolleys. When the chain is powered, the carriers move forward. Based on the product/part being handled, there is a wide range of designs used for the carrier, or

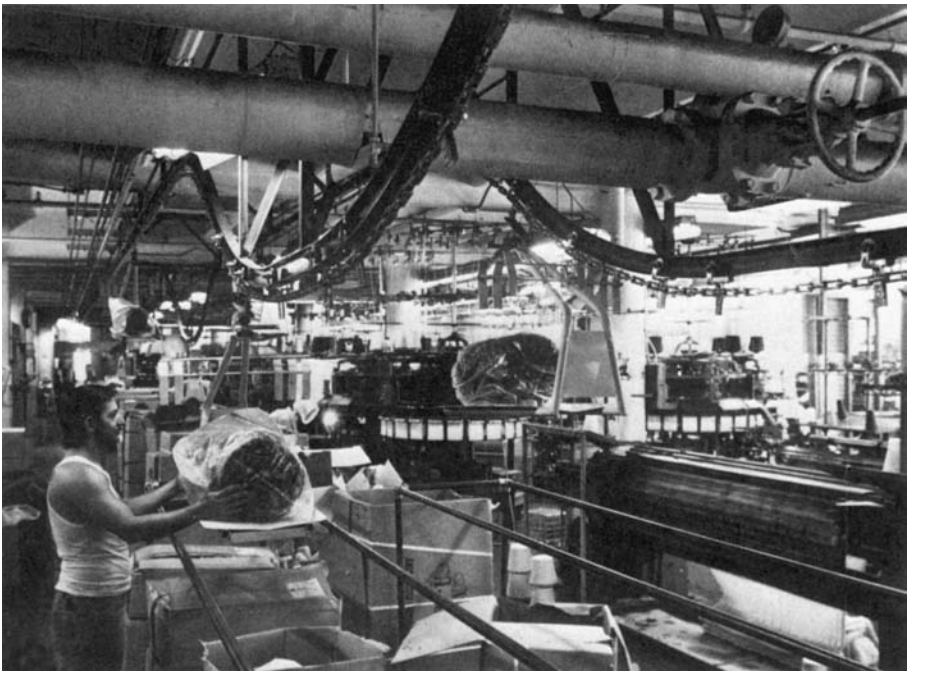

Figure 15 Trolley Conveyor. (Courtesy of Rapistan Systems)

hook attached to the carrier. Again, the type of motion provided is synchronized motion. Trolley conveyors have been used extensively in manufacturing, and similar applications to move parts from, say, the paint department, to workstations and assembly stations where parts are needed. They often travel overhead but can dip to deliver the parts to human operators.

Power-and-free conveyors have also been used in manufacturing and similar applications. Often they are installed overhead, although floor-supported versions (known as inverted power-and-free) are also available. A power-and-free conveyor consists of two tracks: a power track, which is similar to a trolley conveyor in design, and a free track. The carriers or hooks are placed on the free track via trolleys. When the dog on the power track catches (or engages) the trolley on the free track, the load moves forward. To stop motion (or to divert the load), the free track moves away from the power track and the dog disengages. Hence, merge and divert points can be created by using a power-and-free conveyor. Also, loads can be accumulated by disengaging the dog. The power track may run directly above the free track, or the two tracks may run side by side. Note that a power-and-free conveyor provides synchronized motion as long as the dog is engaged with the carrier in the free track.

Conveyors that provide asycnchronized motion are more advanced in design. One example is the cart-on-track conveyor and its variations, which allow the carts to be stopped or moved at different speeds on the conveyor at the same time. (The ''cart'' is often a fixture to hold the part.) Monorails, which strictly speaking are not classified as conveyors, also provide asynchronized motion since each carrier on a monorail is individually powered through an electric motor attached to the carrier. Power for the electric motor is received from the track, which also serves as a conduit to serve information to/from each carrier on the track. By moving sections of track vertically or horizontally, monorails can move individual carriers between floors, or they can route individual carriers in different directions (i.e., a carrier arriving at an ''intersection'' may continue straight through, or it may be diverted off to another segment of the track).

There is also a family of special-purpose conveyors known as sortation conveyors. (Interestingly, the word ''sortation'' is not in the English dictionary, but it has been used in the material-handling literature for a long time.) As the name implies, the primary function of a sortation conveyor is to sort incoming (mixed) items into specific lanes based on specific characteristics of each item. For example, if incoming items represent shipments to various retail stores, then a sortation conveyor can be used to sort all the items so that items destined to store A are diverted into lane A, items

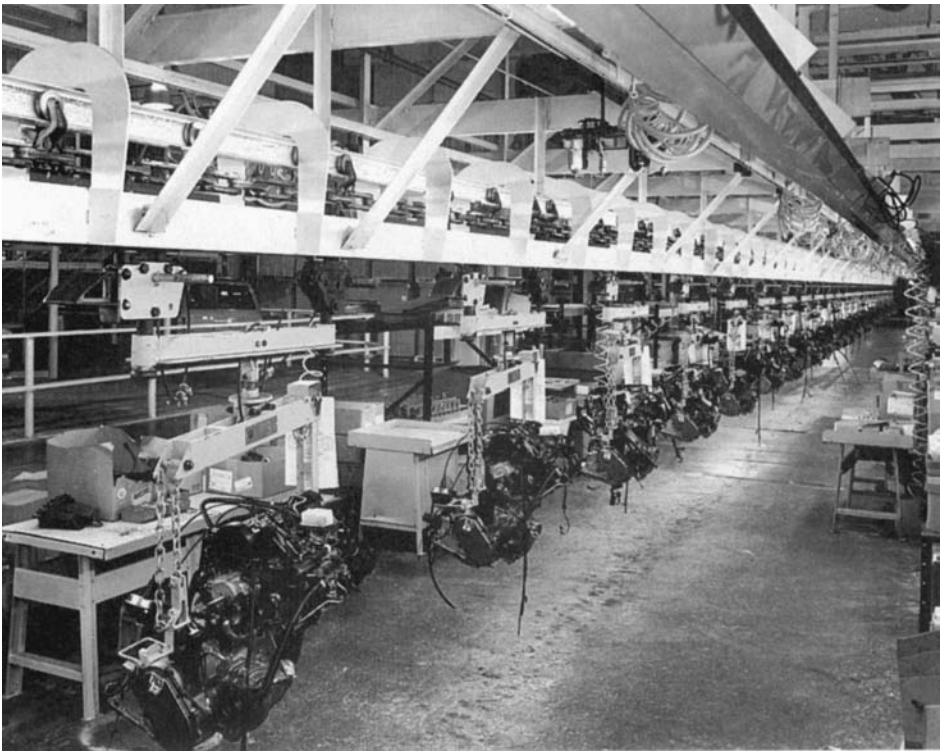

Figure 16 Power-and-Free Conveyor. (Courtesy of Jervis B. Webb Co.)

destined to store B are diverted into lane B, and so on. Naturally, sortation conveyors play a significant role in distribution centers and similar facilities where a large number of items must be sorted by customer, or by destination, or some other user-specified criteria.

With sortation conveyors, the items to be sorted are moved in a fashion similar to those conveyors described above, but their main distinguishing characteristic is the fact that loads can be automatically diverted off at specific points and at high speeds. (As described earlier, loads can also be diverted off at specific points with an in-floor tow-line conveyor, for example, but the tow-line conveyor would be exceedingly slow for most sortation purposes.)

Items to be sorted enter the sortation conveyor at a point known as the ''induction point.'' (There may be multiple induction points.) In high-volume systems, the induction point is typically fully automated; the item is automatically identified (often via bar coding the item and using laser scanners) and it is automatically ''inserted'' into the sortation conveyor. The insertion mechanism depends on the type of sortation conveyor used. For example, most sortation conveyors (except for tilt tray and cross-belt sorters, described below) require a minimum amount of clearance (or physical distance) between the items to be sorted; this clearance is automatically inserted at the induction point, which releases the items with the proper clearance between them.

There is a wide variety of sortation conveyors available. Naturally, the sortation rate (number of items sorted per minute) depends on the type of conveyor used. Generally speaking, although it is often not up to the user, it is easier and less costly to achieve high sort rates if all the items are uniform in size and weight and they are packaged/containerized in a consistent fashion. The sortation function slows down or becomes more sophisticated as more variance in item weight/size (or packaging) is encountered.

Basic types of sortation conveyors, their method of operation and basic characteristics (including sort rates), are presented in Table 2 (Kulwiec 1999). As can be seen in Table 2, sort rates may be as small as 20 items/min (or 3 sec per item) and as large as 670 items/min, which is less than 0.1 sec per item! Among the conveyors described in Table 2, the sliding shoe conveyor and the cross-belt sorter are sortation conveyors that have been introduced relatively recently.

TABLE 2 Sortation Conveyor Equipment Guide (Kulwiec 1999)

Sortation Device	Operation Details	Application Notes
Deflector	Stationary or movable arm deflects carton from a conveyor to another line or chute. Usually does not contact conveyor belt or rollers.	Low sorting rate (20–100 sorts per min). Handles up to 150 lb loads. Can be used for bidirectional sorting.
Diverter (pusher)	Moving arm with paddle sweeps across conveyor to push carton or item off opposite side. Pusher face retracts until next divert.	Sort rate is 20–100 sorts per minute (spm). Unit design allows for close grouping of spurs and for dual side sorting.
Pullers (rake)	Rake puller uses rows of chains equipped with tines to lift and pull off carton.	Can be used where space limits installation of a pusher. Sort rates to 80 spm; load capacity to 300 lb.
Pullers (pop-up belt and chain)	Pop-up devices rise up between rollers to change direction of item.	System handles heavy, durable loads, usually built into live roller conveyor. Has bidirectional capability.
Pop-up (wheels)	Powered wheels, usually skewed, rise up to contact bottom of carton and convey it to a spur.	Maximum load to 300 lb, sort rates of 60–150 spm. Gentle impact on load.
Pop-up (rollers)	Powered rollers rise up between conveyor chains or rollers to lift carton above conveyor surface and propel it off to the side.	Provides good load orientation. Sort rates to 150 spm; loads to 500 lb.
Sliding shoe	A series of sliding shoes (or moving slats) slide across conveyor surface to contact product and move it off the main conveyor.	High speed, up to 200 spm. Separates single line of items into multiple discharge lines.
Tilting devices (tilt tray) (tilt slat)	Cartons or hinged products are carried in hinged trays that can tilt in either direction at discharge point. Slat type carries items on flat surface; slats tilt up to effect discharge.	Various products and shapes can be handled. Sort rates range to 365 spm. System operates with elevation changes.
Cross-belt	Product is carried on short belt segments mounted 90° to conveyor line travel. Belt carries off item at discharge point.	Very high sort rates, to over 670 spm. Large number of divert points can be handled. Continuous-loop or train-style operations.

Source: Kulwiec 1999.

In addition to those conveyors listed in Table 2, special-purpose sortation systems have been developed for overnight delivery companies and the United States Postal Service (USPS) for mail/parcel handling. Although a very small fraction of parcels/mail may be lost, delayed, or misdirected, such systems have been used successfully for many years to sort mail and parcels that show considerable variation in size/weight. Given the increasing volume of domestic and international air travel, sophisticated sortation systems have also been developed for some of the world's largest airports, where thousands of pieces of luggage must be moved and sorted among a large number of arriving and departing flights every day.

6. STORAGE SYSTEMS

Various types of racks have been developed to store loads of different sizes and shapes. One of the simplest storage systems is block stacking, where loads (which may or may not be palletized) are simply stacked on top each other with no separate support structure. While block stacking is inex-

pensive and provides dense storage (i.e., little or no space is lost due to air between the loads), its use is limited in practice because only certain types of loads (such as appliances or furniture packed properly in cartons) can be stacked without crushing/damaging the loads at the bottom and access to individual loads (i.e., load selectivity) is very limited. In fact, loads must be removed from a stack, starting with the load at the top. This leads to last-in-first-out (LIFO) stock rotation, which is not desirable for many storage systems.

A fundamental trade-off that exists in storage systems design is that between storage density (how well the cubic volume is utilized) and load selectivity (how easily and how fast one can store or retrieve each load). Loss in storage density often occurs due to aisles and due to space created between individual loads when they are palletized and/or stored in a rack. Generally speaking, higher-density storage systems offer lower selectivity. A well-designed and well-engineered storage system provides the right level of load selectivity while maximizing the storage density. It must also provide the right level of support for the loads and must be compatible with the device/method used for storing and retrieving the loads.

For example, in many storage systems, stock is rotated on a first-in-first-out (FIFO) basis, which implies that random access to every single load in the system may not be necessary. Hence, the right level of selectivity would ensure that, given a set of loads of the same type, only the oldest load needs to be easily accessible. This concept has, in fact, led to pallet flow racks, where loads are stored in lanes and each lane holds multiple loads of the same type. At any given time, only the loads in the front of each lane (which, by definition, are the oldest loads in each lane) are easily accessible. Pallet flow racks increase storage density by minimizing the space required by aisles. However, some space is wasted within each lane because the number of loads in a lane varies over time and, at any given instant, some lanes may be full while others are nearly empty.

Note that block stacking has another advantage: flexibility. Since there is no permanent rack structure, when stacked loads are retrieved (or if the need for storage space decreases over time), the floor space that opens up may be used for other purposes, provided new loads are not stored in the system shortly thereafter. To protect and support the loads at the bottom while avoiding the cost and loss of flexibility associated with a permanent rack, some systems use portable racks, also known as stacking frames, (Figure 17), which are basically self-contained steel units made up of four posts attached to a deck. (An alternative design is a frame that is attached to the pallet itself.)

With portable racks, the weight of each load in the stack is transferred to the floor. It must be noted, however, that portable racks create air between the loads (storage density decreases) and load selectivity is still very limited. Also, portable racks are typically designed for use with palletized loads, and the time to store or retrieve a load may be affected when portable racks are used.

Hence, to maintain convenient and fast load access while providing support for each load in the system, many storage systems use permanent racks. Basic examples of permanent racks include (1) single-deep selective rack (Figure 18), (2) double-deep rack, (3) drive-in or drive-through rack, (4)

Figure 17 Portable Racks, Stacking Frames.

Figure 18 Single-deep Selective Rack.

pallet flow rack (Figure 19), (5) mobile rack (which slides on permanent tracks installed on the floor), and (6) Cantilever rack (Figure 20), which is suitable for storing bar stock. When equipped with wooden decks, cantilevered racks may also be used for storing furniture.

With an increasing desire to utilize the cube well and the availability of lift trucks that have higher reach, there is a tendency to build taller rack structures, especially in regions where land or floor space is very limited. While high cube utilization and going up instead of going out are appropriate

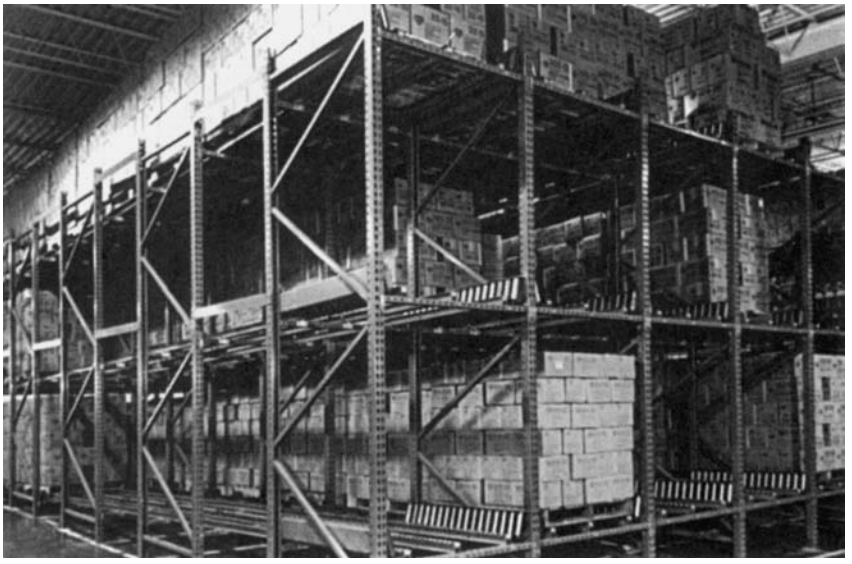

Figure 19 Pallet Flow Rack.

Figure 20 Cantilever Rack. (Courtesy of Jervis B. Webb Co.)

objectives in many instances, it must also be stressed that taller racks can have higher overall cost. As a result, given two storage systems with equal total storage capacity, the one with a taller rack (and smaller footprint) may be more expensive with respect to the total rack cost. (This must of course be traded off against potential savings created by a smaller footprint.)

Two other factors affect the rack cost and rack height. First, racks are more expensive in regions with high seismic activity since they must meet more stringent requirements. Taller racks in such regions may also present a safety hazard. Second, small deviations in the floor surface are amplified when the forks of the truck are raised to the higher tiers of the rack. Consequently, a wavy floor surface may create serious problems for a narrow-aisle truck serving a tall rack. One must also ensure that the floor loading capacity (psi) is sufficient for the rack being considered. A taller rack requires a higher floor loading capacity. Last but not least, one must also consider fire safety and sprinkler systems when selecting the height and type of rack used in a storage system. Tall racks or decked racks may require modifications or enhancements to the sprinkler system.

7. AUTOMATED SYSTEMS

Material handling is often a physically demanding, repetitive task. Although very few handling systems are completely automated, mechanization and automation play a significant role in designing and operating effective and efficient handling systems. Some of the better-known examples of automated material-handling systems include automated storage/retrieval (AS/R) systems, carousels/rotary racks, automated guided vehicle (AGV) systems, and robotic systems.

AS/R systems have been in use since the 1960s, although recent systems are much smaller in size. Each aisle in an AS/R system consists of a storage rack on either side and a S/R machine. (In some systems the S/R machine may not be aisle-captive.) The S/R machine is supported by a guide rail both at the top and bottom; this allows concurrent travel in the horizontal and vertical directions. Load pick-up and deposit is performed via a shuttle mechanism that allows the S/R machine to serve either side of the aisle without turning. Due to the shuttle mechanism, however, the rack used in AS/R systems is a specially-designed rack that is different from a standard single-deep selective (pallet) rack.

AS/R systems are capital-intensive systems. However, they offer a number of advantages, such as low labor and energy costs, high land/space utilization, high reliability/accuracy, and high throughput rates. The expected travel time equations presented earlier for single command (SC) and dual command (DC) cycles under concurrent horizontal and vertical travel [see Eqs. (1) and (2)] apply to AS/R systems as well.

There are many papers in the technical literature for the reader who wishes to obtain more detailed information on AS/R systems. In addition to results such as the expected value and/or distribution of SC and DC travel times (e.g., Chang et al. 1995; Foley and Frazelle 1991; Graves et al. 1977; Hausman et al. 1976; Kouvelis and Papanicolaou 1995; Sarker and Babu 1995), various papers have investigated operational issues such as S/R dwell point strategies, storage-retrieval sequencing, and storage methods (e.g., Chang and Egbelu 1997a, b; Egbelu and Wu 1993; Hwang and Lim 1993; Lee and Schaefer 1996; Peters et al. 1996), twin-shuttle S/Rs (Keserla and Peters 1994; Meller and Mungwattana 1997; Sarker et al. 1994), and storage-retrieval matching or AS/RS control strategies/design models (Han et al. 1987; Elsayed and Lee 1996; Lee 1997; Linn and Wysk 1990; Rosenblatt et al. 1993; Seidmann 1988; Wang and Yih 1997).

Carousels have been used in many storage/retrieval systems involving small to medium-sized parts. A carousel is basically a group of carriers that are suspended via trolleys from an overhead, closed-loop track. (Heavier loads may utilize floor-supported carriers.) Each carrier typically contains a set of shelves to store trays or tote boxes. Using a drive mechanism similar to a trolley conveyor, the carriers can be moved clockwise or counterclockwise around the track. Most readers would recognize a simple version of the carousel used at the dry cleaner, where garments are brought to the operator for retrieval.

Although most carousel applications in industry use human operators to store and retrieve the parts, fully automated systems have also been installed by replacing the human operator with automatic insert/extract devices to remove or insert the trays/tote boxes automatically. Also, depending on the plane of rotation, carousels are classified as horizontal carousels or vertical carousels.

When there are multiple items to be retrieved, the carousel must be turned and stopped several times, once for each item, assuming that the items are located on different carriers. Suppose each carrier in a horizontal carousel contains only one shelf, that is, the carousel is only one-level high. Further suppose several one-level-high carousels are stacked vertically. The result is a ''carousel'' where each level is powered and operated independently. Such a system is known as a rotary rack, which generally yields higher throughput and can support multiple extract/insert devices at the same time.

Another type of automated material-handling system that has been used successfully in manufacturing and warehousing is the automated guided vehicle (AGV) system. An AGV is basically a fully automated cart that can pick up, route, and deliver unit loads from one point to another (within a network of pick-up/deposit (P/D) points) with no human intervention. The vehicle runs under the control of an on-board computer. (Actually, a vehicle may contain two or more microprocessors on board.) If centralized control is used, that is, if a central computer keeps track of all the vehicle movements and move requests in the system, it is quite common to have each AGV communicate with the central computer via radio frequency (RF) communication. Although alternative guidance technologies exist, the most common is wire guidance, which consists of segments of wire buried in the floor. When energized, the wire generates a magnetic field that is sought by the vehicle.

Guidewire-free AGV systems (also known as self-guided vehicles, or SGVs) are also available from several vendors. SGV systems offer increased flexibility in those systems where the load routings and/or the P/D points change frequently. In a typical SGV system, the aisle structure is maintained by each vehicle as a road map. In moving a load, each vehicle follows the road map according to preprogrammed instructions. New road maps can be prepared off-line and downloaded to each vehicle

on an as-needed basis. Initially, the cost differential between AGV and SGV systems was significant. More recently, however, SGV systems have become cost-competitive with AGV systems.

Using the appropriate number of vehicles in an AGV or SGV system is very important. To obtain a quick estimate, one may use the model presented earlier for lift trucks operating under FCFS dispatching. However, due to possible congestion and blocking delays, and to capture more efficient, dynamic dispatching rules, many AGV/SGV systems today are designed via simulation. In fact, many simulation packages in the market have modules or logic built in to facilitate AGV simulation. In addition, the reader will find many papers on AGV systems in the technical literature. These papers address various issues, including system configuration, vehicle dispatching, guidepath design, and gridlock avoidance (see, e.g., Arifin and Egbelu 2000; Borenstein 2000; Bozer and Srinivasan 1991; Bozer and Yen 1996; Ganesharajah et al. 1998; Goetz and Egbelu 1990; Hwang and Kim 1998; Kim et al. 1997, 1999; Srinivasan et al. 1994; Yeh and Yeh 1998).

Robots have also played a significant role in material handling. Perhaps the most common robot used in material handling is the pick-and-place robot, which comes in a variety of configurations. Other robotic or robot-type systems used in material handling include automated item dispensing (similar to, or more advanced versions of, vending machines), palletizers/depalletizers, and gantry robots. Other robots, such as those used in welding and painting, are not considered material-handling robots. For further information on robots, the interested reader may refer to Nof (1999) or Tompkins et al. (1996, Chap. 6), among others.

CHAPTER 57
Storage and Warehousing

JERRY D. SMITH
Tompkins Associates

1. INTRODUCTION

Storage and warehousing operations are a critical part of maintaining a profitable business. With over 300,000 large warehouses and 2.5 million employees in the United States, the cost of American warehousing is over 5% of the gross national product. In the past few years, the field of warehousing has begun to receive the attention it deserves. However, the warehouse management has been asked to increase customer service, reduce inventories, increase productivity, handle a large number of stock-keeping units, and improve space utilization. Warehouse management has realized that these conflicting objectives require a much more professional approach than previously adopted. It is critical that today's warehouse management follow this approach to achieve the results expected by today's upper management.

1.1. Warehousing Defined

The functions performed by a warehouse are:

1. Receiving the goods from a source
2. Storing the goods

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

3. Picking the goods when they are required
4. Shipping the goods to the appropriate customer

Oftentimes, a distinction is made between a finished-goods warehouse and a raw-materials storeroom. The fact is, however, that the functions performed in a finished-goods warehouse—receive, store, pick, and ship—are identical to the functions performed in a raw-materials storeroom. Consequently, both are warehouses. The only true distinctions between the two are the source from which the goods are received and the user to whom the goods are shipped. A raw-materials storeroom receives goods from an outside source, stores the goods, picks the goods, and ships the goods to an inside user. A finished-goods warehouse receives goods from an inside source, stores the goods, picks the goods, and ships the goods to an outside user. Likewise, an in-process inventory warehouse receives goods from an inside source, stores the goods, picks the goods, and ships the goods to an inside user, while a distribution warehouse receives goods from an outside source, stores the goods, picks the goods, and ships to an outside user. The differences among these various warehouses are restricted to the perspectives of the sources, management, and users of the warehouses. If the primary functions of an activity are receive, store, pick, and ship, the activity is a warehouse, regardless of its position in a company's logistics. The tools and techniques presented in this chapter can be successfully used to plan and manage that activity.

1.2. The Value of Warehousing in Today's Economy

It is important to ponder the question "Does warehousing add value to a product?" The traditional school of thought has concluded that no, warehousing does not add value to a product; warehousing is strictly a cost-adding activity that is a necessary evil. In firms that follow this school of thought, warehousing costs are typically classified as indirect costs. Often these cost categories are spread over the direct costs of the firm in such a way that the cost of warehousing is not distinguishable.

2. STORAGE AND WAREHOUSING

To convince yourself of the value of warehousing, consider the value of the refrigerator in the home. The refrigerator is essentially a warehouse. You purchase food at the supermarket, deliver the food to the refrigerator, store it in the refrigerator, pick the food from the refrigerator as needed, and ship the food to some location where it will be processed or consumed. What is the value of the refrigerator? What is the value of having milk where needed, when needed? If the answer is not yet clear, consider the costs that would be incurred if you did not own a refrigerator. What are the costs of not having milk for cereal at breakfast in the morning? Some of the costs are hunger from not eating, indigestion from eating dry cereal, the inconvenience of having to go to the supermarket before breakfast, and the actual expense of going to the supermarket before breakfast.

The true value of warehousing lies in having the right product in the right place at the right time. Thus, warehousing provides the time-and-place utility necessary for a company to prosper.

Without a complete and accurate understanding of the value of warehousing, companies have failed to give warehousing the same scientific scrutiny as the other aspects of their business. For a profession as important as warehousing, this is not acceptable. A more scientific approach must be taken to the warehouse of today.

3. SCIENTIFIC APPROACH TO WAREHOUSE PLANNING

Warehouse planning is more than pouring a concrete slab and installing some rack and tilting up some walls. Warehouse planning is not a static, one-time activity. The changing, dynamic environment within which warehouses are planned quickly renders existing plans obsolete. Therefore, warehouse planning must be a continuous activity in which the existing plan is constantly being scrutinized and molded to meet anticipated future requirements. For a warehouse to accomplish its objectives, warehouse managers must consider the variable warehouse resources and mold them into an effective plan. A successful warehouse maximizes the effective use of the warehouse resources while satisfying customer requirements.

3.1. Requirements for Successful Warehousing

To be successful into the 21st century, warehouse planning must be accomplished within the framework of a clear, long-term, consistent vision of where the warehousing operations are headed. The following strategies should form the basis of this vision.

1. *Professionalism:* Warehousing will be viewed as a critical supply chain enabler and a competitive strength, not as an inert facility.
2. *Customer awareness:* Serving the customer is only the foundation; satisfying them is vital to their continuing to patronize your organization.

3. *Measurement:* Warehouse standards will be established, performance will be measured against these standards, and timely actions will be taken to overcome any deviations.
4. *Operations planning:* Systems and procedures will be put into effect that allow the warehouse manager to plan the operations proactively rather than reactively respond to external circumstances.
5. *Supply chain network:* Warehouses will not be viewed as independent operations but as an element of the overall, well-planned supply chain.
6. *Third party/outsourcing:* More intelligent use of third-party logistics (3PL) is the norm so that organizations can focus on core competencies.
7. *Pace:* The reduction of lead times, shorter product lives, and increased inventory turnover result in an increase in the pace of the warehouse.
8. *Variety:* More different SKUs and more special customer requirements result in an increase in the variety of tasks performed in the warehouse.
9. *Adaptability:* Due to the increase in warehouse pace and variety, all warehouse systems, equipment, and people will be able to handle products that vary in size and weight.
10. *Uncertainty:* All uncertainty will be minimized; discipline will be increased.
11. *Integration:* Integration needs to be understood as not only a method of improvement within, or even between, processes but rather as a method of improvement of the whole process.
12. *Inventory accuracy:* Inventory above 99% is the norm with real-time warehouse management systems, bar coding, and electronic order processing. Annual physical inventories are eliminated and cycle counting is fully embraced.
13. *Space utilization:* Space utilization will be enhanced through dynamic slotting or the placement of product in a facility for the purpose of optimizing material handling and space efficiencies.
14. *Housekeeping:* There is efficiency in order in the warehouse. The certainty that the work areas are safe, free of congestion, and properly organized enables personnel to move through a day's work with just the work on which to concentrate.
15. *Orderpicking:* The criticality of orderpicking will be understood, and procedures and layouts will be designated to maximize orderpicking efficiency.
16. *Business process continuous improvement* (*BPCI*)*:* The power of the people will be unleashed via a methodical process of continuous improvement.
17. *Continuous flow:* There will be a clear focus on pulling product through the logistics system and not building huge inventories.
18. *Warehouse management systems:* Real-time, bar code-based, RF communication Warehouse management systems (WMS) will be required to meet today's requirements.
19. *Change:* Organizations that will usher in the new century successfully will be the organizations that proactively embrace change.
20. *Leadership:* There must be a balance between the control aspects of management and harnessing the energy of change to create peak-to-peak performance of leadership.

3.2. Warehouse Objectives

The resources of a warehouse are space, equipment, and personnel. The cost of space includes not only the cost of building or leasing space but also the cost of maintaining the space. Typically, the cost of space in a warehouse is $0.20 to $0.30 per cubic foot per year for taxes, insurance, maintenance, and energy. A company that is ineffectively using its available cubic space is incurring excessive operating costs.

The equipment resources of a warehouse include data-processing equipment, dock equipment, unit load equipment, material-handling equipment, and storage equipment, all of which combine to represent a sizable capital investment in the warehouse. In order to obtain an acceptable rate of return on this investment, the proper equipment must be selected and it must be properly used.

Oftentimes, the personnel resource of the warehouse is the most neglected resource, even though the cost of this resource is usually the greatest. Approximately 50% of the costs of a typical warehouse are labor related. Reducing the amount of labor, pursuing higher labor productivity, good labor relations, and worker satisfaction, will significantly reduce warehouse operating cost.

Customer requirements are simply the demand to have the right product in good condition at the right place at the right time. Therefore, the product must be accessible and protected. If a warehouse cannot meet these requirements adequately, then the warehouse does not add value to the product and, in fact, very likely subtracts value from the product.

Therefore, the following objectives must be met for a warehouse to be successful:

1. Maximize effective use of space.
2. Maximize effective use of equipment.
3. Maximize effective use of labor.
4. Maximize accessibility of all items.
5. Maximize protection of all items.

The two distinct types of continuous warehouse planning needed to result in an efficient and effective warehouse operation are contingency planning and strategic master planning.

3.3. Contingency Planning

Contingency planning is a *defensive* tool used to guard against a predictable future change in warehouse requirements whose timing is extremely difficult, if not impossible, to anticipate. In other words, a contingency plan answers the question "What do I do *if* some unexpected event or condition arises?" Contingency plans are needed to guard against the following short-term situations:

1. Equipment downtime
2. Labor problems
3. Surges of activity
4. Material supply disruptions
5. Other emergencies

Contingency planning is not crisis management or putting out fires, which entail developing solutions to problems *after* the problems occur. Proper contingency planning develops the action plan to the fullest extent possible *before* the problem occurs. Consequently, proper contingency planning can significantly reduce the lead time required to correct or accommodate the unexpected event. One does not wait until after a fire starts in the warehouse to install a sprinkler system; instead, one installs the sprinkler system long before as a contingency against a fire whose timing is unpredictable. Likewise, formal contingency plans can protect the warehouse for other conceivable circumstances with unpredictable timing.

To develop contingency plans for a warehouse, use the following procedures:

1. Make a list of the conceivable "bad things" that can happen to or within the operation.
2. Rank the bad things with the events having the greatest probability of occurrence, and/or the most adverse consequences if they do occur, at the top of the list.
3. Starting with the highest-ranked bad thing, carefully determine, in as much detail as possible, the proper steps and actions that should take place to resolve, eliminate, and deal with the consequences to the warehouse operations of the bad thing if and when it occurs.
4. Review these steps and actions with the key warehouse people and refine them based on the inputs received.
5. Publish the resulting contingency plans in print and drill those persons responsible for executing the plans at the time of need in the details of the plans so that everyone knows exactly when, how, and by whom the plan is to be executed.
6. Periodically review and update the contingency plans to keep them current with existing conditions in the operation.

3.4. Strategic Master Planning

Strategic master planning is an *offensive* tool designed to guard against a predictable future change in warehouse requirements whose timing can be anticipated. Strategic master planning is directed at forecasting future warehousing needs sufficiently in advance of the actual requirement to allow enough lead time to efficiently and effectively meet those needs.

Warehousing strategic master plans are needed to accommodate:

1. Forecasted growth or decline in the throughput
2. Space, labor, and equipment deficiencies
3. Product mix changes
4. Inventory increases or reductions
5. Warehouse control problems

Most of these "problems" do not develop overnight. Future inventory levels and product mixes typically can be predicted, based on historical and future business plans, years in advance. Granted,

forecasting with long planning horizons is risky. Forecasts are often inaccurate. Nevertheless, the forecast is the best available information concerning the future we have, and it is folly not to use that information to advantage. With today's costs of warehouse space, labor, and equipment, more and more decision makers are demanding that future warehouse requirements be expressed in quantitative terms rather than in subjective, qualitative assessments of needs. That is what strategic master planning is all about.

Contingency planning and strategic master planning are complementary. Strategic master planning without effective contingency plans will subject the warehouse to unanticipated problems that do not show up in a forecast of future requirements. Likewise, the absence of good strategic master planning will subject the warehouse to a continuous barrage of "fires" to be dealt with by contingency plans, many of which could have been avoided through proper insight and strategic planning. In either situation, the absence of one planning approach severely limits the effectiveness of the other.

3.4.1. Qualities of a Strategic Master Plan

A warehousing strategic master plan is a set of documents describing what actions must be accomplished and when they must be accomplished to satisfy the warehousing requirements of an enterprise over a given planning horizon. A closer examination of this definition reveals the important attributes of a good warehouse strategic master plan.

First of all, a good warehouse strategic master plan is a formal set of documents. It should not consist simply of ideas, thoughts, possibilities, desires, and so forth that are casually recorded "somewhere," if at all. A good plan is a formal set of documents that have been created, collected, edited, and so forth specifically as a strategic master plan of action. Common components of this set of documents include an implementation plan, a descriptive narrative, scaled facility drawings, and supporting economic cost and justification data.

Second, a good warehouse strategic master plan is action oriented. Where possible, the plan should set forth very specific actions to be taken to meet requirements rather than simply stating the alternative actions available to meet those requirements. The strategic master plan is established based on a set of premises concerning future production volumes, inventory levels, manpower levels, available technology, and so forth. As long as these premises are clearly stated as a part of the strategic master plan, and understood, problems should not arise with regard to implementing actions that prove to be based on false premises.

The strategic master plan should be time phased to indicate when each recommended action should be implemented to meet changing warehousing requirements. Typically, scaled facility drawings should accompany each recommended action to illustrate what the facility will look like after a given action has been implemented.

Finally, a good warehouse strategic master plan should encompass a specified planning horizon. It should have a definite beginning point and a definite ending point. Typically, the planning horizon is stated in terms of years. A five-year master plan might serve the years 1991 through 1996.

3.4.2. Strategic Master Planning Methodology

The general methodology for developing a warehouse strategic master plan consists of the following seven-step procedure:

1. Document the existing warehouse operation.
2. Determine and document the warehouse storage and throughput requirements over the specified planning horizon.
3. Identify and document deficiencies in the existing warehouse operation.
4. Identify and document alternative warehouse plans.
5. Evaluate the alternative warehouse plans.
6. Select and specify the recommended plan.
7. Update the warehouse master plan.

Step 1 involves obtaining or developing scaled drawings of the existing warehouse facilities and verifying their accuracy. The accuracy of existing drawings should never be assumed. It should always be physically verified on the warehouse floor.

Existing warehouse equipment should be identified and documented. The labor complement of each area of the warehouse should be determined and the general responsibilities of each person documented. Existing standard operating procedures should be scrutinized and compared against what actually takes place on the shop floor. The first step of the master planning process establishes a baseline against which recommendations for improvement can be compared.

Step 2 involves defining what materials will be stored in the warehouse and the volume anticipated during the planning horizon. Items to be stored in the warehouse should be classified into categories according to their material-handling and storage characteristics.

Forecasts or production schedules should then be used to predict the storage volumes and turnover rates of each category of material over the specified planning horizon. Ideally, these volumes would be stated in terms of the unit loads in which the materials would be stored and handled.

Step 3 involves identifying potential areas of improvement in the existing warehouse operation. The potential for improvement may exist because the operation lacks sufficient capacity to handle future requirements or because existing facilities, methods, equipment, and/or labor forces are not the most efficient or effective available.

Step 4 deals with identifying alternative facility, equipment, procedural, and/or personnel plans that will eliminate or minimize the deficiencies identified in the existing warehouse operation. From these alternative plans of action will come the specific time-phased plan of action to be recommended for meeting the warehouse requirements over the given planning horizon.

Step 5 of the master planning process involves performing both an economic and a qualitative assessment of the alternative plans of action. The economic evaluation should consist of a time-value-of-money assessment of the total life-cycle costs of competing alternative plans of action. The qualitative assessment of alternatives requires that the alternatives be subjectively compared on such attributes as personnel safety, flexibility, ease of implementation, maintainability, potential product damage, and so forth.

Step 6 involves selecting the best of the alternative plans of action implicated by the economic and qualitative evaluations and specifying the recommended warehouse strategic master plan. The master plan will document the space, equipment, personnel, and standard operating procedure requirements of the warehouse over the planning horizon. In addition, scaled facility drawings should be included showing the recommended warehouse layout for all revisions recommended by the plan of action.

The first six steps of this procedure will result in a warehouse strategic master plan. The strategic master planning process, however, will not be complete. In fact, it will never be completed, since strategic master planning is a continuous activity. Step 7 is the process, therefore, of updating the master plan. By its very nature, a strategic master plan is inaccurate. Since it is based, to a large extent, on predictions of the future, the warehouse strategic master plan will require updating as better information concerning the future is obtained. Consequently, it should never be used as a precise tool but only as a valuable guideline for planning future warehouse operations.

4. STORAGE SPACE PLANNING

Space planning is the part of the science of warehousing concerned with making a quantitative assessment of warehouse space requirements. As is true of any science, space planning possesses a very specific methodology. The space planning methodology consists of the following general steps:

1. Determine what is to be accomplished.
2. Determine how to accomplish it.
3. Determine space allowances for each element required to accomplish the activity.
4. Calculate the total space requirements.

The first two steps of the space planning process define the activity and techniques, equipment, information, and so on to be used in performing that activity. Step 3 involves determining the space requirements of each element that goes into performing the activity. In warehousing, these elements might include personnel and personnel services, material handling and material storage equipment, maintenance services, and utilities. Finally, step 4 combines the space requirements of the individual elements to obtain total space requirements.

Storage-space planning is particularly critical because the storage activity accounts for the bulk of the space requirements of a warehouse. Inadequate storage-space planning can easily result in a warehouse that is significantly larger or smaller than required. Too little storage space will result in a world of operational problems, including lost stock, inaccessible material, poor housekeeping, damaged material, safety problems, and low productivity. Too much storage space will breed poor use of space so that it appears that all the available space is really needed. The result will be high space costs in the form of land, construction, equipment, and energy.

To avoid these problems, storage-space planning must be approached from a quantitative viewpoint, as opposed to a qualitative assessment of requirements. The following sections present the scientific methodology of storage-space planning, which when followed, will generate a quantitative and defensible assessment of storage-space requirements.

4.1. Define the Materials to Be Stored

The first step in storage-space planning is to define what is to be accomplished; that is, to define the materials to be stored. A useful tool in defining the materials to be stored is the storage analysis chart (SAC) given in Table 1. Columns 1–5 of the SAC define what materials are to be stored,

TABLE 1 Storage Analysis Chart

Company A.R.C., Inc. Date March 18, 1991 Raw Materials _____ In-Process Goods _____

Prepared by J. Smith Sheet 1 of 1 Plant Supplies _____ Finished Goods _____

	Unit Loads				Quantity of Unit Loads Stored			Storage Space			
Description (1)	Type (2)	Cap (3)	Size (4)	Weight (5)	Max. (6)	Avg. (7)	Planned (8)	Method (9)	Specs (10)	Area (ft^2) 11	Ceiling Height Required (12)
Steel pipe plug 1.00 in. diameter × 0.50 in.	Wooden crate	3200 pieces	2 ft × 2 ft × 4 ft	825 lbs	14	8	12	Pallet rack	25 ft × 10 ft × 3 ft	66	9 ft
Aluminum bar 2.75 in. × 2.50 in. × 16 ft	Bundles	25 bars	12.5 × 14 in. × 16 ft	1625 lbs	30	17	30	Cantilever racks	Four-Arm dual rack 5 ft × 16 in. ×x 8 ft	160	8 ft
Stainless steel bar 0.875 in. × 12 ft	Bundles	36 bars	6 in. × 6 in. × 12 ft	900 lbs	7	4	7	Cantilever rack	Four-Arm dual rack 4 ft × 12 in. × 10 ft	48	10 ft
Rubber O rings 0.75 in. diameter	Cartons	40,000 O rings	12 in. × 18 in. × 3 ft	125 lbs	2	1	2	Storage shelf	Metal frame 12 ft × 2 ft × 8 ft	24	8 ft
Brass bar 0.75 in. diameter × 12 ft	Bundles	36 bars	6 in × 6 in × 12 ft	720 lbs	15	8	14	Cantilever rack	Four-Arm dual rack 4 ft × 12 ft × 6 ft	48	6 ft

columns 6–8 specify how much is to be stored, and columns 9–12 define how the materials are to be stored. The information requirements for columns 1–5 of the SAC can be obtained by physically surveying the existing storage areas. The survey would proceed by identifying, generically classifying, measuring, and weighing the unit loads presently in the storage areas.

Columns 6 and 7 of the SAC list the maximum and average number of unit loads of each category of material that should be on hand. Column 8 cites the planned inventory level of each type of material for which storage area will be planned. Determining the proper inventory level is directly related to the storage philosophy that will be used for each category of materials. The different storage philosophies and the decision process one should use to determine the proper planned inventory level will be discussed in the next section of this chapter.

The last four columns of the SAC define the physical characteristics of the storage area being planned. These physical characteristics include the method of storage and the space requirements of that method.

4.2. Determine Storage Philosophy

Once the maximum and average inventory levels have been recorded, the inventory level that will be used as a basis for planning required storage space must be determined. The planned inventory level depends on the philosophy followed in assigning material to storage space. There are two major material-storage philosophies: fixed (or assigned) location storage and random (or floating) location storage. In fixed-location storage each individual stock-keeping unit will always be stored in a specific storage location. No other stock-keeping unit may be stored in that location, even though that location may be empty.

With random-location storage, any stock-keeping unit may be assigned to any available storage location. A stock-keeping unit in location A one month might be stored in location B the following month and a different stock-keeping unit stored in location A.

The amount of space planned for a stock-keeping unit is directly related to the method of assigning space. If fixed-location storage is used, a given stock-keeping unit must be assigned sufficient space to store the maximum amount of the stock-keeping unit that will ever be on hand at any one time. For random-location storage, the quantity of items on hand at any time will be the average amount of each stock-keeping unit. In other words, when the inventory level of one item is above average, another item will likely have an inventory level that is below average; the sum of the two will be close to the average.

Oftentimes, the storage philosophy chosen for a specific stock-keeping unit will not be strictly fixed-location storage or random-location storage. Instead, it will be a combination of the two. A grocery store is an excellent example of combination, or hybrid, location storage. Fixed-location storage is used in the front room of a grocery store where the consumers shop. Pickles are assigned a fixed location, and only pickles will be stored in that location. Pickles will not be found in any other location in the front room of the grocery store. In the back room, or storeroom, of the grocery store, however, the excess, or overstock, merchandise is usually stored randomly. Pickles may be found in one location one week and in a different location the next week. Because combination-location storage is based on a mixture of fixed-location storage and random-location storage, its planned inventory level falls between the fixed-location quantity and random-location quantity. At what point between the fixed-location and random-location quantity the planned inventory level falls is dependent on the percentage of inventory to be assigned fixed locations.

To summarize, the planned inventory level recorded in column 8 of the storage analysis chart in Table 1 should be equal to the maximum inventory level (column 6) for fixed-location storage, the average inventory level (column 7) for random-location storage, or a value between the maximum and average quantities for combination-location storage.

Little has been said at this point about the advantages of one storage philosophy over another. Should the storage philosophy be fixed-, random-, or combination-location storage? Unfortunately, an unequivocal answer to this question does not exist. Choosing one storage philosophy over another means making a number of trade-offs, which must be evaluated. Table 2 presents a qualitative comparison of fixed-, random-, and combination-location storage for three extremely important criteria: use of space, accessibility to material, and material handling.

Use of space in a fixed-location system is poor because space for the maximum amount of inventory that will ever be on hand has been allocated although actual on-hand inventory will normally approach the average inventory level. Therefore, a great deal of empty space is common in fixed-location storage. Random-location storage is extremely space efficient because the space requirements are only about 15% above the average amount of inventory expected on hand. Use of space for combination-location storage is better than it is for fixed location storage and worse than it is for random-location storage because the space requirements are based on a planned inventory level somewhere between the fixed-location and random-location quantities.

TABLE 2 Comparison of Storage Philosophies

Criteria \ Philosophy	Fixed Location Storage	Random Location Storage	Combination Location Storage
Use of space	Poor	Excellent	Good
Accessibility to material	Excellent	Good, if there is a good material locator system; poor otherwise	Good
Material handling	Good	Good	Poor

Material in fixed-location storage has excellent accessibility because a given storage location contains only one stock-keeping unit. The location of every item is fixed: it is known. Blocked stock is avoided and every stock-keeping unit is readily accessible. Accessibility to material in random-location storage is good as a long as a good material-locator system exists. The material-locator system keeps track of the present location of every item in storage. Once a specific stock-keeping unit is committed to a storage location, no other stock-keeping unit can be placed in that location until the original stock-keeping unit is completely removed. However, if a material-locator system does not exist, or is poorly designed and maintained, then accessibility to material in a random-location storage system will be extremely poor. Blocked stock, lost material, and obsolete material will inevitably result. Even with a good material-locator system, accessibility to material will never be as good in random-location storage as in fixed-location storage. Accessibility to material in combination storage is good if a good material-locator system exists for the randomly-stored portion of storage, or if the percentage of inventory stored randomly is small.

Fixed-location storage and random-location storage score equally well on the material-handling criterion. In each philosophy, material is received, placed into storage, retrieved from storage, and shipped to a user. The flow of material is straightforward and economical. Material is received, placed in the random-location storage area, retrieved, placed into the fixed-location storage area, retrieved, and shipped to a user. Consequently, combination-location storage involves several extra handling steps not required by either fixed-location storage or random-location storage.

In summary, fixed-location storage trades efficiency in use of space for easy accessibility to material; random-location storage trades accessibility to material for efficiency in use of space; and combination-location storage trades material-handling efficiency for middle-of-the-road efficiency in use of space and accessibility to material. However, a clear-cut decision still cannot be made on the best storage philosophy. Perhaps the only general conclusion that can be drawn is that poor use of space by fixed-location storage is a big factor. Compared to the use of space by random-location storage for the same materials, fixed-location storage will generally require 65–85% more space. With the escalating costs of money, land, and construction, few firms can afford to build a fixed-location storage warehouse, which would be 75% larger than that required for random-location storage. The expense of developing and maintaining an effective material-locator system for random-location storage—when compared with these costs—is easily justified. Consequently, one should always carefully evaluate random-location storage before deciding to use fixed-location storage. Rarely will the gains in accessibility to material made by fixed-location storage be enough to offset its high space costs. Occasionally, however, efficient use of space is not a critical factor, so fixed-location storage is preferred. For example, when the items to be stored are extremely small and/or extremely valuable, accessibility to them and accountability for them may be all-important. Few jewelers care about the use of space when they are storing diamond rings.

4.3. Determine Alternative Storage Method Space Requirements

The space requirements of a storage alternative are directly related to the volume of material to be stored and the use-of-space characteristics of the alternative. The two most important use-of-space characteristics are aisle allowances and honeycombing allowances. Aisle allowance is the percentage of space occupied by aisles within a storage area. Aisles are necessary within a storage area to allow accessibility to the material being stored. The amount of aisle allowance depends on the storage method, which dictates the number of aisles required, and on the material-handling method, which dictates the size of the aisles. Expected aisle allowance must be calculated for each storage alternative under consideration.

Honeycombing allowances are the percentage of storage space lost because of ineffective use of the capacity of a storage area. Honeycombing is illustrated in Figure 1. Honeycombing occurs whenever a storage location is only partially filled with material. The unoccupied area within the storage

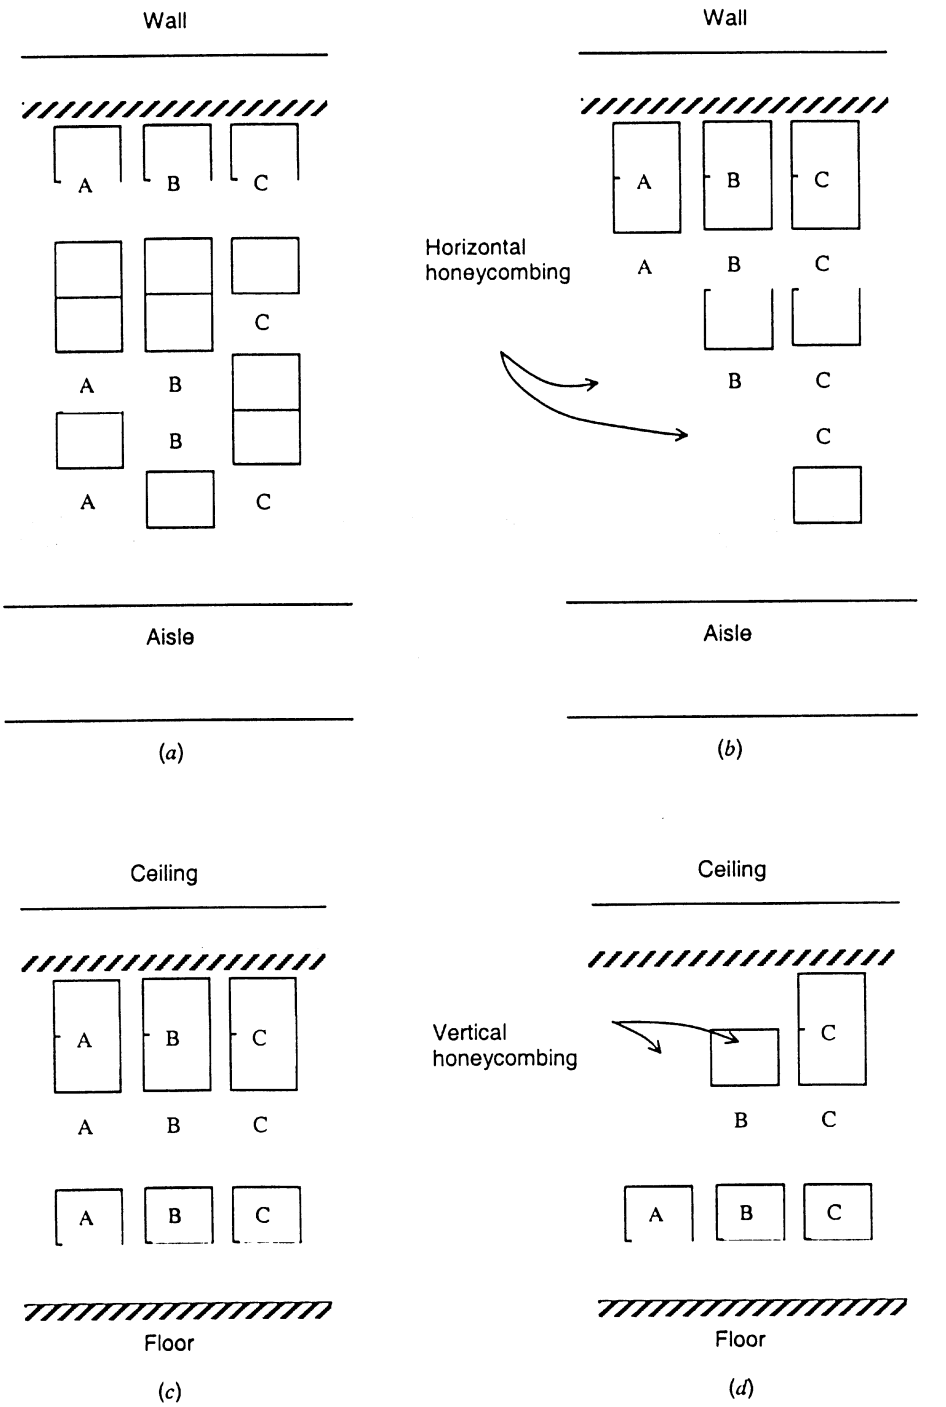

Figure 1 Horizontal and Vertical Honeycombing. (*a*) Plan view of bulk storage area—no honeycombing. (*b*) Plan view of bulk storage area showing horizontal honeycombing. (*c*) Elevation view of bulk storage area—no honeycombing. (*d*) Elevation view of bulk storage area showing vertical honeycombing.

location is honeycombed space. Honeycombing may occur horizontally and vertically. For example, Figure 1(*a*) presents a plan view of a bulk storage area in which material can be placed four units deep. Because the bulk storage area is full, no honeycombing occurs. In Figure 1(*b*), however, two units of product A and one unit of product B have been removed, leaving three empty slots. No other items can be placed in these slots until the remaining units of A and B have been removed (otherwise, blocked stock will result); so these slots are horizontal honeycombing losses. Figure 1(*c*) is an elevation view of a bulk storage area in which material can be stacked three units high. Here again, the storage area is full and no honeycombing occurs. In Figure 1(*d*), however, two units of product A and one unit of product B have been removed, leaving three empty slots. To avoid blocked stock or poor stock rotation, no other units can be placed in these slots until the remaining units of A and B have been removed. Consequently, the empty slots are vertical honeycombing losses. Horizontal and vertical honeycombing losses will occur. Efforts to totally eliminate honeycombing may improve space utilization but will assuredly result in increased material-handling costs related to double handling loads, material damage, and lost productivity. Honeycombing, while it should be minimized, must be considered a natural and allowed-for phenomenon of the storage process. For each storage alternative under consideration, the expected honeycombing allowance must be estimated.

Once the aisle and honeycombing allowances for a storage method alternative have been determined, a space standard can be calculated for that storage method. A space standard is a benchmark

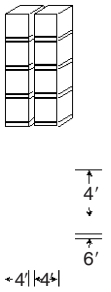
Item A requires special environmental control. A special storage area must be established to house the maximum quantity of item A, which is to be stored on pallets, four pallets high. In a bulk storage analysis chart, how much space should be allocated for the storage of item A?

Case size = 2 ft × 1 ft × 1 ft (height) = 2 ft^3

Palletized = 48 in. × 48 in. × 48 in. pallet × 4 tiers high = 64 ft^3 (32 cases/pallet)

Step 1: The aisle allowance (AA) has been estimated from a proposed layout to be 10%. The honeycombing allowance (HA) has been estimated to be 25%.

Step 2: The pallet height is 6 in. and the clearance between stacks is 4 in. The total space required for one four-pallet-high stack of item A is therefore:



Stack width × stack depth × stack height = (4 ft + 0.33 ft) × 4 ft × [(4 ft + 0.5 ft) × 4] = 312 ft^3 for 128 cases of item A

Step 3: The inclusion of allowances for aisles and honeycombing results in the following space standard:

$$\frac{312\ ft^3}{(1 - AA)(1 - HA)(128\ cases)} = \frac{312\ ft^3}{(1 - 0.10)(1 - 0.25)(128\ cases)} = 3.61\ ft^3/case$$

Step 4: A total storage space required for the maximum anticipated volume of item A, using the proposed storage method, is:

Total storage space required = 300,000 cases × 3.61 ft^3/case

= 1,083,000 ft^3

or 60,167 ft^2 having a clear stacking height of 18 ft

Figure 2 Example Space Standard Calculation for Storage Area.

that defines the amount of space required per unit of product stored. Given the space standard and the total inventory of a class of items to be stored, the total space required for that class of items may then be calculated. Figure 2 presents an example illustrating the calculation and use of space standards.

5. WAREHOUSE LAYOUT PLANNING

5.1. Objectives of a Warehouse Layout

Before layout planning can begin, the specific objectives of a warehouse layout must be determined. In general, the objectives of a warehouse layout are:

1. To use space efficiently
2. To allow the most efficient material handling
3. To provide the most economical storage in relation to costs of equipment, use of space, damage to material, and handling labor
4. To provide maximum flexibility in order to meet changing storage and handling requirements
5. To make the warehouse a model of good housekeeping

The astute observer will notice that the first three objectives are essentially identical to the overall objectives of a warehouse. Recall that the objectives of a warehouse are:

1. To maximize effective use of space
2. To maximize effective use of equipment
3. To maximize effective use of labor
4. To maximize accessibility of all items
5. To maximize protection of all items

It is true that the objectives of a warehouse layout are redundant. This shows the importance of layout planning to warehouse planning. Without a good warehouse layout, it is impossible to have a good warehouse. The objective of layout planning is to arrange and coordinate the space, equipment, and labor resources of the warehouse. Poor layout planning can undermine superior space, equipment, and personnel planning. Put another way, accomplishing the objectives of warehousing depends on having a good layout. If the warehouse layout is bad, the warehouse as a whole will be bad. Conversely, if the warehouse as a whole is bad, chances are the warehouse layout is bad.

The fourth objective of a warehouse layout recognizes the fact that warehousing exists not within a static, unchanging environment but within a dynamic, ever-changing environment. If the mission of a warehouse changes, the warehouse layout should very likely change, too, to adapt to the new mission. However, a good warehouse layout possesses the flexibility to absorb minor variances in expected storage volumes and product mixes with few or no alterations required. This flexibility allows the warehouse to function even if the forecasts on which it was planned prove to be wrong, as they inevitably do.

The last objective of warehousing follows the principle that there is efficiency in order. Good housekeeping is essential to good warehousing; a good warehouse cannot exist without good housekeeping. Yet good housekeeping by itself will not ensure a good warehouse. If the space, equipment, personnel, and layout are not properly planned, all the housekeepers in the world could not get a warehouse to function. But poor housekeeping will surely undermine good space, equipment, personnel, and layout planning.

5.2. Layout Planning Methodology

Warehouse layout planning methodology consists of two steps:

1. Generate a series of warehouse layout alternatives
2. Evaluate each alternative against specific criteria to identify the best warehouse layout

These two steps are discussed in the following sections.

5.3. Generate Alternative Layouts

Generating alternative warehouse layouts is as much art as science. The quality of the layout alternatives will largely depend on the skill and ingenuity of the layout planner. This fact is crucial to the most common approach to generating layout alternatives: template juggling. The word ''juggle'' means ''to skillfully manipulate a group of objects to obtain a desired effect.'' Consequently, template juggling is the skillful manipulation of a group of templates, models, or other representations of

warehouse space, equipment, and personnel in order to obtain a warehouse layout that meets objectives. In other words, template juggling is a trial-and-error approach to finding the proper arrangement and coordination of the physical resources of the warehouse.

The quality of the alternatives created from template juggling depends on the creativity of the layout planner. Unfortunately, layout planners often either lack creativity or do not attempt to express their creativity. Many layout planners approach the problem with a preconceived idea about what the solution should be. They tend to base the layout planning process on that preconceived solution. As a result, creativity is stifled. Oftentimes, the layout chosen for a new warehouse looks exactly like the layout used for the old warehouse. The generation of layout alternatives thrives on the creativity of the layout planner, yet many layout planners withhold this basic and essential ingredient.

The generation of warehouse layout alternatives should be accomplished by the following procedure:

1. *Define the location of fixed obstacles.* Some objects in a warehouse can be located only in certain places, and they can have only certain configurations. These objects should be identified and placed in the layout alternative first, before objects with more flexibility are located. Some fixed obstacles are building support columns, stairwells, elevator shafts, lavatories, sprinkler system controls, heating and air conditioning equipment, and, in some cases, offices. Failure to consider the location of these types of items first will prove disastrous. The warehousing corollary to Murphy's law states: ''If a column can be in the wrong position, it will be.'' Don't be the layout planner who designs a warehouse and buys the storage and material-handling equipment only to find that when the equipment is installed, the location of the building columns makes an aisle too narrow for the handling equipment.
2. *Define the location of the receiving and shipping function.* Oftentimes, the configuration of the warehouse site will dictate the location of the receiving and shipping functions. When this is not true, however, the receiving and shipping location decision becomes an important one. Receiving and shipping are high-activity areas and should be located so as to maximize productivity, improve material flow, and properly utilize the warehouse site. The location of access roads and railroad tracks, if rail service is required, are important considerations in locating receiving and shipping. The question of whether receiving and shipping should be located together or in different areas of the warehouse must be addressed. Common receiving/shipping docks can often result in economies of scale related to sharing space, equipment, and personnel. Separate receiving and shipping areas may, on the other hand, be best to ensure better material control and reduce congestion. Energy considerations are important. Where a choice exists, receiving and shipping docks should not be located on the side of the building that faces north. Avoiding this location reduces the amount of heat loss in the winter from northerly winds entering the warehouse through the open dock doors. The preferred location of the receiving and shipping docks is the south side of the warehouse, with east and west as second and third choices. The particular weather patterns around each warehouse site should be examined, however, to identify the prevailing wind direction at that particular site. Then the docks should be located away from the prevailing wind.
3. *Locate the storage areas and equipment, including required aisles.* The types of storage areas and equipment to be used will dictate to some extent the configuration of the storage layout and the aisle requirements. Be sure to make allowances for the fixed obstacles in the facility. Main warehouse aisles should connect the various parts of the warehouse. The cross-aisle at the end of the storage area may need to be wider than the aisles within the storage area, depending on the type of material-handling equipment used. For example, a side-loading fork truck that can operate with a 7-foot-wide storage aisle may require 12-foot-wide cross-aisles at the ends of the storage aisles to allow maneuvering into and out of the storage aisle.
4. *Assign the material to be stored to the storage locations.* This step in the generation of layout alternatives ensures that storage allowances have been made for all the items to be stored. In addition, it allows the performance of a mental simulation of the activities expected within the warehouse.
5. *Repeat the process to generate other alternatives.* Once a warehouse layout alternative has been established, following the four steps just outlined, the process must be repeated many times to generate additional layout alternatives. Different layout configurations, building shapes, and equipment alternatives should be used. The creativity of the layout planner should be taxed to ensure that each succeeding layout alternative is not essentially identical to the first layout alternative generated.

5.4. Evaluate the Alternative Layouts

A number of warehouse layout philosophies exist to serve as guidelines for the development of an effective warehouse layout. Each warehouse layout alternative should be evaluated against the specific criteria established for each of these warehouse layout philosophies.

1. *Popularity philosophy:* In a typical warehouse, it is not unusual to find that 85% of the product throughout is attributable to 15% of the items, another 10% of the product throughput is attributable to 30% of the items, and the remaining 5% of the product throughput is attributable to 55% of the items. Consequently, the warehouse contains a very small number of highly active items (often called A items), a slightly larger number of moderately active items (often called B items), and a very large number of infrequently active items (often called C items). The warehouse layout philosophy on popularity suggests that the warehouse should be planned around the small number of highly active items that constitute the great majority of the activity in the warehouse. The popularity philosophy maintains that the materials having the greatest throughput should be located in an area that allows the most efficient material handling. Consequently, high-turnover items should be located as close as possible to the point of use. The popularity philosophy also suggests that the popularity of the items helps determine the storage method used. Items with the greatest throughput should be stored by methods that maximize the use of space. For example, if bulk storage is used, high-turnover items should be stored in as deep a space block as possible. Because the items are moving into and out of storage at a relatively high rate, the danger of excessive honeycombing losses is reduced and excellent use of space will result from the high-density storage. Low-throughput items in deep bulk storage blocks will cause severe honeycombing losses because no other items can be stored in that location until the low-throughput item is removed.
2. *Similarity philosophy:* Items that are commonly received and/or shipped together should be stored together. For example, consider a retail auto parts distributor. Chances are that a customer who requires a spark plug wrench will not buy, at the same time, an exhaust system tail pipe. Chances are good, however, that a customer who buys the spark plug wrench might also require a condenser, points, and spark plugs. Because these items are typically sold (shipped) together, they should be stored in the same area. The exhaust system tail pipe should be stored in the same area in which the mufflers, brackets, and gaskets are stored. Sometimes, certain items are commonly received together, possibly from the same vendor; they should be stored together. Similar types of items should be stored together. They will usually require similar storage and handling methods, so their consolidation in the same area results in more efficient use of space and more efficient material handling. An exception to the similarity philosophy arises whenever items are so similar that storing them close together might result in order-picking and shipping errors. Examples of items that are too similar are two-way, three-way, and four-way electrical switches, which look identical but function quite differently. Storing these items close together will inevitably result in order-picking and shipping errors.
3. *Size philosophy:* The size philosophy suggests that heavy, bulky, hard-to-handle goods should be stored close to their point of use. The cost of handling these items is usually much greater than that of handling other items. This is an incentive to minimize the distance over which they are handled. In addition, if the ceiling height in the warehouse varies from one area to another, the heavy items should be stored in the areas with a low ceiling and the lightweight, easy-to-handle items should be stored in the areas with a high ceiling. Available cubic space in the warehouse should be used in the most effective way while meeting restrictions on floor loading capacities. Lightweight material can be stored at greater heights within typical floor loading capacities than heavy materials can. The size philosophy also asserts that the size of the storage location should fit the size of the material to be stored. Do not store a unit load of 10 ft^3 in a storage location capable of accommodating a unit load of 30 ft^3. A variety of storage location sizes must be provided so that different items can be stored differently. In addition to looking at the physical size of an individual item, one must consider the total quantity of the item to be stored. Different storage methods and layouts will be used for storing 2 pallet loads of an item than will be used for storing 200 pallet loads of the same material.
3. *Product-characteristics philosophy:* Some materials have certain attributes or traits that restrict or dictate the storage methods and layout used. Perishable material is quite different from nonperishable material, from a warehousing point of view. The warehouse layout must encourage good stock rotation so that limitations on shelf life are met. Oddly shaped and crushable items, subject to stacking limitation, will dictate special storage methods and layout configurations to use available cubic space effectively. Hazardous material such as explosives, corrosives, and highly flammable chemicals must be stored in accordance with government regulations. Items of high value or items commonly subject to pilferage may require increased security measures such as isolated storage with restricted access. The warehouse layout must be adapted to provide the needed protection. The compatibility of items stored close together must also be examined. Contact between certain individually harmless materials can result in extremely hazardous reactions and/or significant product damage. Specific steps must be taken to separate incompatible materials. Oftentimes, the easiest way to accomplish this objective is through the warehouse layout.

5. *Space-utilization philosophy:* This philosophy can be separated into four areas: conservation of space, limitations on use of space, accessibility of material, and orderliness.
   (a) The conservation-of-space principle asserts that the maximum amount of material should be concentrated within a storage area, the total cubic space available should be effectively used, and the potential honeycombing within the storage area should be minimized. Unfortunately, these objectives often conflict. Increased concentration of material will usually cause increased honeycombing allowances. Therefore, determining the proper level of space conservation is a matter of making trade-offs among the objectives that maximize use of space.
   (b) Limitations on use of space must be identified early in the layout planning process. Space requirements for building support columns, trusses, sprinkler system components, heating system components, fire extinguishers and hoses, and emergency exits will affect the suitability of certain storage and handling methods and layout configurations. Floor loading capacities will restrict storage heights and densities.
   (c) The warehouse layout should meet specified objectives for material accessibility. Main travel aisles should be straight and should lead to doors in order to improve maneuverability and reduce travel times. Aisles should be wide enough to permit efficient operations, but they should not waste space. Aisle widths should be tailored to the type of handling equipment, using the aisle and the amount of traffic expected.
   (d) The orderliness principle emphasizes the fact that good warehouse housekeeping begins with housekeeping in mind. Aisles should be well marked with aisle tape or paint; otherwise, materials will begin to infringe on the aisle space, and accessibility to material will be reduced. Void spaces within a storage area must be avoided, and they must be corrected when they do occur. If a storage area is designed to accommodate five pallets, and, in the process of placing material into that area, one pallet infringes on the space allocated for the adjacent pallet, a void space will result. Because of this, only four pallets can actually be stored in the area designed for five pallets. The lost pallet space will not be regained until the entire storage area is emptied.

The alternative warehouse layouts should be evaluated by comparing each against specific expectations relative to the layout philosophies as discussed here. The layout planner must determine which layout philosophies are most important under the specific circumstances and attempt to maximize the extent to which the recommended layout adheres to those philosophies. Remember, however, that warehousing exists within a dynamic environment; therefore, the layout chosen as best today may not be so as conditions change. The extent and timing of changing requirements in the future should be forecast and a warehouse master plan established to compensate effectively for the changing mission of the warehouse.

6. WAREHOUSE EQUIPMENT PLANNING

Like space planning, effective equipment planning must follow a very specific methodology. The general steps to this methodology are:

1. Specify what functions the equipment must perform.
2. Identify equipment alternatives.
3. Evaluate the equipment alternatives.
4. Select the equipment.

This methodology is appropriate for equipment planning for all warehouse activities: receiving, shipping, storage, order picking, and data processing.

The first step in the equipment planning methodology is to define the function the equipment must perform: what must the chosen equipment be able to do in order to accomplish the desired objective? This question is crucial, and it must be thoroughly answered before one begins to identify alternatives. Failure to adequately specify the objective the equipment must accomplish, and the minimum capabilities the proper equipment should have to achieve that objective, will often result in selection of equipment that fails to solve the real problem. It is amazing how often poor specification of requirements provides a brilliant solution to the wrong problem.

Unfortunately, no standard guidelines exist that guarantee a thorough specification of the capabilities desired of the equipment. What is desired of the equipment will vary, not only from warehouse to warehouse but also from activity to activity performed in a given warehouse. Although each circumstance will require different answers to different questions, the *types* of questions that will allow adequate specification of the capabilities the equipment must have are virtually the same for

all activities within a warehouse. Table 3 lists the types of questions one might have to answer before specifying begins. The specifications of the capabilities desired of equipment should then be detailed; they should be in writing; then they should be reviewed by each member of warehouse management who will be affected by the equipment in order to identify any overlooked specifications.

TABLE 3 Typical Information Required to Specify Capabilities Required of Equipment

Objective of Equipment	Typical Questions That Must Be Answered
Unload incoming truck shipments	1. What types of trucks will be serviced? 2. What types of unit loads will be handled? 3. How heavy are the unit loads that will be handled? 4. What combination of unit loads might be found on a given shipment? 5. Where will the unit loads be deposited after unloading? 6. What constraints in maneuvering space must be met? 7. Is lifting capability required? To what heights? 8. What productivity rates must be achieved? 9. What other activities will this equipment be required to perform?
Place materials into storage racks	1. What type of storage rack will be used? 2. What type of unit load will be handled? 3. How heavy are the unit loads that will be handled? 4. How high must the unit loads be lifted? 5. From where will the unit loads be obtained? 6. What constraints in storage-aisle width must be met? 7. What constraints in maneuvering space outside the storage area must be met? 8. What other activity occurs simultaneously in the operating area of this equipment? 9. What other activities will this equipment be required to perform?
Retrieve materials from storage rack	1. What types of loads will be retrieved? Full unit loads? Full cases? Individual pieces? 2. How much do the loads that will be retrieved weigh? 3. What type of storage rack will be used? 4. How high off the floor is material stored? 5. What constraints in storage aisle width must be met? 6. What constraints in maneuvering space outside the storage area must be met? 7. What order-picking philosophy will be used: zone picking, full-order picking, simultaneous picking of multiple orders? 8. Where will the materials be deposited after retrieval? 9. What productivity rates must be achieved? 10. What other activities occur simultaneously within the operating area of this equipment? 11. What other activities will this equipment be required to perform?
Load materials into carriers for shipment	1. What types of loads will be handled? Unit loads? Loose cartons? What combination of loads? 2. How heavy are loads that will be handled? 3. From where will loads to be handled be obtained? 4. Is lifting capacity required? How much? 5. What types of carriers will be loaded? 6. What maneuvering space constraints must be met? 7. What productivity rates must be achieved? 8. What other activities must this equipment perform?

The next step in equipment planning is to identify specific equipment alternatives that meet the needed specifications. This step is critical because if the ideal equipment for the job is never identified, then obviously the ideal equipment will not be selected.

At this point in the equipment planning process, the intent should not be to identify the specific make or model of each alternative but rather to identify generic categories of alternatives. First, one must compare the various generic equipment alternatives in order to identify the best alternative; then, in step 4 of the equipment planning process, the specific makes and models in that generic category are compared.

Unfortunately, choosing the best equipment alternatives is easier said than done because of the enormous variety of warehouse equipment on the market today. The number of combinations of equipment that can be made to achieve a certain goal is virtually limitless. A great deal of ingenuity and foresight is often required to predict the impact of integrating several types of equipment into a warehouse system. Consequently, the identification of warehouse equipment alternatives is an art as well as a science. The art does not necessarily have to be inborn; it can be acquired by keeping abreast of the capabilities of existing warehouse equipment and new innovations in the state of the art. Excellent sources of continuing education on warehouse equipment are the many trade publications on warehousing and material handling; trade shows, where equipment manufacturers show and discuss their wares; and seminars and conferences on warehousing and material handling.

A proper evaluation of warehouse equipment alternatives must be a *quantitative* comparison of the alternatives. This is not to say, however, that the choice should be based solely on dollars and cents or that the many *qualitative* attributes of the alternatives—flexibility, reliability, or maintainability, for example—have no bearing on the merits of one alternative or another. On the contrary, superior qualitative attributes of an alternative will often overshadow its apparent economic inferiority to the point where this alternative is chosen as best. In fact, where such a decision is made, the "economically inferior" alternative is judged not to be really economically inferior because its qualitative attributes do indeed have economic value. The problem, then, is an inability to express this qualitative value in quantifiable, economic units (dollars and cents). One solution to this problem is to discontinue the attempt to quantify economically the qualitative attributes of an alternative and instead quantify the qualitative attributes in judgmental units and convert the economic units—dollars and cents—into these judgmental units to form a common base for comparison of alternatives.

The first step in the economic evaluation of equipment alternatives is to identify and estimate the relevant costs of each alternative over its useful life. Relevant costs are usually divided into two categories: investment costs and annual operating costs. Investment costs are incurred to obtain the equipment; they occur on a one-time or periodic basis. The most common investment cost is the purchase price of the equipment. Typically, investment costs are depreciable, and they are often subject to capital investment tax credits.

Annual operating costs are the recurring expenses that keep the equipment in operation. Typical annual operating costs are the wages of operating personnel, the costs of equipment maintenance, and the taxes and insurance costs incurred by owning the equipment. Annual operating costs are generally not depreciable.

Once the relevant life-cycle costs of the alternatives have been identified and estimated, a detailed time-value-of-money analysis must be performed for each alternative. Economic analysis techniques are presented in Chapters 52 and 54 of this Handbook.

Consideration of the qualitative attributes of the equipment alternatives may very well result in selection of equipment that might not have been chosen if the economic analysis had been the sole basis of comparison. However, a casual discussion of the intangible, qualitative attributes of the equipment alternatives that causes a reversal of a decision originally based on the tangible dollar costs of the alternatives will often not withstand the scrutiny of those who must review the decision. Consequently, the discussion of the qualitative aspects of equipment alternatives must be explicit and well documented.

Some qualitative factors that are often looked at are:

Ability of the equipment to fit into and serve warehouse operations

Versatility and ability to adapt to day-to-day changes in products and fluctuations in productivity requirements

Flexibility (ease of changing or rearranging the installed methods)

Limitations imposed by the equipment on the flexibility and ease of expansion of the layout, building, or both

Use of space

Safety and housekeeping

Working conditions and employee satisfaction

Ease of supervision and control
Availability of trained operators
Frequency and seriousness of potential breakdowns
Ease of maintenance and rapidity of repair
Volume of spare parts that must be stocked
Availability of repair parts
Quality of product and risk of damage to materials
Ability to pace, or keep pace with, productivity requirements
Personnel problems: training capability, disposition of unnecessary workers, job description changes, and union contracts or work practices
Availability of needed equipment
Tie-in scheduling, inventory control, and paperwork
Effect of natural conditions: land, weather, etc.
Potential delays from required synchronization and peak loads
Supporting services required
Time required to get into operation, i.e., to complete installation, training, and debugging
Availability of capital or investment money
Promotional or public-relations value

The final step of the equipment planning process is to select the specific equipment. The selection process is as follows:

1. Sell management on the proposed equipment and obtain approval for any capital appropriations required.
2. Compose detailed specifications of the equipment required.
3. Identify vendors who can potentially provide the equipment.
4. Prepare and distribute a vendor bid package.
5. Receive and evaluate the vendors' bids.
6. Select and order the equipment.

Evaluating vendors and their specific equipment requires the same decision process that should be used when selecting the desired generic equipment. The decision should be based on a combination of economic and qualitative factors. The obvious economic factor that must be considered is the invoice price, which will include purchase price, sales tax, freight costs, installation costs, and so on. The qualitative factors to be considered will include many of the same factors as the evaluation of generic-equipment alternatives, such as the volume of spare parts that must be kept on hand, the ease of maintenance, the rapidity of repair, and the availability of repair parts and service. In addition, other factors specifically related to vendor selection are the availability of the equipment, installation and debugging services provided, warranties, and the reputation of the manufacturer and its local representative. Consequently, equipment and vendor selection should never be based solely on a low invoice bid. The judgmental units used to select generic categories should be used here.

7. WAREHOUSE OPERATIONS AUDIT

Critical to the ongoing success of storage and warehousing operations is the continuous analysis and evaluation of the day-to-day operations to identify opportunities for improvement. A formal, periodic audit of the existing operations, conducted in a systematic manner, can be an effective tool for achieving continuous improvements. While a number of specific methodologies can be utilized to conduct such an audit, the following discussion will define one approach that has been successfully used.

7.1. Operations Audit Performance Categories

The operations audit is a process that evaluates 10 categories of performance in the warehouse. Utilizing information on the performance of the warehouse in these categories, a quantitative overall performance measure is determined. The 10 categories assessed by the operations audit are:

1. Customer service
2. Control systems
3. Inventory accuracy

4. Space utilization
5. Labor productivity
6. Layout
7. Equipment methods
8. Equipment utilization
9. Building facilities
10. Housekeeping and safety

The first category, customer service, is a primary concern to the warehouse management and upper management. Rating of customer service is based on how well the warehouse performs against its corporate service goals. These goals may include order-to-delivery cycle, order-to-ship cycle, and out-of-stock occurrences.

Control systems is the second category to be evaluated. This is by definition not just computer controls. Evaluation of controls looks at what paperwork is used, how data integrity is used, what duplication of efforts and paperwork exists, how special requests are serviced, and how effective is the use of computer controls, if available. The assessed need for increased computer control is based on the ability of existing manual or computer-controlled operations to adequately control the warehouse. Some indicators that enhanced computer control is needed are the inability to find material, excessive time required to find material, increased obsolescence, and inefficient labor utilization. In most cases a top-rated warehouse has a real-time, online, order entry system that develops truck loads, batches items for picking, preroutes and preposts picking, and manages labor with real-time instructions via data terminals in the warehouse.

Inventory accuracy is critical because many other categories can be affected by poor inventory control. The rating assigned is based on performance against corporate goals. The accuracy of inventory count for all items in total should be considered, as well as the percentage of different items (SKUs, stock-keeping units) found to be accurate in counting. Lack of accuracy on small, inexpensive items can have as big an impact on customer service as on the larger, more expensive items. Item count, dollars on hand, and total part count are all 99% or better, and cycle counting is performed in a top-rated warehouse. Initially, though, the rating assigned should be against the corporate goal, with the goal being improved as consistency is achieved.

Space utilization is calculated for the entire warehouse, based on the storage method being used. The quantity of positions occupied vs. the total available positions is used to calculate the utilization for each type of storage in the warehouse. The utilization of each area, the square footage of the area, and the total square footage of the warehouse are then used to calculate the overall utilization. This overall utilization is compared to the maximum efficient utilization, usually 80–90%, to determine the operating utilization. A review of the projected growth can then be utilized to determine the life expectancy of the warehouse. This life expectancy, the time until operationally full, is used to determine the rating. Typically, a new warehouse takes between 12 and 24 months to design, construct, and occupy. If the life expectancy is less than this time, a low rating is assigned. Also, if the life expectancy is beyond five to six years and growing, a low rating is assigned. Also, if the life expectancy exists, the warehouse space should be reviewed for use by other functions, or for sale.

Labor productivity, category 5, means different things to many warehouse managers. The rating is based on a review of the operating procedures for the warehouse. Each of the major functions in the warehouse—receive, store, pick, and ship—are evaluated. The procedures are reviewed to determine how effectively they support high labor productivity. The existence and use of labor standards is also considered. Effective procedures and proper use of standards is needed for a top rating.

Category 6, layout, is integral to the successful performance of other categories. The objectives of a proper warehouse layout are:

1. To use space effectively
2. To allow the most efficient material handling
3. To provide the most economical storage in relation to costs of equipment, use of space, damage to material, and handling labor

Rating the layout of the warehouse is based on how well these objectives are met. Effective use of space for storage, operational, and support functions is considered here. The transport and storage of material is analyzed to determine how well the layout supports reduced handling costs and increased labor productivity.

Equipment methods refer to the appropriateness of the types of equipment and the use of this equipment in the warehouse. At least two major types of equipment exist in every warehouse: storage equipment and handling equipment. Rating is based not on how much each is utilized, but how well. For example, storage equipment should contain the proper items based on physical characteristics

(e.g., size, weight, fragility) and activity level. Handling equipment is also evaluated based on these same characteristics, as well as how the equipment interfaces with storage and delivery points.

Equipment utilization is calculated for each group of equipment in the warehouse. This may include forklift trucks, storage/retrieval systems, conveyors, carousels, and automatic guided vehicles. The utilization, together with the variation in demand, is considered to assign a rating. Too high a utilization can be as detrimental as too low. The operational utilization must be considered with the actual run time for a vehicle. A forklift should travel with a load the majority of the time. High use of vehicles traveling empty is not acceptable. In a top-rated warehouse, the utilization is at or just below the operational maximum with the growth to meet the life expectancy considered.

Building facilities are often overlooked areas of the warehouse. Building facilities include:

Dock capacity
Lighting
Personnel services (offices, restrooms, break areas, etc.)
Fire protection
Outside space (truck aprons, service areas, etc.)

The utilization of docks depends on two factors: the turnaround time to load or unload and the arrival pattern of trucks at the docks. Typically, the dock utilization should be 70–80%. Also, the use of proper dock equipment is evaluated. Dock locks or chocks, levelers, and light should be available. Lighting should not only be sufficient to support operations but also be located properly to avoid equipment interferences. Personnel services should be properly located and of sufficient size and quantity to support the staff. Fire protection is rated based on the type of facility, the equipment methods used, and the type of material stored. Outside space is most often overlooked in building facilities. Proper allowances for truck access, personnel access, and other services can affect safety and efficiency.

The last category is housekeeping and safety. There is a strong relationship between housekeeping and safety. Poor safety conditions do not necessarily mean housekeeping is poor, but poor housekeeping always impacts negatively on safety. Housekeeping is reviewed in several specific areas. Material should be put away, not lying on the floor and in aisles. Empty pallets, cartons, or tools should be stored neatly. The warehouse should be clean; the rack should be aligned properly on working aisles. The issue of safety in the warehouse is a direct function of professionalism. The equipment operators should be trained, certified, and periodically recertified. The equipment should be in proper working order. Lighting and other environmental conditions should be proper for the work. Personnel access to high-traffic areas for equipment should be limited. All material must be stored properly. Bulk materials should be stacked properly, not exceeding allowable load heights. Pallets in racks should have the proper amount of overhang and be loaded within the capacity limits. The rating is based on these rules being followed throughout the warehouse.

7.2. Operations Audit Methodology

Each performance category is rated on a scale of 1 to 5, with 5 being the highest. The rating is based on both quantitative and qualitative assessments. The auditor should record specific factors or indi-

TABLE 4 Calculation of Performance Index

Category	Rating	Target Rating	Weight	Category Score	Target Score
Customer service	1 2 3 4 5	5	40	120	200
Control systems	1 2 3 4 5	4	30	120	120
Inventory accuracy	1 2 3 4 5	5	30	150	150
Space utilization	1 2 3 4 5	4	20	60	80
Labor productivity	1 2 3 4 5	5	20	80	100
Layout	1 2 3 4 5	5	20	100	100
Equipment methods	1 2 3 4 5	5	10	30	50
Equipment utilization	1 2 3 4 5	5	10	50	50
Building facilities	1 2 3 4 5	5	10	50	50
Housekeeping/safety	1 2 3 4 5	5	10	40	50
Total				800	950
Performance index					84%

TABLE 5 Warehouse Class

Warehouse Class	Performance Index	Rating ≤3
(A+) Excellent	95–100%	0
(A) Very Good	90–94%	2
(B) Good	85–89%	3
(C) Average	80–84%	3
(C−) Below average	70–79%	4
(D) Poor	<70%	>4

cators used to obtain the assigned rating. After rating of each category, determination of overall performance is straightforward. Before the results of the audit are calculated, two additional actions must be performed. The first is to assign weights to the performance categories. Each category varies in importance to a particular warehouse operation. To account for this, a weight is assigned to each category, reflecting its relative importance. The total of all weights is 200, which together with the maximum rating of each category (5) yields a maximum possible score of 1000 points. Second, for a particular warehouse the realistic maximum rating for a category may be less than 5. Due to the warehouse size or activity level, for instance, a computer control system may not be practical. Therefore, a target rating is assigned to each category. In future audits of the same warehouse, this target rating may change to reflect consistent high levels of performance or changes in activity and size.

The category rating and target ratings are multiplied by the category weight to obtain a category score and target score. The total of the category scores is then divided by the total target scores to obtain a performance index (PI). Table 4 shows the results of a typical audit and calculation of the PI. In this particular example, a performance index of 84% is achieved. The performance index is one part of the analysis to determine the warehouse class. The other part of the analysis needed to determine the class is based on the consistency of ratings. The number of categories with a rating of 3 or less is obtained. In the example, this is equal to 3. Table 5 shows how the warehouse class is determined for the example in Table 4.

The first step is to identify a class based on the performance index. In each class, there is a limit to the number of ratings that are less than or equal to 3. In the example, the performance index is 84%, which is a class C, which has a limit of three ratings less than or equal to 3. This warehouse has three ratings less than or equal to three, so the class does not change. Exceeding the number of ratings less than or equal to three causes a drop in class, but the inverse is not true. Class cannot improve over the performance index level achieved.

The results of the audit show warehouse management how well the warehouse is doing and provide a tool to communicate this performance. The breakdown of ratings for each category can be used as a road map to plan improvements. The operations audit should be performed on an annual or semiannual basis to track the results of improvement efforts. Following each audit, new goals for improvement in each category must be set, and plans made to implement required operations changes.

CHAPTER 58

Plant and Facilities Engineering with Waste and Energy Management

JAMES R. ROSS
Resource Management Systems (RMS Inc.)

1. OBJECTIVES AND CONTENT OF THE CHAPTER

This chapter is intended to identify linkages between industrial engineering and plant and facilities engineering, to create an understanding of the scope and breadth of plant and facilities engineering, and to explain selected activities and issues of which industrial engineers assigned to plant and/or facilities engineering duties need to be aware. Where possible, industrial engineering methodologies and techniques will be applied to the design, installation, and management of plant facilities, utilities, and service systems to improve cost effectiveness, productivity, quality, operations, and environment.

While many fundamental principles from the previous edition of this Handbook remain the same, technology, analytical tools, and managerial style that have changed the world in which plant and facilities engineers live and work have been added to make the chapter as current as possible.

2. SCOPE OF PLANT AND FACILITIES ENGINEERING

2.1. Definition of Plant Engineering

Plant engineering may be defined as the entity responsible for providing and maintaining a safe, productive work environment in a constant state of readiness in support of the organization's mission in a cost-effective manner. Facilities engineering deals more specifically with the building, its equipment, utilities, grounds, and closely associated issues rather than those functions that directly support production or general operation (Rosaler and Rice 1983; Rosaler 1994, Higgins 1988).

2.2. Emerging Concept of Enterprise Asset Management

Although the definition of plant and facilities engineering remains the same from the previous edition, a key difference is that plant engineering in many organizations has moved from a discrete functional area within a corporation to providing an enterprise asset management function. The plant or facilities engineer is the steward of assets and resources used by a company and consequently must assume greater responsibilities than in the past. The facility is now viewed as a value-added key to business productivity and competitiveness. As a workplace, the facility is integrated with all other business functions. Specific techniques to facilitate these changes and improve the plant or facility engineer's qualifications are presented throughout this chapter (Davis et al. 1999).

2.3. Relationships between Plant Engineering and Other Departments

2.3.1. Relationships between Plant Engineering and Maintenance

Maintenance is often the operational arm of the plant engineering function, and it may consume over 50% of a plant engineer's total time. Plant engineering and facilities engineering have commonalities with maintenance in problem-solving methods, scheduling, assignment of tasks, and preventive maintenance on the facility and equipment that are used plant-wide. Because many plant engineers are in direct charge of maintenance, procedures for managing both maintenance and plant engineering functions become intermingled. If maintenance is a separate function from plant and facilities engineering, the plant engineer must form strong relationships with maintenance managers to get quick response when critical maintenance problems arise. Chapter 59 of this Handbook describes maintenance in detail (Tatum 1997).

2.3.2. Relationship between Plant Engineering and Production or Operations

In the past, plant and facilities engineering was a separate entity that provided service to production and operations management. With the advent of team management, plant and facilities engineering personnel may be assigned to work directly with production and operations people. The linkage between plant engineering people and production or operations has become indistinct, especially in

manufacturing, where line mechanics may report directly to production managers or team leaders. With greater emphasis on just-in-time production, plant engineering must have greater flexibility to meet fast-track schedules and reduce process cycle time.

Allocation of effort between plant engineering and production depends on the type of operation. Generally speaking, operation and maintenance of plant equipment, such as air compressors, chillers, boilers, electric systems, and HVAC systems remain the sole responsibility of plant engineering, but where production equipment is involved, the trend is to have maintenance readily available to assist in repairing production equipment quickly. Production workers are often trained to do first-line or routine maintenance tasks including preventive maintenance. If specialists such as electricians, instrument mechanics, and electronics technicians are needed, these are normally supplied by the central maintenance group, but on occasion these people are also integrated with production operations.

2.3.3. Relationship between Plant Engineering and Upper Management

Despite the blurring of assignments relative to plant and facilities engineering, the plant and facilities engineer will be held accountable for the proper maintenance and operation of facilities-related systems. It is incumbent upon the plant and facilities engineers to communicate with the managers of all departments to obtain their input on situations that need attention and to report progress to upper management using a variety of measures, some of which are described under the section on productivity improvement in this chapter. Ideally, the plant engineer should report directly to the plant manager or general manager, depending on the senior executive in charge of the facility. Because plant engineering is an extremely important and vital function, lines of communication with decision-makers must be as short as possible to minimize reaction time for decisions, optimize allocation of resources, solve problems, and maintain an effective operation.

2.3.4. Relationship between Plant Engineering and Product and Process Design and Introduction

The concept of concurrent engineering in product design and planning is intended to avoid the ''throw it over the wall'' approach by including everyone concerned with design, marketing, engineering, manufacturing, human resources, warehousing, packaging, and distribution of the product on the product-planning committee. The plant engineer should be involved from the inception of each new product as a member of a team or committee and can contribute to successful product development or introduction in the following ways:

Participate in value analysis studies and help to verify new product manufacturability.
Assist in developing the manufacturing process, flow, and plant layout.
Direct a team to determine facilities needed to produce the new product.
Identify maintenance, utilities, or service requirements for the new product.
Specify, obtain quotes, procure, or fabricate new equipment.
Advise on tooling design and cost with manufacturing engineering.
Determine level of maintenance staffing needed to support the new product.
Manage equipment relocation or new equipment installation.
Concentrate on problem resolution during the startup phase and beyond.
Contribute creative ideas throughout the process.

2.4. Roles of Plant and Facilities Engineers

In some organizations, the plant engineer manages all engineering, maintenance, shops, security, utilities, buildings, and grounds. In other organizations, the plant engineer directs design and construction of new facilities. Often, peripheral functions such as plant safety and security, fire protection, recycling, waste disposal, property records administration, risk management, and pressure vessel inspection and maintenance are included in the plant engineering function. Where no one else is available, the plant or facilities engineer may be called upon to perform other diverse functions that are not engineering but must be done by somebody. This is a compliment to the flexibility of the typical plant engineer. The facilities engineer's scope deals more specifically with the building, its equipment, utilities, and grounds rather than those functions that directly support production. The proliferation of team management in the last few years has changed the character and style of plant and facilities engineering. These changes are addressed throughout this chapter.

Although called an engineer, the plant or facilities engineer in a large corporation may manage a multimillion-dollar operation, a greater responsibility than that of the president of many small companies. By contrast, a small plant may have one engineer whose responsibilities include plant and facilities engineering. Both large or small plants need to have the functions of plant engineering

performed. If these functions are not performed, deterioration in equipment, buildings, grounds, and other facilities can cause cost penalties when repair of damage due to neglect is required later. Every organization pays for plant engineering, whether or not it is actually performed. Plant engineering is a ''pay me now or pay me later'' profession.

The classical functions of management for plant engineers who have managerial responsibility include planning, organizing, motivating, analyzing, controlling, instructing, delegating, disciplining, and communicating, the same as for managing any other type of enterprise. Not all plant engineers have managerial responsibility, but most have technical responsibilities. Some typical responsibilities of plant engineering managers and technical plant engineers include:

Set departmental strategic and tactical objectives.
Develop policies for the department.
Recruit employees to build an effective organization to perform essential functions.
Devise motivational programs for plant engineering employees.
Participate in development and functioning of team management activities.
Plan, schedule, and assign work directly or though supervisors or team leaders.
Prepare and control capital and expense budgets.
Survey condition of the facility, issue work orders for correction of deficiencies.
Acquire a cutting-edge knowledge of all facility equipment and practices.
Conceptualize, prioritize, and manage improvement or major repair projects.
Procure and install new equipment.
Keep an updated layout of the plant.
Develop and execute productivity and quality measurement systems.
Assess training needs and train employees to perform tasks correctly and quickly.
Establish a program of preventive and predictive maintenance.
Manage maintenance work order, cost, and information systems.
Conduct value analysis studies on equipment, parts, and supplies.
See that material inventory is carefully controlled.
Build the status of plant engineering within the organization with peers.
Communicate with top management to get support for the plant engineering function.
Develop and follow procedures as required under ISO 9000 or ISO 14000.
Manage an integrated information technology/data-management system including CMMS.
Assure that computer support systems are adequate for present and anticipated needs.
Coordinate telecommunications systems installation and maintenance.
Oversee contracting and outsourcing of services.
Assure dependable and cost-effective utility services.
Maintain utility systems in optimum condition.
Direct the safety program and proactively find and correct hazards.
Maintain fire-protection systems in a constant state of readiness.
Perform environmental audits and correct deficiencies quickly.
Negotiate with insurance carriers for maximum protection at the best rate.
Manage the security program for the facility.
Establish and maintain the buildings and ground program for the facility.
Conduct an effective energy-management and conservation program.

This list of responsibilities is intended not to be all inclusive, but to describe the diversity of duties that plant and facilities engineers encounter. Additional duties not included above may be suggested throughout this chapter (Tomlingson 1988a,b).

2.5. Industry Characteristics That Affect Plant Engineering

Although plant and facilities engineering may have originated in manufacturing, there are many other industries and businesses that need plant and facilities engineers. Each of these organizations has a set of unique problems that may not be common to manufacturing. Some examples of nonmanufacturing facilities that require plant or facilities engineers are:

- Public buildings have plant engineers to ensure that heating ventilation and air conditioning, utilities, building maintenance, telecommunications, security, and computerized building management are available and properly maintained.
- Military installations have extensive and unique needs for technologies that are available through plant engineers.
- Research laboratories have, in addition to the usual plant engineering activities, reduction and disposal of hazardous biological ands chemical agents that require highly specialized handling.
- Hospitals and other health-care facilities have long had plant engineers to ensure the facility is in top condition, as the lives of patients depend on a perfectly functioning facility.
- Electric utility generating stations rely heavily on plant engineers to maintain equipment and facilities under adverse conditions.
- Coal mining, oil drilling, and other mineral extraction all require extensive maintenance and plant engineering assistance, also under adverse conditions.

Industrial engineers can bring a wealth of skills to plant and facilities engineering positions in any of the above-named facilities and others not previously mentioned. In preparing this chapter, efforts have been made to make materials as generic as possible so that they apply to any industry or business to which an industrial engineer functioning as a plant or facilities engineer may be assigned.

3. INTEGRATING INDUSTRIAL ENGINEERS INTO PLANT AND FACILITIES ENGINEERING

3.1. Why Industrial Engineers Make Good Plant Engineers

An industrial engineer is an excellent choice to be a plant or facilities engineer. By definition, an industrial engineer is a systems designer who integrates materials, machines, people, technology, and energy to produce goods or services in a productive manner. IE's possess a wealth of analytical tools that can be creatively focused on plant engineering problems. The academic course known as facilities planning and design is fundamental for an industrial engineer becoming a plant engineer. The IE plant engineer can overcome a lack of specific knowledge about technical aspects of plant engineering by keeping many details in clear focus simultaneously and by applying good reasoning, system-integration abilities, creativity, judgment, communication skills, flexibility, adaptability, and quality consciousness, excellent human relations skills, and the principles of industrial engineering.

3.2. Problems That May Face an Industrial Engineer as Plant Engineer

Although an industrial engineer brings an impressive array of skills to the job as a plant engineer, long-time employees, for example, may not readily accept a person who has not previously held a plant engineering position. Selling oneself to the existing workforce should take high priority. The new plant engineer must also be a fast learner, and take steps to become familiar with details of the facility itself, in addition to the engineering, business, and human resource aspects of the new job. Seldom is time available to step back and reflect on these issues, as plant engineering, by design, is a pressure job in which the incumbent must take charge immediately.

3.3. Facilities Management as a Resource-Utilization Issue

As the manager responsible for a multimillion-dollar facility, the plant engineer is accountable for utilization of all resources, under the command of the enterprise manager. When the facility is available for use, people, machines, equipment, and the facility itself are well utilized. If the facility fails, all resources are underutilized and materials can be wasted as well. The plant engineer must also be cognizant of energy use at all times and optimize its use.

3.4. Training Needed by Industrial Engineers to Become Good Plant Engineers

3.4.1. Knowledge Needed in Other Engineering Disciplines

The many technological, analytical, and managerial changes that have occurred concurrently both complicate and simplify the work of a plant engineer. An industrial engineer functioning as plant or facilities engineer must acquire knowledge outside of industrial engineering. Some examples of technologies and equipment related to mechanical, electrical, and civil engineering with which the industrial engineer may be unfamiliar include, but are not limited to, the following:

Mechanical	Electrical	Civil
Piping and valving	Primary power system	Site design
Boiler operation/maintenance	Transformers	Surveying/contours
Machine design	Electrical distribution system	Soil test results
Heating, ventilation	Machine hookup	Structural design
Air conditioning	Building automation	Building envelope
Hydraulics, pneumatics	Electrical maintenance	Water, sanitation
Instrumentation and control	Cogeneration	Waste management

In a large organization, specialists in each of these areas may be available, but in a small organization, the plant engineer may be required, without prior training, to address the above issues plus many more. To achieve a level of competence and expand his or her knowledge base, the engineer can acquire additional skills and knowledge through intensive independent study, academic courses, focused short courses, retraining with outside experts, courses sponsored by equipment vendors, or in some cases, conversation with vendors.

3.4.2. New Skill Requirements for Plant and Facility Engineers

In addition to the above, successful plant engineers will be required to be skilled in the following technologies and techniques:

3.4.2.1. Management Skills Classical management skills of planning, organizing, motivating, controlling, and communicating will continue to be essential, but knowledge of emerging managerial techniques will be the key to future success. Team management in many different forms is growing rapidly, and hence it behooves the plant engineer to become skilled in that managerial style. Authoritarian leaders may survive in some organizations if that is the prevailing managerial style, but with changing workforce attitudes, a more democratic/participative managerial style using team approaches is likely to emerge in the future. A description of team management appears in Chapter 37.

3.4.2.2. Project Management Plant engineers are often called upon to manage major construction or installation projects plus innumerable repair projects. While the level of formality differs from large to small projects, the methodologies of concurrent activity, prioritization, and cost control remain the same. Project-management software is available to optimize utilization of resources as well as remove some routine charting and computational work associated with managing projects. See Chapter 46.

3.4.2.3. Training Skills As the plant engineering field becomes more complex and the availability of trained people diminishes, the need for training increases. Training of engineers and hourly employees in everything from basic maintenance techniques to computer building-control systems will help maintain productivity. The topic of training is addressed in detail later in this chapter due to its current and future importance.

3.4.2.4. Computers Applications for computers in plant engineering organizations are almost endless. As industry becomes more computerized, plant engineers must learn computer skills to compete. A few computer systems applicable to plant engineering are:

Computerized maintenance management systems
Management information systems
Computer-automated facilities management systems
Computer-aided design
Computer-assisted manufacturing
Computer numerical control (CNC)
Programmable logic controllers (PLCs)
Machine-specific computer controls

See Chapters 46, 59, and 72 for more details on the above.

3.4.2.5. ISO 9000 In recent years, the use of ISO 9000 has proliferated. ISO 9000 is often mistaken for a quality system, but it is in fact an organized way to document procedures used in managing an enterprise or department, including quality. Plant engineers are often involved in documenting maintenance procedures and systems, such as work order processing, equipment inspections, predictive or preventive maintenance, and data collection using the documentation discipline

of ISO 9000. If a computerized maintenance management system (CMMS) is available, converting data to ISO 9000 requirements should be relatively easy. Although the benefits of documenting procedures can be significant, conversion to ISO 9000 is very time consuming and expensive, and records must be open to auditors who verify that documented procedures are actually followed. See Chapter 74.

3.4.2.6. Quality The need for continuous improvement through application of statistical techniques and the permeation of quality thinking into all aspects of plant and facilities engineering are now a reality. It is no longer possible to accept ''pretty good'' quality of workmanship or to solve problems by guesswork. The only acceptable approach is to identify the problem, find the root cause, and eliminate the cause. An attitude of quality must permeate every aspect of organization, including plant and facilities engineering. See Chapters 66, 67, and 73.

3.4.2.7. Energy Plant engineers are often responsible for energy within a facility. With deregulation of energy, great opportunities for cost reduction exist. Energy conservation must also have a high priority to improve profits. A section of this chapter is devoted to energy management and conservation.

3.4.2.8. Telecommunications Many plants and office buildings have telecommunications systems to support electronic commerce, voice and data transmission, computer networking, and many emerging technologies. Transmission may be by wire, cellular, radio, or satellite. Because technology in this field requires frequent upgrading of equipment and supporting software, a successful plant engineer must work closely with information systems engineers and equipment vendors to maintain the state of the art in telecommunications.

3.4.2.9. Environment More stringent environmental laws and regulations continue to force plant engineers to spend massive amounts of time and money to avoid legal penalties for failure to comply with the laws. Despite this, reduction of hazardous waste, solid waste, air pollution, and water pollution offers significant cost-saving opportunities for industrial, plant, and facilities engineers whose key function is the effective utilization of all enterprise resources. More details on waste reduction appear later in this chapter and in Chapters 16 and 19 of this Handbook.

A new tool to ensure environmental compliance and waste reduction is ISO 14000, in which environmental procedures are documented. The documentation and auditing requirements to maintain ISO 14000 certification, although somewhat cumbersome and time consuming, tend to pressure organizations to comply with their own procedures. Environment must be a consideration in every management and engineering decision.

3.4.2.10. New Maintenance Techniques Advances continue in maintenance technology, including more sophisticated techniques of vibration-signature analysis, tribology, motor meggering, oil and wear particle analysis, laser alignment, infrared thermography, acoustic leak detection, and nondestructive testing. These techniques give plant engineers tools to diagnose and predict and/or prevent equipment failures. The concepts of equipment durability, availability, maintainability, and reliability-centered (or based) maintenance are converting maintenance from a reactive to proactive mode. Concurrently, the emphasis has shifted from a power organization to an empowered organization, a shift largely brought about by total productive maintenance. Successful plant engineers must have the vision to utilize all available techniques and technologies to improve maintenance in a new, more demanding environment.

3.4.2.11. New Problem-Solving and Analysis Techniques For many years, the typical five-step problem-solving technique seemed adequate, but new problem-solving techniques seem to appear almost weekly. These techniques center around finding the real problem and the root causes of the problem, leading to a more effective solution. There is seldom a shortage of problems to be solved by a plant engineer, but how the engineering handles those problems can make the difference between success or failure. New problem-solving techniques such as kaizen, 5 ws, 8d, 5s, and others are described in other chapters in this Handbook and in supplemental books and training programs.

3.4.3. Training as a Motivator

Training is intended to develop and enhance employee understanding of current or new responsibilities and skills, help employees keep abreast of new technologies, and improve employee morale, performance, and productivity. It can also be a motivator and reward to employees. Training should also be regarded as an investment in the future of the company by helping management retain valuable employees. It is usually more cost effective to retrain an employee than to hire someone new.

3.4.4. Assessing Training Needs for Plant Engineering Employees

To determine training needs, the plant engineer may ask questions including the following to make an initial assessment:

Are some plant engineering services lacking?
Is quality of work and service substandard?
Are primitive work methods instead of modern techniques being used?
Is there dependence on one individual for certain essential services?
Are some people failing to reach their full potential?
Are some skills lacking or in short supply?
Are new skills needed for plant expansion or new processes?
Are excessive accidents occurring?
Is labor turnover abnormally high?
Is downtime on equipment excessive?
Do some people lack training in teamwork?
Do people have problems in using computers and technology?

A ''yes'' answer to the above questions can verify the need for training.

A skills inventory that lists each piece of equipment or operation and the skills required for operating or maintaining that equipment can indicate the need for training to fill voids in available skills (Peele and Chapman 1989).

3.4.5. Types of Training

The plant engineer must determine the type, level, method, material, and media to be used in the program. A blend of the following types of training will normally be required for a comprehensive training effort:

3.4.5.1. Orientation An orientation program gives basic information about the organization, its history, mission, organization, benefits, policies, products or services, and mode of operation. Time spent in orientation is well worth the cost because it makes the employee feel part of the organization. Omission of this step may lead to labor turnover and low productivity.

3.4.5.2. On-the-Job Training While employees may learn the job themselves, monitored on-the-job training administered by supervisors can save months of unlearning bad habits acquired from self-instruction. The job instruction training (J.I.T. or show and tell) technique, with adequate explanation, is effective for training in manual skills and repetitive or semirepetitive operations. The J.I.T. method is as follows:

1. *Prepare for training:* Learn the job, write the method if possible, see what the employee already knows, explain value of training, establish rapport with the trainee.
2. *Present training:* Demonstrate and explain each step in the job, point out quality and safety expectations, trouble spots, shortcuts, specifications, and other key points, repeat process as required to ensure understanding.
3. *Practice training:* Let employee do the job while explaining to the supervisor the steps just learned, make corrections as necessary.
4. *Pursue:* Follow up to make frequent checks to ensure training has been absorbed, retrain as required, compliment trainee on progress.

Typical plant engineering tasks suitable for this training approach include scheduled lubrication, boiler water testing and blowdown, lift truck battery filling, belt tightness testing, sprinkler system testing, recurring parts replacement, setup and changeover, and repetitive preventive maintenance activities. If a video camcorder is available, a training tape can be recorded to explain the task, for use when new employees are being trained.

3.4.5.3. Internal or External Training The decision on where to obtain training depends on in-house training skills, organizational needs, educational level of trainees, and expected quality of training. Commercial self-study training programs can be integrated into an in-house program to save development time. External training can be cost effective if new skills must be learned quickly. Equipment suppliers may offer training on equipment-specific topics (boilers, air conditioning, computers). Packaged courses on maintenance and plant engineering, in programmed instruction and/or interactive video or computer, can reduce course training development and presentation time (Phelps 1988).

Apprentice training for machinists , electricians, boiler operators, mechanics, or other jobs requiring exceptional skill levels is one solution for skill deficiencies. An apprentice program may be established by assessing the need for such training, determining interest of employees in becoming

certified in their job disciplines, designing the work processes and training sessions, obtaining approval for the Department of Labor or other accrediting agency, presenting the program, and rewarding employees who complete the program.

Training of the new plant engineer and all plant engineering personnel is an excellent investment that deserves high priority for the benefit of the organization.

4. MANAGING PLANT AND FACILITIES ENGINEERING

4.1. Organization and Management of the Plant or Facilities Engineering Function

The plant engineering organization is shaped by many factors that vary widely among enterprises, including the following:

4.1.1. Strategy for Plant Engineering

First and foremost, be in harmony with the strategic plan of the enterprise. Not all enterprises have the same strategic plan for plant engineering, so the organization must be shaped to support the unique objectives for the specific enterprise. Functions assigned to plant engineering can lead companies into businesses the mission statement does not recognize. A plant engineer may, by default, become the manager of such businesses as real estate, vehicle repair, electric generating, telephone, building construction, machine building, and scrap metal. Management should make a conscious decision to get into or stay out of a business depending on corporate objectives, skills availability, funding sources, and volume and type of business. Without the strategic decision, the company may be in unwanted businesses it can neither manage nor run profitably. Many companies assign side businesses to contractors. Despite higher unit prices, this may be more cost effective than running an unfamiliar business.

4.1.2. Size of Operation

In a larger organization where delegation is possible, the plant or facilities engineer performs chiefly managerial functions, such as assigning and reviewing the work of others and communicating with superiors, peers, and subordinates. In a smaller organization, the plant engineer may perform many of the engineering, managing, and implementation steps individually.

4.1.3. Type of Operation

The plant engineering organization must be patterned to achieve the mission and objectives of the operation being served. A large, continuous chemical complex will have different organizational needs than a five-day-per-week automotive parts manufacturer or an office building. In a small, light manufacturing plant, the plant engineer often has full responsibility for maintenance, support equipment, and the facility itself, with no subordinate employees. Plant engineers in large plants usually have executive status, but inroads by teams and the level of technology and automation are changing organizational relationships and structures. The degree of automation also has an impact on organization of plant engineering.

4.1.4. Managerial Style and Structure

Until recently, plant engineering organizations were essentially hierarchical, but now team management techniques are being used increasingly in industries and businesses. This is particularly true when total productive maintenance is used. In this concept, maintenance people who were formerly in a separate department are integrated into manufacturing or operating departments, where they are part of a close-knit team rather than outside. While maintenance and plant engineering people may lose some of their individuality and visibility, the benefits of teams in improving productivity are well documented. One advantage of TPM is that intradepartmental conflicts are avoided and everyone is motivated toward a single goal of maintaining production in the most efficient manner.

Another new paradigm is that plant and facilities engineering operates as a professional-services firm composed of multifunctional teams of experts who provide services to other departments within the organization. Charges against departmental or activity budgets are made for services rendered.

4.1.5. Area of Responsibility

The organization of the plant engineering activity depends on top management's perception of its responsibilities in relation to other departments. Plant engineering often acquires unwanted or inappropriate, but necessary, functions that do not fit within other departments. In a TPM situation, traditional reporting relationships of plant engineering personnel may be blurred because individuals may report to operating or administrative departments rather than directly to the plant engineer. The plant engineer is obliged to adopt a new organizational structure and concentrate on communicating with manufacturing or other departments that manage plant engineering people. The plant engineering

function should report to the plant manager, general manager, chief engineer, or assistant plant manager. This direct line to key executives can facilitate obtaining the resources necessary to keep the facility operating optimally.

4.1.6. Availability of Qualified Personnel

The availability of qualified personnel relative to operational requirements may force a more pragmatic approach to organization. In highly technical operations, unavailability of qualified people to perform specialized tasks may cause the plant engineer to seek such expertise outside of the organization.

4.1.7. Budgetary Constraints

If upper management views plant and facilities engineering functions as just more overhead, it may be excessively frugal when authorizing budgets. Top managers must realize that plant and facilities engineering are interdependent with production and that adequate funding to perform an optimum job is essential because "You pay for plant engineering whether you have it or not."

Graphical representations of the typical hierarchical organizational structure followed by one of many team configurations are shown in Figure 2 (Lewis and Marron 1973).

MAINTENANCE SKILLS INVENTORY FORM

Equipment Type: Compressors Trade: Mechanic

APPLICABLE EQUIPMENT/SYSTEMS: Compressor #1, #2, #3, #4, #5, #6

MAINTENANCE SKILLS	NAMES OF QUALIFIED MAINTAINERS	CAPABILITY (check one) Fully capable	Partially capable	Not capable
A. SERVICING AND LUBRICATION	1. Tim P. 2. Bob C. 3. Ray W. 4. Tony G.	✓		
B. ROUTINE PREVENTIVE MAINTENANCE	1. Tim P. 2. Bob C. 3. Ray W. 4. Tony G.	✓		
C. TROUBLE-SHOOTING (problem identification)	1. Tim P. 2. Bob C. 3. Ray W. 4. Tony G.		✓	
D. MINOR REPAIR	1. Tim P. 2. Bob C. 3. Ray W. 4. Tony G.	✓		
E. MAJOR REPAIR	1. Tim P. 2. Bob C. 3. Ray W. 4. Tony G.			✓
F. OVERHAUL	1. Tim P. 2. Bob C. 3. Ray W. 4. Tony G.			✓
TRAINING ASSESSMENT/ RECOMMENDATION	Schedule a class on troubleshooting and major repair of compressors for the mechanics. Contract overhauls of compressors with local manufacturer's representative.

4.2. Applying Industrial Engineering Techniques to Plant Engineering Problems

4.2.1. Determining Personnel Requirements

Determining personnel levels is best done by determining the workload for each activity in the plant or facilities engineering department through time study, work sampling, work order estimation, predetermined times, standard data, video camcorder, or other accepted work measurement technique. Although plant engineering work is often regarded as impossible to measure, there are many repetitive or semirepetitive operations that can be measured with reasonable accuracy. The fact that *not all* operations can be measured accurately should not deter the plant engineer from obtaining times for those that can be measured.

When the forecast workload becomes available, the plant engineer should compare total hours needed with those available and compute the difference. A workload and backlog report (Figure 4) prepared on any spreadsheet software or by a CMMS and issued monthly to management can help to justify requests for additional employees.

Station jobs (such as boiler operator), which involve continuous attendance vs. jobs where the workload varies according to assignment or demand for service, should be measured according to the actual work content in the operation. If other work can be done on a station job without sacrificing the primary mission, productivity of the operation can be improved.

Factors affecting personnel requirements include type of industry, size and age of the plant, degree of automation, equipment complexity, amount of capital work, level of preventive maintenance, quality requirements, degree of excellence expected and the qualification, availability of labor, and training level of the existing workforce (Palko 1989). Difficulty in finding qualified people to fill plant engineering and maintenance jobs motivates some companies to invest in retraining to improve employee competence.

Because plant engineering and maintenance labor cost are visible, these functions are frequent targets of cost cutters. Invisible to top management and buried in overhead or other categories are

Workload/Backlog Spreadsheet

A	B	C	D	E
Skill/Craft	Hrs. Avail.	Hrs. Required	Surplus/Deficit	Staffing Change

Totals				

Figure 4 Example Workload and Backlog Report.

costs of excessive downtime, obsolete equipment, utility outages, poorly maintained machines, or other causes of low productivity. Identifying such problems using activity-based costing or value stream analysis allows adequate staffing for plant engineering activities to be justified.

4.2.2. Decision Making and Problem Solving/Data Analysis

As a manager of a significant part of the operation, the plant engineer must be an effective decision maker and problem solver. Unlike the manager of a production operation, the plant engineer is typically faced with new challenges, unusual problems, and nonrecurring decisions almost every minute of every day. Solutions and decisions must be made quickly and accurately for the benefit of the organization. The decision-making and problem-solving process is as follows:

1. Identify the problem, not symptoms—use statistics to find the real problem.
2. Collect all available causes and other data—make fishbone diagrams.
3. Analyze data—develop creative ideas.
4. Select and test alternatives.
5. Pick the best solution—test and implement the solution.

Seldom does a hands-on plant engineer have the luxury of time to implement the formalized approach. Using the above thought process coupled with other industrial engineering knowledge, the plant engineer can intuitively and informally develop solutions to many diverse problems instantaneously. While the above basic method for problem solving is valid, familiarity with kaizen, Ishikawa, 8D, 5 why, brainstorming, decision tree, and other solution-generation methods is advantageous.

4.2.3. Benchmarking Plant Engineering

A plant engineer who wants an organization on the cutting edge of technology should consider benchmarking the organization against others in comparable fields. The benchmarking process involves sharing information with other companies and emulating best practices in critical areas (Gulati and Lach 1997; Raymond 1993).

4.2.4. Productivity and Quality in Plant Engineering

Plant engineering in both manufacturing and service facilities and operations use the same resource inputs of capital, equipment, humans, materials, and energy, but outputs can be quite different. The outputs of manufacturing are chiefly discrete products measured in pieces, tons, gallons, dollars, or other similar measures. Measures of output in a service facility may be in industry-specific terms such as meals served, patients treated, students enrolled, cars parked, nights occupied, or the dollar value thereof.

Productivity measurement is expressed as:

$$\text{Productivity} = \frac{\text{Output}}{\text{Input}}$$

Using the basic formula, meaningful measures of productivity for a variety of inputs and outputs can be developed to track progress toward a more productive plant engineering activity. Examples of productivity measures for plant engineering concerns are:

$$\text{Productivity (Facility)} = \frac{\$ \text{ Value of Production}}{\$ \text{ Facility Cost}} \text{ or } \frac{\text{Pieces Produced}}{\text{Ft}^2 \text{ Floorspace}}$$

$$\text{Productivity (Equipment)} = \frac{\text{productive hours}}{\text{hours scheduled}} \text{ or } \frac{\text{pieces produced}}{\text{equipment hours}}$$

The use of industrial engineering techniques in plant engineering can be the key to improvement of productivity. Work measurement, work sampling, computerized maintenance management, equipment down time analysis, predictive maintenance, proper layout, effective floor utilization, and effective strategy planning for facility utilization all tend to improve productivity of resources. Due to the close relationship between maintenance and plant engineering, the following productivity measures for maintenance can be applied or modified to measure plant engineering effectiveness:

MTBF—mean time between failures

MTTR—mean time to repair

FMEA—failure mode effect analysis

Uptime of equipment or downtime avoided

Accidents avoided/accident rate
Energy losses eliminated
Material costs reduced

The use of productivity formulas is limited only by the imagination of the user. Formulas must be relevant, meaningful to the user, and motivate positive action and continuous improvement in productivity (APC 1981; Steele 1997).

The success of the plant engineering function must be measured not only in quantity but also in quality of work produced and quality of the organization. There are many assessment tools for quality that address plant engineering. If the organization is competing for the Malcolm Baldrige Award, Shingo Prize, North American Maintenance Excellence, or other awards of excellence, going through the process will motivate maintenance and plant engineering to improve performance. Assessment tools such as Tompkins Associates' Maintenance Scoreboard can highlight gaps that when remedied can lead to significant improvements.

4.2.5. Work Measurement Techniques in Plant Engineering

Although there is a widely held perception that maintenance and plant engineering work is not measurable, there have been many successful applications of work measurement to these functions. A number of consulting firms offer maintenance standards, based on MTM or other predetermined time systems, that can be applied to maintenance and plant engineering work. Measurement of plant engineering activities uses a combination of work sampling, time study, and time recording. These times can be used to determine the level of effort and the number of the people required to perform plant engineering tasks.

In some instances, maintenance standards have been developed from extensive time study and converted to standard data, which are then applied to specific jobs being performed by mechanics. The actual time taken by the mechanic is then compared to the computed standard based on work content and the percentage is used to calculate a day work or incentive efficiency. Station jobs such as boiler operators may use a simple reporting system which indicates that assigned work is being done. See Chapter 54 for more information on work measurement.

4.3. Financial Aspects of Plant and Facility Management

4.3.1. Plant Engineering as a Profit Center

Most plant engineering, maintenance, and facilities engineering activities have been viewed by accountants and management as expense items or cost centers. Only recently has the concept of viewing these entities as profit centers been promulgated. While this may seem like a minor change, it can add to the profitability of the enterprise through reducing or controlling cost of the facility. Plant engineering and maintenance activities are viewed in some circles as value-added components of the value stream. By applying preventive and predictive maintenance and effective plant engineering practices, plant engineering departments can increase availability of the facility and equipment, thus adding real value to the organization.

4.3.2. Budgeting

Plant engineers are required to submit budgets for materials, suppliers, labor, and capital investment. The budget is a list of proposed sources of income and expected expenditures. When approved, the budget may be viewed as a bank account against which charges can be made. In some cases, departments are charged as a professional service, and it is possible for plant engineering to earn a surplus.

Many organizations still use the analysis-of-variance method to determine whether cost objectives are being met within budgeted amounts. This approach gives some indication of actual vs. planned expenditures, but because data are released months after actual events occur, it is difficult to trace how activities could have been performed better.

Activity-based budgeting is ideal for tracking plant engineering functions. Identifying activities actually performed along with the cost drivers allows real-time information to be generated and problem areas identified quickly. Cost distributions between plant engineering and other departments can be done more equitably, and non-value-added activity can be spotted more easily.

4.3.3. Costing

As noted in the section on budgeting, it is incumbent on plant engineers, like all managers, to maintain close control of costs, and make decisions based on accurate cost data. While other chapters in this Handbook detail costing systems, and other cost issues have been noted elsewhere in this chapter, a

plant engineer should utilize activity-based costing data to identify non-value-added activity, both within the plant engineering function and throughout the organization. Plant engineers are often blamed for breakdowns, power outages, and other situations that produce non-value-added activity. Elsewhere in this chapter it is noted that a well-run plant engineering function adds value and can enhance profitability for the organization. Activity-based costing is one of the best methods available for collecting cost data and assigning responsibility to the appropriate entity. To implement activity-based costing for plant engineering, the principles are the same as for any other part of the organization, but data from the computerized maintenance management system may be more readily available than in other departments.

4.3.4. Cost Control and Reduction

Plant engineering can add dramatically to the profitability of the company by controlling and reducing costs. A well-run plant engineering organization should establish an annual cost-reduction objective and measure itself against actual achievement. Although careful planning and execution of plant engineering activities can lead to cost reduction and control, the following are specific initiatives plant engineers can take to reduce costs:

1. Ensure cost-effective building designs that have:
   - **(a)** Minimum enclosing ratio (wall area/floor area)
   - **(b)** Minimum partitions
   - **(c)** Efficient heating and air conditioning
   - **(d)** Best utilization of the site (possibly through multiple floors)
   - **(e)** Low maintenance costs
   - **(f)** Standard components
   - **(g)** Lowest-cost material to fulfill function and aesthetics
2. Prepare accurate cost estimates of all construction and repair work.
3. Obtain competitive bids from qualified/reliable contractors.
4. Control construction and repair costs to avoid overruns.
5. Avoid engineering change orders with contractors to control costs.
6. Conduct work sampling studies on plant engineering personnel to solve problems and improve efficiency.
7. Apply methods improvement/work simplification techniques to plant engineering operations.
8. Assist other departments in building equipment jigs, fixtures for cost-improvement projects.
9. Practice effective maintenance management using computerized maintenance management systems if appropriate.
10. Provide optimum machine maintenance to improve productivity and avoid downtime.
11. Train and retrain plant engineering personnel to perform efficiently.
12. Apply incentives to plant engineering activities to motivate higher levels of performance.
13. Motivate plant engineering personnel to improve attitudes and reduce absenteeism and labor turnover.
14. Provide a safe workplace for all employees.
15. Involve plant engineering personnel in teams, problem-solving groups, or other participative groups to solve plant engineering problems. Implement total productive maintenance principles throughout the department
16. Reduce parts and stores inventory.
17. Conduct value engineering studies on repair parts or supply items.
    Use activity-based costing to identify and eliminate non-value-added activity.
18. Use good environmental practices to reduce or recycle solid waste.
19. Apply productivity and quality measures to plant engineering work.
20. Reduce machine setup time through careful planning.
21. Justify capital expenditures on strategic and competitive bases, not solely on discounted cash flow or hurdle rates.
22. Ensure employee comfort through environmental controls and good ergonomic design.
23. Take energy audits and control demand and power factor charges.
24. Automate energy, heating and cooling, security, and related items using computerized building automation systems.

25. Contract out expensive, undesirable, or hazardous operations.
26. Use the most modern maintenance techniques available.

4.4. Conducting a Facility Survey

When a plant engineer assumes responsibility for an existing facility, it is advisable to conduct a facility assessment to determine the condition and appropriateness of the major facility systems and components. The objective is to develop a plan for correcting, upgrading, or retrofitting these systems. The survey requires preparation, observation, analysis, planning, and action.

4.4.1. How to Conduct a Facility Survey (Piper 1988a)

1. Obtain drawings of facility and find location of critical components.
2. Peruse records of all systems, components, and equipment—repair history, material, specifications, purchase date, age of component.

Facility Component	Condition	Action	Location
Facility Site			
Roads, parking lots, walk ways			
Curbs, gutters, storm drains			
Grass and trees			
Flower beds and trees			
Building Structure and Envelope			
Trusses			
Columns			
Decking			
Exterior walls			
Footers			
Foundation			
Floors			
Roofs, flashing			
Roof drains			
Windows, frames			
Interior, Finishes			
Interior doors			
Panic hardware			
Wall coverings			
Ceilings and windows coverings			
Restrooms			
Interior lighting			
Mechanical Equipment			
Boilers, pumps, economizer			
Boiler chemical system			
Blowdown system			
Gas lines, meters, regulators			
Oil tanks, lines , pumps			
Chillers			
Cooling towers			
Water heaters			
Gas distribution systems			
Air compressors, dryer, tanks controls			
Air conditioning, handling units			
Units heaters, Unit ventilators			
Exhaust fans			
Dust collectors, fans, ducts			
Air makeup units			
Control systems			
Electrical			
Primary service			
Transformers			
Switchgear			
Distribution system, duct			
Breaker panels			
Motors			
Lighting			
Building automation system			
Battery chargers			
Uninterruptible power supply			
Meters			
Energy controller			
Electronic Infrastructure			
Telecommunications center			
Telecommunications system			
Satellite communication system			
In=Plant radio, pager, voice system			
Computer data busway, LAN			
CNC download network			
Facsimile systems			

Facility Component	Condition	Action	Location
Service Systems			
Elevators, escalators			
Dock lifters			
Bridge cranes, jib cranes			
Waste handling systems			
Trash compactor			
Waste incinerator			
Recycling baler			
Wastewater, sewer system			
Lunch room, cafeteria			
Nurse station, first aid			
Security, Fire Protection			
Perimeter fences			
Security gates			
Guard house			
Security lights			
Security/key card readers			
Motion detectors			
Video cameras and monitors			
Doors, locks			
Manual/automatic alarms			
Sprinkler pipe, valves pump, tanks			
Hoses, nozzles, hose enclosures			
Extinguishing systems			
Condition/Action/Location Codes			
Condition Codes			
A. Deteriorated			
B. Bad structure			
C. Broken			
D. Rotting			
E. Inoperative			
F. Obsolete			
G. Malfunction			
H. Leaking			
I. Inefficient			
J. Unsafe			
K. Corroded			
L. Dirty			
M. Clogged			
N. Energy loss			
O. Environmental risk			
Action Codes:			
1. Repair now			
2. Repair routine			
3. Test more often			
4. Upgrade/replace			
5. Cleanup/cleanout			
6. Repaint/redecorate			
7. Improved efficiency			
8. Improve safety			
9. Improve environment			
10. Retrain operators			
11. Adjust controls			
12. Reassign operator			
Location Options:

Grid or Column #			
Department/Section #			
Machine #			

Figure 5 Facility Survey and Action Form. (Adapted from *Building Operation Management*)

3. Cite potential trouble spots.
4. Assemble a team of specialists to survey the facility.
5. Prepare an itinerary and schedule for touring the facility.
6. Develop or use a prepared checklist to avoid missing key items.
7. Take a tour or a series of tours, focusing on one or more components during each tour, noting observed conditions.
8. Review corporate strategy to ascertain future use of the facility.
9. Discuss condition of the facility with other engineering and operations personnel, building occupants, or anyone who can provide insight into the condition of the facility or equipment.
10. Generate a report with lists of problems and deficiencies plus recommended corrective actions.
11. Prioritize the lists by classifying problems as critical, serious, routine, or minor.
12. Make cost estimates of required repairs as a part of the report.
13. Issue work orders to have critical and serious problems corrected immediately or within a short time.
14. Schedule other repairs or problem correction as funds and manpower become available.
15. Repeat the survey every three to six months to determine further deterioration or level of correction from previous survey; take further corrective action as required.

An assessment survey would include a thorough review of the facility systems and components shown in Figure 5. Using the above approach, the new plant or facilities engineer can gain control of assigned responsibilities and develop a plan for resolving identified problems as soon as possible after assuming the new duties.

5. OPERATIONAL ISSUES FOR PLANT AND FACILITIES ENGINEERS

5.1. Plant and Facility Design and Construction

A plant or facilities engineer responsible for design, construction, and startup of new facilities or operations manages the project by maintaining liaison among architects, consulting engineers, contractors, and suppliers to ensure the project is on schedule, within budget, according to specifications, and completed according to the terms of the contract.

5.1.1. Design Using CAD/Computerized Layout Techniques

The plant engineer may be called upon to design a new facility or the flow and layout of an existing facility. With the use of CAD and computerized layout techniques such as CORELAP, multiple options can be evaluated qualitatively and quantitatively to select the optimum solution. Performance of the selected solution can be evaluated further using techniques of simulation and optimization discussed in Chapters 93–102.

5.1.2. Building Codes Compliance and Use of Standards

Building codes are detailed listings of design and performance criteria that must be observed before building occupancy is approved. Codes generally describe types of construction, building limitations, environmental requirements, safety systems, repair and alteration procedures, permits, and fee structures and penalties. Codes can be both an asset and liability. While they may add cost to a building, codes compliance generally ensures a safe building. If an inspector makes unreasonable demands, the code can be used to refute these demands. Enforcement and approval procedures vary depending on the jurisdiction in which the facility is located.

Plant engineers must know which code applies to facilities in each locality. The best-known codes publishing organizations are Building Officials and Codes Administrators International (BOCA), International Conference of Building Officials (ICBO), and Southern Building Code Congress International (SBCC). Further information can be obtained from the Internet.

There are also many published standards for various parts of the building or equipment available from such agencies as the American National Standards Institute (ANSI), the American Society for Testing Materials (ASTM), the American Society of Mechanical Engineers (ASME), the American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE), the National Fire Protection Association (NFPA), Underwriters Laboratories (UL), Factory Mutual Engineering Corporation (FMEC), and the Occupational Safety and Health Administration (OSHA). The use of standards in planning and constructing a new or revised facility ensures that safety considerations as well as other building conventions are observed (Steiner 1988).

Standards cover almost every conceivable component of buildings and equipment and are normally followed by architects when the original structure is built. The plant engineer making revisions should

be especially careful to follow standards to maintain the integrity of the building, its processes, or components.

The building permitting and approval process contains the following procedural steps:

1. Determine the type of structure needed.
2. Select the site.
3. Determine zoning of site/apply for variances to zoning board.
4. Submit architectural and engineering plans to building codes administrator (BCA) for approval.
5. Obtain a temporary building permit.
6. Apply for permanent permit, obtain full permit.
7. Select contractor(s).
8. Obtain environmental permits.
9. Begin construction.
10. Cooperate during periodic inspections by BCA.
11. Complete building.
12. Pass final inspection or make revision to comply with codes.

5.2. Plant and Facility Maintenance

Whether the plant or facilities engineer is directly in charge of maintenance, this activity is of paramount importance. Throughout this chapter are noted a number of maintenance issues, and the relationship between maintenance and plant engineering is explained in Section 2.3.1. The key issue relating to maintenance for plant engineer is to ensure that all facilities and services are available for production or operations depending of the type of facility involved. In some cases maintenance reports to the plant engineer, while in other cases maintenance is a separate department or is integrated into operations. Details of maintenance are described in Chapter 59 of this Handbook. See also sections throughout this chapter relating to maintenance.

5.3. FACILITY MANAGEMENT/BUILDING AUTOMATION SYSTEMS

Both manufacturing and service facilities can benefit from the installation of building automation systems that monitor energy consumption and automatically adjust heating and air conditioning systems. These computer-based systems may also permit real-time monitoring and management of security, video surveillance, fire detection, utilities, transportation equipment, elevators, room occupancy, equipment operation, lighting or other facility management-related functions. Newer systems have user-friendly software that can be learned by inexperienced personnel in a relatively short time. Some systems use voice synthesizers for communicating with security, fire, management, or maintenance people. An emerging technology known as computer-assisted facility management not only includes the above-mentioned features but also has the ability to do maintenance planning, facility design, space planning, and property management. CAFM, coupled with computerized maintenance management systems, gives the plant or facilities engineer the resources to manage the facility effectively. To make best use of building automation systems, the plant engineers should audit facility performance by collecting and analyzing data collected from the system. Building automation systems are also capable of managing multiple facilities and controlling processes. Data management has become fully integrated with direct digital control of functions and interconnected systems directed by building specific protocols (Tatum 1990; Katzel 1998).

In addition to saving labor, these systems reduce energy consumption, avoid security breaches, reduce fire damage, and provide other intangible benefits that make justification for automated building systems feasible. In selecting a building automation system, it is essential to design the system properly, select systems to meet organizational needs, purchase quality equipment with user-friendly software and system flexibility, and obtain long-term customer service from a reliable vendor (Piper 1999).

5.4. Buildings and Grounds

As part of their duties, plant engineers are typically in charge of the buildings and grounds department that employs the janitorial staff and groundskeepers. While this may seem far afield from engineering, many opportunities for making the functions efficient are available. The key goal is to maintain an orderly workplace both inside and outside of the facility that positively impacts productivity in the operation. While everyone needs to be involved in keeping order and cleanliness throughout the facility, buildings and grounds employees facilitate and support other workers in maintaining a clean and orderly workplace.

The janitorial workforce is typically involved in cleaning the the plant or facility, handling refuse, and performing sanitation duties. In some instances, power sweepers, scrubbers, and powered handling devices are operated by the janitorial staff.

Some of the more common functions in groundskeeping are caring for flowers, trees, or shrubs, mowing grass and weeds, cutting out fence rows, patching holes in roads or parking areas, opening drainage ditches or culverts, and in winter removing snow from parking lots, sidewalks, or shrubbery, to name a few. In performing these functions, equipment used ranges from rakes and shovels to pruning shears, power mowers, chain saws, tractors, backhoes, front-end loaders, snow plows, and trucks. The equipment used depends on the size of the facility and the assignment of duties by management.

The plant engineer can make significant cost savings by ensuring that buildings and grounds services are provided efficiently by taking the following actions:

1. Recognize the value of employees who perform buildings and grounds work.
2. Set a budget to cover the grounds maintenance needs of the organization.
3. Train people in use of equipment and certify operators of larger equipment, especially in safe use of lawnmowers, chain saws, tractors, and other dangerous machinery.
4. Issue safety shoes, goggles, hard hats, ear muffs, gloves, back supports, and other safety equipment and ensure that equipment is used to protect employees.
5. Simplify tasks by providing adequate equipment for all assigned tasks. (See also Section 6.2 on waste handling.)
6. Apply work measurement to find time for janitor and groundskeeper work, measure efficiency, and determine the correct number of people assigned to the size and type of facility being served (Use work sampling, time study, and published standard data.)
7. Provide adequate supervision to plan and schedule the job to ensure that all necessary work is done on the correct frequency and within time available.
8. Periodically inspect quality of work being performed, reward work well done, and make corrections if work is unsatisfactory.
9. Conduct work sampling studies to identify potential problems and solve problems as they are recognized.
10. Institute teams to reduce reliance on supervision.
11. Keep equipment maintained properly and practice preventive maintenance with reporting/documentation that PM has been performed.
12. Consider outsourcing all or portions of the buildings and grounds functions to contractors whose qualifications, credit ratings, and performance records have been thoroughly screened.

Proactively creating a well-organized buildings and grounds staff can greatly improve productivity and quality of life in the facility and minimize problems associated with this function (Ross 1996).

5.5. Safety and Loss Control

5.5.1. Safety Management

Plant engineers often manage the safety program in plants or other facilities. Although industrial engineers receive a course in industrial safety, they may need to fill knowledge gaps by further study and experience. A comprehensive and effective safety program should include the following process steps, none of which may be omitted:

1. Well-defined management strategy, policy, and commitment to safety
2. Goal for safety improvement set and resources allocated
3. Designated responsibility/authority/accountability for safety
4. Formal rules and procedures for safety
5. Engineering of safety into every process and product
6. Safety training and special awareness programs
7. Supervision committed to and competent in safety
8. Effective safety communication and promotion
9. Positive safety attitudes through motivation and rewards
10. Safety inspections using committees
11. Immediate correction of unsafe acts and conditions

12. Disciplinary action administered for willful unsafe acts
13. Well-equipped, trained, and staffed first aid function
14. Thorough accident investigation with effective remedial action
15. Meaningful safety performance measures with critical analysis
16. Effective preventive and corrective maintenance programs
17. Continual assessment of the safety program
18. An iterative program of continuous safety improvement

The results of an effective safety program not only can be measured in injuries prevented and lives saved but also may have a distinct bottom-line impact on the corporation or entity. Companies that do not have effective safety programs often pay the equivalent cost in terms of workers' compensation and lost productivity. The inference can be made that a safe workplace is a productive workplace (McElroy 1964).

Because an effective safety program in the plant or facility must include training, the ultimate objective of training is to influence the attitudes of employees around the clock. Off-the-job accidents cost industry many times more than on-the-job injuries. Although workers' compensation is not involved, absenteeism from off-the-job injuries results in productivity losses and insurance cost increases. Employees injured off the job may, with the assistance of unscrupulous lawyers, sometimes claim the injury occurred during work time. Such fraud can be combatted by effective record keeping and supervisory vigilance.

A plant engineer charged with the responsibility for safety is obligated to comply with OSHA regulations, but must as a professional obligation administer an effective safety program beyond OSHA regulations that concentrate on conditions. Accidents are caused by people, and a well-trained, safe worker can avoid unsafe conditions and attendant accidents. (See also Chapter 43.)

5.5.2. Loss-Control Programs

Administration of the plant loss-control program may fall to the plant engineer or may be handled jointly with the personnel manager. Loss control includes the insurance program plus fire, security, and safety. The objective of loss control is to provide uninterrupted operations and minimize losses of life and property from fire, theft, accidents, and other such occurrences. Safety and security are addressed elsewhere in this chapter, and a brief treatise on fire protection follows.

Many organizations have regular visits by insurance inspectors who identify potential fire hazards. Although some inspectors may go to extremes (such as sprinklers under desks), it is advisable to follow recommendations by insurance inspectors where feasible. If inspections do not occur, the plant engineer should conduct a fire risk survey to identify fuels, ignition sources, fire propagation routes, fire detection and extinguishing systems, and life-saving measures. The adequacy of fire-detection and extinguishment systems should also be assessed and corrective measures taken immediately.

Sprinklers should be tested regularly to ensure that all systems are ready should a fire strike. If a booster pump is in place, it should also be tested. Because as booster pumps are high horsepower, the testing alone can add to electrical demand charges. Having the pump on a safe circuit and testing during off-peak loads can save some of the demand charges.

A well-trained fire brigade composed of plant employees can respond to a fire within 1–4 minutes in most facilities, compared with 5–15 minutes for a municipal fire department. Most fires can be controlled in the first 5 minutes if a rapid response occurs. Fire brigade members should be recruited from maintenance or operations ranks dispersed throughout the facility. Training should consist of first aid, evacuation procedures, and the location and use of fire extinguishers, hoses, sprinkler valves, and other equipment. Municipal fire departments should also be acquainted with the plant layout, fire-fighting equipment, and special hazards.

5.6. Plant and Facilities Security

The security function usually includes fire prevention and reporting, crime prevention and detection, risk management, and administration of security personnel. A security survey should be taken to determine the scope of the security function, the condition of this service, and the steps necessary to bring security up to standard. Outside guards may be necessary to prevent unauthorized entry to critical manufacturing areas, laboratories, computer rooms, and other sensitive areas. The level of security depends on the sensitivity and confidentiality of the work, the labor situation, the local crime situation, and the proximity of fire and police protection (Piper 1988b).

Special protection should be given to computer records. Not only should access to computer areas be denied to unauthorized persons, but codes and passwords should be carefully restricted. Computer rooms should be fire resistant, with special halon extinguishing systems for protection of electronic circuitry and magnetic media, the loss of which could be catastrophic for the business.

By using the checklist that follows, the plant or facilities engineer can cite deficiencies in the security system and take action to correct deficiencies (Piper 1988b; Pearlman and Cana 1999):

Is a security plan currently in effect?

Is a key control system rigidly enforced?

Are penalties for unauthorized entry or use of keys enforced?

Are safe combinations, computer access codes, and other sensitive information closely controlled?

Have security personnel been thoroughly screened and trained?

Are security patrol schedules revised regularly to avoid established patterns?

Are employees carefully screened for past criminal behavior?

Are security personnel trained in sprinkler system operation and cutoff? In fire extinguisher use?

Are computer operating and records rooms, laboratories, and other sensitive areas secured by modern personnel identification systems (card access, hand print, eye retina)?

Is the perimeter of the plant or facility protected to limit access?

Are gates kept closed when employee access is minimal?

Are fences maintained and inspected regularly?

Are electronic fire, movement, and detection monitoring devices (ultrasonic, seismic, infrared, contact) installed and operational?

Does the electronic building control system automatically notify fire and police as well as plant security personnel of incidents?

Are video monitors/CCTV and intrusion-detection monitors used for constant surveillance of critical areas?

Are positive identification systems for personnel installed at plant entrances?

If contract guards are used, does the guard service have a blemishless record for guard selection and training, service and reliability?

Does a disaster plan and organization exist with delegated responsibilities? Do security personnel know names of all managers, employees, agencies, and emergency services to be contacted in a disaster?

Does a public relations plan exist and is a spokesperson designated to provide information about the disaster to the press and public?

6. WASTE-MANAGEMENT CONCERNS FOR PLANT ENGINEERS

6.1. Management and Legal Issues on Waste Management

Waste management, environmental law, and other environmental issues must be addressed by plant and facility engineers. The information that follows should guide a new plant engineer with an industrial engineering background in gaining control of the waste management and environmental program as quickly as possible.

Industrial engineers by definition eliminate waste, and they can apply industrial engineering methodology to waste reduction. Waste was paid for as part of a purchased item.

Although many managers take a nonchalant attitude toward waste management, management must realize that effective waste management can improve profitability. To prevent waste, management at all levels must learn to think of the *total system or process* and include waste management in all decisions. They should understand that the beginning of the waste stream is not at the trash dock, but in product design, purchasing, engineering, or even top management. It should never be assumed that any waste item cannot be eliminated, utilized more effectively, or recovered.

6.1.1. Legal Issues on Waste Management

Too often, management makes decisions about waste management based solely on avoidance of fines resulting from many environmental laws in and court decisions instead of making rational decisions based on good management practice. It behooves the plant and facilities engineer to become intimately familiar with all applicable environmental laws and regulations. Space in this chapter does not permit a review of laws, but some assistance can be found in Chapter 19 of this Handbook.

6.1.2. Waste Management as a Productivity or Resource-Utilization Issue

Industrial engineering by definition maximizes the utilization of resources including capital, machines, material, people, data, energy, and technology by devising innovative systems for production or service. The objective of productivity improvement is to maximize the utilization of these resources.

Waste avoidance or reduction maximizes the material resource and reduces labor and equipment requirements as a result of less handling and disposal effort.

6.1.3. Environmental and Waste-Management Productivity and Benchmarking Measures

The effectiveness of the waste-management and environmental program can be measured by applying productivity measures internally to the organization or externally as benchmarking measures to compare performance with similar organizations. Measures include:

Labor productivity (output/man hour)
Handling equipment productivity
Operations productivity
Energy productivity (output/M BTU)
Labor content of waste management activities
Cost of waste handling and disposal
Value of waste handled and discarded
Volume of waste handled
Weight of waste handled
Production downtime incurred (or avoided)
Complaints from EPA, OSHA (or avoided)
EPA fines assessed (or avoided)
Operating costs reduced
Material losses (or losses avoided)
Energy saved or converted
Defects avoided
Quantity or value of waste sold or exchanged

6.1.4. Economic Considerations on Waste Management

Industrial engineers learn to weigh alternative proposals using engineering economy principles. Business school graduates are often taught that there must be a short-term, bottom-line impact for an expenditure to be made. Solutions to waste-management problems may be evaluated using life-cycle costing principles with data supplied by activity-based costing. Applying waste-management and disposal costs to the justification process improves the justification dramatically. While waste disposal is a non-value-added activity, finding ways to eliminate or reduce waste at the source can produce savings through one or more of the following:

Lower labor cost
Less material waste
Less expensive raw materials
Reduced material-handling cost
Lower energy costs
Improved product quality
Reduced maintenance costs
Profit through waste exchange
Reduced long-term liability for improper disposal, spills, and accidents
Avoidance of fines for environmental noncompliance
Reduced transportation, tipping fees, and disposal costs

6.2. Waste Streams and Waste Handling

6.2.1. Solid and Hazardous Waste Streams

Industrial waste streams contain nonhazardous materials such as paper, wood, metals, plastics, fibers, and food waste. Paints, some plastics, and metals may be hazardous or nonhazardous depending on their composition. Many chemicals are considered hazardous and require special disposal methods under stringently controlled conditions.

6.2.2. Solid Waste Handling

The typical solid waste stream consists of nonhazardous packaging material, cafeteria and restroom trash, office waste paper, floor sweepings, and waste materials from processing operations. When possible, material should be sent to a recycling area, with nonrecyclables going to a disposal area.

Engineers often give detailed consideration to material handling of product and raw material but often ignore handling of waste material within a plant. Consequently, default material-handling methods for waste material remain primitive and labor intensive. While every effort should be made continually to eliminate waste material, an IE-oriented plant or facilities engineers should devise cost-effective or innovative methods for handling waste material that has not yet been eliminated.

Waste handling should be viewed as a non-value-added but necessary process. All waste-handling activities should be documented or mapped to determine who is spending time to handle waste and how much this activity is costing at each step by applying work measurement. From these cost data, more cost-effective methods of handling and disposal can be developed.

Simply designing a route for waste handlers to follow and monitoring their methods can improve efficiency in waste handling. Savings opportunities exist if the study finds that production people are spending time handling or disposing of waste materials while the production operation remains at a standstill. Lift trucks from production areas are sometimes used for transfering trash to disposal area, but this practice interferes with production when they are needed to deliver or remove palettes from production operations. A lift truck should be assigned to waste handling to avoid this situation, especially if distances to the disposal area is long.

Depending on the type of operation, such handling devices as dumping hoppers, tilt carts, four-wheeled carts, trailer trains, rolling waste cans, scrap conveyors, chutes, and pallets are used to move waste material for recycling or disposal. At the disposal area, waste material is sometimes placed on an open trailer or dumped into a trash compactor. A skid steer loader may also be used to load a trainer or compactor. Mechanization is desirable to reduce costs to the extent possible if waste-reduction efforts have not fully eliminated waste.

If a contractor is engaged to handle waste in the plant, the handling equipment may be owned by the contractor, who may work on a fixed-fee basis either by tonnage or hours expended. While this approach may reduce equipment investment, the contractor should indemnify against liabilities for contractor personnel and ensure that the company is compensated for damage to equipment or interruptions to production caused by the contractor.

6.3. The Industrial Engineering/Environmental Methodology

The industrial engineering-based environmental methodology outlined below is the systems approach to waste management through which industrial and plant engineers can solve environmental problems in a cost-effective and productive manner. The methodology is based on the premise that waste begins at the top management decision-making process. When top management realizes where the value stream containing waste begins, commitment to waste reduction and elimination of non-value-added activity may occur. The revised IE environmental methodology is as follows (Ross 1989, 1999):

1. Help top management understand where the waste stream begins and get support for waste-reduction and environmental-improvement programs.
2. Outline clear objectives and scope for the environmental program.
3. Get everyone involved at all levels of the organization.
4. Handle the legal issues of environment as a top priority as follows:
   Become familiar with all applicable laws.
   Take an environmental audit to find problems before regulators arrive.
   Be sure all paperwork is submitted on time to avoid fines.
   Implement effective environmental controls to keep the organization in the lowest possible environmental risk category.
   If an inspector arrives at your facility, be cooperative and don't try to hide anything (if you're caught, it will cost you dearly).
   Implement changes punctually.
   Protest unfair citations or excessive fines.
5. Organize and train teams to address waste-reduction issues.
6. Make a process map of all activities performed in all processes.
7. Identify, quantify, and prioritize waste streams at any point in each process.
8. Implement effective waste-management tactics, including the following, which appear in descending order of value:
   Eliminate or reduce waste streams at the source.

Redesign the product to reduce waste—use value analysis.
Change processes, conditions, and procedures to reduce waste.
Reevaluate reality of quality requirements that may produce waste.
Purchase good-quality, nonpolluting materials.
Insist on returnable containers—set up a container or pallet pool.
Exchange waste with other companies.
Find another product to use waste productively.
Segregate waste and reduce each type.
Recover resources from waste.
Reclaim, reuse, recycle wastes even if they only break even.
Find secondary outlets for waste.
Improve material handling of waste; avoid makeshift handling methods.
Improve maintenance procedures on equipment to reduce waste
Mix wastes into compost for landscaping and ground cover.
Cogenerate waste material to make electricity and reduce waste volume.
Incinerate waste material for process, water, or comfort heating.
Dispose of waste that cannot be reclaimed to a landfill as a lost resort.

9. Take a long-range perspective; don't look for a quick fix.
10. Do justifications based on activity-based and life-cycle costing, including environmental and social costs.
11. Train people in the organization to reduce waste and reward people for exceptional effort in the environmental area.
12. Benchmark with similar organizations and emulate best waste practices.
13. Seek outside assistance such as universities and trade associations.
14. Develop or recognize economic incentives for waste reduction.
15. Make the process of waste reduction iterative and repeatedly review processes to make further waste reductions.
16. Evaluate results and make changes in the program as necessary.

By using the methodology outlined above and keeping cognizant of the many industrial engineering-related resource conservation issues, plant engineers can improve the environment, resource productivity, organizational profitability, and quality for all stakeholders.

7. TECHNOLOGICAL CONCEPTS FOR PLANT ENGINEERING

Throughout this chapter, reference has been made to many electronic and computer applications with which plant and facilities engineers need to be familiar. Notable among these is the computerized maintenance management system (CMMS), which is often used by plant engineers to schedule and control maintenance and operations in plant engineering areas. This system is described in some detail in Section 3.4.

The second electronic system under the control of plant engineers is the facility management or building automation system, which usually includes an energy controller. These systems are described in Section 5.3.

Depending on the type of operation, process-control computer systems interconnected with manufacturing, engineering, and administration are often needed. Key to interconnectivity is the installation of a fieldbus through which data are transmitted among users. Manufacturing execution systems operate on a distributed control network ring (Kamal Zafar 1998).

Another group of electronic systems used by plant engineers pertains to preventive and predictive maintenance. A description of these systems appears briefly in Section 3.4 and is described more fully in Chapter 59, which pertains specifically to maintenance.

The importance of understanding new technologies has been emphasized in this chapter by outlining the knowledge and skills that a successful plant and facilities engineer needs upon assuming that position. Because the above-mentioned systems are highly varied and extremely complex, it is not within the scope of this chapter to describe these technologies in detail. By being aware of the many possibilities for improvement through technological concepts, the plant engineer can take steps to become competent in the use of electronic equipment and/or to be able to manage persons who are familiar with the details.

8. MANAGING ENERGY

8.1. Why Energy Is an Important Resource

Until 1973, when the oil embargo occurred, energy was regarded as an uncontrollable overhead item, but rapid escalation in energy costs changed this perception and elevated energy to the status of a

key resource to be productively utilized. Since energy has become plentiful, many enterprises have simply adjusted their budgets to higher prices and have forgotten the easily implemented opportunities for energy conservation and cost reduction.

This section offers an integrated approach for finding, evaluating, prioritizing, and implementing energy conservation opportunities and energy and utility system improvements. Plant or facilities engineers or other managers should devote a significant amount of time to energy management. If techniques described here are applied, significant energy-saving opportunities should be found.

8.1.1. Why Engineers Should Be Concerned about Energy

Engineers should be aware of and take action to overcome these conditions:

Failure to recognize energy as one of the five key resources to be managed
Missed conservation opportunities sapping profits
Emphasis by engineers on other resources (labor, machines)
Lack of concern about energy in capital decisions
Ignoring that energy price increases continue to occur
A lack of understanding of the total cost of energy
Ignoring that energy savings drop directly to the bottom line
Poor administrative controls of energy costs
Poor maintenance of energy equipment and systems

8.1.2. What Are Enterprise Resources?

Resources are needed to activate any enterprise. Most enterprises have the following resources at their disposal:

Labor/manpower
Material
Machines
Technology/data
Energy

How and in what proportion resources are consumed depends on the type of activity or operation in which the enterprise is engaged. Although energy may be a small portion of running a garment factory or manual assembly plant, a metal fabricating shop with large punch presses or a heavy chemical plant may have a large proportion of its budget in energy. Energy is sometimes an essential part of the process (melting, heat treating, welding, chemical processing), while at other times it may facilitate the operation (heating, comfort, driving machines).

8.1.3. Energy Productivity

As a key enterprise resource, energy productivity can be computed. By definition, productivity measures the output vs. the input, and the index is found by applying formulas similar to the following:

$$\text{Energy productivity index} = \frac{\$ \text{ value of plant outputs}}{\text{kWh}} \text{ or } \frac{\$ \text{ value added by plant pperations}}{\$ \text{ energy cost}}$$

Other combinations may reveal trends in particular situations. Productivity measures plotted over time can show trends in utilization of the energy resource relative to a baseline that can signal problems or show progress in energy reduction.

8.1.4. Energy Myths

To begin an energy conservation program, engineers must overcome myths that inhibit consideration of many opportunities that if implemented would produce sizeable savings for this valuable resource. Some myths are:

Energy costs are a small part of the budget.
We have no big energy consumers.
We've already minimized energy consumption.
Its not in the budget.
We don't have time to reduce energy.

Its cheaper to let machines run.
Energy is plentiful.

8.2. Energy and Utility Concerns for Plant Engineers

8.2.1. The Energy Process

The entire effort to obtain and maintain an adequate, dependable, and cost-effective supply of energy is a process that is more extensive than most people realize. The process should be conceptualized in terms of a business process in which all steps from conception to termination are considered. Although the energy process may vary with the type of enterprise, some typical steps in the energy process include:

1. Planning the process
2. Determining energy needs for process, building heat, and other uses
3. Selecting of energy form
4. Negotiating rates with utilities
5. Designing the optimum system installation
6. Anticipating future needs
7. Detailing maintenance requirements of the system (periodic, preventive, predictive)
8. Conducting daily operation of the system
9. Accommodating environmental concerns
10. Using waste heat or material for energy
11. Conducting energy-related waste disposal
12. Administering the energy effort (invoice processing, etc.)
13. Taking regular energy assessments for continuous improvement in energy conservation
14. Justifying and replacing equipment
15. Replacing energy sources with more efficient or lower-cost sources
16. Iteratively reassessing and reengineering the process

8.2.2. The Energy System

The energy system includes not only the equipment in the plant or facility, but utilities that supply energy (gas, electric, water) to the plant. The system also includes secondary energy supplies such as steam and compressed air. The distribution system, the protective devices, and all equipment needed to supply energy to the process or operation of the facility, equipment, or operations are parts of the energy system. Aside from maintaining good relationships with utility companies, the main concern of a plant engineer or plant manager is to keep the in-plant system functioning effectively at all times.

While this chapter focuses predominately on energy conservation and cost reduction, the importance of system operation and maintenance cannot be overemphasized. We tend to take energy for granted, but continual vigilance is needed to ensure that energy is available for the process to run, the building to be heated, and paychecks to be printed on time. Some action items on energy system operation and maintenance are included in the energy-assessment procedure in Sections 8.6–8.8.

8.2.3. Managing Utility and Service Systems

The effective management of utilities and services is a primary responsibility of most plant and facilities engineers. The scope of utility and service systems includes:

Electric, gas, and water supplied by outside utility systems
Piping systems
Steam generation and distribution systems
Chiller systems, cooling towers
Heating, ventilation, refrigeration, and air conditioning systems
Building instrumentation and control systems
Pollution-control systems, dust-collection systems
Telephone and communication systems
Compressed air systems

To be able to manage these complex systems, the plant engineer should (Rospond 1999):

1. Become familiar with all utility and service equipment
2. Establish contact with all utilities; gain their cooperation
3. Conduct an audit of each system to determine current condition and needed corrective measures
4. Determine availability of installed spares, spare components and replacement parts, and backup systems
5. Ascertain ownership of utility equipment such as substations, transformers, and lift pumps
6. Develop effective preventive and corrective maintenance programs
7. Implement continuous improvement of utility and service operations
8. Upgrade training of employees responsible for these systems
9. Justify and install state-of-the-art equipment where possible
10. Monitor power quality, upgrade system for digital computer systems
11. Improve transformer efficiency

See the Appendix for specific improvement possibilities.

8.2.4. Demand and Power Factor

Demand and power factor are often major invisible electric costs. Many electric utilities do not show data on these items on electric bills, and it is incumbent upon the energy manager to obtain these data. Electric utilities base demand charges on an integrated peak demand in kilowatts over the highest 30 minutes during any 1-, 6- or 12-month period, depending on the utility's policy. Power factor charges occur when inductive or capacitive loads get out of phase with current supplied, as shown in Figure 6.

Power factor is the difference between current used in kilowatts (kW) and current supplied in kilovolt amperes (kVA) as shown in this example.

A small factory has a monthly demand of 237 kW and 324 kVA as measured by utility meters.

$$\text{Power factor} = \frac{\text{kW demand}}{\text{kVA metered}} = \frac{237}{324} \times 100 = 73\%$$

If the utility requires 85% power factor to avoid penalty,

$$0.85 \times 324 \text{ kVA} = 275 \text{ kW billing demand}$$

Billing demand = 275 KW
Actual demand = −237 kW
Excess demand = 38 kW

Excess demand is charged at utility demand charges of \$4.00–10.00 per kW depending on rate structures. Even at \$4.00 the cost of 38 kW/month would be \$152.00, or \$1824.00/year.

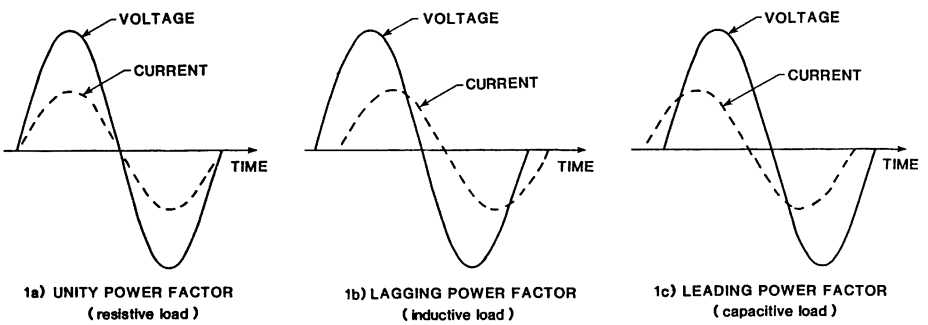

Figure 6 Graph of Reactive/Out of Phase Current.

When capacitors are installed, power factor increases to 93% (well above the 85% level), thus avoiding the penalty. The payback is as follows:

$$\frac{\$1200 \text{ capacitor cost}}{\$1824 \text{ power cost saving}} \times 12 \text{ months/year} = 8 \text{ months}$$

Adding capacitors means the circuit capacity is thus increased to allow adding more load. Note: Demand and power factor calculations in each utility area differ, hence the above example would have to be revised to meet local conditions.

Demand and power factor charges are often a major percentage of the total power cost and to a large extent are controllable. Demand can be controlled by shedding loads when peak demands are approached, either manually or through the use of a programmable energy controller. Power factor can be eliminated by replacing inefficient motors or installing capacitors that limit reactive current to levels acceptable to the utility. Controlling demand and minimizing reactive current makes significant reductions in power costs obtainable. Solutions to reducing costs of these items are included in Sections 8.6–8.8

8.3. Financial Considerations about Energy Management

8.3.1. Assessing the Cost of Energy

The real cost of energy is not just the price per gallon, Mcf or kWh but in executing the process that provides energy to run the business. Because energy is an essential resource for almost any manufacturing or processing operation, massive effort must be expended to keep the supply of energy available in the proper quantity and quality at the minimum cost consistent with keeping the enterprise in effective operation.

The most costly aspect of energy is unavailability. When energy becomes unavailable, costs soar and adverse consequences result:

Production interruptions
Missed schedules
Lost customers
Penalties for shutting down customers production lines
Spoiled work, rework, non-value-added activity
Costly cleanout of ruined product from processing equipment

Likewise, the benefits of effective energy management can be measured in terms of lost production avoided, productivity improvement, continued customer satisfaction, and profitability increases. The real cost of energy is in executing the process that provides the energy supply to run the business.

By having the cost of energy failures highlighted through the use of activity-based costing, the engineering manager can determine the cost–benefit ratio of operating the system to avoid future failures.

Another caveat in determining the real costs and benefits of effective energy management is where to focus effort. Prevalent philosophies today include ''pick the low-hanging fruit'' and ''don't sweat the small stuff.'' Often these philosophies lead to missing the really big winners. While there may be some merit to each of these philosophies, the real savings in energy systems may be from finding less obvious, high-return savings that will provide long-term solutions to complex problems.

8.3.2. Justifying Energy-Conservation Opportunities Using Activity-Based Costing

While energy costs are typically considered overheads, costs can be traceable to specific activities within the operation. Applying activity based costing, life-cycle costing, or other systems that provide accurate data on energy use allows opportunities for conservation and system upgrade to be identified and justified.

Too often, worthwhile energy projects are killed by the one-year payback syndrome. In addition to being too strict, the one-year payback concept ignores the time value of money, a fundamental of engineering economy. In many energy and environmental projects, the payback is nowhere close to a one-year undiscounted payback.

To get top management's attention, the project author must get outside of the narrow confines of labor or utility savings and include the benefits of a dependable, cost-effective energy process to justify energy related projects. Management reacts best to $$$$ and ####, so it is essential that you speak their language. The basis, for these savings is in keeping records using activity-based costing. If energy problems cause lost production, customer dissatisfaction, or excessive costs, ABC cost data that quantify these problems should get top management project approval.

Especially useful in justifying energy improvements is rework, reinspection, repackaging, or any other re-word that connotes non-value activity caused by energy failures or inadequacies.

8.3.3. Using Life-Cycle Costing to Assess Return on Energy Projects

Life-cycle costing is also useful in justifying energy projects because all benefits and costs throughout the expected life of the project or equipment are predicted, and disposal costs at the end of the project are included. Placing a value on environmental conservation, energy availability, and system dependability in a LCC calculation can further assist in justifying energy projects.

Data from ABC can also be used to substantiate life-cycle costing. The use of activities as the basis for cost justification gives a true representation of what actually happens in the organization, and can demonstrate interdependencies of energy with other activities in the organization. See Chapters 88–92 for more detail on costing.

8.3.4. Impact of Utility Deregulation

Until recently, utility companies had monopolies in certain areas of the country, but as a result of deregulation, it is now possible to purchase gas or electric from other utility companies and have it delivered through systems of the former utility company. The impact on energy users is that opportunities for significant savings now exist as a result of deregulation. Energy managers should investigate the possibilities for accessing savings from deregulated utilities to improve profitability of the company.

8.4. Relationship between Energy and Environment

8.4.1. Pollution from Energy Production and Waste Heat Recovery

Energy and environment are inextricably intertwined issues. Energy production is one of the chief causes of air pollution, and conversely, energy production can be a major solution to environmental problems. Acid rain caused by burning fossil fuels and discharging pollutants such as nitrous oxide and sulfur dioxide results in harm to aquatic life, animals, vegetation, and humans.

Some solutions for both energy and environmental problems lie in burning trash or other waste material after all recyclables have been removed. While this approach reduces waste streams by over 90%, so-called environmentalists raise a loud cry about burning anything, even though benefits far outweigh costs. The ultimate solution to energy-related pollution is conservation.

8.4.2. Cogeneration

The concept of cogeneration is both environmentally friendly and energy cost effective. Definitions of cogeneration include topping and bottoming systems. A topping system primarily generates electricity, and an alternative use is found for the exhaust steam. The bottoming system produces heat to facilitate a process, and the excess is captured for electric power generation or other uses as a byproduct.

Typical cogeneration methods include use of waste process gases to drive gas turbines for electric generation, recapture of low-pressure steam for electric generation or driving machinery, and use of waste steam or heat for electric generation and peak shaving. Incineration of waste materials as fuel for steam generation, process heat, district heating or air conditioning, or electric generation is a growing cogeneration option.

8.5. Establishing Strategies for an Effective Energy-Management Program

8.5.1. Strategies and Tactics for Major Energy Improvements

1. Convince your management of the value of energy conservation and systems improvement.
2. Get energy improvement into the budget.
3. Develop a strategic objective to have the best installed energy systems and make the most efficient use of energy possible.
4. Develop and implement a specific plan for taking energy assessments.
5. Identify every energy-consuming device in the facility.
6. Conduct a comprehensive analysis of all energy equipment.
7. Develop a plan to upgrade technology of all energy equipment.
8. Review energy bills and find demand power factor and contract rates.
9. Negotiate with utilities to get lower rates and better breaks on charges.
10. Audit past bills, and get adjustments where possible.
11. Find real costs of energy deficiencies and unavailability.

12. Justify new technologies and permanent solutions to energy problems.
13. Reengineer the energy process, and stop doing business as usual.
14. Make energy an iterative process that is under frequent review.
15. Use steps in the detailed procedure that follows.

8.5.2. Starting an Energy-Management Program

Central to an energy-improvement effort is an energy assessment. Whether techniques of energy improvement are called surveys, audits, or assessments depends on objectives and individual preferences. An audit focuses on the quantitative aspects of energy consumption and finds savings opportunities by analysis of current energy use patterns and consumption data. A survey usually focuses on qualitative opportunities that produce easily implemented improvements. An assessment usually follows a structured approach to identify, evaluate, and implement energy saving projects or system improvements. Often the terms are interchangeable, and all approaches yield good results. In the remainder of this chapter the term *assessment* will be used most frequently Managers or engineers finding ways to reduce energy requirements should not be concerned with terminology as much as results.

The methodology shown in the Appendix provides a step-by-step approach to energy conservation and cost reduction. It includes practical solutions, many of which can be implemented at little or no cost. Examples will be discussed along with application of the methodology. By following the steps in the methodology, the energy-analyst should find numerous energy-saving opportunities.

Generally, an energy assessment will include finding energy-saving and system-improvement opportunities. The procedure in the Appendix shows the detailed steps to assess energy opportunities. Before the assessment starts, one person and/or a multidisciplinary team should be assigned to conduct the assessment, and each member should be trained in their specific roles. The composition of the team depends on skills available in the organization. Normally a combination of engineers, supervisors, operators, and human resource people have sufficient diversity of background to generate creative ideas for energy improvements.

8.6. Steps in an Energy Assessment

Prepare for the assessment:
- Make a commitment to energy improvement.
- Select an individual or a team to improve energy.
- Collect data for energy bill analysis.
- Identify operations and components of the energy system to include in the assessment.
- Obtain instrumentation to do a credible technical assessment.
- Determine who controls those operations or components.
- Obtain agreement from operations chiefs to proceed with the assessment.
- Get a computerized energy analysis program if available.

Collect data on energy consumption, practices:
- Review energy bills for past two years.
- Record demand and power factor data.
  - Get utility to show power factor and demand on monthly bills.
  - Find criteria for power factor and demand charges.
- Input to computer spreadsheet and make charts and graphs, convert to BTU/caloric equivalent.

Take plant tours to identify energy opportunities:
- Observe present/potential energy waste and system problems.
- Record nameplate data, load rating, etc.
- Review the energy system.
- Find all energy system equipment, including invisible.
- Fill out energy data sheets.
- Compute theoretical load, compare with billed load.
- Make inferences about discrepancies.

Analyze data from steps 1 and 2.
- Correlate data with production or activity level.
- Find the big energy consumers.
- Apply activity-based costing to find energy-related delays.

Develop and evaluate energy conservation solutions.
- Revise team assignment to develop solutions.
- Use teams to get ownership of improvements.
- Use checklists to find energy savings.
- Follow energy-improvement opportunities (see Section 8.7).
- Apply analytical techniques:
  - What, where, when, who and why?
  - Eliminate, combine, resequence, and simplify operations.
- Apply systematic creative thinking, brainstorming.

Evaluate solutions, select best alternatives:
- Conduct economic evaluation.
- Use ABC and LCC.
- Consider people aspects.
- Assess feasibility.

Quantify and prioritize energy-improvement opportunities.
- Avoid the one-year payback syndrome.
- Show costs of energy unavailability.

Present findings to management:
- Develop each recommendation fully.
- Prepare a coherent report.
- Show why management should accept your recommendations.
- Express recommendations in management's language ($$$$ and ####).
- Rehearse the presentation, and present the report succinctly.
- Gracefully accept management's decision.

Implement improvements and monitor results:
- Assign responsibility for implementation.
- Establish measures of specific improvements.
- Verify savings.
- Chart energy productivity.
- Modify improvements if required.
- Avoid false savings due to external changes.

8.7. Energy-Improvement Possibilities

Facility
- Install enough insulation, weather stripping.
- Seal off leakage through windows, cracks.
- Evaluate refenestration (window replacement).
- Install vestibules at doors.
- Seal around dock doors/use flap doors to seal out cold air.
- Reduce solar gain (insolation) to reduce cooling load.
- Close all doors and other openings in winter.

Energy infrastructure in the plant
- Give the energy infrastructure and other energy delivery systems constant attention.
- Make someone responsible for operating and maintaining energy systems in the facility.
- Check ownership of interface devices with the utility supplier.
- Set up a preventive maintenance program for every part of the system, including:
  - Contacts, insulation, dust and dirt on equipment, heat buildup in ducts and switches.
- Note failure points and correct the root problem immediately.
- Reengineer the system to bring it to state of the art.

Electrical

Upgrade electrical distribution systems.
Control peak load demand, shed loads using prioritized controller.
Run equipment off peak where possible.
Retrofit for higher voltages.
Correct power factor by using energy-efficient motors or capacitors.
Turn off equipment when not needed.
Monitor and upgrade power quality for digital equipment.

Natural Gas

Check for leaks and explosion hazards.
Check piping for corrosion.
Check for improper installations.

Utility deregulation

Become familiar with new regulations and procedures.
Contact potential energy suppliers for quotes, interview alternate suppliers.
Beware of bogus suppliers offering unrealistic deliverables.
Carefully evaluate economics of all offers; determine the *real cost*.
Negotiate rate reductions.
Take full advantage of deregulation.

Lighting

Reduce number of fixtures.
Avoid electrician's dream (excessive lighting).
Install more efficient lighting fixtures, electronic ballasts, and long-life bulbs.
Use task lighting, reduce lighting in nonproduction areas.
Turn off lights when not in use.
Balance lighting heat load with air conditioning.
Install occupancy sensors or more switches to turn off unneeded lights.
Utilize photocell and/or timers on lighting, especially outdoors.
Tie lighting into building control systems.

Process

Run process equipment only when needed.
Avoid short runs on process equipment.
Consider energy in scheduling production.
Make energy a prime consideration in replacing process equipment.
Schedule operations/production around energy considerations.
Reduce run times of equipment to bare minimums.
Use waste heat to run the process or supplement primary energy sources.

Heating, ventilation

Select heating equipment carefully for maximum efficiency.
Install programmable thermostats, energy controllers.
Control heating using computer building controllers.
Avoid pulling out heat, make up air loss with waste heat.
Burn waste material for building heat.
Don't heat seldom used space.
Use radiant heat in isolated spots.
Install ceiling fans to bring heated air to the floor level.
Change to cheaper energy sources.
Keep filters, coils, and ductwork clean.

Expand comfort zone in summer and winter.
Use passive/low-energy cooling where possible.

Air conditioning systems (see also heating and air ventilation ideas)
Use outside air to cool building before using ACU.
Clean ACU filters.
Use timers to control HVAC.
Install energy-management systems to control HVAC.
Replace refrigerant compressors or chillers with more efficient units.
Redesign system for best efficiency and maximum output/kwh.
Evaluate gas cooling as an alternative to electric cooling.
Conduct vigorous preventive/predictive maintenance on system.
Insulate ductwork and piping in AC system.

Indoor air quality
Eliminate pollutants (smoke, dust, vapors)
Introduce properly filtered fresh air
Do more frequent changes of the air in the building
Change controls, improve dampers, use variable speed blowers
Rebalance system to accommodate varying demands

Boilers, steam, hot water
Check fuel air ratio, NOX
Check flame pattern
Check stack temperature
Check CO content in stack
Insulate pipes
Preheat makeup water with waste heat
Heat air using heat exchangers.
Return steam condensate and keep it warm.
Repair hot spots in fire box.
Correct steam leaks and repair traps.
Install automatic controlled blowdown.
Implement effective boiler water treatment.
Consider cogeneration or alternate fuels.

Compressed air system
Repair air leaks.
Run at lowest possible pressure.
Reclaim waste heat for winter heating or heating restroom water.
Install refrigerant air dryers and maintain effectively.
Install cooling towers for water-cooled compressors.
Discontinue running cooling water down the sewer.
Replace energy-inefficient motors and compressors.
Keep maintenance records to justify new equipment.
Automate compressor system controls to minimize energy use.
Evaluate load/unload against intermittent stop/start cycle.
Avoid improper use of compressed air (blowing chips).
Obtain high-quality intake air using filters and coolest possible air.
Practice effective preventive maintenance.
Consider alternative energy to power compressors.
Install remote monitoring of air compressors with diagnostics.

Motors/drives

Replace old motors with energy-efficient motors.

Install capacitors on poor power factor motors.

Turn off motors when not needed (unless startup demand negates savings).

Install variable-speed drives where possible.

9. SUMMARY: CREATING EXCELLENCE IN PLANT AND FACILITIES ENGINEERING

A key goal of this chapter has been to motivate industrial engineers assigned to plant and facilities engineering duties to strive for excellence. By keeping mindful of organizational strategy and applying effective industrial engineering and management techniques, including those described in this chapter, the industrial engineer can function as a plant or facilities engineer to create continuous improvement in productivity and quality for the benefit of the organization.

CHAPTER 59

Maintenance Management and Control

RALPH W. "PETE" PETERS
Tompkins Associates, Inc.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. OBJECTIVES AND CONTENT OF THE CHAPTER

The key objectives of this chapter are to provide a firm understanding of the importance of the physical asset management and maintenance process, to review the key requirement for maintenance success, and to review some of today's best maintenance practices. This chapter includes how the results of continuous maintenance improvement can be measured, the methods to use for measurement, and how the results and ROI can be validated. The IE principles and practices that can support maintenance process improvement will be highlighted. Current strategies and trends in computerized maintenance management systems (CMMS) and enterprise asset management (EAM) systems technology to support physical asset management will also be covered.

An important look at maintenance management for the new millennium and the emerging role of a chief maintenance officer (CMO) and new technologies, will be presented. The chapter will help the new and experienced IE, the engineering manager, the operations manager, as well as the CEO, to understand better their own maintenance operation. It will outline specific methodologies to help improve mission-essential maintenance operations. It will also help all to view the maintenance process as a profit center and key contributor to total operations success

2. INTRODUCTION

2.1. The Maintenance Process: A Key Element of Plant and Facilities Engineering

The maintenance process is one of the most important elements within the overall scope of plant and facilities engineering function. It is a broad-based technology area for the industrial, commercial, institutional, and business communities. As covered within a previous chapter, the broad scope of plant and facilities engineering is continuously changing and growing in importance as a key contributor to the success of a total operation. Elements within it, such as maintenance, energy management and regulatory compliance, have all evolved to new levels of importance for the total operation.

Plant and facilities engineering is a multidisciplinary field of engineering concerned with the physical infrastructure of industrial, commercial, institutional, healthcare, and business facilities. It embraces the design, installation, operation, maintenance, modification, construction, modernization, and protection of physical facilities and equipment used to produce a product or provide a service (Dunn 1997). It includes, but is not necessarily limited to, the following areas of physical asset management:

- Design of facilities and systems
- Construction of facilities and systems
- Installation of facilities and systems
- Start-up of systems
- Operation of systems
- Maintenance of facilities and systems
- Retrofit of facilities and systems
- Environmental controls
- Safety and health
- Security and fire protection
- Production processes and equipment (in industry)
- Regulatory compliance (local, state, and federal)
- Energy management and building control
- Administration, supervision, organization, planning
- Other support functions as required by the enterprise owner or manager

2.2. The Scope of Maintenance and Physical Asset Management

Maintenance is about the care of physical assets: production equipment, plant facilities, office buildings, hospitals, trucks, cars, forklifts, and computers. It is very important to understand fully the scope of the maintenance management process because maintenance is much more than just the care of physical assets used in a production operation. The maintenance management and control functions, operations, and activities that may be required within a maintenance operation are very broad. Likewise, the application of the actual maintenance process—the hands-on, wrench time of doing the work—applies to many different types of operations. The maintenance processes in discrete manufacturing, continuous processing equipment, facility and building systems, property management, and fleet operations maintenance all have uniquely different challenges and types of assets. There are other unique applications of the maintenance process in areas such as health care, research facilities, and pharmaceutical operations. Physical assets, whether production equipment, a health care facility, or the assets that make up a trucking fleet or an airline, all have maintenance requirements to perform their primary function at a reasonable cost over their expected economical life. A maintenance operation may include, but also is not limited to, the following (Dunn 1997):

- Installation and maintenance of all utilities systems and components for electricity, water, steam, gas, oil, compressed air, communications, data networks, etc.
- Provision of services for construction, maintenance, and repair of buildings and structures
- Provision of services for alterations and modifications of buildings, structures and manufacturing type assets
- Installation, operation, and maintenance of all heating, ventilating, air conditioning, and refrigeration systems and components
- Installation, relocation, modification, maintenance, and repair of other equipment and systems, as determined by coordination with tenants
- Testing of electrical systems and backup utilities
- Maintenance of appropriate equipment records and histories
- Management of maintenance planning, scheduling, and work execution
- Implementation of preventive and predictive maintenance strategies and practices
- Management of spare parts and materials storerooms and inventories
- Coordination of federal, state, local, and insurance licensing inspections and compliance
- Management of special projects as required
- Provision of housekeeping, janitorial, and custodial services
- Preparation and control of budgets
- Control of maintenance contracts
- Maintenance of reports from inspectors and insurance carriers
- Work management: processing of work requests; preparation of project cost estimates; planning and scheduling of work; provision of required parts, materials, and equipment; and maintenance of all related labor and equipment records

- MRO materials management: management of maintenance repair operations (MRO) parts, materials, and special equipment for which the maintenance operation is held accountable
- Preparation of appropriate reports, statistics, and recommendations on activities
- Planning, coordination, and scheduling of predictive, preventive maintenance and other asset reliability programs.
- Maintenance of appropriate records pertaining to labor, MRO items, and asset history
- Ensuring compliance with all applicable life safety, building codes, and regulatory items
- Ensuring maintenance of all fire protection and security systems
- Operation and maintenance of all utilities systems and equipment
- Operation and maintenance of backup utility systems.
- Maintenance of environmental monitoring systems
- Organization, administration, and supervision of safety activities in accordance with all federal, state, and local requirements
- Initiation of safety-related work requests
- Compliance with all safety procedures.

2.3. Effective Maintenance Management Requires Industrial Engineering Principles

The maintenance process should be viewed as an internal business opportunity. Since Tompkins Associates introduced the concept of "maintenance as a profit center" (Tompkins 1999), this modern view of maintenance has emerged in literature and in practice. Business process continuous improvement (BPCI) and most of the traditional IE principles have application to maintenance operations. When we consider that there are countless contract service providers for all types of maintenance services competing to replace or supplement internal maintenance departments, it becomes apparent that internal maintenance with the help of IE techniques can be improved.

2.4. Maintenance as an Internal Business Opportunity and Profit Center

Traditional thinking about maintenance has changed dramatically. Maintenance was once considered a necessary evil, but it is now being viewed as a key contributor to profit in a manufacturing or service providing operation. For example, what if the net profit ratio of an operation is 4%? What does a 4% net profit ratio mean in terms of the amount of equivalent sales needed to generate profits? A net profit ratio of 4% requires $25 of equivalent sales for each $1 of net profit generated. Therefore, when we view maintenance in these terms, we can readily see that a small savings in maintenance can mean a great deal to the bottom line and equivalent sales. From Table 1, maintenance as a profit center is illustrated, showing that only a $40,000 savings is required to translate into the equivalent of $1,000,000 in sales. There are many more areas, such as the value of increased asset uptime, increased net capacity and just-in-time throughput, increased product quality and increased customer service, that all contribute to the bottom line and subsequently to profit (Peters 1994a).

3. THE 25 REQUIREMENTS FOR EFFECTIVE MAINTENANCE MANAGEMENT

When an organization prepares for business process continuous improvement and the application of IE technology and techniques, it should include the evaluation and improvement of the current maintenance processes. A number of key principles and practices that are fundamental to the BPCI journey.

TABLE 1 Maintenance as a Profit Center

Maintenance Savings to Impact Net Profit	Equivalent Sales Required for Generating Net Profit
$1	$25
$1,000	$25,000
$10,000	$250,000
$20,000	$500,000
$30,000	$750,000
$40,000	$1,000,000
$80,000	$2,000,000
$120,000	$3,000,000
$200,000	$5,000,000

They provide the foundation upon which to develop improvements. It is important to understand the requirements for maintenance success because they in turn provide the foundation for today's best maintenance practices.

These fundamental principles become the cornerstone for achieving, maintaining, and continually improving the maintenance process. Organizations that are establishing best practices for world-class maintenance will be actively pursuing the following 25 requirements for effective maintenance management (Peters 1994b).

1. *Priority:* The process of performing maintenance and managing physical assets will be recognized as a top priority within successful organizations.
   - Maintenance will be viewed as a top-priority operation, not as a necessary evil. It will be viewed as another area that contributes directly to the bottom line when a strategy for continuous maintenance improvement is adopted. The future capable leader will have identified top priority areas for improvement, based upon a total benchmark evaluation of the maintenance operation, and investments will be made to implement best practices.
2. *Leadership and understanding:* Maintenance leaders must understand the challenges of maintenance and provide effective maintenance leadership with a vision of continuous maintenance improvement.
   - Maintenance leadership must continually develop the skills, abilities and attitudes to lead maintenance into the future. Maintenance leaders must completely understand the 25 requirements for effective maintenance management and develop priorities for action. Maintenance leaders must create understanding within the organization about maintenance and develop a vision of continuous maintenance improvement shared throughout the organization.
3. *PRIDE in Maintenance*. Maintenance operations in the future capable company will experience fundamental improvements in work ethic, attitude, values, job performance, and customer service to achieve real pride in maintenance excellence.
   - Tangible savings and improvements will occur as a result of continuous maintenance improvement. The successful maintenance operations will experience other fundamental improvements that develop more PRIDE: People Really Interested in Developing Excellence in Maintenance. Improvements in work ethic, performance, attitudes, teamwork, and concerns for customer service will occur. Successful maintenance operations will have leadership that instills PRIDE in maintenance with a vision of maintenance excellence that creates inspiration, cooperation, and commitment throughout the organization.
4. *Maintenance profession:* The profession of maintenance will gain greater importance as a key profession for success within all types of organizations as the role of chief maintenance officer becomes well established.
   - Maintenance leaders will be recognized as critical resources that are absolutely necessary for the success of the total operation. The chief maintenance officer (CMO) within large multisite operations will create and promote standard best practices. The complexity and importance of the maintenance and physical asset management will continue to grow. New technologies and added responsibilities will require a higher level of technical knowledge and skills.
5. *Maintenance personnel:* A significant upgrade in the level of personnel involved with maintenance will take place to keep pace with new technologies and responsibilities.
   - Maintenance operations within future capable companies will achieve a significant upgrade in the skill level of maintenance crafts people in order to keep pace with new technology and responsibilities. Successful maintenance operations will continually upgrade the skill level of crafts people through more effective recruiting with higher standards and through more effective craft training programs. Pay increases will be more directly linked to performance and demonstrated competency levels in required craft skills.
6. *Craft skills development:* Successful maintenance operations will continually assess craft training needs and provide effective skills development through modern technical learning systems.
   - A complete assessment of craft training needs will be accomplished to identify priority areas for skill development that is competency based, to provide demonstrated technical capabilities for each craft skill. The successful maintenance operations will develop an ongoing program for craft skill development. Continuous maintenance education, based on modern technical learning systems, will be viewed as a sound investment and an important part of continuous maintenance improvement.

7. *Adaptability and versatility:* The maintenance crafts person will become more versatile and adaptable by gaining value with new technical capabilities and multi-craft skills.
   - The development of more crafts people with multiskills will occur to provide greater versatility, adaptability, and capability from the existing workforce. Multiskilled personnel will have added value and will be compensated according to well-defined policies. Craftspeople will become more adaptable, versatile, and valuable as a result of ongoing programs for craft skill development.
8. *Teamwork:* Maintenance will be team players and maintain a leadership-driven, team-based approach to continuous maintenance improvement.
   - Maintenance leadership will accept its role as a top priority operation and will set the example as team players within the organization. The strategy for continuous maintenance improvement will be a leadership-driven, team-based approach that captures the knowledge, skills, and ideas of the entire maintenance workforce. Cross-functional teams with representatives from maintenance, operations, engineering, etc. will be formally chartered to address improvements in equipment effectiveness, reliability, and maintainability.
9. *Maintenance and operations:* Maintenance and operations will become integrated, and function as a supportive team through improved planning, scheduling, and cooperative team-based improvement efforts. Operations will be viewed as an important internal customer.
   - Improved planning and scheduling of maintenance work will provide greater coordination, support, and service to manufacturing type operations. Maintenance and operations of all types will recognize the benefits of working together as a supportive team to reduce unplanned breakdowns, increase equipment effectiveness, and reduce overall maintenance costs. Operations will be viewed as an important internal customer. Operations will gain greater understanding of the 25 requirements of effective maintenance management and accept its important partnership role in supporting maintenance excellence.
10. *Pride in ownership:* Equipment operators and maintenance will develop a partnership for maintenance service and prevention and take greater pride in ownership through operator-based maintenance.
    - Equipment operators will assume greater responsibilities for cleaning, lubricating, inspecting, monitoring, and making minor repairs to equipment. Maintenance will provide training support to operators to achieve this transfer of responsibility and to help operators with early detection and prevention of maintenance problems. Operators will develop greater pride in ownership of their equipment with their expanded responsibilities.
11. *Equipment effectiveness:* A leadership-driven, team-based approach will be used by maintenance and operations to evaluate totally, and subsequently improve all factors related to equipment effectiveness. The goal is maximum availability of the asset for performing its primary function.
    - Continuous improvement of equipment effectiveness will address major losses due to equipment breakdowns, set-up/adjustments, idling/minor stoppages, reduced speeds, process defects, and reduced yields. Equipment improvement teams will be established to meet on a regular basis to identify and resolve equipment-related problems. They will work constructively as cross-functional teams to exchange and implement ideas for improving equipment effectiveness. They will use techniques such as continuous reliability improvement (CRI) and reliability-centered maintenance (RCM). Chronic problems will be analyzed using tools such as statistical process control, graphs, process charts, and cause-and-effect analysis. Maintenance operations within successful future capable companies will use a total team effort by operators, engineering, operations staff, and maintenance to identify and resolve root causes of equipment problems.
12. *Maintenance and engineering:* Maintenance and engineering will work closely during systems specification, installation, startup and operation to provide maintenance with the technical depth required to maintain all assets and systems.
    - Engineering will provide technical resources and support to ensure maintenance has the total technical capability to maintain all equipment and systems. Engineering will play a key support role with maintenance in improving the effectiveness of existing equipment. Maintenance and engineering will work closely in developing specifications for new equipment. During installation and start-up, maintenance and engineering will also work closely to ensure operating specifications are achieved.
13. *Reliability and maintainability:* Machines and systems will be specified, designed, retrofitted, and installed with greater reliability and ease of maintainability.
    - Equipment design will focus on maintainability and reliability and not primarily on performance. Design for maintainability will become an accepted philosophy that fully rec-

ognizes the high cost of maintenance in the life-cycle cost of equipment. The causes for high life-cycle costs will be reduced through the application of good maintainability and reliability principles during design. Design will be focused on life-cycle reliability by identifying potential problems before they are designed into the equipment. Equipment design will include a higher level of internal diagnostic capabilities and provide for greater use of expert systems for troubleshooting. Maintenance will work closely with equipment designers to share information about problems with existing equipment and to provide possible maintenance-prevention solutions for new equipment.

14. *Modularity:* Physical assets and systems will be modularly designed so that failures can be easily identified and repaired quickly.
    - Overall maintainability will be further improved through modular design of physical assets and systems. Highest-failure parts and components should be the most accessible, easily identified and designed for easy repair. Components should be designed for easy disassembly and assembly using the lowest skill level possible. Modularity of design will be an important part of the design for maintainability philosophy.
15. *Obsolescence:* The life-cycle costs of physical assets and systems will be closely monitored, evaluated, and managed to reduce total costs.
    - Successful maintenance operations will achieve significant reductions in total life-cycle costs through an effective design process prior to purchase and installation. During the equipment's operating life, systems will be developed to monitor equipment costs continually. Information to identify trends will be available to highlight equipment with high maintenance costs. Action can be taken to address critical high-cost areas in order to reduce future costs. A complete equipment history of repair costs will assist maintenance in making decisions on equipment replacement, equipment overhaul/retrofit, and overall equipment condition.
16. *Redundancy:* Critical assets and systems will have backups provided so that if something fails, a secondary asset or system will take over.
    - Critical operations will be identified where backup equipment or systems are economically justified. Redundancy of critical equipment and systems will ensure that continuous operation is achieved when something fails. Maintenance will focus attention on critical operations in order to increase equipment effectiveness, reduce unplanned breakdown and increase the effectiveness of preventive/predictive maintenance.
17. *Uncertainty:* Uncertainty will be minimized through effective preventive/predictive maintenance programs and through continuous application of modern predictive maintenance technology and expert systems.
    - Effective preventive/predictive maintenance programs will be used to anticipate and predict maintenance problems in order to eliminate the uncertainty of expected breakdowns and high repair costs. Predictive maintenance will not be limited solely to the detection of failure but will proactively identify and eliminate the root causes of chronic problems. Preventive/predictive maintenance programs will be adequately staffed to cover all major assets within the operation. Maintenance will maintain current technical knowledge and experience for applying a combination of predictive technologies that is best suited for the specific application or system.
18. *Computerized maintenance management and enterprise asset management:* Systems that support the total maintenance operation will improve the quality of maintenance and physical asset management and be integrated with the overall business system of the organization.
    - Computerized maintenance management systems (CMMS) will provide greater levels of manageability to maintenance operations. CMMS will cover the total scope of the maintenance operation, providing the means to improve the overall quality of maintenance management. Enterprise asset management (EAM) will provide a broader scope of integrated software to manage physical assets, human resources, and parts inventory in an integrated system for maintenance management, maintenance, procurement, inventory management, human resources, work management, asset performance, and process monitoring. Vast amounts of data associated with maintenance tasks will come under computer control and be available as key information for planning, scheduling, backlog control, equipment history, parts availability, inventory control, performance measurement, downtime analysis, etc.
19. *Maintenance information system:* The maintenance information system and database will encompass the total maintenance function and provide real-time information to improve maintenance management.
    - The implementation of CMMS and EAM provides the opportunity for improved maintenance information systems. With CMMS and EAM, the maintenance information system

can be developed and tailored to support maintenance as a true business operation. Information to support planning, scheduling, equipment history, preventive/predictive maintenance, storeroom management, etc. can be established to improve decision making and overall maintenance management. Improved maintenance information will allow for an open information flow to exist between maintenance, operations and all departments within the organization. Maintenance will become an important part of the overall information flow and be kept well informed about current and future operational plans.

20. *Maintenance storeroom:* The maintenance storeroom will be orderly, space efficient, labor efficient, and responsive and provide the effective cornerstone for maintenance excellence.

- The maintenance storeroom for maintenance repair operations (MRO) items will be recognized as an integral part of a successful maintenance operation. Initial storeroom design or modernization will include effective planning for space, equipment, and personnel needs while providing a layout that ensures efficient inventory control and includes maximum loss control measures. It will be professionally managed and maintained in a clean, orderly, and efficient manner. The trend will be towards larger centralized storerooms with responsive delivery systems to eliminate crafts people waiting or traveling to get parts. An effective maintenance storeroom catalog will be maintained to provide a permanent cross-reference of all storeroom items and serve as a tool for identifying and locating items.

21. *Maintenance inventory:* The proper quantity of the proper spare parts will be on hand due to progressive MRO procurement and internal storeroom controls, all to support maintenance excellence.

- The implementation of CMMS and EAM will include an inventory system that totally supports the requirements of maintenance and the storeroom. Maintenance inventory will be managed to ensure that the right part is available at the right time without excessive inventory levels. Information from all available sources will be used to determine optimum stock levels. A continuous review of stock levels will be made to eliminate excess inventory and obsolete parts. Inventory reductions will be achieved through more partnerships with suppliers and vendors that establish joint commitments to purchase based on responsive service and fast delivery. Positions within MRO material management and procurement will increase in their importance and level of technical knowledge to perform effectively

22. *Working environment:* Successful maintenance operations will be safe, clean, and orderly because good housekeeping is an indicator of maintenance excellence.

- Maintenance leaders will provide a working environment where safety is a top priority, which in turn allows maintenance to set the example throughout the organization. Maintenance shop and work areas will be clean and orderly. Good housekeeping practices in maintenance will provide the basic foundation for safety awareness. Maintenance will provide support throughout the organization to ensure that all work areas are safe, clean, and orderly.

23. *Environment, health, and safety:* Maintenance must provide proactive leadership and support to the organization's regulatory compliance actions.

- Maintenance leaders must maintain the technical knowledge and experience to support compliance with all state and federal regulations under OSHA, USEPA (Clean Air Act), the U.S. Department of Transportation, and the Americans with Disabilities Act. The issue of indoor air quality must receive constant attention to eliminate potential problems. Maintenance must work closely with other staff groups in the organization, such as quality and safety, to provide a totally integrated and mutually supportive approach to regulatory compliance.

24. *Maintenance performance and service:* Broad based measures of maintenance performance and customer service will provide a continuous evaluation of the value of maintenance.

- CMMS and EAM will allow for a broad range of measurement for maintenance performance and service. Investment in maintenance best practices will require valid return on investment. Projected savings will be established and results will be validated. Measures will be developed in areas such as labor performance/utilization, compliance to planned repair and preventive/predictive maintenance schedules, current backlog levels, emergency repair hours, storeroom performance, asset uptime and availability, etc. Leaders of successful maintenance operations will continuously evaluate performance and service in order to manage maintenance as a business. They will adopt the philosophy of continuous maintenance improvement and have a method to measure progress.

25. *Maintenance planning and scheduling:* Maintenance customer service and the utilization of available craft time will improve through more effective planning and scheduling systems.

- The development of more effective planning and scheduling systems will be a top priority for the future capable maintenance operation. As reductions in breakdown repairs occur through more effective preventive/predictive maintenance, the opportunity to increase planned maintenance work will result. Maintenance and operations work closely to schedule repairs at the most convenient time. Maintenance will become more customer oriented and focus on achieving greater customer service by completing scheduled repairs on time. The utilization of craft time will increase as levels of planned work increases and as the uncertainties and inefficiencies associated with breakdown repairs are reduced.

World-class maintenance starts with a total commitment to a strategy of continuous maintenance improvement with maintenance as a top priority within the organization. It is the realization that maintenance is a key contributor to profit. It is the realization that maintenance best practice, plus people assets, plus MRO assets and information technology asset, all combine for the success and improvement of the total maintenance operation. It is the application of business process improvement techniques such as industrial engineering that generates the results and enhances the improvement process. Section 7, A Review of Other Selected Maintenance Best Practices, will give the reader greater understanding of maintenance management technology, principles and practices.

4. BENCHMARKING THE TOTAL MAINTENANCE OPERATION

Benchmarking can be defined as the continuous process of measuring our products, services, and practices against our toughest competition. Often our toughest competitor is our own organization, which does not understand the true value of maintenance, the high cost of deferred maintenance, or the dangers of gambling with a run-to-failure strategy of continuous reactive maintenance. It is important to realize that there are two basic forms of benchmarking, internal and external, and to understand why both are essential during the journey to maintenance excellence.

4.1. Internal vs. External Benchmarking

External benchmarking within maintenance allows for taking the global view of identifying best practices and determining how they can be transferred and applied successfully within your own unique maintenance operation. External benchmarking provides for developing broad-based comparisons with other maintenance operations in terms of best practices, standard operating procedures, and industry-wide statistical data. *The Scoreboard for Maintenance Excellence*, reviewed within this chapter, is today's most comprehensive guide for external benchmarking. It covers 18 best practice categories and 200 evaluation criteria (Peters 1994).

Think global—start local: Internal benchmarking starts locally within the maintenance operation at the shop floor. It focuses on measuring the successful execution of best practices such as CMMS, preventive and predictive maintenance, maintenance planning and scheduling, and effective maintenance storeroom operations (Peters 1997).

Internal benchmarking is about developing specific internal metrics or performance indicators. It is about determining progress from an internal baseline or starting point and measuring the progress toward a performance goal specific to your type of maintenance operation. For example, an internal benchmark could be the current level of maintenance-related downtime hours for a critical asset or the maintenance cost per unit of output, such as cost per ton, cost per carton, or cost per equivalent standard hour if a standard cost system is in place (Peters 1998).

4.2. The Scoreboard for Maintenance Excellence

4.2.1. Global Best Practices as External Benchmarks

There are many maintenance best practices that can serve as the global external benchmarks. External benchmarking is about gaining the knowledge and understanding of best practices and then applying them within the maintenance operation to help pursue and gain a manufacturing or service edge. Today's best maintenance practices are in areas such as:

- Preventive/predictive maintenance
- Continuous reliability improvement
- Reliability-centered maintenance
- Maintenance parts/materials control
- Maintenance storeroom operations
- Work order and work control
- Maintenance planning/scheduling
- Maintenance budget and cost control

- Operator-based maintenance
- Team-based continuous improvement
- Improving and measuring equipment effectiveness and reliability
- Craft skills development
- Maintenance performance measurement
- Computerized maintenance management systems
- Continuous maintenance improvement

Effective benchmarking should start locally, with a total evaluation of current maintenance practices and procedures, and then lead to the development of a strategic maintenance plan. The strategic maintenance plan provides the road map for applying maintenance best practices through a long-term process of continuous maintenance improvement. Benchmarking at its best is when maintenance effectively measures its level of services and practices and develops its own unique benchmarking criteria with high standards for maintenance excellence.

4.2.2. Conducting an Assessment of the Total Maintenance Process

Today's most comprehensive benchmarking guide, *The Scoreboard for Maintenance Excellence*, has been discussed in this chapter to support external benchmarking of your maintenance operation. *The Scoreboard for Maintenance Excellence* includes 18 maintenance best practice categories and 200 benchmark evaluation items. It has been used by over 4000 international organizations of all types to include translations into a number of languages. A complete copy of this very comprehensive document, with a guide for doing a self-assessment, can be downloaded from *www.tompkinsinc.com*. A summary of the evaluation categories and the number of evaluation items per category is included in Table 2.

Table 3 provides a general assessment of the overall benchmark rating, which has a maximum point value of 2000 points; 10 points maximum for each of the 200 benchmark evaluation items. Overall ratings of excellent (90–100%), very good (80–89%), good (70–79%), average (60–69%), and below average (less than 60%) are defined with general assessment comments.

Using *The Scoreboard for Maintenance Excellence*: It is recommended that the benchmark evaluation be conducted through a team effort within an organization or through an outside resource that can provide an objective and unbiased evaluation. When using an outside consulting resource, it is important to select a firm with broad-based experience in maintenance management as well as knowledge and experience with CMMS implementation.

When using an internal team, it is important to select knowledgeable members from maintenance as well as representatives from the storeroom, purchasing, accounting, production, and engineering

TABLE 2 Maintenance Evaluation Summary

Section	Evaluation Category	Evaluation Items
A.	Maintenance and organization culture	10
B.	Organization and administration	12
C.	Work authorization and work control	10
D.	Budget and cost control	11
E.	Maintenance planning and scheduling	12
F.	Maintenance storeroom	16
G.	Preventive and predictive maintenance	22
H.	Lubrication program	11
I.	Overall equipment effectiveness	9
J.	Operator-based maintenance	8
K.	Engineering support	9
L.	Safety, housekeeping, and regularity compliance	12
M.	Craft skills development	9
N.	Maintenance performance measurement	9
O.	Maintenance supervision/leadership	6
P.	Computerized maintenance management systems (CMMS)	13
Q.	Maintenance facilities, equipment, and tools	7
R.	Continuous maintenance improvement	14
	Total evaluation criteria	200

TABLE 3 General Assessment of Overall Benchmark Rating

General Assessment of Overall Benchmark Rating	
Total Point Range	Overall Rating Summary
1800 to 2000 (90–100%)	*Excellent:* Practices and principles in place for achieving effective maintenance and world-class performance based on actual results. Reconfirm overall maintenance performance measures. Maintain strategy of continuous maintenance improvement. Set higher standards for maintenance excellence and measure results.
1600 to 1799 (80–89%)	*Very good:* Fine-tune existing operation and current practices. Reassess progress on planned or ongoing improvement activities. Redefine priorities and renew commitment to continuous maintenance improvement.
1400 to 1599 (70–79%)	*Good:* Reassess priorities and reconfirm commitments at all levels to maintenance improvement. Evaluate maintenance practices and develop and implement plans for priority improvements. Ensure that measure to evaluate maintenance performance and results are in place. Initiate strategy of continuous maintenance improvement.
1200 to 1399 (60–69%)	*Average:* Conduct a complete assessment of the maintenance operation and current practices. Determine total costs/benefits of potential improvements. Develop and initiate strategy of continuous maintenance improvement.
Less than 1200 (<60%)	*Below average:* Same as Average, plus depending on the level of the rating and major area that is Below average, immediate attention may be needed to correct conditions adversely affecting on life, health, safety, and regulatory compliance. Priority to key issues, major equipment, or increasing costs that are having a direct impact on the immediate survival of the business.

and computer systems. An outside consultant can also be used as part of the team approach to performing the benchmark evaluation. It is recommended that maintenance provide the team leader to support overall coordination of the benchmarking evaluation.

A self-assessment will provide benefits; however, an assessment conducted by an outside resource provides a greater sense of the big picture in terms of objectivity and completeness. Should you want to begin with an internal study of maintenance, here are some guidelines to consider when using *The Scoreboard for Maintenance Excellence.*

- *Obtain Leadership Buy-in:*
  - Establish a firm commitment from company leadership to take action based upon results of the assessment.
  - Gain commitment from company leadership for the necessary resources.
- *Charter maintenance excellence team:*
  - Establish a maintenance excellence strategy team to guide and promote improved maintenance practices within the operation.
  - Utilize a team-based approach with a cross-functional assessment team specifically chartered for conducting and preparing the results of your assessment.
  - Have at least one team member with solid background in each of 18 evaluation categories.
- *Define and weight benchmarking criteria:*
  - Gain complete understanding of each evaluation criterion (200 total).
  - Modify existing evaluation criteria as required.
  - Add evaluation criteria as required.
  - Ensure that all team members understand the scoring process and develop consistency in scoring each area.
- *Develop action plan:*
  - Determine information required, persons to interview, and observations needed prior to start of assessment.
  - Develop schedule and implementation plan for the assessment.

- *Conduct assessment:*
  - Assign team members to specific evaluation categories (ideally, in two-person teams for each category).
  - Conduct kickoff meeting, firm up schedules, etc.
  - Conduct the assessment, record observations, and assign scores to each evaluation criteria.
- *Analyze and review results:*
  - Review all scoring for consistency.
  - Develop final results of the assessment and document in a written report.
  - Determine strengths/weaknesses, priorities for action, and benefits.
  - Present results to company leadership, define benefits and get commitment for investments.
- *Develop path forward for maintenance excellence:*
  - Develop a strategic maintenance plan (SMP) and implement best practices.
  - Measure benefits and validate ROI.
  - Maintain a continuous maintenance improvement process (i.e., repeat assessment process).

Each of the 200 benchmark items will include evaluation criteria to provide a means to rate each item with up to 10 points maximum. Examples from *The Scoreboard for Maintenance Excellence* are shown in Tables 4 and 5 to illustrate the two methods for establishing benchmark rating values. Ratings are established as follows:

- *Based on point value:* The benchmark item is rated as excellent (10 or 9 points), very good (8 points), good (7 points), average (6 points), below average (5 points) and poor (4 points or less), as shown in the example in Table 3. This method of rating requires that a consistent judgment be made on assigning point values, particularly in the areas rated average and below average.
- *Based on specific conditions:* The benchmark criteria will describe a number of specific conditions that are assigned point values. Table 4 provides two examples of this type of rating from the maintenance storeroom category. For example, benchmark item 6 rates whether storeroom inventory accuracy is being measured and is over 95% for a score of 10. In turn, inventory accuracy levels within 90–95%, 9 points, 80–89%, 8 points, 70–79%, 7 points, and below 70%, 5 points.

The benchmark evaluation score: As the benchmark evaluation is completed, it is important to realize that the total point value is not an absolute value but represents an important baseline value unique to your maintenance operation. It provides a baseline value as to where you are with best

TABLE 4 Example for Benchmark Rating Based on Point Values

Item #	Benchmark Item	Benchmarking Criteria	Rating
A.	Maintenance and Organization Culture		
1.	The organization's vision, mission, and requirements for success include physical asset management and maintenance as a top priority.	The organization has written mission statement/goals that include maintenance and/or preventive maintenance as a top priority and key goal. Rated as: Excellent—10 or 9, Very good—8, Good—7, Average—6, Below average—5, Poor—4 or less.	
2.	Senior management is visible and actively involved in continuous maintenance improvement and is obviously committed to achieving maintenance excellence.	Management commitment is rated as: Excellent—10 or 9, Very good—8, good—7, Average—6, Below average—5, Poor—4 or less.	

TABLE 5 Example for Benchmark Rating Based on Specific Conditions

Item #	Benchmark Item	Benchmarking Criteria	Rating
F.	Maintenance Storeroom		
5.	Inventory accuracy is determined by an effective cycle-counting program.	• Cycle counting used—10 • Count once per year—7 • Count occasionally—5 • Do no inventory counts—0	
6.	Inventory accuracy is regulary measured and is 95% or above.	Inventory accuracy 95% or above—10 90%–95%—9 80%–89%—8 70%–79%—7 <70%—5	

practices from *The Scoreboard for Maintenance Excellence.* In Section 5, very specific metrics for internal benchmarking and measurement of progress will be reviewed.

At this point, the benchmarking process has helped define current strengths and weaknesses within a maintenance process. Benchmarking helps to identify where we are with best practices that are essential to an effective asset management. By using a benchmarking guide such as *The Scoreboard for Maintenance Excellence*, you can easily see the status of current practices:

- Work order/work management
- Equipment/asset management
- Preventive/predictive maintenance
- Planning and scheduling
- Parts inventory management/purchasing
- Budgeting and cost control

The benchmark evaluation may reveal weaknesses related to the primary CMMS modules. A wide range of scores have come from the benchmark assessments conducted by Tompkins Associates and others using *The Scoreboard for Maintenance Excellence*. The important point was not the numeric score but that each organization had taken the first step with a total benchmark evaluation of their maintenance operation and used the results to develop and implement a strategic plan for improvement.

4.2.3. Internal Benchmarking: The Key to Validation of Results and ROI

Measurement of improvement internal to a maintenance operation is the real value of internal benchmarking. It's knowing exactly where we are with applying best practices, gaining a commitment from the organization to implement those needed, and then measuring the results. Internal benchmarking provides the means to validate results of maintenance improvement, define the ROI, and manage and control maintenance as a business.

It makes little sense to develop and worry about industry-wide benchmark statistics when, for example, an operation does not measure its own maintenance-related downtime. Industry-wide benchmark statistics can be very misleading when we try to compare our maintenance operation to them. On the other hand, when we understand today's best practices for effective maintenance, apply them, and measure the results, we are providing real value (Peters 1998).

5. PERFORMANCE MEASUREMENT: KEY TO MAINTENANCE CONTROL

5.1. Techniques for Measuring Maintenance Activities

Maintenance work, by its very nature, seldom follows an exact pattern for each occurrence of the same job. Traditional work-measurement techniques are not readily adaptable to maintenance-type work. Therefore, exact methods and exact times for doing most maintenance jobs cannot be established as they can for discrete manufacturing-type work. However, the need for having reliable per-

formance measures for maintenance planning becomes increasingly important as the cost of maintenance labor rises and the complexity of production equipment increases.

Various methods for establishing maintenance performance standards have been used, including:

- *Reasonable estimates:* A knowledgeable person, either a supervisor or planner, uses his or her experience to provide their best estimate of the time required. This approach does not scope out the job in much detail to determine method or special equipment needed.
- *Historical data:* The results of past experience are captured via the CMMS or other means to get average times to do a specific task. Over time, a database of estimated time is developed that can be updated with a running average time computed for the tasks.
- *Predetermined standard data:* Standard data tables for a wide range of small maintenance tasks have been developed. A standard data example is shown for one task for the pipefitting craft of cutting with a pipe machine. Standard data represent the building blocks that can then be used to estimate larger, more complex jobs. Each standard data table provides what the operation is, what is included in the time value, and the table of standard data time for the variables that are included. The variables for the example standard data sheet is the size of the pipe from ½ in. diameter up to 8 in. diameter.

Example: Maintenance Standard Data—Pipefitting

Code PF-2-1

SKILL: Pipefitting

OPERATION: Pipe—Cut with Pipe Machine

Includes:

1. Pick up pipe, place in chuck, and tighten chuck jaws.
2. Measure pipe for cut and position carriage.
3. Hand feed parting tool to cut piece off pipe.
4. Hand feed parting tool to remove burrs.
5. Loosen chuck jaws, remove pipe from chuck, and set aside.
6. Dispose of scrap or set aside unused piece.

The three techniques described previously require that an outside party establish the standards that are then imposed upon the maintenance force as an estimated time on the work order. These approaches to craft performance measurement often bring about undue concern and conflict between management and the maintenance workforce over the reliability of the standards. Rather than progressing forward together in a spirit of continuous improvement, the maintenance workforce in this type environment often works against management's program for maintenance improvement. Some other very progressive options to the challenging task of work measurement within nonrepetitive maintenance operations are available.

5.2. The ACE Team Benchmarking System

As a means to overcome many of the inherent difficulties associated with developing maintenance performance standards, the ACE (A Consensus of Experts) team benchmarking system relies primarily on the combined experience and estimating ability of a group of skilled crafts personnel. The objective is to determine reliable planning times for a number of selected benchmark jobs. This system places a high emphasis on continuous maintenance improvement and the changing of planning times to reflect improvements in performance and methods as they occur.

Generally, the ACE team benchmarking system parallels the UMS (universal maintenance standards) approach in that the range of time concept and slotting are used once the work content times for a representative number of benchmark jobs have been established. The ACE team benchmarking system focuses primarily on the development of work content times for representative benchmark jobs that are typical of the craft work performed by the group (Peters 1996a).

Once a number of benchmark job times have been established, these jobs are then categorized onto spreadsheets by craft and task area and according to work groups which represent various ranges of times. A spreadsheet is then set up for four work groups, such as for jobs in the E, F, G, and H time slots. In this case, work group E would be for benchmark jobs ranging from 0.9 hr up to 1.5 hr and assigned a standard time (slot time) of 1.2 hr. Likewise, work group F would be for benchmark jobs ranging from 1.5 hr up to 2.5 hr and assigned a standard time of 2.0 hr. This spreadsheet would

TABLE 6 Standard Data: Pipe Size ½ in. to 8 in.

Pipe Size	Normal Minutes per Cut
1/2 in.	0.9
3/4 in.	1.0
1 in.	1.1
1-1/4 in.	1.2
1-1/2 in.	1.3
2 in.	1.4
2-1/2 in.	1.6
3 in.	1.8
3-1/2 in.	2.2
4 in.	2.5
5 in.	3.4
6 in.	4.4
8 in.	6.2

also include brief descriptions of the benchmark jobs that have work group times of 1.2 (E), 2.0 (F), 3.0 (G), and 4.0 (H) hr respectively. All of the work groups, and their respective time ranges, are shown in Table 7.

Spreadsheets provide the tool: After spreadsheets have been prepared based on the representative benchmark jobs from various craft/task areas, a planner/analyst now has the means to establish planning times for many different maintenance jobs using a relatively small number of benchmark jobs as a guide for work content comparison. By using work content comparison combined with a good background in craft work and a knowledge of the benchmark jobs, a planner now has the tools to establish reliable performance standards consistently, quickly, and with confidence. The ACE team benchmarking system allows a wide range of tasks to be estimated with a 95% confidence level by using work content comparison to a small but representative sample of well-defined benchmark jobs.

TABLE 7 ACE System Time Ranges and Work Groups

	Time Range		
Work Group	From	Standard Time (Slot time)	To
A	0.0	0.1	0.15
B	0.15	0.2	0.25
C	0.25	0.4	0.5
D	0.5	0.7	0.9
E	0.9	1.2	1.5
F	1.5	2.0	2.5
G	2.5	3.0	3.5
H	3.5	4.0	4.5
I	4.5	5.0	5.5
J	5.5	6.0	6.5
K	6.5	7.3	8.0
L	8.0	9.0	10.0
M	10.0	11.0	12.0
N	12.0	13.0	14.0
O	14.0	15.0	16.0
P	16.0	17.0	18.0
Q	18.0	19.0	20.0
R	20.0	22.0	24.0
S	24.0	26.0	28.0
T	28.0	30.0	32.0

Since the actual times assigned to the benchmark jobs are so critical, it is very important to use a technique that is readily acceptable. The ACE team benchmarking system provides such a technique, since it is based on the combined experience of a group of skilled crafts personnel, and their consensus agreement on the range of time for the benchmark jobs. The following is a recommended approach for using the ACE team benchmarking system (Peters 1996a).

1. *Select benchmark jobs:* Review past historical data from work orders and select representative jobs that are normally performed by the craft groups. Special attention should be paid to determine the 20% of total jobs (or types of work) that represent 80% of the available craft manpower. Focus on determining repetitive jobs where possible in all craft areas.
2. *Select and train experts* (*ACEs*): It is important to select experienced crafts people and/or supervisors who, as a group, have had experience in the wide range of jobs selected as benchmark jobs. All craft areas should be represented in the group. In order to ensure that this group understands the overall objectives of the maintenance planning effort, special training sessions should be conducted to cover the procedures to be used, reasons for establishing performance measures, etc. A total of 6 to 10 craft people is the recommended group size.
3. *Develop major elemental breakdown for benchmark job:* For each benchmark job that is selected, a brief element analysis should be made to determine the major elements of the total job. This listing of the major steps of the job should provide a clear, concise description of the work content for the job *under normal conditions*. It is important that the work content for a benchmark job be described and viewed in terms of what is a *normal* repair and not what may occur as a rare exception.

   An excellent resource to consider for doing the basic element analysis for each benchmark job is the crafts (ACEs) that are selected for doing the estimating. Brief training on methods/operations analysis can be included in the initial training for the ACEs. This process leads to the question "Are we using the best method, equipment, or tools for the job?" Often significant methods improvements are discovered and implemented as a result of this step.

   Major exceptions to a routine job should be noted if they are significant; generally an exception will be analyzed as a separate benchmark job, along with an estimate of time required for such repair. This portion of the procedure ensures that the work content of each benchmark job is clearly defined so that each person doing the estimating has the same understanding about the nature and scope of the job. When the benchmark jobs are finally categorized into spreadsheets, the work content description developed in this step is used as key information about the bench job on the spreadsheet.
4. *Conduct first independent evaluation of benchmark jobs:* Each member of the group is now asked to review the work content of the benchmark jobs and to assign each job to one of the UMS time ranges or slots. Each member of the group provides an independent estimate that represents an unbiased personal estimate of the pure work content time for the benchmark job.

   It is important here for each member of the group to remember that only the work content of the benchmark job description is to be estimated, and not the make ready and put away activities associated with the job. This part of the procedure is concerned only with estimating the pure work content, *excluding* things such as travel time, securing tools and parts, delays, and personal allowances.

   The estimate should be made for each job under these conditions:

   (a) An average skilled craftsman is doing the job giving 100% effort, i.e., a fair day's work for a fair day's pay.

   (b) The correct tools are available at the job site or with the craftsman.

   (c) The correct parts are available at the job site or with the craftsman.

   (d) The machine is available and ready to be repaired.

   (e) The craftsman is at the job site with all of the above and proceeds to complete the job from start to finish without major interruption.

   The work accomplished under these conditions therefore represents the pure work content of the job to be performed. Establishing the range of time estimate for this pure work content is the prime objective of the first evaluation. It is important for each estimator to remember that to develop a planning time requires pure work content time plus additional time allowances to cover make ready and put away-type activities associated with each job.

5. *Summarize first evaluation:* Results of the first evaluation are then summarized to check the agreement among the group as to the time range for each benchmark job. A coefficient of concordance can be computed from the results. A value of 0.0 denotes no agreement, while a value of 1.0 denotes complete agreement, or consensus among the ACEs.

   Group members who are significantly higher or lower than the rest of the group for a particular benchmark job are asked to explain their reasons for their high or low estimates. This information will then be used during the second evaluation to refine the next estimates from the entire group.
6. *Conduct second independent evaluation of benchmark jobs:* A second evaluation is conducted using the overall results from the first evaluation as a guide for the group. Various reasons for high or low estimates from the first evaluation are provided to the group prior to the second evaluation. This allows for adjustment to individual estimates if the other experts' reasons are considered to be valid.
7. *Summarize second evaluation:* Results of the second evaluation are then summarized to evaluate changes or improvements in the agreement or consensus among the ACEs as to the time range for each benchmark job. This evaluation should produce improved agreement among the group. If an extreme variance in time range estimates still exists, further information regarding the work content of the job may be needed.
8. *Conduct third independent evaluation if required:* This evaluation is required only if there remains a wide variance in the estimates among the group.
9. *Conduct group session to review final results:* This session serves to finalize the results achieved and to discuss any of the high or low estimates that have not been resolved completely. A final group consensus on all time ranges is the objective of this session.
10. *Develop spreadsheets:* The benchmark jobs with good work content descriptions and agreed-upon time ranges can now be categorized onto spreadsheets. From these spreadsheets, which give work content examples for a wide range of typical maintenance jobs, a multitude of individual maintenance performance standards can be established by the planner through the use of work content comparison. The basic foundation for the maintenance planning system is now available for generating consistent planning times that will be readily acceptable by the maintenance work force that developed them.

The ACE Team Benchmarking System approach combines the DELPHI technique for estimating along with the inherent and inevitable ability of most people to establish a high level of performance measures for themselves. As used in this application, the objective is to obtain the most reliable, reasonable estimate of maintenance-related work content time from a group of experienced crafts personnel.

This approach allows for independent estimates by each member of the group, which in turn builds into a consensus of expert opinion for a final estimate. The final results are therefore more readily acceptable because they were developed by skilled and well-respected crafts people from within the work unit. Application of the ACE team benchmarking system promotes a commitment to continuous maintenance improvement and provides reliable planning time for a wide range of maintenance activities.

5.3. Establishing Key Performance Indicators

This section will outline and describe key performance indicators that can be used to measure the overall effectiveness of a maintenance operation.

- *Percent craft utilization* (*CU*): Evaluates actual wrench time (hands-on time) for craft labor. Provides one of the two key elements for measuring the overall craft effectiveness (OCE). Measures the overall increase in craft labor wrench time due to a proactive, planned maintenance strategy with effective planning and scheduling, positive impact from the PM/PdM program, effective MRO materials management service, and improved CMMS.
- *Percent craft performance* (*CP*): Evaluates actual craft performance against a reasonable/reliable planned time for a planned repair job or task such as PM inspections. Where craft labor utilization measures effectiveness, this measure addresses the efficiency factor for overall craft effectiveness (OCE). This measure is improved by having effective craft skills to do the job, along with the motivation to work efficiently. It is directly impacted by shop working areas, having the right personal and special tools available, and safe working conditions.
- *Overall equipment effectiveness* (*OEE*): A world–class metric that originated from the total productive maintenance (TPM) movement, which evaluates critical equipment in terms of equip-

ment availability, equipment performance, and the quality of output. Improving OEE focuses on eliminating the six major losses:

Availability issues:	1. Breakdowns
	2. Set-up and adjustments
Performance issues:	3. Idling and minor stoppages
	4. Reduced speed
Quality Issues:	5. Process defects
	6. Reduced yield

The average OEE factor is in the 40–50% range before an improvement process starts. A world-class OEE factor is around 85%, which means that all three elements must be around 95%, i.e. 0.95 (availability) $\times$ 0.95 (Performance) $\times$ 0.95 (Quality) = 0.857 $\times$ 100 = 85.7% OEE factor.

$$\text{The OEE factor} = \text{availability \%} \times \text{performance \%} \times \text{quality \%}$$

- *The overall craft effectiveness* (*OCE*) *factor:* The OCE factor relates to craft labor assets, as compared to the metric for OEE, which measures the combination of equipment asset availability, performance, and quality output. The OCE factor focuses upon measuring and improving the value-added contribution that people assets make to total asset management. Section 7.5 includes more detailed information about the OCE factor.
- *Number of call-backs* (*or percentage of craft rework*): Measures the quality of maintenance repair work and provides one key indicator for maintenance customer service. It helps focus on doing the repair right the first time.
- *Schedule compliance* (*percent jobs completed as scheduled*): Evaluates the overall effectiveness of executing the planned work on the agreed-upon schedule by the craft workforce.
- *Percent planned work:* Measured by either the percent work orders planned or percent actual craft hours on planned work. This metric evaluates the overall effectiveness of the planning process as well as the impact of all maintenance best practices to promote a proactive maintenance repair strategy, i.e., PM, PdM, reliability improvement actions, effective MRO support, etc.
- *Percent work orders with planned time:* Provides one very key measure for the maintenance planner position. Evaluates the ability and effectiveness of the maintenance planner/coordinator position to establish reliable planning times, using maintenance standard data or other available data for determining planning times. The objective for the planning process is to have as many jobs scoped and planned as possible, to the level that reliable estimates are established.
- *Percent planned work orders generated from PM/PdM program:* Provides valuable feedback that the PM/PdM effort is helping avoid catastrophic failure and is truly providing benefits. Measures how well PM/PdM program is detecting deficiencies before catastrophic failure or downtime occurs. The reliability improvement goal, however, is not to continue to fix before failure but to eliminate root causes of failure and in turn the failure rate. However, this is an important metric as a client's PM/PdM program is reinforced or renewed and in turn begins to provide measurable results.
- *Percent PM/PdM compliance:* Measures the execution and compliance to completing scheduled PMs, PdM data collection, lube services, scheduled structural/process inspections, calibrations, etc. Typical completion of scheduled PM/PdM actions required within a week's window of time is used as criterion for compliance. This metric can also apply to instrumentation calibration and to any regulatory inspections such as crane, fire protection testing/PM, etc.
- *Number of stock outs:* Evaluates the MRO inventory/materials management process capability to have the on-hand quantities needed for stock items that are normally stocked in the maintenance storeroom. Provides an excellent countermeasure to ensure planned inventory reduction goal is not detrimental to storeroom customer service. Does not measure nonstock items that require requisitioning/purchasing as direct purchases or availability of project-related items.
- *Percent inventory accuracy:* Maintains accurate fiscal accountability of stocked items to ensure total confidence in current inventory levels and dollar value of MRO inventories. Measures the effectiveness of the cycle-counting process and storeroom control.

- *Dollar value of MRO inventory reductions:* Helps to ensure that proactive MRO inventory management practices and those well-planned MRO inventory reductions are given proper credit and recognition within the organization. This reduction may also serve to offset additions to inventory of more useful items and critical spares.
- *Percent asset utilization:* A good metric that evaluates how well the overall capacity of an asset is being used in the operation. It should be supplemented by measurement of overall equipment effectiveness (OEE).
- *Maintenance cost per unit of output:* Measures bottom-line maintenance cost per unit of output and evaluates net improvements related to maintenance improvements on total operation costs. Excellent metric for process-type industries and/or for discrete manufacturers with major single product output and a strong standard cost and production-reporting system.
- *Maintenance cost as percent of total operations cost:* Provides an overall comparison of how maintenance cost impacts total cost.
- *Other metrics to consider:*
  - Overtime
  - Craft time charged to work orders
  - Overdue work orders
  - Emergency craft hours

TABLE 8 Sample Maintenance Excellence Index

MAINTENANCE EXCELLENCE INDEX

	Performance Measurement Categories

- PM/PdM coverage, i.e., the equivalent craft hours invested in PM/PdM tasks, which can also be shown as equivalent crafts people
- Response time to priority jobs
- Closed work orders without time
- Craft hours charged back to customers
- Jobs by one-person crew
- Percent craft hours by work order type
- Percent craft hours by work/cost center

5.4. Developing a Maintenance Excellence Index

Often performance measurement is something new to the maintenance operation, but it is highly recommend that a performance-measurement system be put in place. Justification for investments in maintenance best practices must be validated. One approach used by Tompkins Associates has been to help clients create a maintenance excellence index (MEI) that includes 10–15 key performance indicators. These metrics, with agreed-upon weighted values, are developed into a composite total performance value (Peters 1998). The metrics that are selected should cover areas such as:

√ Craft Productiivty
√ Budget/cost
√ Planning and scheduling
√ Parts inventory management
√ PM compliance
√ Asset uptime/OEE
√ Asset utilization
√ Customer service

- *The Maintenance Excellence Index* (*MEI*): The sample MEI shown in Table 8 provides a composite index that integrates a number of key metrics. Each metric can also be monitored and trended individually. The MEI helps keep in focus the fact that the success of maintenance operations depends on many factors. Therefore, one or two metrics can't provide the total performance picture. The MEI concept provides a complete approach to maintenance performance measurement. If a maintenance process improvement has been justified on craft productivity increases, parts inventory reduction, maintenance cost per unit of output reduction, or value of increased asset uptime, the original projection of benefits and savings can be validated with the MEI.
- *The basic format of the MEI calculations:* The total MEI performance value is the composite score of all metrics, considering current performance of each metric as compared to the goal and the weighted value of each individual metric. The total possible score for the total MEI performance value is 1000. The key steps in developing and using the MEI are as follows:

Step	Description	Comments
A	Performance metrics	From 10 to 15 metrics are selected and agreed upon by the organization.
B	Current month performance	This is the acutal performance level for the metric for the reporting month. This value will also be noted in one of the incremental values blocks below the performance goal. This value will correspond to a value for F, the performance level scores which go from 10 down to 1.
C	Performance goal	This is the preestablished performance goal for each of the MEI metrics. For example, if the current month's performance is at the performance goal level, the performance level score for that goal will be a 10, the maximum score.
D	Baseline performance	The baseline performance level prior to start of MEI performance measurement

Step	Description	Comments
E	Current performance score	Depending on the current month's performance, a performance level score (F) will be obtained. This value then goes to the current performance score row and serves as the multiplier for (G) the weighted value of the performance metric.
F	Performance level score	Values from 10 down to 1, denote the level of current performance compared to the goal. If current performance achieves the predetermined goal, a performance value of 10 is given. Each metric is broken down into incremental value, from the baseline to the goal. Each incremental value in the column corresponds to a performance level value. This value becomes the current performance score.
G	Weighted value of the performance metric	The values along this row are the weighted value or relative importance of each of the metrics. These values are obtained via a team process and a consensus on the relative importance of each metric that is selected for the MEI. All of the weighted values sum to 100.
H	Performance value score	The weighted values (G) are multiplied by (E) the current performance scores to get the performance value score (H).
I	Total MEI performance value	The sum of the performance value scores for each of the 15 metrics and the composite value of monthly maintenance performance on all MEI metrics.
J	Total MEI performance values over time	Location for tracking total MEI performance values over a number of months

Investments in maintenance and total operations improvements should be measured and bottom-line return on investment validated. The proven methodology of the MEI utilizes existing data to provide a very effective multifactored system to measure mission-critical maintenance and its contribution to total operation performance and success. Organizations will make a wise decision to start this process, for example, as a new CMMS system is purchased and begins implementation. Positive trends on the Maintenance Excellence Index will validate the projected results: tangible benefits and savings that were used to justify the capital investment for this and many other types of maintenance-improvement projects.

6. INFORMATION TECHNOLOGY TO SUPPORT MAINTENANCE MANAGEMENT AND CONTROL

6.1. Introduction to Computerized Maintenance Management Systems/Enterprise Asset Management

The purchase of information technology in the form of a CMMS/EAM system is not a quick fix or a panacea. Many excellent systems are available, but surveys have consistently shown that only 80% of CMMSs are actually being used. In turn, typically only 30% of CMMSs functional capabilities are being used. Expenditures for CMMSs were $553 million in 1995 and have grown to over $1 billion in 2000. Therefore, gaining full value from your CMMS investment should be a top priority.

Basically, CMMS/EAM provides computer software programs designed to assist in the planning, management, and administrative procedures required for an effective maintenance process. The need for a maintenance management system, whether manual or computerized, is determined by the need to perform effective maintenance on assets, equipment and facilities. We can think of CMMS/EAM as providing the business system for maintenance operations.

Choosing a CMMS/EAM and determining how it will operate and what it will do should occur only after recognizing that a system is needed or that an existing system needs improvement. The need for, and use of a CMMS/EAM is not specific to any one industry or type of application. Anyplace where maintenance is done is a candidate user, and all users have the same basic system needs as dictated by the maintenance process itself. The scope of maintenance is broad and technically challenging. Likewise, the scope of today's CMMS/EAM is broad based to include a number of integrated modules to manage the maintenance process.

- *CMMS/EAM facilitates best practices:* Implementation of a CMMS is most successful in an organization that has committed to a total reevaluation and internal benchmarking of current practices and procedures, as reviewed previously in this chapter. Organizations should realize that lack of a CMMS is never the main problem. The main problem is the lack of best practices. A CMMS provides the framework to fully integrate best practices into the maintenance process; to provide the systems, procedures, and information to manage maintenance as a business. The effective use of a CMMS is important, but it is only part of the process for improving maintenance management. The maintenance organization plays a big part; it needs to be refined before a CMMS is put in to support it. Successful implementation of a CMMS will facilitate applying best practices discussed previously, and will provide tangible benefits and savings. Improved performance of the following maintenance activities can be expected to support justification of a CMMS/EAM (Peters 1999):
- *Improved work control:* The work order module is the heart of any CMMS. It provides the basis for work management, cost tracking, equipment history, and performance reporting. Effective CMMS supports improved control of work requests by craft, monitoring backlogs, determining priorities, and scheduling of overtime.
- *Improved planning and scheduling:* Unplanned maintenance work typically costs two to three times as much as planned work. A CMMS provides the systems and procedures to establish a more effective maintenance planning and scheduling function, which is a key contributor to improved craft labor utilization.
- *Enhanced preventive and predictive maintenance* (*PM/PdM*): Automatic scheduling of repetitive PM activities is possible through CMMS. PM tasks and inspection frequencies can be documented on the PM module and printed as part of the PM work order. A CMMS enhances PM by providing a method to monitor failure trends and highlight major causes of equipment breakdowns and unscheduled repairs.
- *Improved parts availability:* A well-organized stockroom with accurate inventory records, stock locator system, stocking levels, and a storeroom catalog can significantly improve the overall maintenance operation. Having the right part at the right time is the key to effective maintenance planning and increased maintenance customer service.
- *Reduced storeroom inventory:* A CMMS provides the means for more effective management and control of maintenance parts and material inventories. Information for decisions on inventory reduction is readily available to identify parts usage, excess inventory levels, and obsolete parts.
- *Improved failure and repair analysis:* A CMMS provides the means to track work order and equipment history data related to types of repairs, frequencies, and causes for failure. It allows maintenance to have key information on failure trends that leads to eliminating root causes of failures and improving overall equipment reliability.
- *Increased budget accountability:* A successful CMMS requires greater accountability for craft labor and parts/materials through the work order and storeroom inventory modules. This increased level of control provides greater accountability of the overall maintenance budget by individual pieces of equipment and by using department or work center.
- *Increased capability to measure performance:* The CMMS database provides a vast source of maintenance information to allow more effective measurement of maintenance performance and service. Successful CMMS applications will establish internal benchmarks to provide a measurement for improvements in the areas of craft labor utilization, PM/PdM compliance, downtime, store inventory control, backlog, level of planned maintenance, etc.
- *Increased level of maintenance information:* A major benefit of a CMMS comes from developing the historical database that becomes readily available as critical maintenance information. Many types of maintenance data are normally available, but it is often not in the form that helps manage and control maintenance operations. Now such data can be turned into valuable maintenance information with an effective CMMS.

6.2. Overview of CMMS/EAM System Functionality

This section provides an introduction to the overall scope, functionality summaries, and the primary CMMS modules that make up a typical integrated system. Many other system functions are available.

The modules described here are provided in various levels of functionality by over 100 CMMS/EAM vendors. These modules and the respective functionality they provide to the user comprise the basic elements needed for effective management of the maintenance process (Peters 1999).

- *Work order/work management module:*
  - Manages and controls approvals of work requests for correcting faults or improving an asset's condition. May be configured to require that certain types of work requests go through a review or approval cycle before they are submitted to maintenance.
  - Opens, edits, and records work orders as history. Basic work order information on the work request might include the equipment/asset number to be worked on, a description of the problem or work to be done, who requested the work, when they wanted it completed, the priority of the work, and the date the request is made.
  - This module records the basic work order information and supports editing the details on the work needed, parts and materials required, sequence of work, job steps, and other pertinent data.
  - Planning and scheduling of work orders may be available to associate each step with specific equipment, craft foreman, estimated and standard duration, lists of tasks, and special tools and equipment required.
  - Provides linking of craft resources, parts requisitions, bill of materials, routes and checklists, safety documentation/permits, material, and labor costing to a job step.
  - Work order completion is recorded with final information and closed to work order history file.
  - Reporting may be available to work orders in current backlog as well as in the work order history file.
- *Equipment/asset management module:*
  - Provides listing and basic data for equipment/assets owned and maintained. May include breakdown of asset information related to hierarchies of system/subsystems.
  - Information recorded may include equipment/asset number, location, maintenance priority, cost, manufacturer, model and serial numbers, and the dates of purchase and installation.
  - Defines assemblies and spare parts lists and supporting information, such as calibration data, which may also be kept in this module.
  - May include detailed support documentation associated with the asset: drawings, specifications, technical reference manuals, performance standards, extended descriptions, etc. Can be referenced for presentation on screen or printed on demand.
  - Support documentation data may be stored as free text, formatted, or a combination of both.
  - Parts lists usually are formatted and within an integrated system are linked with the inventory management module for data validation.
  - Operational data such as hour meter or temperature readings may be captured in this module to allow usage information to trigger the need for maintenance work or inspection.
  - Tracks failure information at the asset system/subsystem level through information entered when closing work orders and provides capability to compute various key performance indicators.
  - Tracks detailed cost history data by type of cost associated with asset system/subsystems.
- *Planning and scheduling:*
  - Manages the detailed planning of the labor, materials, and all other resources needed to complete a work order.
  - Permits defining and sequencing the specific job steps, identifying the required craft labor types, determining estimated times, as well as all other resources, such as special tools and equipment, contract services, etc.
  - Planned work orders for which all planned resources are available may then be scheduled. This may be a separate module or part of the work order/work-management module.
  - Provides ability to allocate and level craft resources for individual jobs as well as larger projects.
  - Supports building a schedule that includes corrective, preventive, and predictive work in a future period. Allows performing availability check on one or more work orders before issuing a final schedule.
- *Preventive maintenance/predictive maintenance (PM/PdM) module:*
  - Manages work orders for predefined repetitive and rigidly scheduled PM tasks to preserve good equipment condition.

- Opens and edits work orders and automatically schedules and records when jobs are completed. Jobs done under PM usually include inspections, lubrications, and changes of finite-lifetime items such as filters or seals.
- An important assignment of PM is discovering needed corrective work, which results in writing the required work order and creating a planned job to make the correction.
- PM may exist as a separate module or be a subfunction within the work order module.
- Allows for links to process control or PdM systems to obtain critical readings and determine current conditions that initiate actions such as an inspection work order or a troubleshooting call.
- Predictive readings are interpreted by software/hardware devices to determine whether a problem exists and what is its nature. If a problem is found, a corrective work order is written for the needed work. Any or all parts of this process may be automated.

- *Inventory management module:*
  - Manages MRO parts and materials inventory with the necessary record keeping of items received, stocked, and dispersed as well as their locations in the stockroom.
  - This module provides the information needed for managing the stock of parts and materials used in performing maintenance work in multiple stockrooms.
  - Provides data showing what items are to be ordered, what are available, and what are on order. Data in this module are directly supportive of the planning and scheduling effort.
  - This module is typically integrated with the purchasing module to fully support MRO procurement.
  - Warranty information and records may be included as a separate module or within this module, coded by vendor with description of warranties and warranty coverage. May include printing of exception reports, warranty claims and follow-up information.
- *Procurement/purchasing module:*
  - This module provides the mechanism to ensure that proper resources of stock material, nonstock items, raw materials, and outside services are available in an adequate manner to ensure adequate planning of maintenance work.
  - Provides for the creation and processing of purchase orders. This module manages the purchasing function, beginning with the automatic creation of a purchase order when the reorder point of a stock item is reached.
  - Data include a list of primary and alternative vendors and prior purchase history information along with vendor performance.
  - Reports available would include current items on order, delivery status, and vendor status and history.
  - May include processes to manage quotations, provide invoice matching, and manage blanket orders and service contracts.
- *Budgeting and cost:*
  - Development and management of cost estimates and budgets for maintenance projects and their distribution to various other operating departments.
  - Data managed in this module would include the details of the maintenance budget and provide current cost experience at cost center, project number, equipment location, system/subsystem level, etc.
  - Reports would be designed and used for control of maintenance expenses, charge-backs to customers, and/or activity codes, variance reporting, etc.
  - This module may be structured for easy linkage and distribution of applicable costs to the general ledger.
- *Project management:*
  - Typically works in conjunction with the work management module for grouping of work orders into specific projects. Where more than one work order is needed to describe a job, grouping as a project is convenient and helps to ensure that all jobs will be done.
  - May offer the ability to time-phase a job and to do sophisticated interactive planning for needed resources such as labor, materials, and production facilities.
  - Provides ability to manage projects from a capital project or a larger-scale construction management point of view.

- *Standard maintenance procedure/job library:*
  - A compilation of standard maintenance repair procedures to be used on work orders for specific jobs. The sequence of job step activities, labor requirements, parts, and materials required are listed, along with special permitting and safety requirements.
  - Serves as a valuable guide to work order planning for larger jobs and is updated whenever a standard repair procedure is changed or created.
  - May include a library of standard times needed to perform specific maintenance tasks. This can be used in planning the estimated time to perform the repair job steps.
- *Personnel:*
  - Provides complete management of in-house crafts personnel as well as contract individuals.
  - Maintains a roster of available employees, their skills, and their training for job-assignment purposes.
  - Maintains a history of where employees have worked for compliance with quality and safety programs.
  - Union agreement restrictions on assignments and past assignment histories, would also be used for scheduling of the work force.
- Data within the personnel module could be shared with, and in some cases updated by, other enterprise systems, such as payroll, labor reporting, safety, and contract management.

These basic modules provide the foundation for an effective maintenance management system. Many other system functions are offered, depending on the CMMS sophistication and intended application. CMMS software packages are now being sold by more than 300 vendors for applications on personal computers, minicomputers, and mainframes.

It is very important that a CMMS/EAM be viewed as an information technology tool for more effective maintenance management and not as a panacea that provides a quick fix. Effective installation of a CMMS/EAM is a maintenance best practice that must be tailored to the specific needs of each unique maintenance operation. Implementing a CMMS/EAM also forces the issue for applying other maintenance best practices.

An effective CMMS/EAM requires that a work order system be in place for control of work requests, monitoring of backlogs, control of maintenance labor, maintaining equipment history, and so on. Full utilization of the basic CMMS/EAM modules requires a sound commitment to establishing best practices for PM/PdM, maintenance planning and scheduling, and maintenance storeroom inventory management.

6.3. Benchmarking the CMMS/EAM Installation

Today's information technology for computerized maintenance management offers the maintenance leader an exceptional tool for managing and controlling the maintenance process as an internal business and profit center. However, maintenance surveys and benchmark evaluations conducted by Tompkins Associates and others validate that poor utilization of existing CMMS/EAM systems is a major improvement opportunity.

6.3.1. The CMMS Benchmarking System

To help improve utilization of this information technology for maintenance, many things were needed, especially a tool for benchmarking the actual CMMS/EAM installation. There was a real need to see how well the systems were working, and being utilized in the real world of maintenance management and control. There was also the requirement to validate benefits expected to reach the projected ROI. These needs, in turn, led to the development of the CMMS Benchmarking System by Tompkins Associates in 1997. It is designed as a methodology for developing a benchmark rating of an existing CMMS (Class A, B, C or D) to determine how well this tool is supporting best practices and the total maintenance process. The system is not designed to evaluate or rate levels of CMMS functionality or to compare vendors of various systems (Peters 1999).

The CMMS Benchmarking System can also be used as the process to benchmark the future success of a CMMS system that is now being installed. It can be very easily tailored to include more advanced CMMS functionalities included with a large, multisite installation. By benchmarking an existing CMMS/EAM installation, it can be determined if the operation is receiving the maximum benefits possible from their investment.

The CMMS Benchmarking System includes a total of nine evaluation categories, along with 50 specific evaluation items. The major categories and evaluation items per category are as follows:

Benchmark Evaluation Category	Evaluation Items
CMMM data integrity	6
CMMS education and training	4
Work control	5
Budget and cost control	5
Planning and scheduling	7
MRO materials management	7
Preventive and predictive maintenance	6
Maintenance performance measurement	4
Other uses of CMMS	6
Total evaluation items	50

6.3.2. The CMMS Benchmarking System Rating Process

Each evaluation item that is rated as being accomplished satisfactorily receives a maximum score of 4 points. If an area is currently being ''worked on,'' a score of 1, 2, or 3 points can be assigned, based on the current level of progress being achieved. For example, if spare parts inventory accuracy is 92%, compared to the target of 95%, a score of 3 points is given. A maximum of 200 points is possible. A CMMS rating of ''Class A'' is within the 180–200-point range, or 90% + of total possible points. The complete CMMS Benchmarking rating scale is shown below:

CMMS Benchmarking Rating Scale	
Class A	180–200 points (90% +)
Class B	140–179 points (70%–89%)
Class C	100–139 points (50%–69%)
Class D	0–99 points (up to 49%)

6.3.3. Conducting the CMMS Benchmark Evaluation

The CMMS Benchmark Evaluation can be conducted internally by the maintenance leader or via an internal team effort of knowledgeable maintenance people. Other options include using support from consultants as an independent and objective maintenance benchmarking resource. Used by over 4000 operations, the Tompkins Associates *Scoreboard for Maintenance Excellence has* proven to be today's most comprehensive benchmarking tool for evaluating the total maintenance process. In combination with a complete CMMS Benchmark Evaluation and implementing results from *The Scoreboard for Maintenance Excellence,* maintenance leaders in all types of operations can move toward greater value-added service to the customers of maintenance.

Complete copies of the CMMS Benchmarking System, along with *The Scoreboard for Maintenance Excellence,* are available for download from www.tompkinsinc.com or by calling 1-800-789-1257.

7. A REVIEW OF OTHER SELECTED MAINTENANCE BEST PRACTICES

Previous sections reviewed a number of best practices such as performance-measurement techniques, internal benchmarking, selection of metrics, assessment of the total maintenance operation and CMMS/EAM. This section will review eight more best-practice areas. Readers must remember that the scope of plant and facilities engineering is very broad and technical. The material presented in this chapter is the maintenance management piece; how to lead, manage and control the execution of maintenance. The sciences and technologies that underlie the practice of maintenance are found in publications such as the Maintenance Engineering Handbook (Higgins 1995) and in many other handbooks specifically related to mechanical, electrical and reliability engineering. The following best-practice areas can all contribute significantly to bottom-line results.

7.1. Continuous Reliability Improvement (CRI)

Continuous reliability improvement is the application of the traditional reliability centered maintenance (RCM) processes, using the best from total productive maintenance (TPM) and going beyond

these traditional approaches to include all maintenance resources: equipment/facility, craftspeople/operators, MRO material management, and maintenance information resources. CRI includes effective team processes to create synergy and serve as people asset multipliers. CRI also includes maximizing the capability of the asset through comprehensive asset facilitation.

CRI, developed by Tompkins Associates, is a total maintenance operations improvement process to support the total operation. The CRI approach to leadership driven teams is defined in Tompkins (1998). CRI focuses team processes on continuous reliability improvement opportunities, considering:

- *Physical asset:* Use of reliability improvement technologies; reliability-centered maintenance, preventive/predictive maintenance, and knowledge-based/expert systems for maintenance of the physical asset. Asset facilitation to gain maximum capacity at the lowest possible life-cycle cost.
- *MRO material resources:* Effective maintenance repair operations (MRO) parts, supplies and materials for quality repair with effective storeroom and procurement processes.
- *Information resources:* Quality information resources for maintenance management and control from CMMS, EAM, ERP, vendor and customer.
- *Craft resources:* Quality skill improvement by people assets for the maintenance process to support customer service to the total operation.
- *Operator resources:* The added value of equipment operators instilled with pride in ownership at the most important level—the shop floor.
- *Synergistic team processes* as multipliers of people assets.

7.1.1. Asset Facilitation

This very comprehensive process is a component of CRI. It is conducted for critical assets and, typically, discrete manufacturing equipment. The objective is to maximize the capability of the asset to perform its primary functions. It takes a complete look at the requirements for maintenance, set-up, operations, changeover and shutdown, and documents these into standard operating and maintenance procedures. The results of a typical asset-facilitation process would include the following:

- Development of a quality operations and maintenance guide for the asset that provides complete operating and maintenance guidelines, procedures, and documentation for:
  - Equipment safety and housekeeping requirements
  - Defining operator and extrusion departmental requirements for the 5S Process
  - Defining requirements for subsequent 5S evaluations and ratings
  - Asset documentation references and drawings, either manual or electronic medium, using electronic document imaging capabilities.
  - Preventive and predictive maintenance requirements
  - Setup/validation/changeover/operator inspection procedures
  - Start-up, operating, and shutdown procedures for the asset
  - Quality control requirements
  - Operator-based maintenance (OBM) tasks with details on:
    - Recommended operator-level PM tasks and lubrication services
    - Other well-defined maintenance tasks to be performed by the operators
    - Operator training and certification requirements; production; related tasks
    - Operator training and certification requirements for maintenance related (OBM) tasks
    - Develop visual management to support OBM and production operation tasks
    - Quality requirements for ISO/QS compliance

7.2. Preventive Maintenance

Preventive maintenance is an interval-based surveillance method in which periodic inspections are performed on equipment to determine the progress of wear in its components and subsystems. When wear has advanced to a degree that warrants correction, maintenance is performed on the equipment to rectify the worn condition. The corrective maintenance work can be performed at the time of the inspection or following the inspection as part of planned maintenance. The decision of when to perform the corrective repair related to PM inspections depends on the length of shutdown required for the repair (Tompkins 1998).

Consideration is given to the impact of the shutdown on the operation caused by the repair vs. how immediate is the need for repair. If it is judged that the worn component will probably continue to operate until a future repair can be scheduled, major repairs are postponed until they can be planned and scheduled.

Periodically, a preventive maintenance inspection is made. If the inspection reveals serious wear, some maintenance operation is performed to restore the component or subassembly to a good state of repair, and reduce the probability of failure. A PM system increases the probability that the equipment will perform as expected without failure until the next inspection due date.

Determining the interval between inspections requires considering the history of maintenance for the equipment in each unique operation. Time between PM inspections (intervals) will ultimately be guided by a number of resources. These include manufacturer's recommendations, feedback information from repair history of breakdowns, and the subjective knowledge of the maintenance craftsmen and supervisors who daily maintain the asset. Equipment operators may also be a good source of information in some operations.

A central characteristic of preventive maintenance is that in most major preventive maintenance applications, the asset must be shut down for inspection. For example, a heat exchanger must be shut down and isolated when a nondestructive eddy current inspection is made on its tubes. The inspection process would require a discrete amount of downtime for the unit, which is typical for preventive maintenance.

The loss of operational time when significant preventive maintenance inspections are made is one of the reasons PM programs are often less than successful. This is especially true in applications where there are few redundant units and equipment must operate at 100% of capacity. In some situations the loss form shutdown is considered too high a penalty and preventive maintenance inspections are resisted.

7.3. Predictive Maintenance (PdM)

In contrast to preventive maintenance, predictive maintenance is a condition-based system. PdM measures some output from the equipment that is related to the degeneration of the component or subsystem. An example might be metal fatigue on the race of a rolling element bearing. The vibration amplitude produced by the rolling element as it passes over the degenerating surface is an indicator of the degree of severity of wear. As deterioration progresses, the amplitude of vibration increases. At some critical value, the vibration analyst concludes that corrective action should be taken if catastrophic failure is to be avoided.

Predictive maintenance usually permits discrete measurements that may be trended compared to some predefined limit (baseline) or tracked using statistical control charting. When an anomaly is observed, warning is provided in sufficient time to analyze the nature of the problem and take corrective action to avoid failure. Thus, predictive maintenance accomplishes the same central objective as preventive maintenance (Higgins 1995).

Confidence in the continued on-specification operation of the asset is increased. By early detection of wear, you can plan for and take corrective action to retard the rate of wear or prevent or minimize the impact of failure. The corrective maintenance work restores the component or subassembly to a good state of repair. Thus, the equipment operates with a greater probability of trouble-free performance.

The enhanced ability to trend and plot numbers collected from PdM measurement gives this method greater sensitivity than traditional preventive maintenance methods. The technique yields earlier warning of severe wear and thus provides greater lead-time for reaction. Corrective actions may be scheduled so that they have minimum impact on operations.

A principal advantage of predictive maintenance is the capability it offers the user to perform inspections while the equipment is operating. In particular, in order to reflect routine operating conditions, the technique requires that measurements be taken when the equipment is normally loaded in its production environment. Since the machine does not need to be removed from the production cycle, there is no shutdown penalty. The ability to conduct machine inspections while equipment is running is especially important in continuous operations such as in utilities, chemical, and petrochemical manufacturing.

Another advantage of predictive maintenance is that the cost of surveillance labor is much less than the cost of preventive maintenance activities. Although the technical knowledge required for predictive maintenance inspections is usually higher than that for preventive maintenance, the inspection time required per machine is much less. With predictive maintenance, the machines do not have to be disassembled for inspection. For example, with vibration analysis, 50 to 60 machines may be inspected in a single day using modern computer data collectors. When comparing cost advantages of predictive maintenance over preventive maintenance, consider production downtime costs, maintenance labor costs, maintenance materials costs, and the cost of holding spare parts in inventory.

If predictive maintenance methods are superior to preventive maintenance, why use preventive maintenance at all? The answer is simple. The nature of your operation will determine which methods are most effective. In actual practice, some combination of preventive and predictive maintenance is required to ensure maximum reliability. The degree of application of each will vary with the type of equipment and the percent of the time these machines are operating.

Pumps, fans, gear reducers, other rotating machines, and machines with large inventories of hydraulic and lubricating oils lend themselves to PdM surveillance methods. On the other hand, machines such as those that might be involved in high-speed packaging may be better inspected using traditional preventive maintenance methods. Machines that have critical timing adjustments, which tend to loosen and require precision adjustments, or that have many cams and linkages that must be reset over time lend themselves to preventive maintenance activities.

The strategy for selecting the appropriate or predictive approach involves the following decision process:

- Consider the variety of problems (defects) that develop in your equipment.
- Use the predictive method if a predictive tool is adequate for detecting the variety of maintenance problems you normally experience. One or a combination of several predictive maintenance methods may be required.
- Use preventive maintenance if it is apparent that predictive maintenance tools do not adequately apply. Inspection tasks must be developed that reveal the defects not adequately covered by preventive maintenance.
- After you have decided the combination of inspection methods, determine the frequency at which the particular inspection tasks must be applied.

Some equipment will be satisfactorily monitored using only predictive maintenance. Other equipment will require preventive maintenance. Ultimately, some combination of methods will provide the required coverage for your operation to assure reliable performance. In most operations, it is wise to apply a combination of methods to ensure that equipment defects do not go undetected. The following provides a brief summary of some of the leading predictive maintenance technologies.

7.3.1. Vibration Analysis

Today, electronic instrumentation is available that goes far beyond the human limitations with which the old time craftsmen had to contend when trying to interpret vibration signals with a screwdriver-handle-to-the-ear method. Today's instruments can detect, with accuracy and repeatability, extremely low-amplitude vibration signals. They can assign a numerical dimension to the amplitude of vibration and can isolate the frequency at which the vibration is occurring. When measurements of both amplitude and frequency are available, diagnostic methods can be used to determine the magnitude of a problem and its probable cause. When you use electronic instruments in an organized and methodical program of vibration analysis, you are able to:

- Detect machine problems long before the onslaught of failure
- Isolate conditions causing accelerated wear
- Make conclusions concerning the nature of defects causing machine problems
- Execute advance planning and scheduling of corrective repair so that catastophic failure may be avoided
- Execute repair at a time that has minimum impact on operations

7.3.2. Shock Pulse

Shock pulse is a method of surveillance that is specific to rolling element bearings. Since rolling element bearings (sometimes referred to as antifriction bearings) are so common in machines, the method has many applications. A secondary but important feature of the shock pulse method is that it permits maintenance workers to judge the adequacy of the lubrication program applied to this type of bearing.

7.3.3. Spectrometric Oil Analysis

Oil in machines carries the products of deterioration resulting from wear and mechanical failure. Analyzing the oil resident in a machine or the debris the oil carries allows predictions to be made about the state of health of the machine. The critical measurement reflecting the condition of machine wear is the number of microscopic metal wear particles that are suspended in the oil system of the machine. The spectrometric oil analysis process is a laboratory technique that uses various instruments to analyze a used oil sample from a machine. The spectrometric result is compared to a baseline level of metal found to be typically suspended in the oil under normal operating conditions. When the wear is meaningful, the sample will show high levels (in parts per million) of wear metals compared to the baseline oil sample.

7.3.4. Standard Oil Analysis

In addition to the spectrometric analysis, the oil laboratories also check the oil using common oil-analysis techniques. For example, the oil is usually checked for viscosity. Other types of standard oil analysis might include total acid number, percent moisture, particle count (for hydraulic systems), total solids, or percent silicon (representing dirt from the atmosphere in the form of silicon dioxide or perhaps just from an additive).

7.3.5. Ferrographic Oil Analysis

Ferrography provides the maintenance manager with two critical sets of decision support information: condition monitoring, which prevents unnecessary maintenance, and precise trend information, which allows maintenance to initiate repairs before equipment failure. This is accomplished by the analysis of wear particles in lubricants to determine their size, distribution, quantities, composition, and morphology (form and structure).

Ferrography is a technique that provides microscopic examination and analysis of particles separated from fluids. Developed in the early 1970s as a predictive maintenance technique, it was initially used to precipitate ferrous wear particles from lubricating oils magnetically. This technique was used successfully to monitor the condition of military aircraft engines. That success has led to the development of other applications, including testing of fluids used in vacuum pumps within the semiconductor industry.

7.3.6. Infrared Thermography

The use of infrared thermography has grown significantly in the past 10 years. Equipment is easier than ever to use and more effective. The real power of thermography is that it allows quick location and monitoring of problems. It then presents critical decision-making information in *visual* form, making it easy for management to understand. Infrared imaging systems, as they are generally called, produce a picture, either black and white or color, of the invisible thermal patterns of a component or process. These thermal patterns, when understood, can be used to monitor actual operating conditions of equipment or processes.

For instance, viewing a thermogram (heat picture) can clearly show the heat of a failing bearing or a pitted contact on a disconnect switch. Today's sophisticated imaging equipment is capable of acquiring a thermal video. This allows us to see *dynamic* thermal patterns of a casting process or a belt wear pattern in real-time, for instance. When teamed with the power of computer-based analysis systems, it can go one step further to compare and trend the critical thermal changes that often precede equipment failure or loss of production quality.

Thermography can be used to quickly locate and prevent recurrence of many equipment and process problems, such as:

- Catastrophic electrical failures
- Unscheduled electrical outages or shutdowns
- Chronic electrical problems in a piece of equipment or process
- Excessive steam usage
- Frozen or plugged product transport lines
- An inability to predict failures accurately
- Inefficient use of downtime maintenance opportunities
- Friction failures in rotating equipment
- Poor product quality due to uneven heating or cooling or moisture content
- A fire in a wall or enclosed space
- Inability to locate or verify a level in a tank
- Replacement of refractory in a boiler, furnace, or kiln
- A leaking flat roof
- Uneven room temperatures affecting product quality or employee productivity
- Trouble locating underground water, steam, or sewer lines

7.3.7. Ultrasonic Detection

A variety of tools using airborne ultrasound technology (commonly called ultrasound) have revolutionized many maintenance programs, allowing inspectors to detect deteriorating components more accurately before they fail. Ultrasound, by definition, is beyond the limits of normal human hearing, so an inspector uses a sophisticated detector to transpose ultrasonic signals to the range of human hearing.

Fluid and gas systems and other working machinery have constant ultrasound patterns. Changes in the ''sonic signatures'' can be recognized as wear in components. An ultrasonic detector senses such subtle shifts in the signature of a component and pinpoints potential sources of failure before they can cause costly damage.

7.4. Maintenance Storeroom Operations and MRO Materials Management

Maintenance repair operations (MRO) parts, materials, and supplies are the key material resources necessary for the execution of the maintenance process. Often the physical storage, control, and procurement of MRO items is never recognized for its value to the total operation. The effective operation of a maintenance storeroom is a cornerstone for maintenance excellence, but it is often a neglected area for management attention.

Best practices for maintenance storeroom operations parallel those for a finished goods warehouse in some cases but nonetheless are distinctively different. For more information on storage and warehousing, material and information handling systems, and warehouse management, readers should also refer to the respective chapters for these best practices that have general application to the maintenance storeroom operation. The following key strategies should be applied to the maintenance storeroom operation (Newhouse 1999):

- *Professionalism:* The company needs to view the maintenance storeroom as an important activity and not as a necessary evil. Both the dollars invested in maintenance storeroom materials and the impact of downtime have highlighted the need for a more professional approach to maintenance storerooms.
- *Customer awareness:* Successful maintenance storerooms will have a high regard for the customer, will know the customer requirements, and will consistently meet these requirements. The right materials will be available at the right time, in the right quantity, at the right location.
- *Measurement:* The maintenance leader will establish storeroom standards, performance will be measured against these standards, and timely actions will be taken to overcome any problems. Performance reports will be distributed to management on a monthly basis.
- *Operations planning:* Systems and procedures will be put into effect that allow the storeroom manager to plan the storeroom operations proactively as opposed to responding reactively to external circumstances.
- *Materials planning:* Systems and procedures will be put into effect that will assure having the right materials on hand in the right quantity at the right time. The materials-planning systems will provide for good inventory rotation, a minimum of stock outs, the elimination of obsolete materials, and the addition of new items, when new equipment and systems are installed.
- *Centralization:* The trend will be towards larger, centralized storerooms with responsive material-delivery systems instead of smaller, decentralized storerooms to which people travel and where they wait for required materials.
- *Adaptability:* Maintenance storeroom facilities, operations and personnel must become more adaptable. The pace of the storeroom will continue to increase: reduction of lead times, shorter equipment lives, increased inventory turns, more SKUs, and more customer demands require that storeroom adaptability be present to satisfy customers.
- *Uncertainty:* All uncertainty must be minimized; all interactions with the maintenance storeroom must be based on meeting expectations. No surprises.
- *Integration:* The activities within the maintenance storeroom will be integrated (from storeroom item identification to item issue), and the maintenance storeroom will be more integrated with the overall organization.
- *Material control:* Maintenance storeroom facilities, procedures, and systems will be designed to provide for the control of all materials. The importance and enforcement of maintenance storeroom security will be widely understood and accepted.
- *Maintenance information system:* The maintenance information system will support exceeding customer expectations. The information system will include the maintenance catalog system and the management of inventory.
- *Inventory accuracy:* Cycle counting will be used to manage inventory accuracy, and accuracy above 98% will be the norm.
- *Space utilization:* Space will be more efficiently and effectively utilized.
- *Housekeeping:* Quality housekeeping will be a priority. There will be an acceptance of that fact that there is efficiency in order.
- *Human resources:* A priority in the maintenance storeroom will be establishing a positive culture and the training and education required to achieve quality maintenance.

- *Team players:* Everyone associated with the maintenance storeroom and MRO procurement functions within the organization must be integrated into a single service-providing activity.

7.4.1. Storeroom Inventory Management

It is also important to establish an inventory planning methodology. As part of this, a determination must be made of what to stock, what the inventory policy will be, and how the inventory will be managed. A bar coding system could be just the solution for improving accountability and accuracy. This would be just one part of a strategic plan to introduce many new technologies for a major upgrade of the maintenance storeroom.

Inventory accuracy is a must for a maintenance storeroom. It must have 98% or better accuracy. If not, the craftspeople will bypass the storeroom to order a new part. It is critical that they have confidence in the accuracy. In order to attain this level of accuracy, it is necessary to cycle count. Timely detection of errors and correction of causes for the errors are essential to good control. All storerooms must have a proper cataloging system as a permanent record of all storeroom items and as a tool for identifying and locating items.

A maintenance storeroom strategic master plan is a prerequisite for success. There is efficiency in order. We must know what is to be done and what is the proper order to do it. It all starts with a plan, and successful planning requires teamwork.

7.5. Planning and Scheduling

Planning for maintenance excellence requires planning at the strategic level and the shop-floor level. This section introduces the need for implementing the maintenance best practice for planning and scheduling at the operational, shop-floor level. Surveys consistently show that only about 30–40% of an eight-hour craft day is devoted to actual hands-on wrench time. Without effective planning and scheduling, maintenance operations continue to operate in a reactive, fire-fighting mode, wasting their most valuable resource: craft time. Gambling with maintenance costs is not an option for today's organization that wants long-term survival and profitability. Achieving world-class status requires a world-class maintenance operation. World-class maintenance requires strategic planning, especially at the shop-floor level. The effective planning and scheduling of the most valuable maintenance resource, craft skills and labor, can provide an important step forward in a strategic maintenance plan.

Effective planning and scheduling improves the overall craft effectiveness (OCE) factor, which focuses upon measuring and improving the value-added contribution that people assets make to total asset management. There is also a very real concern within many areas of the United States and the world about the availability of craft skills. Technical resources and craft skills are terrible things to waste because they are so hard to find and keep. A review of the three key elements for measuring OCE shows how they very closely align with the three elements for determining the OEE factor for equipment assets.

7.5.1. The Overall Craft Effectiveness (OCE) Factor

Measuring and improving overall craft effectiveness (OCE) is one of the key benefits from maintenance planning and scheduling. The OCE factor includes three key elements very closely related to the three elements of the OEE factor.

Overall Craft Effectiveness (OCE)	Overall Equipment Effectiveness (OEE)
Craft utilization (CU)	Availability/utilization
Craft performance (CP)	Performance
Craft methods and quality (CM&Q)	Quality

7.5.1.1. Craft Utilization The first element of the OCE Factor is craft utilization, which measures how *effective* we are in planning and scheduling craft resources so that these assets are doing value-added, productive work. Craft utilization is about wrench time. Effective planning/scheduling within a proactive maintenance process is key to increased wrench time and craft utilization. It's having the right part at the right place in time to do scheduled work with minimal nonproductive time on the part of the craftsperson or crew assigned to the job. Craft utilization is expressed simply as the ratio of:

$$\text{CU\%} = \frac{\text{total productive (wrench time)}}{\text{total craft hours available/paid}} \times 100$$

Improving craft utilization provides additional craft capacity in terms of total productive craft hours available It is gained value and additional equivalent hours that can be used to reduce overtime, devote to PM/PdM, reduce the current backlog, and attack deferred maintenance, which doesn't go away.

Even if an operation does nothing to improve the other two elements of OCE (craft performance and the craft methods and quality level), significant tangible benefits can be realized with improving wrench time and craft utilization. An improvement of from 20–30% in craft utilization can typically be expected from effective maintenance planning and scheduling.

For the 30-person craft workforce, operating at 40% craft utilization, a 10% gain in wrench time hours represents a 25% increase in craft labor capacity from baseline performance. With only a 10% increase in craft utilization for a 30-person craft workforce, more than a 5:1 return can be achieved to offset a maintenance planner position, and implementation of planning and scheduling.

7.5.1.2. Craft Performance The second key element affecting overall craft effectiveness is craft performance. This element relates to how *efficient* we are in actually doing hands-on craftwork when compared to an established planned time or performance standard. Craft performance is directly related to the level of individual craft skills and overall trades experience, as well as the personal effort of each craftsperson or crew. Effective craft skills training and technical development contribute to a high level of craft performance. Craft performance (CP) is expressed as the ratio of:

$$\text{CP\%} = \frac{\text{total planned time (hours)}}{\text{total actual craft hours required}} \times 100$$

An effective planning and scheduling function requires that reasonable estimates and planning times be established for as much maintenance work as possible. Since maintenance work is not highly repetitive, the task of developing planning times is more difficult. However, there are a number of methods for establishing planning times for maintenance work, as outlined in Section 5.

Planning times are essential. They provide a number of key benefits for the planning function. First, they provide a means to determine existing workloads for scheduling by craft areas and backlog of work in each area. Planning times allow the maintenance planner to balance repair priorities against available craft hours, and to establish repair schedules realistically that can be accomplished as promised. Secondly, planning times provide a target or goal for each planned job, that allows for measurement of craft performance. Here we are not as concerned with measuring individual craft performance but rather with the overall performance of the craft workforce as a whole. Individual craft performance can be determined by comparing the group performance to individual performance over a period of time. Training needs are normally identified when individual craft performance is consistently below the group norm.

7.5.1.3. Craft Methods and Quality Level The third element affecting overall craft effectiveness relates to the relative level of the methods being used, considering personal and shop tools, special shop equipment, shop work areas, repair methods, and so on, as compared to current state-of-the-art methods. This element can include call-backs, where the poor quality of the initial repair requires another trip to fix it right the second time. Typically, the CM&Q element is a more subjective value, and is not determined based on actual data such as craft utilization and performance. However, the craft methods and quality level do affect overall craft labor productivity. The overall craft effectiveness factor is determined by multiplying each of these three elements:

$$\text{OCE} = \underset{\text{craft utilization}}{\text{CU\%}} \times \underset{\text{craft performance}}{\text{CP\%}} \times \underset{\text{craft methods and quality level}}{\text{CM\&Q\%}}$$

Due to the subjective nature of determining the value of craft methods and quality, this element is typically not used, but it is still an important part of effective planning and scheduling. One key part of planning is determining the scope of the repair job and the special tools or equipment that might be required. A continuing concern of the maintenance planning function should be on improving existing repair methods, whether by using better tools, repair procedures, or diagnostic equipment. Providing the best possible tools, special equipment, shop areas, and repair procedures is a key contributor to improving craft performance and craft morale. It should be recognized that the value for craft methods and quality is subjective. The overall craft effectiveness Factor is best determined by:

$$\text{OCE} = \text{craft utilization} \times \text{craft performance}$$

7.5.2. Getting Started with Planning and Scheduling

Select from within the maintenance workforce the best-qualified candidate possible. Normally 1 planner per 25–30 craft personnel is sufficient. The planner position requires knowledge of existing equipment repair needs and a strong craft skill background. It also requires new skills for planning/scheduling, estimating, parts coordination, computer use, personal relations, customer service, and so on. Sufficient time must be invested in formal training of the planner(s), and for on-the-job training to get the planning function off to a smooth start. Since the planning function is often the focal point for successful CMMS utilization, planners must understand all functions of the CMMS and be capable of helping to train others in the organization.

7.5.3. Focus on Customer Service

The ultimate success of maintenance planning and scheduling will be determined by whether or not the customer is satisfied. All preliminary work to develop a plan and coordinate the scheduled repairs is wasted if execution of the schedule does not occur as promised. The customer (operations) will determine the true success of the planning process. The entire maintenance workforce must understand their service role to operations. As a formal planning process is implemented, an increased focus on customer service must be established. Operations will expect better service and maintenance must commit to providing it.

7.5.4. Measure Effectiveness of the Planning Function

The planning function should provide the focal point for measuring overall maintenance performance. However, the measurement process should start within the planning function. Planning requires an investment in staff resources. Develop and use performance measures to evaluate the return on investment and the effectiveness of the planning function.

7.6. Reliability-Centered Maintenance

7.6.1. The Evolution of Reliability-Centered Maintenance

In the early 1960s, the developmental work for reliability-centered maintenance was done by the North American civil aviation industry. During that period, the airlines began to see that many of their maintenance philosophies were not cost effective. But most importantly, they did not achieve the best possible conditions for safety. The airline industry then put together a series of Maintenance Steering Groups (MSGs) to reexamine all aspects of their aircraft maintenance operation. Representatives from the aircraft manufacturers, the airlines, and the Federal Aviation Authority were members of the MSG team. The Air Transport Association completed the first attempt at formulating maintenance strategies in 1968. Known as MSG 1, this document was later refined to MSG 2 in 1970.

In the mid-1970s, the U.S. Department of Defense commissioned a report by Stanley Nowlan and Howard Heap of United Airlines (Nowlan and Heap 1978) to define state-of-the-art strategies for maintenance within the airlines industry. It is still one of the most important documents in the history of physical asset management.

A considerable advance in thinking, well beyond MSG 2, was achieved in Nowlan and Heap's report. It was used as a basis for MSG 3 in 1980, which was revised in 1998 (Rev 1) and in 1993 (Rev 2). It is still used to develop prior-to-service maintenance programs for new aircraft types such as the Boeing 777 and the Airbus 330/340.

Nowlan and Heap's report and MSG 3 have since been used as a basis for various military RCM standards and for nonaviation-derivative programs with acronyms such as FMECA, MSG3, TPM, RCA, RBI, and RCM2. Continuous reliability improvement (CRI), developed by Tompkins Associates, uses the best from RCM, TPM and the total operations approach to leadership-driven teams, as defined in Tompkins (1998).

7.6.2. Overview of the RCM Process

The key elements of the RCM process include the following:

- Analysis and decision on what must be done to ensure that any physical asset, system, or process continues to do whatever its users want it to do. Includes essential information gathering.
- Define what users expect from their assets in terms of primary performance parameters such as output, throughput, speed, range, and carrying capacity.

- As applicable, the RCM 2 process defines what users want in terms of risks, process and operational safety, environmental integrity, quality of the output, control, comfort, economy of operation, customer service, etc.
- Identify ways in which the system can fail to live up to these expectations (failed states) and failure consequences.
- Conduct failure modes and effects analysis (FMEA) to identify all the events that are reasonably likely to cause each failed state.
- Identify a suitable failure management policy for dealing with each failure mode in the light of its consequences and technical characteristics. Failure management policy options include:
  - Predictive maintenance
  - Preventive maintenance
  - Failure finding
  - Changing the design or configuration of the system
  - Changing the way the system is operated
  - Run-to-failure (if preventive tasks not found)

7.7. Total Productive Maintenance

Total productive maintenance (TPM) is a maintenance-improvement program concept and philosophy that resembles total quality management (TQM). The TPM movement has excellent objectives:

- Zero unplanned downtime
- Zero defects
- Zero machine capacity losses
- Zero accidents
- Minimum life-cycle asset care cost

It requires a total commitment to the program by upper-level management and employees to be empowered to initiate corrective action. It is a long-term strategy, so a long-range outlook must be accepted. TPM may take more than a year to implement and is an ongoing process. Changes in employee mindset toward their job responsibilities must take place as well. TPM brings maintenance into focus as a necessary and vitally important part of the business. It is no longer regarded as a nonprofit activity.

To successfully apply TPM concepts to plant maintenance activities, the entire workforce must first be convinced that upper-level management is committed to the program. Typically, a TPM coordinator is hired or recruited to sell the TPM concepts to the workforce through an extensive training program. To do a thorough job of educating and convincing the workforce that TPM is just not another ''program of the month'' will take time, perhaps a year or more. Once the coordinator is convinced that the workforce is sold on the TPM program and that they understand it and its implications, the first study and action teams are formed. These teams are usually made up of people who directly have an impact on the problem being addressed. Operators, maintenance personnel, shift supervisors, schedulers, and upper management might all be included on a team. Each person becomes a stakeholder in the process and is encouraged to do his or her best to contribute to the success of the team effort. Usually, the TPM coordinator heads the teams until others become familiar with the process and natural team leaders emerge. The action teams are charged with the responsibility of pinpointing problem areas, detailing a course of corrective action, and initiating the corrective process. Recognizing problems and initiating solutions may not come easily for some team members. They will not have had experiences in other plants where they had opportunities to see how things could be done differently. In well-run TPM programs, team members often visit cooperating plants to observe and compare TPM methods and techniques and to observe work in progress. Publicity of the program and its results is one of the secrets of making the program a success. The initial stages of TPM will include taking the machine out of service for cleaning, painting, adjustment, and replacement of worn parts, belts, hoses, and so on. As a part of this process, training in operation and maintenance of the machine will be reviewed. A daily checklist of maintenance duties to be performed by the operator will be developed. Factory representatives may be called in to assist in some phases of the process. After success has been demonstrated on one machine and records begin to show how much the process had improved production, another machine is selected, then another, until the entire production area had been brought into a world-class condition and is producing at a significantly higher rate. This is one of the basic innovations of TPM. The attitude of ''I just operate it!'' is no longer acceptable. Routine daily maintenance checks, minor adjustments, lubrication, and minor parts

change become the responsibility of the operator. Extensive overhauls and major breakdowns are handled by plant maintenance personnel, with the operator assisting in some cases.

7.8. Operator-Based Maintenance

Pride in ownership and the process of operator-based maintenance started early in American history. It is also a key element of TPM called autonomous maintenance. Operator-based maintenance is also a key element in the very successful and effective maintenance program of the U.S. armed services.

Operator-based maintenance began with the entrepreneurial spirit of the cottage industry in the U.S. free enterprise system. In most cases, the owners fixed the sawmills, the cotton gins, the printing presses, and the wagon wheels. Owners were the skilled crafts people working within a free enterprise culture and system. For many Americans, OBM started with Henry Ford's Model T, which came with tools—a crescent wrench, slip-joint pliers, screwdriver, and hammer, and so on—for the do-it-yourself repairs.

Early American culture did not normally employ the philosophy of "I own—you fix—you operate." Back then it was an attitude of "We are all responsible for the equipment." However simplistic it may have been prior to the industrial revolution, it was a matter of necessity and survival, just as it is in a combat zone.

Ironically, we have returned to the world-class attitude toward maintenance in many organizations, that being "We are all responsible for our equipment." The key word in the TPM world-class attitude is "our": *our* equipment, not *the* equipment. These objectives can and will be achieved in varying degrees for organizations that include OBM as part of the total operations/maintenance strategy. The following is a basic strategy for developing successful operator-based maintenance:

- Start with an overall strategic maintenance plan, and include defined goals/objectives for OBM within this plan.
- Understand that OBM is a deliberate process for gaining commitment by operators toward:
  - Keeping equipment clean and properly lubricated
  - Keeping fasteners tightened
  - Detecting symptoms of deterioration
  - Providing early warning of catastrophic failures
  - Making minor repairs and being trained to do them
  - Assisting maintenance in making selected repairs
- Start with the first things first. Provide the necessary communication between maintenance operations and the rest of the total operation to gain the commitment and internal cooperation needed to start OBM.
- Clean the equipment to like-new condition, make minor repairs, and develop a list of major repairs for the future.
- Utilize leadership-driven, self-managed teams with whatever team names that evolve. For example, "equipment improvement team," "SWAT Team," or "continuous reliability improvement team."
- Develop a written and specific team charter.
- Avoid use of self-directed teams with no technical leadership "driver" for the process.
- Have teams evaluate/determine the best methods for operator cleaning, lubrication, inspection, minor repairs, and level of support during major maintenance repairs.
- Develop standard written OBM procedures for operators and include them in the quality operations and maintenance guide.
- Evaluate your current predictive and preventive maintenance procedures and include those that the operator can do as part of OBM.
- Document start-up/operating/shut-down procedures along with set-up/changeover practices.
- Consider quality control and safety requirements.
- Document operator training requirements and what maintenance must do for support.
- Develop operator certification to validate operator-performed tasks.

There are many organizational roadblocks to effective OBM. However, the roadblocks to the world-class attitude "We are all responsible for our equipment" exist only by self-imposed limitations we create by our attitude toward maintenance.

8. MAINTENANCE MANAGEMENT FOR THE NEW MILLENNIUM

A number of positive trends will occur within maintenance operations of the future. Just as the last 10 years of the 20th century saw extraordinary technological advances related to the physical asset,

the use of CMMS/EAM, and the use of the computer and the Internet, the new millennium will see extraordinary advances. There will be a positive revolution within maintenance management, based upon four key principles from Tompkins (1998):

1. "Revolution is never a spur-of-the-moment decision. It is a process, and in a true scenario, a continuous process." Continuous reliability improvement and leadership-driven, self-managed teams will enhance the application of emerging new technologies.
2. "Although revolution is a grassroots effort, it is characterized by its leaders." Maintenance leaders will emerge to support the continuous improvement process at the grass-roots, shop-floor level. There will be a progression from maintenance manager to true maintenance leadership.
3. "A revolution cannot be managed, it must be led." An individual who is profit-centered yet understanding of the fact that people assets are the most important assets will lead new millennium maintenance. The evolution of a chief maintenance officer (CMO) will occur in both large and small operations. Successful maintenance leaders will be profit centered, establish strategic maintenance plans that are integrated with the business plan, and validate return on investment with effective measurement processes.
4. "A Revolution cannot be carried out by individuals, it must be a collaborative effort." The maintenance leader of the new millennium will recognize needs of the customer, serve the customer, and bring together all maintenance resources to maximize the value of maintenance. The synergistic effect of teams and collaborative interactions among individuals will be an additional resource and measurable gain in productivity.

8.1. The Emergence of the Chief Maintenance Officer (CMO)

The chief maintenance officer (CMO) will emerge as a recognized corporate leadership position. The CMO (or an equivalent) will be absolutely essential for long-term profitability in the new millennium and will eventually evolve into a recognized corporate position. The CEO/COO of a multisite operation that does not have a CMO accountable for physical asset management will be gambling with stockholder's equity. The small single-site operation without a CMO equivalent will realize the high cost of bad maintenance. The CEO must understand the state of maintenance in the operation and the physical asset management process. The emerging CMO with profit ability and effective leadership and technical skills will facilitate this process in larger multisite operations. The future capable company will require a proactive, capable CMO just as it needs a CFO, CIO and CEO.

8.2. Growth of Reliability-Improvement Technologies

New reliability-improvement technologies will continue to evolve and greater use of existing tools will occur. Greater use of radio frequency (RF) technology to support condition-based monitoring will occur. RF technology will enable mobile, timely, and vital communications with the mobile workforce of craftspeople.

Process-control systems will become more integrated with condition-based monitoring systems that in turn link to CMMS/EAM systems or even back to the condition-based equipment suppliers for real-time troubleshooting. Condition-based monitoring systems will eventually link data collection directly back to suppliers such as CSI, ENTEK, SKF, and others via the Internet or RF. Reliability data analysis by off-site reliability experts providing contract services will be as close as e-mail.

Information technology for the life-cycle information loop will be available. for critical assets from the internet, Intranets, and real-time data collection. The result will be "real information" on the shop floor. Information will be available to take life-cycle costing, equipment design/redesign, reliability improvement, and execution of maintenance to new levels. The craftsperson doing the repair will be in the life-cycle information loop with the OEM, subsystem and MRO providers, the asset designers, local engineering, the local asset-documentation sources, and the customers of maintenance.

A new generation of handheld computers, personal digital assistants (PDAs), and smart phones give the craftspeople their own terminal and will link them firmly to the network. Advances in voice recognition will make data collection on the shop much easier. All the necessary components are falling into place: price, performance, and communications. Since these devices are Internet capable, they will be much easier to integrate into a Web-based EAMS/CMMS package than earlier generations of handheld computers that required proprietary software.

8.3. The Role of the Internet

The use of the Internet will expand exponentially. Client/server solutions that became main stream in the 1990s have their drawbacks. From an IT standpoint, their "thick" client software is costly to deploy and support. They are difficult to integrate with other external applications. Their client software also tends to run on only one type of device, a desktop PC. Using development tools like

Java, software vendors are starting to provide solutions featuring ''thin'' client software or web browsers as their front end. These solutions draw their application services from centralized servers instead of megabytes of software installed on the desktop. Since they utilize the Web as a transport medium, they are much easier to integrate with the outside world. They can also support nondesktop PC devices such as handheld PDAs.

The top-tier EAMS/CMMS vendors will complete the process of developing new versions of their software, featuring a Web-centric architecture. Most of the industry will follow their lead in the coming years. They will do so because of the benefits that the technology has to offer.

8.4. MRO Materials Management

E-commerce will continue to expand, and direct links to the overall supply chain will enhance procurement of MRO parts/materials and services. E-procurement over the Internet with electronic purchasing is just too cost effective for both buyers and suppliers for it not to become the dominant MRO procurement method.

An integrated MRO supply chain management process began with MRO vendor websites as the start of this process. The creation of large trading networks of hundreds of vendors and the provision of EAMS/CMMS packages access to these networks will complete the equation. True point-and-click MRO purchasing, from requisition generation to order fulfillment, is going to be commonplace in both large and small organizations. Top-tier EAMS/CMMS vendors are now releasing e-procurement solutions and developing or joining the trading networks (Singer 2000).

8.5. The Growth of Contract Maintenance

Contract maintenance will continue to grow. The core requirement for maintenance will be even more important in the next millennium due to technology advances. Organizations will focus on core competencies. Some forget the core requirement for maintenance and also lose their core competencies to do effective maintenance. Profit-centered contract maintenance providers will consume internal maintenance operations that continue a cost-centered approach. In-house maintenance operations will continue to lose when they are unable to replenish and/or maintain their core competencies in maintenance.

Maintenance is forever. Maintenance of our bodies, minds, souls, cars, and computers and all physical assets providing products or services in today's global economy will always be required. Some organizations today have neglected maintaining their core competencies in maintenance to the point that they have lost complete control. The core requirement for good maintenance remains (forever), but the core competency to do good maintenance may be missing. In some cases, the best, and often only, solution is value-added outsourcing.

The neglect of the past and the future will be overcome by services from a growing number of profit-centered maintenance providers that clearly understand how to provide value-added maintenance service at a profit. Neglect of the past can also be overcome internally by the emergence of an internal CMO who can lead maintenance forward to profitability as if he or she owned the internal maintenance business.

9. CONCLUSION

This chapter helps to provide a firm understanding of the physical asset management and maintenance process and its important role. The contribution of maintenance to total operations success and profitability is now being more fully recognized. Effective maintenance and physical asset management are closely linked to enterprise wide performance success and profitability.

This chapter presented the 25 key requirements for maintenance success, as well as a review some of today's best maintenance practices. It outlined how the results of continuous maintenance improvement can be measured, reviewed methods for measurement, and showed how results and ROI can be validated.

There are many IE principles and practices that can support maintenance process improvement. The new and experienced IE, the engineering manager, the operations manager, and the CEO can now better understand the maintenance operation and how to improve mission-essential maintenance operations. The next step is to take action on the journey to maintenance excellence.

1. INTRODUCTION

The design and improvement of the performance of manufacturing and service systems requires that we have efficient ways by which we can (1) predict the performance of the systems and (2) identify the effects of key design parameters on the system performance. Manufacturing and service systems have to cope with a wide range of variability, uncertainty, and disturbances. Different customers require different tasks to be performed, people and machines can vary in their time to perform standardized tasks, machines can break down unexpectedly, repair can prove more complicated than anticipated. So we need approaches to predicting the performance that take into account this uncertainty and variability and also help us reduce their adverse impacts. Queueing models are particularly useful in describing variability and predicting its impact on performance. This chapter contains an overview of the key models that are relevant to analysis of manufacturing and service systems. The focus of these models is on predicting throughput, inventory levels, queue lengths, and service levels after allowing for disturbances such as machine breakdowns, human operator performance variability, and quality problems.

Queueing models can be used at the system-design stage to rapidly explore alternatives and see the sensitivity to parameter values. The models can also be of great value in assessing the performance of systems once they are installed because they enable the sources of loss of productivity to be

identified. Models provide understanding and insights of complex production systems and enable one to obtain answers to a variety of ''what-if'' questions with little effort.

Our focus in this chapter will be on manufacturing and service systems where each job or customer is distinct. Most service systems have to deal with the requirements of individual customers. In manufacturing, each job is distinct in the mechanical, electrical, and electronics industries making products such as cars, refrigerators, electric generators, and computers. Systems that process fluids, like those found in the chemical and metallurgical industries, will not be considered, although sometimes in these industries fluids are processed in distinct batches or packets and, if such a packet is taken as the unit of manufacture, then the system can be considered to process discrete jobs. For simplicity, we will call an item, part, subassembly, or assembly processed by a machine or workstation in manufacturing a *job.* In service applications, we will call each order or person a *customer.*

While each job or customer is distinct, different jobs or customers can be in all respects identical and in particular have the same processing requirements. If the system only processes one type of job or customer, then some aspects of its design and operation will be simplified because all jobs or customers can then be handled the same way. However, if the system processes many different types of jobs or customers, instructions for each type will be required and control will tend to be more complex. Particularly in service systems, it is often not known what the processing requirements of a customer will be until after the customer arrives and some diagnosis can be carried out. Even in manufacturing, quality problems can result in the processing requirements of a job changing after processing has begun. Models have to be able to represent this evolution of knowledge about processing requirements and how the information is used to modify instructions on what has to be done.

1.1. Models

Traditionally, manufacturing and service system designers relied on experience and rules of thumb in order to identify the effect of design parameters on the performance. However, the increasing cost and complexity of modern systems, and the often lengthy time required to bring them up to their designed performance targets, have resulted in designers using formal models of the system to assess performance.

1.1.1. Basic Approach to Modeling

The process of modeling involves the following steps:

1. *Identifying the issues to be addressed:* Ascertain the needs of the user. What decisions is the model required to support? These can range from the very specific, such as how large a specific storage location should be, to the somewhat vague, such as whether it is possible to identify when a particular way of operating the system is optimal.
2. *Learning about the system:* Identify the components of the system, such as the people, machines, material handling, storage and the data collection and control system. Determine the characteristics of the jobs or customers and the target volumes, quality, and cost. This step can involve close contact with the system designers and a review of any existing models to identify their capability and their shortcomings.
3. *Choosing a modeling approach:* Various types of modeling approaches can be used, ranging from formal mathematical models through computer simulations to the development of a ''toy'' system in which toy parts or people physically move from one toy machine to another. The choice of modeling approach is determined by the time and cost budget for model development and the anticipated way in which the model will be used.
4. *Developing and testing the model:* This step requires obtaining data on the parameters of the model, and often the lack of desirable data forces the model to be substantially simplified.
5. *Developing a model interface for the user:* If the model is to be of value in making decisions, it has to be provided with some interface so that it can be used by managers. This requires the modeler either to embody the model in a decision support system or to present the model and its implications in a way that managers can understand.
6. *Verifying and validating the model:* The model has to be checked to see that it is a reasonably correct representation of the reality it seeks to represent. Verification is the process of ensuring that the model results are correct for the assumptions made in developing the model. Validation is the process of ensuring that the model is an accurate representation of the real system. This may also involve convincing the user that the model is adequate for the decision he or she requires it to support.
7. *Experimenting with the model:* This requires exploring the impact of changes in model parameters and developing understanding of the factors influencing performance of the system so that the manager can be confident in the decisions made using the model.
8. *Presenting the results:* Using the model, the manager should come up with a recommended course of action. This recommendation may have to be presented to higher-level management

and the role of the model in aiding the decision explained. Alternatively, the model and the results of its use will be presented in a report or paper that, apart from describing the model itself, should explain what the model can do, what it cannot do, and how accurate are its predictions.

1.1.2. Types of Models

For systems processing discrete jobs or customers, there are three types of models in common use:

Physical models represent the real system by another physical system, in which jobs or customers move from one machine or service center to another and the machines or service centers perform processing operations on the jobs or customers. The major difference to the real system is that the model uses a different dimensional scale, so a large system will occupy a table top. Physical models can use toy-sized components, but they can be provided with a control system that employs the same logic as the real system. Physical models are excellent as a means of educating management and workers about the control of the system, but they do not lend themselves for assessing the long-run behavior of the system, as it is difficult to represent the statistical properties of events such as machine failures or worker absenteeism.

Simulation models represent the events that could occur as a system operates by a sequence of steps in a computer program (see Chapters 93–96). This means that the logical relationships that exist between events can be described in detail. The probabilistic nature of many events, such as machine failure, can be represented by sampling from a distribution representing the pattern of occurrence of the event, for example, the distribution of the time between machine failures. Thus, in order to represent the typical behavior of the system, it is necessary to run the simulation model for a sufficiently long time that all events can occur a reasonable number of times. Simulation models can be provided with an interactive graphic display to demonstrate the movement of jobs or customers. This can be of great value in communicating the assumptions of the model to engineers and others.

Analytical models describe the system using mathematical or symbolic relationships. These are then used to derive a formula or define an algorithm or computational procedure by which the performance measures of the system can be calculated. Analytical models can also be used to demonstrate properties of various operating rules and control strategies. Sometimes it is not possible, within a reasonable amount of computer time or space, to obtain the performance measure from the relationships describing the system without making further assumptions that modify these relationships. The resulting model is thus approximate rather than exact. Testing the approximation may then require a simulation model, so approximate models are useful only if they are easy to use and provide insight into what determines the system behavior.

1.1.3. Why Model?

Models can be developed for a variety of reasons, in particular:

- *Understanding:* The model is used in order to explain why and how. The model is intended to convey insight. Sometimes the model just indicates the direction of influence of some variable on performance, that is, as the variable increases in value does performance improve? Alternatively, the model can be quite complex but with the major function of explaining why the system behaves in certain ways.
- *Learning:* As well as providing insight, a model may be intended to teach managers or workers about the factors that determine performance. The model may omit many features of the real system and focus on those aspects that are considered crucial for those people responsible for effective operation of the system.
- *Improvement:* The model is used to improve system design and operation. Changes in parameters and rules can be explored, and factors critical for achieving performance targets can be identified. To make sure that conclusions drawn from the model will apply to the real system, such models pay particular emphasis to the adequacy with which they describe the system behavior.
- *Optimization models:* Given a model that predicts performance as a function of various parameters, an optimization model determines the optimal combination of these parameters. This usually means that the optimization problem is formulated as a mathematical programming problem, generally with a mixture of integer and continuous variables.
- *Decision making:* The model is to be used to aid decisions about either the design or operation of the system. The model has to be able to discriminate the effects of different courses of action and project their impact over time.

1.1.4. Requirements of Models

Models are based on certain assumptions about the system and its components and how the system is going to be operated. Then there are the assumptions about the nature of the disturbances that will

impact the system and the range of responses to these disturbances. The hierarchy of control and the flow of information also have to be represented in the model.

- *Complexity vs. simplicity:* Modeling involves compromises in deciding how much detail to represent. A large amount of detail means that the model should be a more precise representation of reality, but the disadvantages are that the model will be more difficult to verify and validate, be harder for users to understand, and take longer to develop. A simple model may not represent the system adequately and thus may give inaccurate predictions and omit key decisions or useful responses to disturbances.
- *Flexibility:* A model may be used to support decision making as the system evolves over time. That is, from initial concept through planning, detailed design, installation, and operation, there is a need for models to support decisions. While no one single model will support all decisions, it is desirable for a model to be useful at a number of different stages in system evolution. This means that the model should permit changes in the system modeled. Some of these changes may relate to the structure of the system, such as the number of machines or service representatives, the way in which jobs or customers move through the system, or the way in which the control hierarchy is set up. Other changes may relate to the values of parameters such as the frequency of machine failures or the demand rate. A model or a modeling approach has to be evaluated with respect to the ease of making both these sorts of changes.
- *Data requirements:* While there is often a great deal of data available in manufacturing or service, it is rare that the data are in the form required by the model. At the planning stage, there is often doubt as to the applicability of data collected from different systems in different environments, while when the system is operational, the data may well only apply over a limited range of operating conditions. Thus, a model should use the least amount of data required in order to make adequate predictions, and an important component of the validation of a model is assessing the sensitivity of the model to errors in the data.
- *Transparency:* Since the model has to be accepted by its users, it is desirable that the assumptions and procedures used in the model be reasonably transparent to others beside the model developer. The developer should be able to convince the user that the model is a reasonably accurate representation of reality.
- *Efficiency:* Models can consume significant resources, both in their development and in their use. Modeling approaches differ in their requirements on the knowledge, skill, and elapsed time required for development. Since most models will be implemented on a computer, such issues as running time and storage requirements can also be important.
- *User interface:* If a model is going to be of real value, it should be usable by managers rather than only by the model developer. A user interface is essential in order to guide the user in the correct use of the model, ensuring that it is clear what data should be provided and avoiding any ambiguity in interpreting the results.

1.2. Queueing Models

Queueing models are particularly useful for determining the following performance measures of a system:

- *Capacity or throughput:* This is the maximum rate at which the system can accept jobs or customers over some long time interval. We will use the symbol TH to denote it, and it is usually measured in jobs or customers per hour (or some other suitable time interval). Individual components of the system will, of course, have a higher short-term capacity than TH, but over the long run they will lose capacity because of machine breakdowns or worker absences. Capacity will also be lost because of interaction between the different parts of the system. For example, too few pallets will reduce work flow through a machine.
- *Flow Time or Lead Time:* The flow time, sometimes called the lead time in manufacturing, is the time from when a job or customer arrives at the system until the job or customer departs the system. It will be greater than the actual processing time because jobs are held in inventory buffers and customers wait in queues. Queueing models usually focus on determining the average flow time, but it is usually also possible to determine the variance and higher moments.
- *Inventories and queue lengths:* It is often important to know where inventories and queues are distributed through the system. The average total flow time and the average total queue length are connected by Little's law:

$$\bar{l} = \lambda \bar{w}$$

where $\bar{l}$ is the average queue length, $\bar{w}$ is the average flow time, and λ is the average rate at

which jobs or customers flow through the system. So given either queue length or flow time, the other performance measure can be readily determined.

- *Service level:* The service level can be measured in a variety of different ways, such as the fraction of demands met immediately or the average time to fill a customer demand. Service level is a particularly important performance measure when finished product inventories are kept and it is necessary to trade off the inventory investment with the penalties of delay in meeting customer demand.

1.2.1. Using Queueing Models

Queueing models are particularly useful in designing and improving system performance. In particular, they are of great value for addressing the following issues:

1. *Investigating alternative configurations:* There are usually alternative ways of allocating tasks to machines or people, and each alternative will result in different patterns of work flow. Queueing models are particularly valuable in rapidly exploring a wide range of alternatives and seeing how system performance is modified.
2. *Exploring the impact of parameters set by management:* Typically, management have to choose values for such parameters as inventory buffer capacities, the number of kanbans, or base stock levels. Queueing models enable their impact on performance measures such as throughput or service level to be found. If costs are available, then it is possible to determine the values that optimize performance.
3. *Comparing alternative scheduling and work-allocation rules:* Queueing models can be used to compare different scheduling rules. They can also be used to explore the way in which performance is changed as more information about jobs or customers is acquired and that information used to modify the routing and allocation of jobs or customers to machines or servers.
4. *Understanding the impact of variability:* Typically, less variability improves performance. But since reducing variability can be costly, it is desirable to know by how much performance is improved. Variability reduction is typically the aim of quality management efforts, and queueing models can help focus that effort.

1.3. Modeling Manufacturing and Service Systems

Queueing theory is described in Chapter 83. To apply it to modeling manufacturing or service systems, it is necessary to develop an understanding of the key features of the system and how these translate into queueing models. Considerable expertise is necessary. Often, as the system becomes more complex, it is necessary to develop approximations, and these have to be tested by extensive simulations. So a number of software packages have been developed that incorporate tested queueing models and approximations. These packages have user interfaces that guide the user through the selection of the appropriate model and allow the user to specify parameters values.

Alternatively, most queueing models can be easily incorporated into spreadsheets because they are either formulas or fairly straightforward iterative calculations.

Before giving the details of typical models, it is useful to describe briefly how the main features of various manufacturing and service systems are viewed as queues.

1.3.1. Manufacturing Systems

1.3.1.1. Job Shops and Flow Lines The two traditional forms of organizing manufacturing systems are the job shop and the flow line. The *job shop* consists of a variety of different types of machines, some of which can perform operations on different types of jobs, although this may require some setup or changeover time between job types. Material handling is such that different types of jobs can visit machines in different sequences. In a queueing model, the job shop is viewed as a network of queues, with each machine or machine center regarded as a server. Job routing determines the movement of jobs between the different servers. Rather than tracking individual jobs in the queueing model, it is usual to represent all the different jobs by a small number of job types or classes. By contrast, the *flow line* requires all jobs to visit machines and work centers in the same sequence, thus simplifying material handling. The simple material handling, combined with the standard routing, makes it easier to control work flow and instruct machines and workers on their tasks and thus enables high volumes to be produced economically. The queueing model thus consists of a number of queues in series. However, buffer space between machines is often limited, resulting in blocking or starving of machines, and this has to be represented by the model.

1.3.1.2. Transfer Lines Many flow lines produce only a single type of product, and with increasing volume it becomes attractive to automate individual machines and replace human operators by automatic devices and machines. The *automatic transfer line* goes one step further. Not only are

the machines and the material handling from one machine to the next automated, but all machines are linked so that they begin their tasks simultaneously and thus material movement is synchronized. In this way, the number of jobs in process can be kept small and extremely high productivity is potentially possible. If any machine should fail, then the tight linkage means that the whole line stops. To overcome this, the line may be divided up into sections, with buffers between the sections. The queueing model has to capture this linkage and the impact of buffers.

1.3.1.3. Flexible Transfer Lines Initially, when automatic transfer lines came into widespread use in the 1950s, the instructions on how to perform the tasks at a machine were embodied in physical information storage devices such as cams, jigs, and other fixtures. This has been called ''hard automation,'' and obviously it made it difficult to change instructions. However, as electronic devices for storage and processing of information were developed, combined with numerical control (i.e., transducers that convert digital information into physical motion of tools), changing the instructions on performing tasks became simpler. This resulted in the development of automated *flexible transfer lines* and *flexible flow lines,* distinguished by whether synchronized movement of jobs was retained or not. If job movement is not synchronized, then it is essential to provide some storage space between machines, otherwise job movement will always be determined by the slowest machine. Flexible transfer lines and flexible flow lines can manufacture more variants of a product than traditional automatic transfer lines, but unless the variation between jobs is very small, there may still be a requirement to change tools between jobs. The queueing model now has to describe the movement of the different job types through the system.

1.3.1.4. Flexible Manufacturing Systems Transfer lines are essentially automated flow lines, and thus all jobs have to visit all the machines in the same sequence. If numerically controlled machines are combined with a material-handling system that enables different jobs to visit machines in different sequences, then the resulting system is known as a *flexible manufacturing system* (FMS). Such systems were first implemented in the 1970s for machining tasks, so FMS sometimes implies a flexible machining system. An FMS is essentially an automated job shop. It can produce a reasonable range of products, although initially this range was limited by the ability to store or deliver the required tools to individual machines. Usually parts are mounted on pallets and the number of pallets is limited, so the queueing model represents the system as a network of queues in which the total number of customers is limited by the number of pallets.

1.3.1.5. Flexible Assembly Systems Assembly tasks are difficult to automate economically unless the tasks have unusual characteristics such as size, weight, or temperature or chemical or radiation hazards. However, beginning in the clothing and shoe industries and then spreading to the electronic industry in the early 1980s, it was recognized that *flexible assembly systems* with automated job movement to assembly, inspection, and test stations, linked to automated job-identification systems, resulted in significant improvement in work flow and control in assembly systems, producing a variety of different jobs, even though many individual tasks are still performed by human operators. Some flexible assembly systems enable jobs to move between any pair of workstations, while others, such as those introduced in the mid-1980s by the automobile industry to replace the traditional assembly line, have a generally series structure but with paralleling of workstations and some feedback loops so that jobs can be readily reprocessed if they do not meet required quality standards. Again, the number of work carriers may be limited, and there may be requirements to maintain sequence of jobs as they go through parallel work stations. Flexible assembly systems sometimes store all work in progress centrally and assign it to work stations as they become available. Alternatively, jobs may circulate through the system on conveyors. Queueing models have to be able to represent job circulation, storage, and processing.

1.3.2. Service Systems

As yet, there is no established approach for categorizing the different configurations of service systems, although there are a variety of approaches proposed (Schmenner 1986, Silvestro et al. 1992). From the perspective of developing queueing models, perhaps the most useful approach is to focus on the range and features of the tasks assigned to the people providing service (Buzacott 2000).

1.3.2.1. Narrow-Range Tasks If the system is configured so that each individual server only performs a narrow range of tasks, then this usually means that a number of different servers are required in order to perform all the required tasks for a customer. This means that the system will often be similar to a manufacturing flow line and so can be represented by queues in series. Of course, if there is some flexibility in the sequence in which tasks are done, then the system becomes more like a manufacturing job shop and can be represented by a network of queues.

1.3.2.2. Broad-Range Tasks Alternatively, individual servers can be assigned a broad range of tasks. This means that they are often able to do all the tasks required by a specific customer. However, in order to cope with increasing volume of customers, many servers are required. The system can

then be represented as a number of servers in parallel. There are a variety of ways in which customers can be allocated to servers; for example, some servers may specialize on particular types of customers; alternatively, customers can be allocated to servers according to some allocation rule, such as allocate to free servers in order of customer arrivals or allocate according to a round-robin or cyclical rule (first arrival, to server 1, next to server 2, next to server 1, next to server 2, and so on).

1.3.2.3. Specialized Diagnosis In many service situations the tasks to be done on or for a customer are not known until the customer arrives and some diagnosis is carried out. As a result, it is sometimes desirable to have a first stage of service that determines the service tasks required and then allocates customers to specialized service providers capable of performing the required tasks. The appropriate queueing model now consists of a network of queues in which customer flow out of diagnosis to a specific specialized facility is random, with probability equal to the frequency of the facility being required by the diagnosis. In some situations, multiple diagnostic steps are required, depending on whether a step is able to determine the service requirements.

1.3.3. Supply Chains and Logistic Systems

A developing field for applying queueing models is in determining service levels and inventories in supply chains. For modeling purposes, the supply chain is viewed as a network of cells, where in each cell manufacturing, transport, inspection, and other functions are performed. Cells are connected by material flow from raw material through parts manufacture through assembly, test, and distribution through warehouses and retail outlets to customers. However, cells are also connected by information flow from customer orders through retailer orders, warehouse shipment instructions, production schedules, part requisitions, and raw material requests. Because material flow occurs only as a result of requisitions and orders, it is necessary to include in the queueing model not only the representation of material flow but also the representation of information flow and how the two interact. Certain types of coordination schemes for controlling work flow use advance information—for example, forecasts of receipts of customer orders are used in Material Requirements Planning—and it is then necessary to represent this in the model. We will illustrate the combined modeling of material flow and information flow by some simple models.

1.4. Description of Available Models

The remainder of this chapter will be devoted to a description of some of the available analytical models of manufacturing and service systems and supply chains. The discussion will emphasize analytical models that yield a formula-type result, as such results are most readily implementable. When no formula exists, we will outline the general principles of the computational algorithms. We will also illustrate a number of approximate approaches for determining performance.

1.4.1. Assumptions of Models

Every model is based on certain assumptions about the composition of the system, the work flow through it, and the availability of resources, such as the number of operators, the number of repair crews, and the way in which these resources are allocated when there are competing demands for them. These assumptions describe the essential features of the system. Then there are further assumptions that relate to the nature of disturbances to the system operation, such as the distribution of time between successive failures of a machine, the distribution of time to repair a machine, the distribution of time to perform a task, and the pattern of occurrence of defective parts. In some models, the results depend critically on these distributions, while in others the mean of the distribution is all that is required. Usually it is easier to derive results for certain distributions than for others; in particular, it is possible to derive explicit formulas for the performance of some systems when the associated distributions are exponential or geometric, but not for other distributions. Fortunately, in many cases the results are not particularly sensitive to the form of the distribution or, at least, they give the right general shape of the relationship of the system design parameters to the system performance measures. Thus, the results can be used to give general insight. Almost all analytical models make the following assumptions:

1. Distributions are stationary (i.e., process parameters do not change with time or cumulative output).
2. Successive events of a particular type occur at intervals that are independent of each other (i.e., there is no serial correlation).
3. Events at one machine or service center are independent of events at another machine.

These assumptions are often not strictly correct in reality. However, it would be difficult to derive results that would relax them. In most real systems, when the assumptions fail, the system would be

considered out of control and managerial action would be taken to restore control (e.g., a significant worsening in quality with time would demand managerial intervention).

2. SINGLE-STAGE SYSTEMS

In a single-stage system all work required by a job or a customer is done by one service facility. However, this facility may consist of a number of servers or machines in parallel, and system performance will depend on how jobs or customers are allocated to the machines or servers.

We distinguish between two situations. One is that where no work is done prior to a job or customer's arrival. The second is where jobs are done prior to arrival of a demand, or work is done on anticipated customer requirements prior to the customer arriving.

2.1. Make-to-Order Manufacturing or Service with No Tasks Done Prior to Customer Arrival

2.1.1. Single-Server System

The system is then equivalent to a single-server queueing system for which numerous results are available (see sections 4.2 to 4.5 of Chapter 83). With Poisson arrivals, the performance measures are usually obtainable from fairly simple formulae. However, for general arrival times and general service times, it is usually necessary to resort to bounds and approximations, although such results are often remarkably accurate when the server utilization is reasonably high (see Daley et al. (1992) for a comprehensive description of various bounds and approximations). Suppose that the mean time between arrivals is $1/\lambda$ and the squared coefficient of variation (scv = variance/mean^2) of the time between arrivals is C_a^2. The service time of a job has mean $1/\mu$ and scv of C_S^2. Let $\rho = \lambda/\mu$. Then a good general upper bound on the number of jobs in the system is

$$E[N] \leq \frac{\rho(2 - \rho)C_a^2 + \rho^2 C_S^2}{2(1 - \rho)} + \rho \tag{1}$$

while for interarrival times that are DMRL, i.e., decreasing mean residual life, or in other words, as the time since the last arrival increases, the expected time to the next arrival becomes less, a lower bound is

$$\frac{\rho C_a^2 - \rho(1 - \rho) + \rho^2 C_S^2}{2(1 - \rho)} + \rho \leq E[N] \tag{2}$$

Note that the difference between these upper and lower bounds is $\rho(C_a^2 + 1)/2 < \rho$, since with DMRL arrivals $C_a^2 < 1$.

An approximation for the mean number of jobs in the system, $\hat{n}$, that gives good results for relatively high utilizations is the following:

$$\hat{n} = \left\{\frac{\rho^2(1 + C_S^2)}{1 + \rho^2 C_S^2}\right\}\left\{\frac{(C_a^2 + \rho^2 C_S^2)}{2(1 - \rho)}\right\} + \rho \tag{3}$$

At low utilizations, none of the approximations or bounds that just use information on the mean and variance of the interarrival times and service times are particularly good when the criterion is the percentage error. This is because the performance of the queue tends to be determined by the burstiness of arrivals, a property not captured by the second moment.

For some situations, where all that is required is to get insight into the impact of variability in interarrival times and service times at high utilizations, it is possible to use the heavy traffic result

$$\lim_{\rho \to 1} 2(1 - \rho)E[N] = C_a^2 + C_S^2 \tag{4}$$

2.1.2. Multiple Servers

2.1.2.1. Identical Servers Suppose there are c parallel servers with identical capabilities. The mean time between arrival of jobs is $1/\lambda$ and the mean time to serve a job is $1/\mu$. Jobs wait in a single queue and the first job in the queue is allocated to the first free server. Let $\rho = \lambda/c\mu$. Then with general arrivals and general service time distributions there are no exact results. One approach is to approximate the system by a $G/G/1$ queue and then modify the performance measures by the relationship between $M/M/c$ and $M/M/1$ results. When the multiple server system is represented by a $G/G/1$ queue, the arrival process at the queueing system is unchanged but the service time of the

single server equivalent to the c parallel servers is scaled by a factor of $1/c$. That is, if the service time at any one of the c servers had mean $\bar{s}$, variance σ_S^2, and squared coefficient of variation (scv) $C_S^2 = \sigma_S^2/\bar{s}^2$, the equivalent single server has service time with mean $\bar{s}/c$, variance σ_S^2/c^2, and scv $= C_S^2$. Then the number of jobs in service and waiting can be approximated by

$$\hat{n}_{G/G/c} = \frac{E[L]_{M/M/c}}{E[L]_{M/\mathbf{M}/1}} (\hat{n}_{G/G/1} - \rho) + c\rho \tag{5}$$

where $\hat{n}_{G/G/1}$ is an approximation for the number of jobs in service and waiting in the approximating $G/G/1$ system. $E[L]_{M/M/c}$ is given by a well-known queueing theory result

$$E[L]_{M/M/c} = \frac{(c\rho)^c}{c!} \left(\frac{\rho}{(1-\rho)^2} \right) p(0)$$

where $p(0) = 1/\{\Sigma_{k=0}^{c-1}(c\rho)^k/k! + (c\rho)^c/(1-\rho)c!\}$. Also note that $E[L]_{M/M/1} = \rho^2/(1-\rho)^2$.

2.1.2.2. Nonidentical servers Assume that all jobs have essentially the same work content. However, machines or servers differ in the time that it takes for them to perform the required work. Suppose that there are c servers or machines and the time required to perform the required work for a job or customer by server j, $j = 1,2, \ldots, c$, is a random variable S_j with mean $\bar{s}_j$.

2.1.2.3. Throughput Then the following table shows the throughput for a number of different rules for allocating jobs to machines or customers to servers.

Allocation rule	TH
First free server	$\Sigma_{j=1}^{c} 1/\bar{s}_j$
To server j with probability p_j	$\min_j 1/p_j\bar{s}_j$
Round robin or cyclic	$\min_j c/\bar{s}_j$

Note that these results depend only on the mean of the S_j. Also note that the first free server rule gives the greatest throughput, although the random allocation can reach the same throughput if p_j is chosen, so $\bar{s}_j p_j = 1/\Sigma_{u=1}^{c} 1/\bar{s}_u$. If, however, $p_j = 1/c$ for all j, then random allocation and cyclic allocation give the same throughput. In service systems, it is usual that servers differ in their capabilities even though they perform the same tasks. It can be seen that these differences will have significant impact on throughput unless it is feasible to use the first-free-server rule.

Suppose the time between arrivals has mean $1/\lambda$ and squared coefficient of variation (scv) C_a^2. With the cyclic allocation rule, the time between arrivals at a given server will have mean c/λ and scv of C_a^2/c. With random allocation, the time between arrivals at server j has mean $1/p_j\lambda_j$ and scv of $1 - p_j + p_j C_a^2$. Thus, if $p_j = 1/c$, the mean time between arrivals at a server are the same but the random allocation has higher scv of arrivals and hence will have longer queues.

2.2. Make-to-Stock Manufacturing Systems or Service Systems where Work Is Done in Advance of Customer Arrival

Assume throughout this subsection that there is a single server.

2.2.1. Exponential Service Time, Poisson Demands

Suppose the target stock level is set as z. Then, as soon as a demand arrives, it is satisfied by an item taken from inventory. A job is then released to the machine or server to begin manufacturing or serving the replenishment. Mean service time of a job is $\bar{s} = 1/\mu$.

2.2.1.1. Backlogged Demands In a system where unmet demands are backlogged, it follows that jobs will arrive at the machine in exactly the same way as demand arrives. Hence the queue length at the machine is the same as the queue length in a make-to-order system, with the same pattern or arrivals of demands and the same service time distribution at machines. However, if N is the length of the queue, then the inventory in the output store will be $\max\{z - N,0\}$ while the size of the backlog will be $\max\{0,N - z\}$. Hence it follows that the expected backlog $E[B]$ is given by

$$E[B] = \frac{\rho^{z+1}}{1 - \rho} \tag{6}$$

and the expected delay in meeting a demand is $\bar{s}(\rho^z/(1 - \rho))$. The probability a demand cannot be met immediately will be ρ^z, so the service level, the fraction of demand met from stock, is $1 - \rho^z$.

2.2.1.2. Lost Sales Alternatively, suppose that demands that cannot be met from stock are lost. Now SL, the fraction of demand met from stock, is given by

$$\text{SL} = \frac{1 - \rho^z}{1 - \rho^{z+1}} \tag{7}$$

2.2.2. Single Machine with Interruptible Demand (Stopped Arrival Queue)

Suppose now that as soon as the store is empty, the demand process is turned off. It is turned on again once there is an item in the store. The arrival and service of jobs at the machine is now equivalent to a *stopped arrival* queue, that is, a queue in which the arrival process turns off once the queue length reaches z. Now the service level is defined by the ratio of the number of demands met to the number that would have been generated if the arrival process were never turned off. This is equal to the fraction of time that the inventory level in the store is greater than zero. With exponential arrivals and exponential service time, the service level is the same as the lost sales case. However, when the interarrival process is general, then the results are somewhat different. Consider a $G/G/1$ queue with arrivals equal to the arrival process of demands and service equal to the machine service time. Let $\hat{n}$ be an approximation for the queue length in this queue and ρ its traffic intensity. Then define σ by $\sigma = (\hat{n} - \rho)/\hat{n}$. If $\rho > 1$, then define $\sigma = 1/\sigma_R$ where $\sigma_R = (\hat{n}_R - \rho_R)/\hat{n}_R$ and $\hat{n}_R$ is the average queue length in a $G/G/1$ queue with arrivals having a distribution equal to the service process and service distribution equal to the interarrival distribution in the original system. ρ_R is defined as the ratio of the mean interarrival time of demands to the mean service time (i.e., $\rho_R = 1/\rho$). Then a good approximation for the service level in this system is given by

$$\text{SL} = \frac{1 - \rho\sigma^{z-1}}{1 - \rho^2\sigma^{z-1}}, \qquad \rho \neq 1$$

$$\text{SL} = \frac{1 + (z - 1)\nu}{2 + (z - 1)\nu}, \qquad \rho = 1 \tag{8}$$

where $\nu = \lim_{\rho \to 1} d\sigma/d\rho$. For example, if the heavy traffic approximation (4) is used, $\nu = 2/(C_a^2 + C_s^2)$ and so when $\rho = 1$,

$$\text{SL} = \frac{C_a^2 + C_s^2 + 2(z - 1)}{2(C_a^2 + C_s^2 + z - 1)} \tag{8}$$

2.2.3. Multiclass Backlogged Demand

Suppose now that there are r types of items produced on a common single machine. The demand rate for type i, $i = 1, \ldots, r$, is λ_i. The service time distribution is identical for all types and has an exponential distribution with mean $1/\mu$. Suppose that there is a target stock level of z_i for type i. Then define $\hat{\rho}_i$ by $\hat{\rho}_i = \lambda_i/(\mu - \Sigma_{j \neq i}\lambda_j)$. The service level for type i is then given by

$$\text{SL}_i = 1 - \hat{\rho}_i^{z_i} \tag{10}$$

2.2.4. Multiclass Lost Sales

Again there are r classes with the target stock z_i for class i, $i = 1,2, \ldots, r$. Demand rate for class i is λ_i while all types are produced on a single machine with the same service time distribution. It is possible to show that the probability of observing the number of jobs of each type in the machine queue of $n_1, n_2, \ldots, n_i, \ldots, n_r$ is given by

$$p(\mathbf{n}) = p(n_1, n_2, \ldots, n_i, \ldots, n_r) = G(\mathbf{Z})^{-1} \binom{\Sigma_{i=1}^r n_i}{n_1, \ldots, n_r} \prod_{i=1}^r \rho_i^{n_i}, \quad 0 \leq n_i \leq z_i;\ i = 1, \ldots, r \tag{11}$$

where the normalizing constant $G(Z)$ is determined by

$$G(\mathbf{Z}) = G(z_1, z_2, \ldots, z_r) = \sum_{n_1=0}^{z_1} \cdots \sum_{n_r=0}^{z_r} \binom{\Sigma_{i=1}^{r} n_i}{n_1, \ldots, n_r} \prod_{i=1}^{r} \rho_i^{n_i} \tag{12}$$

Note that $(\Sigma_{i=1}^{r} n_i / n_1, \ldots, n_r)$ is the multinomial coefficient, that is the number of ways to allocate $\Sigma_{i=1}^{r} n_i$ items to r cells in which cell i, $i = 1, 2, \ldots, r$, contains n_i items.

The service level for type i items is given by

$$\begin{aligned} \mathrm{SL}_i &= \lambda_i \left(1 - \sum_{n_1=0}^{z_1} \cdots \sum_{n_i=z_i} \cdots \sum_{n_r=0}^{z_r} p(\mathbf{n})\right) \\ &= \lambda_i \frac{G(z_1, z_2, \ldots, z_{i-1}, z_i - 1, z_{i+1}, \ldots, z_r)}{G(\mathbf{Z})}, \quad i = 1, \ldots, r \end{aligned} \tag{13}$$

2.2.5. Produce to Stock with Advance Information

Suppose that it is possible to obtain information about future demands in advance. That is, the arrival of the nth demand, $n = 1, 2, \ldots$, at time t is signaled at time $t - \tau$. If the target or initial stock of finished products is zero, then the item to meet the demand at time t can be released for manufacture at time $t - \tau$. Now if a target stock z of finished products is held, release of an item to manufacture will still take place at time $t - \tau$, but the nth demand, which arrives at time t, will actually be met by an item released for manufacture prior to time $t - \tau$ and triggered by the advice of demand $n - z$. Suppose service times are exponential with parameter μ and advices about future demands arrivals are Poisson with rate λ. Let $\rho = \lambda/\mu$. Then the service level SL, i.e., the fraction of demands that are met from stock, is given by (Buzacott and Shanthikumar 1994).

$$\mathrm{SL} = 1 - \rho^z e^{-\mu\tau(1-\rho)} \tag{14}$$

and the average delay in meeting a demand is given by

$$\overline{w}/\overline{s} = e^{-\mu\tau(1-\rho)} \frac{\rho^z}{1 - \rho} \tag{15}$$

The average inventory is given by

$$\overline{i} = z + \lambda\tau - \frac{\rho}{1 - \rho}(1 - \rho^z e^{-\mu\tau(1-\rho)}) \tag{16}$$

3. FLOW LINES AND SERIES SYSTEMS

3.1. Introduction

Flow lines and series systems can be divided up into two broad classes, based on their influence on the worker: *paced* and *unpaced*. In a *paced* system the time allowed to perform a task is limited and once this time is up the job or customer can no longer be worked on, so it is possible that the task may not be completed. In an *unpaced* system there is no maximum time limit imposed on the time for the worker to perform the task.

Paced systems lose throughput because of the incomplete processing of jobs or customers, while unpaced systems lose throughput because of the variability of task times.

3.2. Models of Paced Systems

In a paced system, the tolerance time, τ, the maximum time available to perform the tasks at any workstation, is set. Thus if T_i, the time required by the worker at station i to perform their required tasks, exceeds τ, the tasks will be incomplete and defective products will result. Hence the probability $Q(\tau)$ that a product will not contain any defects is

$$Q(\tau) = P\{T_1 \le \tau, T_2 \le \tau, \ldots, T_m \le \tau\} = \prod_{i=1}^{m} P\{T_i \le \tau\} \tag{17}$$

To meet a given quality target Q, the probability that the product is nondefective should be at least Q. So the minimum tolerance time is the solution to

$$F_i(\tau) = Q^{1/m} \tag{18}$$

One of the managerial controls in a paced system is the tolerance time τ, which is related to the line

speed. Too short a tolerance time means that the quality is low, while too high a tolerance time reduces the utilization of the workers and so lowers productivity. For example, if $m = 10$ and the quality target $Q = 0.98$ then $F_i(\tau)$ must be at least 0.998. This means that if task times were exponential, and with the same distribution at all stations, the tolerance time τ has to be set at $6.2 \times$ the mean processing time of a job at a station. If task times have a normal distribution with mean θ and standard deviation σ, then the tolerance time will have to be set as $\tau = \theta + 2.9\sigma$. It is clear that this would lead to a substantial loss in labor productivity unless the variability of task times can be kept small.

Note that for Q close to 1, $F_i(\tau)$ is approximately given by

$$1 - F_i(\tau) \approx \frac{1 - Q}{m} \tag{19}$$

The gross output rate will be $1/\tau$ but the system throughput of nondefectives will be

$$TH = \frac{Q(\tau)}{\tau} \tag{20}$$

3.3. Models of Unpaced Lines

The unpaced line consists of m stages. Once a job is completed at stage i, it moves on to stage $i + 1$, although it may pass through an intermediate buffer of capacity b_i, $i = 1, 2, \ldots, m - 1$, where capacity is made up of the space for jobs in process at the stage plus the space in the buffer.

3.3.1. Infinite Buffer Systems

Suppose that there is one machine or server at each stage. The processing time of a job at stage i is exponential with mean $1/\mu_i$. Jobs or customers arrive at the system according to a Poisson process with rate λ. In an infinite buffer system, we have

$$\text{TH} = \min_i \left(\frac{1}{\mu_i}\right) \tag{21}$$

and if $\lambda < \text{TH}$ and $\rho_i = \lambda/\mu_i$, then the distribution of N_i, the inventory at station i, is given by

$$P(N_i = k_i) = \rho_i^{k_i}(1 - \rho_i)$$

It follows that the average inventory at stage i is given by

$$E[N_i] = \frac{\rho_i}{1 - \rho_i}$$

and hence the total inventory $\overline{n}$ is given by

$$\overline{n} = \sum_{i=1}^{m} \frac{\rho_i}{1 - \rho_i} \tag{22}$$

3.4. Two-Stage Flow Lines

Consider a flow line that consists of two stages separated by a buffer of capacity z. Each stage consists of a single server, so $b = z + 1$.

3.5. Exponential Service Times

Assume that the service time at each stage is exponentially distributed with mean $1/\mu_i$, $i = 1,2$. Let $\rho = \mu_1/\mu_2$. Then, using a Markov model, it is possible to show that the throughput of this system is given by

$$\begin{aligned} \text{TH} &= \mu_1 \frac{(1 - \rho^{b+1})}{1 - \rho^{b+2})} \qquad \rho \neq 1 \\ &= \mu_2 \frac{(b + 1)}{b + 2} \qquad \rho = 1 \end{aligned} \tag{23}$$

Alternatively, write

$$\text{TH} = \mu_1(1 - B(\mu_1, \mu_2, b + 1)) = \mu_2(1 - I(\mu_1, \mu_2, b + 1))$$

where

$$B(\mu_1, \mu_2, b + 1) = \frac{\rho^{b+1}(1 - \rho)}{1 - \rho^{b+2}} \quad \rho \neq 1$$
$$= \frac{1}{b + 2} \quad \rho = 1 \tag{24}$$

$$I(\mu_1, \mu_2, b + 1) = \frac{1 - \rho}{1 - \rho^{b+2}} \quad \rho \neq 1$$
$$= \frac{1}{b + 2} \quad \rho = 1 \tag{25}$$

Note that $1/\text{TH}$ is the mean time between parts arriving at the line and equals the mean time between parts leaving the line. That is, the system behaves as if it were equivalent to a single machine with mean service time $1/\mu^*$ given by the two equivalent expressions

$$\frac{1}{\mu^*} = \frac{1}{\mu_1} + \frac{1}{\mu_2} B(\mu_1, \mu_2, b) \tag{26}$$

$$= \frac{1}{\mu_2} + \frac{1}{\mu_1} I(\mu_1, \mu_2, b) \tag{27}$$

3.6. General Service Times

If the service times at the two stations are general, then a good approximation can be obtained by viewing the system as a stopped arrival queue, where stage 1 corresponds to the arrival process and stage 2 corresponds to the service process (Buzacott et al. 1995). Suppose the service time at stage i is a random variable S_i, $i = 1, 2$. Define $\rho = E[S_2]/E[S_1]$, $\rho_R = 1/\rho$, and $\lambda = 1/E[S_1]$. If the buffer capacity is z, then the maximum number of jobs in the system is $z + 2$ and $b = z + 1$. Then the approximation is

$$\text{TH} = \lambda \frac{(1 - \rho\sigma^b)}{1 - \rho^2\sigma^b} \quad \rho \neq 1$$
$$= \lambda \frac{C_{S1}^2 + C_{S2}^2 + 2b}{2(C_{S1}^2 + C_{S2}^2 + b)} \quad \rho = 1 \tag{28}$$

with

$$\sigma = (\hat{n} - \rho)/\hat{n} \quad \rho < 1$$
$$= \hat{n}_R/(\hat{n}_R - \rho_R) \quad \rho > 1$$

where $\hat{n}$ is the approximate average number of jobs in a $G/G/1$ queueing system with arrival distribution S_1 and service distribution S_2, while $\hat{n}_R$ is the approximate average number of jobs in a $G/G/1$ queueing system with arrival distribution S_2 and service distribution S_1. The two moment approximations given above can be used to find $\hat{n}$ or $\hat{n}_R$ as appropriate. Table 1 shows the accuracy of the approximation for the case where S_1 and S_2 have Erlang-3 distributions.

3.7. Three-Stage Flow Lines

Consider a three-stage flow line with finite buffer storage space. The number of spaces in the buffer i between stages $i - 1$ and i is z_1. Set $b_i = z_i + 1$. Assume that the service time at each stage is exponentially distributed with mean $1/\mu_i$, $i = 1, \ldots, m$.

Such a system is best analyzed using a Markov process model. Then the state of the system is defined by $\{n_2, n_3\}$, where n_i is the number of jobs in the system that have been processed by station $i - 1$ but have not yet completed processing by station i, $i = 2, 3$. The state space $\mathcal{S} = \{(n_2,n_3)$: $0 \leq n_2 \leq b_2 + 1$, $0 \leq n_3 \leq b_3 + 1$, $n_2 + n_3 \leq b_2 + b_3 + 1\}$. Note that when $n_i = b_i + 1$, stage $i - 1$ is blocked by stage i. Let $\mathbf{p} = (p(n_2, n_3), (n_2, n_3) \in \mathcal{S})$ be the stationary probability vector of this Markov process. The steady-state balance equations for $\mathbf{p}$, obtained by equating the rate of leaving a state with the rate of entering the state, are given by

(\mu_2+\mu_3)p(b_2+1,b_3) &= \mu_1 p(b_2,b_3)
\end{aligned}
$$

These $|\mathcal{S}| = (b_2+1)(b_3+1) - 1$ equations along with the normalizing equation

$$\sum_{(n_2,n_3)\in\mathcal{S}} p(n_2,n_3) = 1$$

can be solved for **p**. Unfortunately, they do not possess a formula type solution.

With present computing facilities, direct solution of the equations using a standard procedure is probably as easy a method to use as any other. However, as b_2 and b_3 increase, it would be desirable to make use of the fact that the coefficient matrix has a large number of zero entries and thus a sparse matrix solution procedure would be appropriate. Once **p** has been computed, the throughput can be obtained by

$$\mathrm{TH} = \mu_3 \left(1 - \sum_{n_2=0}^{b_2+1} p(n_2,0)\right)$$

For the special case of no (extra) buffer capacity (i.e., $b_2 = 1$, $b_3 = 1$), an explicit formula for the throughput can be obtained. It is

$$\mathrm{TH}(\mu_1,\mu_2,\mu_3) = 1 \Bigg/ \left\{ \frac{1}{\mu_2} + \frac{\mu_2(\mu_1+\mu_3)}{\mu_1\mu_3(\mu_1+\mu_2)(\mu_2+\mu_3)} \left[\frac{(\mu_1^2+\mu_3^2)(\mu_1+\mu_2+\mu_3)^2 - \mu_1^2\mu_3^2}{(\mu_1+\mu_3)^3 + \mu_2(\mu_1^2+\mu_1\mu_3+\mu_3^2)} \right] \right\} \tag{29}$$

This approach of setting up and solving a Markov model can be used for other similar systems with exponential service times. Typically, the number of equations to be solved increases rapidly

with the number of stages and the size of the buffers, so while straightforward it becomes increasingly difficult to use.

3.8. Multiple-Stage Flow Lines with Exponential Processing Times

The flow line is modeled by a tandem queueing system with m stages and with finite buffer capacities $b_2, \ldots, b_m$ with $b_i = z_i + 1$, where z_i is the number of spaces in buffer i, and exponentially distributed processing times with mean $1/\mu_i$, $i = 1,2, \ldots, m$. The jobs arrive at the flow line according to a Poisson process with rate λ.

We use this situation to illustrate a particular approach to developing approximate models of manufacturing and service system performance that is of wide applicability.

The basis of the approximate approach is to consider stage i as if it were isolated from the rest of the system, and so we model it as an $M/M/1/b_i + 1$ queue. Jobs are assumed to arrive as a Poisson process with rate $\hat{\lambda}_i$ and service is exponentially distributed with rate μ_{id}, so the probability that an arriving job is blocked is given by $B(\hat{\lambda}_i, \mu_{id}, b_i + 1)$, where $B(\hat{\lambda}_i, \mu_{id}, b_i+1)$ is given by Eq. (24). Observe that if $\lambda < \mathrm{TH}$, the job departure rate for stage i is λ. Thus,

$$\hat{\lambda}_i(1 - B(\hat{\lambda}_i, \mu_{id}, b_i + 1)) = \lambda \tag{30}$$

Also, considering stage $i + 1$ as a two-stage flow line, using Eq. (26) we approximate μ_{id} by

$$\frac{1}{\mu_{id}} = \frac{1}{\mu_i} + \frac{1}{\mu_{i+1d}} B(\hat{\lambda}_{i+1}, \mu_{i+1d}, b_{i+1}), \qquad i = 1, \ldots, m - 1 \tag{31}$$

and $\mu_{md} = \mu_m$. That is, we have the recursive relations (30) and (31) to solve for $\hat{\lambda}_i$, $i = 1, \ldots, m - 1$ with the initial condition $\mu_{md} = \mu_m$. Note that for (30) to have a solution, we require $\mu_{id} > \lambda$, $i = 1, \ldots, m - 1$. The mean number of jobs in the system and at the different stages can be approximated by $\Sigma_i \overline{N}_i$ and $(\hat{N}_i, i = 1, \ldots, m)$ delivered by the following algorithm. Let $\hat{N}_{m/M/1/b}(\lambda, \mu, b)$ be the mean number of customers in an $M/M/1/b$ queueing system with arrival rate λ, service rate μ, and buffer capacity b. If $\rho = \lambda/\mu$,

$$\hat{N}_{M/M/1/b}(\lambda, \mu, b) = \frac{\rho}{1 - \rho} - \frac{(b + 1)\rho^{b+1}}{1 - \rho^{b+1}}$$

3.8.1. Algorithm 1: Work-in-Process (Finite Buffer Flow Lines: Single Servers, Exponential Processing Times)

Step 1: Set $\mu_{md} = \mu_m$.
Step 2: For $i = m, \ldots, 2$,
  if $\mu_{id} < \lambda$, then the system is unstable, go to step 4;
  else, solve $\hat{\lambda}_i(1 - B(\hat{\lambda}_i, \mu_{id}, b_i + 1)0 = \lambda$ for $\hat{\lambda}_i$
  Set $1/\mu_{i-1d} = 1/\mu_{i-1} + 1/\mu_{id}\, B(\hat{\lambda}_i, \mu_{id}, b_i)$.
  Compute $N_1 = \hat{N}_{M/M/1/b}(\hat{\lambda}_i, \mu_{id}, b_i + 1)$.
Step 3: Compute $N_1 = \hat{N}_{M/M/1}(\lambda/\mu_{1d})$.
Step 4: Stop.

In step 2 we need to solve the nonlinear equation $\hat{\lambda}(1 - B(\hat{\lambda}, \mu, b + 1)) = \lambda$ for the unknown $\hat{\lambda}$ when $\mu > \lambda$. Since $\hat{\lambda}(1 - B(\hat{\lambda}, \mu, b+1))$ is increasing and concave in $\hat{\lambda}$, the following iterative scheme

$$\hat{\lambda}^{(k)} = \hat{\lambda}^{(k-2)} + \frac{(\hat{\lambda}^{(k-1)} - \hat{\lambda}^{(k-2)})(\lambda - \hat{\lambda}^{(k-2)}(1 - B(\hat{\lambda}^{(k-2)}, \mu, b + 1)))}{\hat{\lambda}^{(k-1)}(1 - B(\hat{\lambda}^{(k-1)}, \mu, b + 1)) - \hat{\lambda}^{(k-2)}(1 - B(\hat{\lambda})^{k-2}, \mu, b + 1))}, \quad k = 2, \ldots,$$

starting with $\hat{\lambda}^{(0)} = 0$; $\hat{\lambda}^{(1)} = \lambda$, will monotonically converge to the solution.

In algorithm 1 we see that if $\lambda > \mu_{id}$ for any i, $i = 1, \ldots, m$, the system is unstable. Let $\lambda^* = \max\{\lambda : \mu_{id} \geq \lambda, i = 1, \ldots, m\}$. We will use λ^* as our approximate throughput of the flow line. It can be verified that the following iterative scheme will converge and provide λ^*. Let

$$I(\lambda, \mu, b) = \frac{1 - \rho}{1 - \rho^{b+1}}$$

be the steady-state probability that the server is idle in an $M/M/1/b$ queueing system with arrival rate λ, service rate μ, and buffer capacity b.

3.8.2. Algorithm 2: Throughput (Finite Buffer Flow Lines: Single Servers, Exponential Processing Times)

Step 1: Set $\mu_{1u} = \mu_1$; $\mu_{id} = \mu_i$, $i = 2, \ldots, m$.
Step 2: For $i = 2, \ldots, m$, compute
$1/\mu_{iu} = 1/\mu_i + 1/\mu_{i-1u}\, I(\mu_{i-1u}, \mu_{id}, b_i)$
Step 3: For $i = m, \ldots, 2$, compute
$1/\mu_{i-1d} = 1/\mu_{i-1} + 1/\mu_{id}\, B(\mu_{i-1u}, \mu_{id}, b_i)$
Step 4: If $|\mu_1(1 - B(\mu_1, \mu_{2d}, b_2 + 1)) - \mu_m(1 - I(\mu_{m-1u}, \mu_m, b_m + 1))| < \epsilon$, set $\lambda^* = \mu_1(1 - B(\mu_1, \mu_{2d}, b_2 + 1))$ and stop. Otherwise go to step 2.

3.9. General Service Time Approximation

Suppose that the service times at the stages are random variables S_j, $j = 1, \ldots, m$. Let $1/\mu_j$ and C_{Sj}^2 be the mean and squared coefficient of variation of the service time at stage j. Suppose the buffer capacity between stage $j - 1$ and j is z_j, $j = 2, \ldots, m$.

The basis of the approximation is to analyze each stage j, $j = 2, \ldots, m$ as a $GI/GI/I/z_j + 2$ stopped arrival queue. The effective arrival process and service times at stage j, $j = 2, \ldots, m$ will be chosen so that they effectively reflect the upstream and downstream portions of the flow line, where upstream means the overall effect of stages $1, \ldots, j - 1$ and downstream means the overall effect of stages $j, \ldots, m$. Let $(1/\mu_{j-1u}, C_{S_{j-1u}}^2)$ denote the mean and scv of the effective input or arrival process to stage j when turned on (i.e., when stage $j - 1$ is not blocked because the queue is full), and let $(1/\mu_{jd}, C_{S_{jd}}^2)$ be the mean and scv of the effective service or output process at stage j (i.e., when stage j is not starved because the stage is empty). Also let TH_j be the throughput of the stage j stopped arrival queue, obtained using a $GI/GI/1/b_j + 1$ stopped arrival queue approximation with input parameters $(1/\mu_{j-1u}, C_{S_{j-1u}}^2)$ and service parameters $(1/\mu_{jd}, C_{S_{jd}}^2)$.

There are useful equations relating μ_{ju} and μ_{jd}. Consider stage j. The time between the $k - 1$th and kth job departures from stage j can be written as

$$T_k^{(j)} = I_k^{(j)} + S_k^{(j)} + H_k^{(j)} \tag{32}$$

where $I_k^{(j)}$ is the idle time of stage j waiting for the next job to arrive and $H_k^{(j)}$ is the holding or blocking time of the job while it waits for queue space in the buffer at stage $j + 1$. Next observe that $S_k^{(j)} + H_k^{(j)}$ is the effective service time experienced by a job in the stopped arrival queue corresponding to stage j, that is $E[S_k^{(j)} + H_k^{(j)}] = 1/\mu_{jd}$. Also note that $I_k^{(j)} + S_k^{(j)}$ is the effective interarrival time in the stopped arrival queue corresponding to stage $j + 1$, that is, $E[I_k^{(j)} + S_k^{(j)}] = 1/\mu_{ju}$. Also, $E[T_k^{(j)}]$ is the mean interdeparture time from the original system and $1/\mathrm{TH}_{j+1}$ is from the decomposed system. In order for $1/\mathrm{TH}_{j+1}$ to be correct, we must have $E[T_k^{(j)}] = 1/\mathrm{TH}_{j+1}$. Thus, rewriting (32),

$$S_k^{(j)} + H_k^{(j)} = S_k^{(j)} + T_k^{(j)} - (I_k^{(j)} + S_k^{(j)})]$$

and taking expectations, we obtain

$$\frac{1}{\mu_{jd}} = \frac{1}{\mu_j} + \frac{1}{TH_{j+1}} - \frac{1}{\mu_{ju}}$$

Note that the average blocking time of stage j is $1/\mathrm{TH}_{j+1} - 1/\mu_{ju}$.

Similarly, by considering the time between successive job inputs to stage $j + 1$ it can be shown that

$$\frac{1}{\mu_{j+1u}} = \frac{1}{\mu_{j+1}} + \frac{1}{\mathrm{TH}_{j+1}} - \frac{1}{\mu_{j+1d}}$$

That is, we get the following set of $2(m - 1)$ equations

$$\frac{1}{\mu_{jd}} = \frac{1}{\mu_j} + \frac{1}{\mathrm{TH}_{j+1}} - \frac{1}{\mu_{ju}}, \quad j = 2, \ldots, m-1 \tag{33}$$

$$\frac{1}{\mu_{md}} = \frac{1}{\mu_m}$$

$$\frac{1}{\mu_{1u}} = \frac{1}{\mu_1}$$

$$\frac{1}{\mu_{j+1u}} = \frac{1}{\mu_{j+1}} + \frac{1}{\mathrm{TH}_{j+1}} - \frac{1}{\mu_{j+1d}}, \quad j = 1, \ldots, m-2 \tag{34}$$

Given the $C^2_{S_{ju}}$ and the $C^2_{S_{jd}}$ (see below as to alternative approaches for determining these quantities), the above $2(m-1)$ equations plus the $m-1$ equations to determine TH_j, $j = 2, \ldots, m$, the throughput of each stopped arrival queue from the mean and scv of the (equivalent) arrival and service processes, give $3(m-1)$ equations in the $3(m-1)$ variables TH_j, μ_{j-1u} and μ_{jd}, $j = 2, \ldots, m$. These equations can be solved recursively.

3.9.1. Algorithm 3: Throughput (Finite Buffer Flow Lines: Single Servers, General Processing Times)

Step 0: Set $\mu^{(0)}_{jd} = \mu_j$, $j = 2, \ldots, m$.

Step 1: For $k = 1, 2, \ldots$ and for $j = 1, \ldots, m-1$, calculate (i) $\mathrm{TH}^{(k)}_{j-1}$ using the $GI/GI/1/b_{j-1}+1$ stopped arrival queue approximation with input parameters $(1/\mu^{(k)}_{ju}, C^2_{S_{ju}})$ and service parameters $(1/\mu^{(k-1)}_{j+1d}, C^2_{S_{j+1d}})$, (ii) $\mu^{(k)}_{j+1u}$ using

$$\frac{1}{\mu^{(k)}_{j+1u}} = \frac{1}{\mu_{j+1}} + \frac{1}{\mathrm{TH}^{(k)}_{j+1}} - \frac{1}{\mu^{(k-1)}_{j+1d}}, \quad j = 1, \ldots, m-2,$$

and (iii) $\mu^{(k)}_{jd}$ using

$$\frac{1}{\mu^{(k)}_{jd}} = \frac{1}{\mu_j} + \frac{1}{\mathrm{TH}^{(k)}_{j+1}} - \frac{1}{\mu^{(k)}_{ju}}, \quad j = 2, \ldots, m-1$$

Step 2: Stop once

$$\left|\mathrm{TH}^{(k)}_m - \mathrm{TH}^{(k-1)}_m\right| < \epsilon$$

It can easily be verified that at convergence $\mathrm{TH}^{(k)}_i = \mathrm{TH}^{(k)}_j$ for all $i \neq j$.

3.9.2. Squared Coefficient of Variation Recursions

So far it has not been specified how to calculate the scv $C^2_{S_{ju}}$ and $C^2_{S_{jd}}$. Two approaches are possible. The simplest, approximation (a), is to set

$$C^2_{S_{ju}} = C^2_{S_j}, \quad j = 1, \ldots, m-1$$

$$C^2_{S_{jd}} = C^2_{S_j}, \quad j = 2, \ldots, m$$

This approximation considers only the immediate upstream and downstream stations and ignores the impact of possible blocking or starving on the variance of the equivalent service times or arrival times.

The other approach [see Buzacott et al. 1995, approximation (b)] tries to take account of the impact of possible blocking and starving on the variance of the service times. It uses the following set of $2(m-2)$ equations by which the scv's can be determined

$$E[S^2_{jd}] = E[S^2_j] + \delta_{j+1d}(E[S^2_{j+1d}] + 2E[S_j]E[S_{j+1d}]), \quad j = 2, \ldots, m-1$$

with $E[S^2_{md}] = E[S^2_m]$ and δ_{j+1d} defined by

$$\delta_{j+1d} = \mu_{j-1d}\left(\frac{1}{\mathrm{TH}_{j+1}} - \frac{1}{\mu_{ju}}\right), \quad j = 2, \ldots, m-1.$$

and

$$E[S_{ju}^2] = E[S_j^2] + \delta_{ju}(E[S_{j-1u}^2] + 2E[S_j]E[S_{j-1u}]) \quad j = 2, \ldots, m-1$$

with $E[S_{1u}^2] = E[S_1^2]$ and

$$\delta_{ju} = \mu_{j-1u}\left(\frac{1}{\mathrm{TH}_j} - \frac{1}{\mu_{jd}}\right) \quad j = 2, \ldots, m-1$$

Table 2 illustrates the approximation for a four-stage system where the service times are exponentially distributed. Note that the case (a) approximation is now identical to algorithm 2 given above for the throughput of an exponential flow line.

4. TRANSFER LINES

In a transfer line, movement of jobs at all stations in a section of the line is synchronized. Thus, transfer can only begin when the slowest station has completed its operation. If no station fails, then the mean time between successive transfers is the *cycle time*, τ. The cycle time will consist of the maximum time to perform operations at a station in the section, plus the time required for transfer. The *gross production rate* is $1/\tau$. The *net production rate* is TH and is less than the gross production rate because of line stoppages due to station or transfer mechanism failure. Note that if any station in the section fails and thus its operation is not completed, then no transfer will occur and all stations in the section will be forced down. The extent to which this section stoppage will affect other sections of the line depends on the degree of integrated linkage and control between sections. If no inventory can be kept between sections, then the rest of the line will be forced down almost immediately. In lines with many stations, there is much equipment that can break down, so the net production rate can be much less than the gross production rate. The efficiency of the transfer line is defined by

$$\eta = \frac{\text{net production rate}}{\text{gross production rate}} = \mathrm{TH}\tau$$

One means of increasing the net production rate of a transfer line and reducing the impact of stoppages is to insert in-process storage or a bank between the two sections of the line. A bank has the effect of decoupling the two sections of the line, allowing each section to operate independently.

4.1. Models

4.1.1. Transfer Lines with No Inventory Banks

Consider a transfer line with m stages or stations. The station failures can be either time dependent (failure is possible when the station is idling) or operation dependent (failure only occurs when the station is working on a part).

4.1.2. Time-Dependent Failures

Suppose the stations can fail even when they are idling. Let the mean time to failure, and repair times of stage i, be $\overline{U}_i$ and $\overline{D}_i$ respectively, for $i = 1, 2, \ldots, m$. With no inventory bank, all stations in the line stop as soon as any station fails. Then it follows that

TABLE 2 Four Stage Throughput with Exponential Service Times

Parameters							TH		
μ_i				z_i				App.	
1	2	3	4	2	3	4	Exact	(a)	(b)
1	1.1	1.2	1.3	1	1	1	0.710	0.689	0.700
1	1.2	1.4	1.6	1	1	1	0.765	0.746	0.756
1	1.5	2	2.5	1	1	1	0.861	0.850	0.855
1	2	3	4	1	1	1	0.929	0.925	0.927

From Buzacott et al. 1995. Reproduced with permission of Kluwer Academic Publishers.

$$\eta = \prod_{i=1}^{m} A_i^T \tag{35}$$

where

$$A_i^T = \frac{\bar{U}_i}{\bar{U}_i + \bar{D}_i} \qquad i = 1, \ldots, m$$

4.1.3. Operation-Dependent Failures

Suppose that stations can fail only when they are working on a part. Let $\bar{T}_i$ be the mean number of cycles station i operates between failures, $\bar{D}_i$ be the mean downtime of station i, and τ be the average cycle time when the line is running and $x_i^o = \bar{D}_i/(\bar{T}_i\tau)$. Then the line consisting just of station i would have efficiency

$$A_i^o = \frac{\bar{T}_i}{\bar{T}_i + \bar{D}_i/\tau} = \frac{1}{1 + x_i^o} \qquad i = 1, \ldots, m$$

Then it can be shown that

$$\eta = \frac{1}{1 + \Sigma_{i=1}^{m} x_i^o} \tag{36}$$

If, however, the part in process at the instant of failure must be scrapped, then

$$\eta = \frac{\Pi_{i=1}^{m}(1 - 1/\bar{T}_i)}{1 + \Sigma_{i=1} m x_i^o \Pi_{j=1}^{i-1}(1 - 1/\bar{T}_j)} \tag{37}$$

If only a fraction q_i of the failures result in scrapping of the part, then

$$\tau = \frac{\Pi_{i=1}^{m}(1 - q_i/\bar{T}_i)}{1 + \Sigma_{i=1}^{m} x_i^o \Pi_{j=1}^{i-1}(1 - q_j/\bar{T}_j)} \tag{38}$$

4.1.4. Systems Separated by Infinite Inventory Banks

Suppose the stages in an m-stage transfer line are separated by inventory banks of infinite capacity. Let the mean time to failure and repair times of stage i be $\bar{U}_i$ and $\bar{D}_i$ respectively, for $i = 1, \ldots, m$. Define

$$x_i = \frac{\bar{D}_i}{\bar{U}_i} \qquad i = 1, \ldots, m$$

4.1.4.1. No Parts Scrapped The efficiency of the line is

$$\eta = \min\left\{\frac{1}{1 + x_i} \qquad i = 1, \ldots, m\right\} \tag{39}$$

4.1.4.2. Scrapping of Parts Suppose when station i fails, the part being processed is scrapped, with probability q_i, $i = 1, \ldots, m$. Then

$$\eta = \min_{1 \le j \le m}\left\{\prod_{k=j}^{m}\left(\frac{1 - q_k/\bar{T}_k}{1 + x_j}\right)\right\} \tag{40}$$

4.1.5. Two-Stage Synchronized Line with Finite Capacity Inventory Banks

Consider a series transfer line with two stations, one finite intermediate inventory bank with capacity z and synchronized part transfer. Suppose

$a_i = P$(station i is failed at time $n + 1$|station i is working at time n)
$\hat{a}_i = P$(station i is failed at time $n + 1$|station i is either blocked or idle at time n)
$b_i = P$(station i is up at time $n + 1$|station i is down at time n) $\quad i = 1, 2$

$\hat{a}_i$ is zero if failures are operation dependent, and equal to a_i if failures are time dependent.

Then a discrete time Markov chain model with the system observed just prior to the beginning of transfer can be used to show that the line efficiency is given by

$$\eta(z) = \frac{1 - r^*\rho^z}{1 + x_1 - (1 + x_2)r^*\rho^z} \qquad a_1b_2 \neq b_1a_2 \tag{41}$$

where $x_i = a_i/b_i$, that is, $1/(1 + x_i)$ is the efficiency of station i if it operates on its own,

$$r^* = \frac{(\hat{a}_1 + b_1)(\hat{a}_2\alpha_1 + a_2\beta_1)}{(\hat{a}_2 + b_2)(\hat{a}_1\alpha_2 + a_1\beta_2)} \tag{42}$$

$$\rho = \frac{\beta_1\alpha_2}{\alpha_1\beta_2} \tag{43}$$

and

$$\begin{aligned}
\alpha_1 &= a_1 + a_2 - a_1a_2 - b_1a_2 \\
\alpha_2 &= a_1 + a_2 - a_1a_2 - a_1b_2 \\
\beta_1 &= b_1 + b_2 - b_1b_2 - a_1b_2 \\
\beta_2 &= b_1 + b_2 - b_1b_2 - b_1a_2.
\end{aligned} \tag{44}$$

4.1.5.1. Balanced Stages (Case Where $a_1b_2 = b_1a_2$) This means that $x_1 = x_2 = \hat{x}$, $\alpha_1 = \alpha_2 = \alpha$, $\beta_2 = \beta_2 = \beta$, $\rho = 1$ and $\hat{x} = \alpha/\beta$. Then it can be shown that

$$\eta(z) = \frac{\hat{a}_1 + b_1 + \hat{a}_2 + b_2 - (\hat{a}_1 + b_1)(\hat{a}_2 + b_2) + (\hat{a}_1 + b_1)(\hat{a}_2 + b_2)z(1 + \hat{x})}{(\hat{a}_1 + b_1 + \hat{a}_2 + b_2)(1 + \hat{x}) + (\hat{a}_1 + b_1)(\hat{a}_2 + b_2)(\hat{x}(b_1 + b_2)/b_1b_2 + (z - 1)(1 + \hat{x})^2)} \tag{45}$$

Note that if $\hat{a}_1 = \hat{a}_2 = \hat{a}$, $b_1 = b_2 = b$, that is, the stations are identical,

$$\eta(z) = \frac{2 - b - \hat{a} + (b + \hat{a})z(1 + \hat{x})}{2(1 + 2\hat{x} + \hat{x}\hat{a}/b) + (b + \hat{a})(z - 1)(1 + \hat{x})^2} \tag{46}$$

4.1.6. Operation-Dependent and Time-Dependent Failures

Two limiting cases are of interest: (1) operation-dependent failures: $\hat{a}_1 = \hat{a}_2 = 0$, and (2) time-dependent failures: $\hat{a}_1 = a_1$, $\hat{a}_2 = a_2$. For operation-dependent failures and identical stations,

$$\eta(z) = \frac{2 - b + bz(1 + \hat{x})}{2(1 + 2\hat{x}) + b(z - 1)(1 + \hat{x})^2} \tag{47}$$

and for time-dependent failures

$$\eta(z) = \frac{2 - b(1 + \hat{x}) + bz(1 + \hat{x})^2}{2(1 + \hat{x})^2 + b(z - 1)(1 + \hat{x})^3} \tag{48}$$

4.1.6.1. Failure-Transfer Coefficients The quantities $\delta(z)$ and $\delta'(z)$ defined next are the failure transfer coefficients.

$$\delta(z) = Pr\{\text{bank is empty}|\text{station 1 is failed}\} \tag{49}$$

$$\delta'(z) = Pr\{\text{bank is full}|\text{station 2 is failed}\} \tag{50}$$

These quantities will be used later to describe an approximation for the efficiency of m-stage transfer lines. Later we will use $\delta(z, a_1, b_1, a_2, b_2)$ and $\delta'(z, a_1, b_1, a_2, b_2)$ for $\delta(z)$ and $\delta'(z)$ respectively to show explicitly the failure and repair probabilities of the two stages.

It can be shown that

$$\delta(z) = \frac{1 - r^*}{1 - r^*\sigma^z}, \qquad x_1 \neq x_2,$$
$$= \frac{b_1 + b_2 - b_1b_2}{b_1 + b_2 - b_1b_2 + zb_1b_2(1 + \hat{x})}, \qquad x_1 = x_2 = \hat{x} \tag{51}$$

and

$$\delta'(z) = \frac{\sigma^z(1 - r^*)}{1 - r^*\sigma^z}, \qquad x_1 \neq x_2,$$
$$= \frac{b_1 + b_2 - b_1b_2}{b_1 + b_2 - b_1b_2 + zb_2b_2(1 + \hat{x})}, \qquad x_1 = x_2 = \hat{x} \tag{52}$$

They can be expressed in an alternative way that provides further insight into their meaning.

For other two-stage transfer line models, see Buzacott and Shanthikumar (1993).

4.2. Multiple-Stage Transfer Lines

Consider a transfer line with m stages and $m - 1$ banks of capacities $z_1, z_2, \ldots, z_{m-1}$. The number of cycles of operation before failure and the repair times all have geometric distributions with mean $1/a_i$ and $1/b_i$ respectively for stage i, $I = 1, \ldots, m$. The parameters of stage i are then (a_i, b_i).

4.2.1. Approximation

The basic concept of the approximation approach is the recognition that viewed from any inventory bank the line appears to have two stages, with the arrivals at the bank determined by the upstream stages and the departures from the bank determined by the downstream stages. If the upstream stages are replaced by a single equivalent station and the downstream stages are replaced by a single equivalent station, then, viewed from the bank, the system appears to consist of the bank and two stations. If the equivalent stations have time to failure and repair time distributions for which the two station system can be solved, then the throughput of the system can be determined. The approximation arises because, even when the individual stages have distributions that in a two-station system would be solvable, grouping the upstream or downstream stages results in the grouped stages no longer having the same form of distributions of time to failure and time to repair as their constituent stages. However, in order to use the known two-stage results, it is necessary to approximate the actual distributions by distributions for which the two-stage system has a solution.

The specifics of the approximation procedure will be described for a system where each stage j, $j = 1, \ldots, m$ has geometric operation-dependent time to failure with failure probability a_j and geometric repair time with repair probability b_j. However, the procedure can easily be adapted to the case where the stages have geometric time to failure and identical deterministic repair time $\overline{D}$ with all banks having a capacity such that $z_j = l_j\overline{D}$ where l_j is an integer. Viewed from bank j, the upstream stages will be assumed to have a geometric time to failure with failure probability a_j^U and geometric repair time with repair probability b_j^U, while the downstream stages will be assumed to have geometric time to failure with failure probability a_{j+1}^D and geometric repair time with repair probability b_{j+1}^D. These parameters are given by

$$a_j^U = a_j + (1 - a_j^D)a_{j-1}^U\delta_{j-1,j}, \qquad 2 \leq j \leq m - 1$$
$$b_j^U = a_j^U \Bigg/ \left(\frac{a_j}{b_j} + \frac{a_{j-1}^U}{b_{j-1}^U}\,\delta_{j-1,j}\left(1 - a_j^D\,\frac{b_{j-1}^U}{b_j^D + b_{j-1}^U - b_j^Db_{j-1}^U}\right)\right), \qquad 2 \leq j \leq m$$

$$a_1^U = a_1$$
$$b_1^U = b_1$$

$$a_{j+1}^D = a_{j+1} + (1 - a_{j+1}^U)a_{j+2}^D\delta_{j+2}\delta_{j+2,j+1}, \qquad 0 \leq j \leq m - 2,$$
$$b_{j+1}^D = a_{j+1}^D \Bigg/ \left(\frac{a_{j+1}}{b_{j+1}} + \frac{a_{j+2}^D}{b_{j+2}^D}\,\delta_{j+2,j+1}\left(1 - a_{j+1}^U\,\frac{b_{j+2}^D}{b_{j+1}^U + b_{j+2}^D - b_{j+1}^Ub_{j+2}^D}\right)\right),$$
$$1 \leq j \leq m - 2$$
$$a_m^D = a_m$$
$$b_m^D = b_m$$

where

$$\delta_{j-1,j} = \delta(z_{j-1}, a^U_{j-1}, b^U_{j-1}, a^D_j, b^D_j)$$

and

$$\delta_{j+1,j} = \delta'(z_j, a^U_j, b^U_j, a^D_{j+1}, b^D_{j+1})$$

There are thus $4m - 2$ equations in $4m - 2$ unknowns. Let $(a^U_j, b^U_j, a^D_j, b^D_j, j = 1, \ldots, m)$ be a solution to these equations. Then it can be shown that the efficiency $\eta(z_j,a^U_j,b^U_j,a^D_{j+1},b^D_{j+1})$ of the two stage line is the same for all $j = 1, \ldots, m - 1$. Specifically, we have

$$\eta^O := \frac{1}{1 + a^U_m/b^U_m} = \eta(z_j, a^U_j, b^U_j, a^D_{j+1}, b^D_{j+1})$$
$$= \eta^I := \frac{1}{1 + a^D_1/b^D_1}, \quad j = 1, \ldots, m - 1 \tag{53}$$

Since the equations are nonlinear, they are best solved using an iterative technique, where convergence is checked by determining whether $\eta^I = \eta^O$.

4.2.2. Algorithm 4: Multistage Transfer Line

Step 0: Set $k = 1$, $a^D_j(0) = a_j$, $b^D_j(0) = b_j$, $j = 2, \ldots, m$.

Step 1: Set $a^U_1(k) = a_1$, $b^U_1(k) = b_1$. For $j = 1, 2, \ldots, m - 1$, analyze the two stage transfer line with parameters $(a^U_j(k),b^U_j(k))$ and $(a^D_{j+1}(k - 1), b^D_{j+1}(k - 1))$ and determine $a^U_{j+1}(k)$ and $b^U_{j+1}(k)$.

Step 2: Set $a^D_m(k) = a_m$, $b^D_m(k) = b_m$. For $j = m - 1, m - 2, \ldots, 1$ analyze the two-stage transfer line with parameters $(a^D_{j+1}(k), b^D_{j+1}(k))$ and $(a^U_j(k),b^U_j(k))$ and determine $a^D_j(k)$ and $b^D_j(k)$.

Step 3: Calculate $\eta^O = 1/(1 + a^U_m(k)/b^U_m(k))$ and $\eta^I = 1/(1 + a^D_1(k)/b^D_1(k))$. If $|\eta^O - \eta^I| < \epsilon$ stop, otherwise set $k = k + 1$ and go to step 1.

The convergence of this algorithm is shown in Buzacott and Shanthikumar (1993). Convergence to a solution is usually very rapid, and the solution is usually very close to the exact line efficiency. Table 3 shows exact and approximate results for a number of three-stage lines. There are some situations where convergence of the algorithm is very slow, such as, in some three station systems where the failure probability of the middle stage is much less than that of the outer stages (case 6 in Table 3). If all the b_j are identical and equal to b and the a_j's are sufficiently small that it is unlikely more than one stage is failed at any time, then the above $4(m - 1)$ equations can be reduced to the following $2(m - 1)$ equations by seting $b^U_j = b^D_{j+1} = b$ for $1 \le j \le m - 1$:

$$\begin{aligned} a^U_j &= a_j + a^U_{j-1}\hat{\delta}_{j-1,j}, \qquad 2 \le j - m \\ a^D_{j+1} &= a_{j+1} + a^D_{j+2}\hat{\delta}_{j+2,j+1}, \qquad 0 \le j \le m - 2 \\ a^U_1 &= a_1 \\ a^D_m &= a_m \end{aligned} \tag{54}$$

Here

$$\begin{aligned} \hat{\delta}_{j-1,j} &= \hat{\delta}(z_{j-1}, a^U_{j-1}, b, a^D_j, b) \\ \hat{\delta}_{j+1,j} &= \hat{\delta}'(z_j, a^U_j, b, a^D_{j+1}, b), \\ \hat{\delta}'(z, a_1, b, a_2, b) &= \hat{\delta}(z, a_2, b, a_1, b) \end{aligned} \tag{55}$$

and

$$\hat{\delta}(z, a_1, b, a_2, b) = \frac{1 - a_2/a_1}{1 - \dfrac{a_2}{a_1}\left(\dfrac{a_1 + a_2 - a_1 b}{a_1 + a_2 - a_2 b}\right)^z}$$

TABLE 3 Throughput of Three-Station Systems

Case	a_1	a_2	a_3	b_1	b_2	b_3	z_1	z_2	η exact	η approx
1	0.03	0.05	0.02	0.20	0.20	0.20	15	15	0.777846	0.777759
2	0.01	0.02	0.005	0.20	0.10	0.15	15	3	0.814949	0.814970
3	0.7	0.9	0.6	0.3	0.4	0.9	7	5	0.285463	0.285463
4	0.9	0.05	0.6	0.4	0.4	0.4	10	10	0.307692	0.307692
5	0.001	0.0003	0.005	0.7	0.02	0.3	8	4	0.970335	0.970337
6	0.6	0.04	0.6	0.8	0.4	0.8	9	9	0.565423	0.571365

When $a_1 = a_2$,

$$\hat{\delta}(z, a, b, a, b) = \frac{1}{1 + \dfrac{zb}{2 - b}}$$

The efficiency of the line can be found from $\eta^O = 1/(1 + a_m^U/b)$ or $\eta^I = 1/(1 + a_1^D/b)$, or by determining the efficiency of any of the two stage lines with parameters (a_j^U, b) and (a_{j+1}^D, b) and inventory bank capacity z_j by the efficiency formula

$$\hat{\eta}(z_j, a_j^U, b, a_{j+1}^D, b) = \frac{1}{1 + (a_j^U \hat{\delta}_{j,j+1} + a_{j+1}^D)/b} \tag{56}$$

It is not difficult to show that the same efficiency is obtained for all j. That is,

$$\hat{\eta}(z_j, a_j^U, b, a_{j+1}^D, b) = \hat{\eta}(z_{j+1}, a_{j+1}^U, b, a_{j+2}^D, b), \qquad j = 1, \ldots, m - 2 \tag{57}$$

Therefore, the preceding $m - 2$ equations may be used to replace $(m - 2)$ of those specified above for a_j^U's and a_{j+1}^D's and still solve for $\{(a_j^U, a_{j+1}^D), j = 1, \ldots, m - 1\}$.

5. DYNAMIC JOB SHOPS

The models in this section were originally developed to describe job shops in manufacturing, but they are also applicable to service systems where customers take different routes through the system, depending on their service requirements or diagnosis. So while we will use the language of manufacturing job shops, the reader can easily replace this with comparable language from service applications.

5.1. Open Jackson Queueing Network Model

A single class of jobs arrive at the job shop according to a Poisson process with arrival rate λ. The fraction of jobs that will join machine center i on their arrival is γ_i, $i = 1, \ldots, m$. $(\Sigma_{i=1}^m \gamma_i = 1)$. The fraction of jobs that complete service at machine center i that will directly go to machine center j is p_{ij}. Then $1 - \Sigma_{j=1}^m p_{ij}$ is the fraction of jobs among those completing service at machine center i, that will directly leave the system. Of course, at least for one or more $i = 1, \ldots, m$, $1 - \Sigma_{j=1}^m p_{ij} > 0$ so that all jobs entering the system will eventually leave the system. The service times of jobs at machine center i are i.i.d. exponential random variables with mean $1/\mu_i$, $i = 1, \ldots, m$. All the service times and the arrival times are mutually independent.

The rate at which a job is processed at machine center i when there are n jobs is assumed to be $\mu_i r_i(n) = 0, 1, \ldots$. This allows us to represent, as special cases, single or multiple machines in parallel at the machine center i. Specifically if there are c_i machines in parallel at machine center i, we set $r_i(n) = \min\{n, c_i\}$, $n = 0, 1, \ldots$; $i = 1, \ldots, m$. Leaving this representation as a general function r_i allows one to model the effect of the number of jobs in a machine center on the worker efficiency.

Assume that the job shop uses service protocols such as first come first served or last come first served that are independent of the job service time requirements.

We model this system by a Markovian open queueing network (i.e., Jackson open queueing network) where jobs are routed from one service center to another according to a transfer probability matrix $\mathbf{P} = (p_{ij})_{i,j=1,\ldots,m}$. Let $N_i(t)$ be the number of jobs at machine center i at time t; $i = 1, \ldots, m$ and $\mathbf{N}(t) = \{N_1(t), \ldots, N_m(t)\}$. Then $\mathbf{N}(t)$ is a continuous time Markov process on $\mathfrak{N}_+^m$. Define the stationary distribution of $\mathbf{N}$ by $p(\mathbf{n}) = \lim_{t\to\infty} P\{\mathbf{N}(t) = \mathbf{n}\}$, $\mathbf{n} \in \mathfrak{N}_+^m$. Then it can be shown (see Jackson (1963))

$$p(\mathbf{n}) = \prod_{i=1}^{m} p_i(n_i), \qquad \mathbf{n} \in \mathcal{N}_+^m \tag{58}$$

where if the λ_i, $i = 1, \ldots, m$ are the solution to the set of linear equations

$$\lambda_i = \lambda\gamma_i + \sum_{j=1}^{m} \lambda_j p_{ji} \qquad j = 1, \ldots, m \tag{59}$$

then

$$p_i(n_i) = p_i(0) f_i(n_i) \qquad n_i = 0,1, \ldots, i = 1, \ldots, m \tag{60}$$

$$f_i(0) = 1; \; f_i(n_i) = \frac{f_i(n_i - 1)\lambda_i}{\mu_i r_i(n_i)}, \qquad n_i = 1, 2, \ldots; \; i = 1, \ldots, m \tag{61}$$

$$p_i(0) = 1 \Big/ \sum_{n_i=0}^{\infty} f_i(n_i), \qquad i = 1, \ldots, m \tag{62}$$

Note that λ_j is the rate of job arrivals (including both internal and external arrivals) to the machine center j, $j = 1, \ldots, m$. Furthermore, note that $p_i(.)$ is the same as the stationary distribution of the number of jobs in an $M/M(n)/1$ queueing system, with arrival rate λ_i and state-dependent service rate $\mu_i r_i(n_i)$, when there n_i jobs in it, $n_i = 0,1, \ldots$ Therefore, the results given in Chapter 83 for the $M/M/1$ and $M/M/c$ queueing systems can be directly applied to this queueing network model. Particularly when there is only a single machine at each machine center (i.e. $c_i = 1$, $i = 1, \ldots, m$), we have

$$p(\mathbf{n}) = \prod_{i=1}^{m} (1 - \rho_i)\rho_i^{n_i}, \qquad \mathbf{n} \in \mathcal{N}_+^m \tag{63}$$

where $\rho_i = \lambda_i/\mu_i < 1$, $i = 1, \ldots, m$. In this case, the average number of jobs in machine center i is

$$E[N_i] = \frac{\rho_i}{1 - \rho_i}, \qquad i = 1, \ldots, m \tag{64}$$

and the total number of jobs in the job shop is

$$E[N] = \sum_{i=1}^{m} \frac{\rho_i}{1 - \rho_i} \tag{65}$$

Applying Little's formula, one then obtains the average flow time of an arbitrary job as

$$E[T] = \frac{1}{\lambda} \sum_{i=1}^{m} \frac{\rho_i}{1 - \rho_i} \tag{66}$$

Since $\lambda_i = \lambda v_i$, where v_i is the expected number of visits made to machine center i by an arbitrary job before it leaves the system, (66) can be
rewritten as

$$E[T] = \sum_{i=1}^{m} v_i E[T_i] \tag{67}$$

where

$$E[T_i] = \frac{1}{\lambda_i} \frac{\rho_i}{1 - \rho_i} \tag{68}$$

is the average flow time of an arbitrary job in machine center i each time it visits machine center i, $i = 1, \ldots, m$.

The independence of $N_1, \ldots, N_m$ allows one to compute the variance of the total number of jobs in the job shop. Particularly since $\text{var}(N_i) = \rho_i/(1 - \rho_i)^2$, $i = 1, \ldots, m$, we have

$$\text{var}(N) = \sum_{i=1}^{m} \frac{\rho_i}{(1 - \rho_i)^2} \tag{69}$$

Even though the stationary number of jobs in the machine centers is statistically independent, which we used in obtaining (69), the stationary flow time of arbitrary jobs through the different machine centers is, in general, not independent. Consequently, we cannot obtain a simple expression for the variance of the flow time of an arbitrary job. In Buzacott and Shanthikumar (1993), a good approximation for this variance is given.

5.2. Multiple-Job-Class Open Jackson Queueing Network Model

In some situations, aggregation of all job types into a single job class is unacceptable in a queueing network model. We concentrate on situations where the operation/machine sequence is different for different classes of jobs, but the service requirements of the different classes at any machine center are probabilistically almost the same. In addition, we will assume that jobs are selected for service according to a First-Come-First-Served service protocol.

Class l jobs arrive at the job shop according to Poisson process with rate $\lambda^{(l)}$, $l = 1, \ldots, r$. All these r arrival processes are mutually independent. The fraction of class l jobs that join machine i is $\gamma_i^{(l)}$ ($\Sigma_{i=1}^m \gamma_i^{(l)} = 1$) and the fraction of class l jobs among those class l jobs that complete service at machine center i, that proceed directly to machine center j as a class k job, is $p_{ij}^{(l)(k)}$, $i, j = 1, 2, \ldots; l,k = 1,2, \ldots, r$. For each l ($l = 1, \ldots, r$) we assume that there exist at least one or more i such that $\Sigma_{k=1}^r \Sigma_{i=1}^m p_{ij}^{(l,k)} < 1$ so that class l jobs that enter the system will eventually leave the system. The service time of a class l job at machine center i is exponentially distributed with mean $1/\mu_i$, $i = 1, \ldots, m$. Jobs are served at a rate $r_i(n_i)$ at machine center i when there are n_i jobs, $r_i(0) = 0$, $r_i(n_i) > 0$, $n_i = 1, 2, \ldots$ Note that this service rate is independent of the number of individual classes of jobs, but depends only on the total number. The arrival, service, and job transfers from one machine center to another are mutually independent. Assuming that each job is transferred from one machine center to another and from one class to another, according to a transfer probability matrix $(p_{ij}^{(l)(k)})_{i,j=1,\ldots,m}^{l,k=1,\ldots,r}$ we model this job shop by a multiple-job-class open Jackson queueing network.

Let $N_i(t)$ be the number of jobs at machine center i at time t and $X_{i;j}(t)$ be the class index of the job in the jth position of the queue at machine center i,$j = 1, \ldots, N_i(t)$; $i = 1, \ldots, m$. We assume that the job in the first position is in service, being served at a rate $r_i(n_i)$ when $N_i(t) = n_i$, $i = 1, \ldots, m$. Then $\{\mathbf{X}(t) = (X_{i;j}(t), j = 1, \ldots, N_i(t), i = 1, \ldots, m), t \geq 0\}$ is a continuous-time Markov process. Let $q(\mathbf{x}) = \lim_{t\to\infty} P\{\mathbf{X}(t) = \mathbf{x}\}$ be the stationary probability distribution of $\mathbf{X}$. Then it can be shown that

$$q(\mathbf{x}) = \prod_{i=1}^{m} q_i(\mathbf{x}_i) \tag{70}$$

and

$$q_i(\mathbf{x}_i) = \frac{1}{\Sigma_{n=0}^{\infty} f_i(n)} \prod_{s=1}^{n_i} \frac{\lambda^{(x_{i;s})}}{\mu_i r_i(s)}, \qquad i = 1, \ldots, m \tag{71}$$

with $\lambda_j^{(l)}$, $l = 1, \ldots, r$; $j = 1, \ldots, m$ the solution to

$$\lambda_i^{(l)} = \lambda^{(l)}\gamma_i^{(l)} + \sum_{j=1}^{m} \sum_{k=1}^{r} \lambda_j^{(k)} p_{ji}^{(k)(l)}, \qquad l = 1, \ldots, r; i = 1, \ldots, m \tag{72}$$

and $\lambda_j = \Sigma_{l=1}^r \lambda_j^{(l)}$, $f_i(0) = 1$, and $f_i(n_i) = f_i(n_i - 1)\lambda_i/\mu_i r_i(n)$; $n = 1,2, \ldots, m$.

We can now use (70) to obtain the joint probability distribution of $\mathbf{N}$, the number of jobs of each class at each machine center. Let $p(\mathbf{n}) = P\{\mathbf{N} = \mathbf{n}\}$ and $p_i(\mathbf{n}_i) = P\{\mathbf{N}_i = \mathbf{n}_i\}$. Here $\mathbf{n}_i = (n_i^{(1)}, n_i^{(2)}, \ldots, n_i^{(r)})$ and $n_i^{(l)}$ is the number of class l jobs at machine center i. Then one has

$$p_i(\mathbf{n}_i) = \binom{n_i}{n_i^{(1)}, \ldots, n_i^{(r)}} \prod_{l=1}^{r} \left(\frac{\lambda_i^{(l)}}{\lambda_i}\right)^{n_i^{(l)}} \frac{f_i(n_i)}{\Sigma_{n=0}^{\infty} f_i(n)}, \qquad \mathbf{n}_i \in \Im\!\mathfrak{l}_+^r \tag{73}$$

where $n_i = \Sigma_{l=1}^r n_i^{(l)}$.

Therefore the joint distribution of $\mathbf{N}$ is

$$p(\mathbf{n}) = \prod_{i=1}^{m} \binom{n_i}{n_i^{(1)}, \ldots, n_i^{(r)}} \prod_{l=1}^{r} \left(\frac{\lambda_i^{(l)}}{\lambda_i}\right)^{n_i^{(l)}} \left\{\frac{f_i(n_i)}{\Sigma_{n=0}^{\infty} f_i(n)}\right\}, \qquad \mathbf{n} \in \mathfrak{N}_+^{r\times m} \tag{74}$$

Observe that $f_i(n_i)/\Sigma_{n=0}^{\infty} f_i(n)$, $n_i = 0,1,....$ is the probability distribution of the number of customers in an $M/M(n)/1$ queueing system with arrival rate λ_i and state-dependent service rate $\mu_i r_i(\cdot)$. On the other hand

$$\binom{n_i}{n_i^{(1)},\cdots,n_i^{(r)}} \prod_{l=1}^{r} \left(\frac{\lambda_i^{(l)}}{\lambda_i}\right)^{n_i^{(l)}}$$

is the multinomial probability of choosing $n_i^{(l)}$ of type l items according to a probability $\lambda_i^{(l)}/\lambda_i$, $l = 1, \ldots, r$. Therefore, the joint distribution of the number of jobs at the different machine centers is the same as that in a single-job-class queueing network with arrival rate λ_i to machine center $i = 1, \ldots, m$. We may therefore solve the open queueing network model with single class and obtain the joint distribution of the number of jobs of different classes at different machines using a multinomial sampling with probability $\lambda_i^{(l)}/\lambda_i$ for class l jobs ($l = 1, \ldots, r$) at machine center i ($i = 1, \ldots, m$).

For a machine center that has only one machine, we have

$$p_i(\mathbf{n}_i) = \binom{n_i}{n_i^{(1)},\cdots,n_i^{(r)}} \prod_{l=1}^{r} \left(\frac{\lambda_i^{(l)}}{\lambda_i}\right)^{n_i^{(l)}} (1 - \rho_i)\rho_i^{n_i}, \qquad \mathbf{n}_i \in \mathfrak{N}_+^{r} \tag{75}$$

where $\rho_i = \lambda_i/\mu_i < 1$. For $c_i = +\infty$ we have

$$p_i(\mathbf{n}_i) = \prod_{l=1}^{r} \frac{(\rho_i^{(l)})^{n_i^{(l)}} e^{-\rho_i^{(l)}}}{n_i^{(l)}!}, \qquad \mathbf{n}_i \in \mathfrak{N}_+^{r} \tag{76}$$

where $\rho_i^{(l)} = \lambda_i^{(l)}/\mu_i$, $l = 1, \ldots, r$. The number of jobs of different classes at a machine center with infinitely many machines are independent. In the other cases this need not be true. As we will see next, the marginal distribution of any class of job, say l, at any machine center with a single machine, say i, is exactly the same as that in an $M/M/1$ queue with arrival rate $\lambda_i^{(l)}$ and service rate $\mu_i - \Sigma_{s=1;s\neq l}^{r} \lambda_i^{(s)}$. Then it can be shown that

$$P\{N_i^{(l)} = n_i^{(l)}\} = (1 - \hat{\rho}_i^{(l)})(\hat{\rho}_i^{(l)})^{n_i^{(l)}}, \qquad n_i^{(l)} = 0,1, \ldots \tag{77}$$

where

$$\hat{\rho}_i^{(l)} = \frac{\rho_i^{(l)}}{1 - \rho_i + \rho_i^{(l)}} = \frac{\lambda_i^{(l)}}{\mu_i - \Sigma_{k=1,k\neq l}^{r} \lambda_i^{(k)}}$$

and $\rho_i^{(l)} = \lambda_i^{(l)}/\mu_i$. Therefore, if we are interested only in studying the flow performance of a particular class of job, say l, in a job shop with single or infinite machine centers, all we have to do is redefine the service rates of the single-machine machine center (say i) by $\mu_i - \Sigma_{k=1,k\neq l}^{r} \lambda_i^{(k)}$ and analyze a single open queueing network with only class l jobs and the modified service rates. We cannot, however, do this *job class decomposition* when there are machine centers with a limited number of parallel machines.

We have seen how the number of jobs of different classes in single- and infinite-machine machine centers decomposes. Next we will make an observation about the effect of aggregating the number of jobs at different-infinite machine machine centers. Let $I \subset \{1, \ldots, m\}$ be the set of machine centers that have infinitely many machines. Then one finds that

$$P\{N_i^{(l)} = n_i^{(l)}, l = 1, \ldots, r; i \in I\} = \prod_{i\in I} \prod_{l=1}^{r} \frac{e^{-\rho_i^{(l)}} (\rho_i^{(l)})^{n_i^{(l)}}}{n_i^{(l)}!}$$

Then it is easily verified that

$$P\left\{\sum_{i\in I} N_i^{(l)} = n^{(l)}, l = 1, \ldots, r\right\} = \prod_{l=1}^{r} \frac{e^{-\rho_I^{(l)}} (\rho_I^{(l)})^{n^{(l)}}}{n^{(l)}!} \tag{78}$$

where $\rho_I^{(l)} = \Sigma_{i\in I} \rho_i^{(l)}$, $l = 1, \ldots, r$. Therefore, if we are interested only in the total number of jobs

of different classes in the set I of machine centers, we may aggregate all these $|I|$ machine centers into one infinite-machine machine center.

It should be noted that the results discussed here for the infinite-machine machine centers hold true even if the distributions of the service times are general.

5.2.1. Incorporating Transport and Material Handling in the Jackson-Type Job Shop Model

Consider the material-handling configuration where each link (i,j) that connects machine centers i and $j(i,j = 1, \ldots, m; i \neq j)$ has a sufficient number of transporters or a conveyor system such that when a job completes processing at machine center i, it can immediately begin movement from machine center i to its destination. The average time taken to transfer a job from machine center i to machine center j is $1/\mu_{(i,j)}$, $i,j = 1, \ldots, m$; $i \neq j$. Suppose the job transfers from one machine center to another are represented by a job transfer probability matrix $\mathbf{P} = (p_{ij})_{i,j=1,\ldots,m}$. If we now incorporate the transporters on each link (i,j) as a service center, the job transfer probabilities are $p'_{ii} = p_{ii}$, $p'_{i,(i,j)} = p_{ij}$ and $p'_{(i,j),j} = 1$, $i,j = 1, \ldots, m$; $i \neq j$. All other transfer probabilities are zero. Here (i,j) represents the service center corresponding to the transporters on link (i,j),$i,j = 1, \ldots, m$; $i \neq j$. If we model this system by an open Jackson queueing network, as described earlier, we find that the stationary distribution of the number of jobs in the machine centers (**n**), and the number of jobs in the transporters (**l**), is given by

$$p(\mathbf{n},\mathbf{l}) = \left\{\prod_{i=1}^{m} p_i(n_i)\right\} \prod_{i=1}^{m} \prod_{j=1;j\neq 1}^{m} p_{(i,j)}(l_{(i,j)}), \qquad \mathbf{n} \in \mathfrak{N}_+^m, \mathbf{l} \in \mathfrak{N}_+^{m^2-m} \tag{79}$$

where $p_i(n_i) = f_i(n_i p_i(0)$, $p_i(0) = 1/\Sigma_{n_i=0}^{\infty} f_i(n_i)$, and $f_i(n_i) = \lambda_i f_i(n_i - 1)/\mu_i r_i(n_i)$, $f_i(0) = 1$; $i = 1, \ldots, m$,

$$p_{(i,j)}(l_{(i,j)}) = \frac{e^{-\rho(i,j)} \rho_{(i,j)}^{l_{(i,j)}}}{l_{(i,j)}!}, \quad i,j = 0, 1, \ldots; i \neq j \tag{80}$$

and $\rho_{(i,j)} = \lambda_{(i,j)}/\mu_{(i,j)} = \lambda_i p_{ij}/\mu_{(i,j)}$, $i \neq j, i,j = 1, \ldots, m$. Here n_i is the number of jobs in machine center i and $l_{(i,j)}$ is the number of jobs in transit from machine center i to j, $i \neq j$, $i,j = 1, \ldots, m$. Observe that if $p_{ij} = 0$ then $\rho_{(i,j)} = 0$ and the number of jobs in transit on link (i,j) is also zero, as it should be. If we are only interested in the total number of jobs in transit, we find that

$$P\{l \text{ jobs are in transit}\} = e^{-\hat{\rho}} \hat{\rho}^l / l!, \qquad l = 0,1,... \tag{81}$$

where

$$\hat{\rho} = \sum_{i=1}^{m} \lambda_i \sum_{j=1;j\neq 1}^{m} p_{ij}/\mu_{(i,j)}$$

and $\hat{\rho}$ is the mean number of jobs in transit. Applying Little's law, one sees that the additional average time spent by an arbitrary job in the shop due to material handling is

$$E[\hat{T}] = \frac{1}{\lambda} \sum_{i=1}^{m} \lambda_i \sum_{j=1;j\neq i}^{m} p_{ij}/\mu_{(i,j)} = \sum_{i=1}^{m} \sum_{j=1;j\neq 1}^{m} \frac{v_{(i,j)}}{\mu_{(i,j)}} \tag{82}$$

where $v_{(i,j)}$ is the expected number of times an arbitrary job is moved along the link (i,j), $i \neq j$; $j = 1, \ldots, m$. Now observe that the distribution of the number of jobs at different machine centers given in (79) is independent of the transportation times. Hence we see that the number of jobs at different machine centers is unaffected by the actual transportation time. All it does is to add an additional amount $E[\hat{T}]$ to the average flow time of an arbitrary job.

5.3. General Service Times

The modeling of open queueing networks with general service times, is discussed in Chapter 83, Section 7.2. The basis of the approximation is to assume that the queue length distributions at the different service centers are independent, that is,

$$P\{N_i = n_i, i = 1, \ldots, m\} = \prod_{i=1}^{m} P\{\hat{N}_i = n_i\}, \qquad \mathbf{n} \in \Im_+^M \tag{83}$$

$$E[N] = \sum_{i=1}^{m} E[\hat{N}_i] \tag{84}$$

and

$$E[T] = \sum_{i=1}^{m} v_i E[\hat{T}_i] \tag{85}$$

where N_i is the number of jobs at machine center i, $N = \Sigma_{i=1}^{m} N_i$ is the total number of jobs in the system, and T is the flow time of an arbitrary job. v_i is the average number of visits made to a service center by an arbitrary job.

Each service center i, $i = 1, \ldots, m$ is modeled by a $GI/GI/c_i$ queue. The parameters of this queue will be $(\lambda_i, C_{a}^2, \mu_i, C_{si}^2, c_i)$, where λ_i and $C_{a_i}^2$ are the mean arrival rate and squared coefficient of variation of the time between arrivals at service center i, μ_i and $C_{S_i}^2$ are the mean service rate and squared coefficient of variation of the service time of a job at service center i. Then, using some appropriate approximation, the mean number of jobs at service center i, $\hat{n}_i(\lambda_i, C_{a_i}^2, \mu_i, C_{S_i}^2, c_i)$ and the mean flow time of a job at service center i, $\hat{T}(\lambda_i, C_{a_i}^2, \mu_i, C_{S_i}^2, c_i)$ are estimated.

Given the job transfer probability matrix, $\mathbf{P} = (p_{ij})$, then the λ_i are the solution to the equations

$$\lambda_i = \lambda\gamma_i + \sum_{j=1}^{m} \lambda_j p_{ji}, \qquad i = 1, \ldots, m$$

and $v_i = \lambda_i/\lambda$, $i = 1, \ldots, m$.

The $C_{a_i}^2$ are determined by observing that if $C_{d_j}^2$ is the squared coefficient of variation of departures from service center j, then with probabilistic routing, the stream of jobs from service center j will arrive at service center i with a squared coefficient of variation C_{aj}^2, given by

$$C_{aji}^2 = 1 - p_{ji} + p_{ji} C_{dj}^2$$

Jobs coming from outside the system will arrive in a stream with squared coefficient of variation $C_{a0j}^2 = 1 - \gamma_i + \gamma_i C_a^2$. This job stream will merge with job streams coming from other service centers and from outside the system. Approximately, the squared coefficient of variation of arrivals at service center i, $C_{a_i}^2$, is given by

$$C_{a_i}^2 = \frac{1}{\lambda_i}\left\{\sum_{j=1}^{m} \lambda_j C_{aji}^2 + \lambda\gamma_i C_{a0i}^2\right\} \tag{86}$$

5.3.1. Approximations for $\hat{n}_i$ and $C_{d_i}^2$

In implementing the decomposition approach, a variety of ways of approximating $\hat{n}_i$ and $C_{d_i}^2$ have been used. It can be shown (Buzacott and Shanthikumar 1993) that in a $GI/G/1$ queue, C_d^2 and $E[N]$ are related by

$$C_d^2 = C_a^2 + 2\rho^2 C_S^2 + 2\rho(1 - \rho) - 2(1 - \rho)E[N] \tag{87}$$

so it would seem reasonable to assume that if $c_i = 1$, the approximated $C_{d_i}^2$ and the approximation $\hat{n}_i$ are connected by the same relationship as Eq. (87).

The choice of approximation $\hat{n}_i$ is largely determined by the purpose of the modeling. If the purpose is to arrive at performance predictions that will agree closely with simulation results, then a more complex approximation is used. However, if the purpose of the approximation is to compare a number of different system designs, then simpler approximations are usually quite adequate to get the necessary insight. Whitt (1983) and Shanthikumar and Buzacott (1981) used relatively complex approximations because their purpose was to demonstrate that in many situations the approximate decomposition approach yields remarkably accurate predictions. Harrison and Nguyen (1990) suggest that, in fact, a simple heavy-traffic approximation is often quite adequate. As a general rule, the more there is some randomness in job routings the more accurate the approximations are. The QNA approximations are given in Chapter 83, so we give here are two other approaches:

1. Buzacott and Shanthikumar (1993): For $c = 1$ this sets

$$E[\hat{N}(\lambda, C_a^2, \mu, C_S^2, 1)] = \left\{\frac{\rho^2(1 + C_S^2)}{1 + \rho^2 C_S^2}\right\}\left\{\frac{C_a^2 + \rho^2 C_S^2}{2(1 - \rho)}\right\} + \rho \tag{88}$$

2. Harrison and Nguyen (1990): Assume $c = 1$. Their approximation is

$$E[\hat{N}(\lambda_i, C_{a_i}^2, \mu_i, C_{S_i}^2, 1)] = \frac{\rho_i^2(C_{a_i}^2 + C_{S_i}^2)}{2(1 - \rho_i)} + \rho_i \tag{89}$$

where $\rho_i = \lambda_i/\mu_i$ and they set

$$C_{d_i}^2 = C_{S_i}^2$$

We would, however, recommend setting $C_{d_i}^2$ using Eq. (87), that is,

$$C_{d_i}^2 = (1 - \rho_i^2)C_{a_i}^2 + \rho_i^2 C_{S_i}^2 \tag{90}$$

An even simpler approximation is to set

$$E[\hat{N}(\lambda_i, C_{a_i}^2, \mu_i, C_{S_i}^2, 1)] = \frac{C_{a_i}^2 + C_{S_i}^2}{2(-\rho_i)} + \rho_i \tag{91}$$

and

$$C_{d_i}^2 = C_{S_i}^2 \tag{92}$$

This approximation is particularly useful for gaining insight into alternative ways of allocating tasks to workers in service systems, for example, should workers have a broad range of tasks in a system or should they specialize (Buzacott 1996).

6. FLEXIBLE MACHINING SYSTEMS

The key feature of a flexible machining system that must be represented in queueing models is the limited number of pallets or work holders available for holding jobs in process. This means that the number of jobs in process cannot exceed the number of pallets.

6.1. Single-Class Closed Jackson Queueing Network Model

Consider a flexible machining system consisting of m machine centers $(1, \ldots, m)$ and a load/unload station "0." There are n parts of a single (probably aggregated) class of parts that circulate from one service center to another according to a transfer probability matrix $\mathbf{P} = (p_{ij})_{i,j=0,\ldots,m}$. We will assume that all self transitions have been eliminated so that $p_{ii} = 0$, $i = 1, \ldots, m$. The service requirements of parts at service center i are i.i.d. exponential random variables with mean $1/\mu_i$, $i = 0, \ldots, m$. The sequence of service requirements at the different service centers is mutually independent. The rate at which unit service requirement of a part is processed at a machine center i when there are k parts is assumed to be $r_i(k)$, $k = 1, \ldots, n$; $i = 0, \ldots, m$. This allows us to represent, as special cases, single or multiple servers in parallel at each service center. The parts at each service center are served according to a first-come-first-served service protocol.

Let $N_i(t)$ be the number of parts at service center i at time t, $i = 0, 1, \ldots, m$ and let $\mathbf{N}(t) = \{N_0(t), \ldots, N_m(t)\}$. Then $\{\mathbf{N}(t), t \geq 0\}$ is a continuous-time Markov process on the state space S_n, where

$$\begin{aligned} \mathcal{S}_l &= \{\mathbf{k} : \mathbf{k} \in \mathcal{R}_+^{m+1}, |\mathbf{k}| = l\}, \qquad l = 1, 2, \ldots \\ \mathcal{S}_0 &= \{0, \ldots, 0\} \end{aligned} \tag{93}$$

Define the stationary distribution of $\mathbf{N}$ by $p(\mathbf{k}) = \lim_{t\to\infty} P\{\mathbf{N}(t) = \mathbf{k}\}$, $\mathbf{k} \in S_n$. Then it can be shown that (e.g., see Gordon and Newell (1967))

$$p(\mathbf{k}) = \frac{1}{G(n)} \prod_{i=0}^{m} p_i(k_i), \qquad \mathbf{k} \in \mathcal{S}_n \tag{94}$$

where

$$p_i(k_i) = \frac{v_i^{k_i}}{\prod_{j=1}^{k_i} \mu_i r_i(j)}, \qquad k_i = 0, \ldots, n; \qquad i = 0, \ldots, m \tag{95}$$

v_i, $i = 1, \ldots, m$ is the solution to

$$v_i = \sum_{j=0}^{m} v_j p_{ji}, \; i = 1, \ldots, m \tag{96}$$

with $v_0 = 1$ and

$$G(n) = \sum_{\mathbf{k} \in \mathcal{S}_n} \prod_{i=0}^{m} \frac{v_i^{k_i}}{\prod_{j=1}^{k_i} \mu_i r_i(j)} \tag{97}$$

Let Y_i be a generic random variable representing the stationary distribution of the number of parts in an $M/M(n)/1$ queueing system with arrival rate $\lambda_i = \lambda v_i$ and state-dependent service rate $\mu_i r_i(k_i)$ when there are k_i parts in the system ($k_i = 1, 2, \ldots$). λ can be any value that guarantees the existence of a stationary distribution for the $M/M(n)/1$ queue. For example, if $r_i(k_i) = \min\{k_i, c_i\}$, that is, we have c_i parallel servers at service center i, then we require that $\lambda_i < \mu_i c_i$ or equivalently $\lambda < \mu_i c_i / v_i$. It is easily verified that

$$P\{\mathbf{N} = \mathbf{k}\} = P\{\mathbf{Y} = \mathbf{k} | \, |\mathbf{Y}| = n\}, \qquad \mathbf{k} \in \mathcal{S}_n \tag{98}$$

where $Y_0, \ldots, Y_m$ are independent. It is also clear that the distribution of $\mathbf{Y}$ is the stationary distribution of an open Jackson queueing network with a set of service centers $\{0, \ldots, m\}$, and an arbitrary part visiting service center i, on the average v_i number of times before it leaves the system ($i = 1, \ldots, m$) and the load/unload center twice ($= 2v_0$). The service rate at service center i is $\mu_i r_i(k_i)$ when there are k_i parts for $i = 1, \ldots, m$ and $2\mu_0 r_0(k_0)$ when there are k_0 parts at the load/unload service center. Note that the average load or unload times are $1/2\mu_0$ while the combined load/unload operation (incorporated as a single operation) in the closed queueing network model requires an average of $1/\mu_0$ units of time. The external part arrival rate is λ. Note that this open Jackson network could be our model for the FMS if we had free inflow of raw parts into the system at rate λ. Therefore, the distribution of the number of parts in the closed queueing network model is the same as that in an open queueing network model, provided we observe the open queueing network only when there are a total of n parts in it.

Therefore, the probability distribution of the number of parts in an open queueing network model can be used to compute the probability distribution of the number of parts in the closed queueing network. To do this, we need to compute the convolution of the probability distributions $P\{Y_i = k_i\} = P\{Y_i = 0\} \; (\lambda v_i / \mu_i)^{k_i} / \Pi_{j=1}^{k_i} \; r_i(j)$, $i = 0, \ldots, m$. The following algorithm will compute this convolution and the stationary distribution of the number of parts in the closed queueing network.

6.1.1. Algorithm 5: Convolution Algorithm

Step 1: Set $p_i(0) = 1$, $i = 0, \ldots, m$.

Step 2: For $i = 0, \ldots, m$ and $k = 0, \ldots, n - 1$, set

$$p_i(k + 1) = p_i(k) \frac{v_i}{\mu_i r_i(k + 1)}$$

Step 3: Set $\hat{p}(k) = p_0(k)$, $k = 0, \ldots, n$.

For $i = 1, \ldots, m$ and for $k = 0, \ldots, n$, set

$$\hat{q}(k) = \sum_{l=0}^{k} \hat{p}(l) p_i(k - l)$$

For $k = 0, \ldots, n$, set

$$\hat{p}(k) = \hat{q}(k)$$

Step 4: $p(\mathbf{k}) = 1/\hat{q}(n) \; \Pi_{i=0}^{m} \; p_i(k_i)$, $\mathbf{k} \in \mathcal{S}_n$.

Step 5: Stop.

Let TH(n) be the throughput rate of this closed queueing network. This is the rate at which parts are loaded/unloaded at the load/unload service center, that is, TH(n) = $E[\mu_0 r_0(N_0)]$. Using (98), we see that

$$\begin{aligned} \mathrm{TH}(n) &= E[\mu_0 r_0(Y_0) \mid |\mathbf{Y}| = n] \\ &= \sum_{\mathbf{k} \in \mathcal{S}_n} \frac{\mu_0 r_0(k_0) P\{\mathbf{Y} = \mathbf{k}\}}{P\{|\mathbf{Y}| = \boldsymbol{n}\}}. \end{aligned} \tag{99}$$

Since $\mu_0 r_0(k_0) P\{Y_0 = k_0\} = \lambda P\{Y_0 = k_0 - 1\}$, $k_0 \geq 1$ and $r_0(0) = 0$, we get from (99)

$$\begin{aligned} \mathrm{TH}(n) &= \lambda \sum_{\mathbf{k}' \in \mathcal{S}_{n-1}} \frac{P\{\mathbf{Y} = \mathbf{k}'\}}{P\{|\mathbf{Y}| = n\}} \\ &= \lambda \frac{P\{|\mathbf{Y}| = n - 1\}}{P\{|\mathbf{Y}| = n\}}. \end{aligned} \tag{100}$$

Equivalently,

$$\lambda P\{|\mathbf{Y}| = n - 1\} = \mathrm{TH}(n) P\{|\mathbf{Y}| = n\}, \qquad n = 1, 2, \ldots \tag{101}$$

Hence we see that the total number of parts in the open queueing network is the same in distribution as that in an $M/M(n)/1$ queueing system with arrival rates λ and state dependent service rates TH(n), $n = 1, 2, \ldots$ For the purpose of analyzing the aggregate behavior of the total number of parts in the system, we can aggregate the whole FMS and replace it by an equivalent single-stage server with state dependent service rates equal to the production rates.

Next we will look at another property of the closed queueing network process $\{\mathbf{N}(t), t \geq 0\}$ that will help us to efficiently compute the production capacity of the flexible machining system. Denote by $\mathbf{e}_i$ a vector that is all zeroes except for a one in position i. Let $\tau_n^{(i)}$ be the nth time epoch at which an arrival occurs at service center i. We are interested in

$$p^{(i)}(\mathbf{k}) = \lim_{n \to \infty} P\{\mathbf{N}(\tau_n^{(i)}) = \mathbf{k} + \mathbf{e}_i\}, \qquad \mathbf{k} \in \mathcal{S}_{n-1}$$

the probability distribution of number of parts at different service centers seen by an arbitrary arrival at its arrival epoch to service center i. $\mathcal{S}_{n-1}$ contains all possible states that could be seen by any part excluding itself.

The rate at which an arrival to service center i sees the system state $\mathbf{k}$ at its arrival epoch is $\Sigma_{j=0}^{m} p(\mathbf{k} + \mathbf{e}_j)\mu_j r_j(k_j + 1)p_{ji}$. The rate at which parts arrive at service center i is $\Sigma_{\mathbf{k} \in S_{n-1}} \Sigma_{j=0}^{m} p(\mathbf{k} + \mathbf{e}_j)\mu_j r_j(k_j + 1)p_{ji}$. Then it can be shown that

$$p^{(i)}(\mathbf{k}) = \frac{\prod_{l=0}^{m} \dfrac{v_l^{k_l}}{\prod_{j=1}^{k_l} \mu_l r_l(j)}}{\sum_{\mathbf{k}' \in \mathcal{S}_{n-1}} \prod_{l=0}^{m} \dfrac{v_l^{k_l}}{\prod_{j=1}^{k_l} \mu_l r_l(j)}}, \qquad \mathbf{k} \in \mathcal{S}_{n-1} \tag{102}$$

Observe that $p^{(i)}(\mathbf{k})$ is exactly the same as the stationary distribution of the number of parts in the closed queueing network with a total of $n - 1$ parts. Furthermore, this probability distribution is independent of the service center i. Since we will be using this relationship between the closed queueing network with n and $n - 1$ parts in it to compute the performance measures, we will use an index n to associate the total number of parts to its performance measures. Earlier, we saw how to obtain the joint probability distribution $p(\mathbf{k})$, $\mathbf{k} \in \mathcal{S}_n$. However, in most applications it may be sufficient to compute the marginal probability distribution $p_i(k_i;n)$, $k_i = 0, \ldots, n$; its average (i.e., the average number of parts at service center i), $E[N_i(n)]$, the average sojourn time of an arbitrary part in service center i, $E[T_i(n)]$, $i = 0, \ldots, m$, and the throughput TH(n). Then TH(n) = $\mu_0 E[r_0(N_0(n))]$ is the rate at which parts are being loaded/unloaded at the load/unload service center. Using a simple recursive algorithm over the values of n, we can compute these performance measures with considerably less computational effort than required by the convolution algorithm described earlier.

The rate at which parts arrive at service center i is v_iTH(n). Since the probability that an arrival at service center i sees $k_i - 1$ parts in service center i is $p_i(k_i - 1; n - 1)$, the rate of upcrossings from the compound state $\{\mathbf{k}' : \mathbf{k}' \in \mathcal{S}_n, k_i' = k_i - 1\}$ is $v_i \mathrm{TH}(n) p_i(k_i - 1; n - 1)$. Equating this to the rate of downcrossings ($\mu_i r_i(k_i) p_i(k_i;n)$) into this compound state, we get

$$p_i(k_i; n) = \frac{v_i}{\mu_i r_i(k_i)} \mathrm{TH}(n) p_i(k_i - 1; n - 1), \qquad k_i = 1, \ldots, n$$

$$p_i(0; n) = 1 - \sum_{k_i=1}^{n} p_i(k_i; n), \qquad n = 1, 2, \ldots \tag{103}$$

From (103) and Little's results we find that

$$E[N_i(n)] = \mathrm{TH}(n) \sum_{k_i=0}^{n-1} \frac{(k_i + 1)v_i}{\mu_i r_i(k_i + 1)} p_i(k_i; n - 1) \tag{104}$$

and

$$E[T_i(n)] = \sum_{k_i=0}^{n-1} \frac{k_i + 1}{\mu_i r_i(k_i + 1)} p_i(k_i; n - 1) \tag{105}$$

Since $\Sigma_{i=0}^{m} E[N_i(n)] = n$, we obtain

$$\mathrm{TH}(n) = \frac{n}{\sum_{i=0}^{m} v_i E[T_i(n)]} \tag{106}$$

Equations (103)–(106) provide a recursive relationship for $p_i(\cdot; n)$ and $\mathrm{TH}(n)$. As an initial value for this recursion observe that $p_i(0; 0) = 1$, $i = 0, \ldots, m$. Then $\mathrm{TH}(1) = 1/\Sigma_{i=0}^{m} v_i/\mu_i r_i(1)$. An algorithm to compute these performance measures using this recursion is presented next:

6.1.2. Algorithm 6: Marginal Distribution Analysis Algorithm

Step 1: Set $p_i(0; 0) = 1$, $i = 0, \ldots, m$.

Step 2: For $l = 1, \ldots, n$, compute

$$E[T_i(l)] = \sum_{k_i=0}^{l-1} \frac{k_i + 1}{\mu_i r_i(k_i + 1)} p_i(k_i; l - 1); \qquad i = 0, \ldots, m$$

$$\mathrm{TH}(l) = l \Big/ \left\{ \sum_{i=0}^{m} v_i E[T_i(l)] \right\}$$

$$E[N_i(l)] = v_i \mathrm{TH}(l) E[T_i(l)], \qquad i = 0, \ldots, m$$

$$p_i(k_i; l) = \frac{v_i \mathrm{TH}(l)}{\mu_i r_i(k_i)} p_i(k_i - 1; l - 1), \qquad k_i = 1, \ldots, l; \; i = 0, \ldots, m$$

$$p_i(0; l) = 1 - \sum_{k_i=1}^{l} p_i(k_i; l), \qquad i = 0, \ldots, m$$

Step 3: Stop.

When we have only a single server at a service center i (i.e., $c_i = 1$) the computational effort required for the marginal distribution analysis can be reduced by the following observation $E[T_i(n)] = \{E[N_i(n - 1)] + 1\}/\mu_i$. Particularly if each service center has only a single server (i.e. $c_i = 1$, $i = 0, \ldots, m$), the following mean value analysis algorithm provides an efficient way to compute the system performance measures.

6.1.3. Algorithm 7: Mean Value Analysis Algorithm

Step 1: Set $E[N_i(0)] = 0$, $i = 0, \ldots, m$.

Step 2: For $l = 1, \ldots, n$, compute

$$E[T_i(l)] = \{E[N_i(l - 1)] + 1\}/\mu_i, \qquad i = 0, \ldots, m$$

$$\mathrm{TH}(l) = l \Big/ \left\{ \sum_{i=0}^{m} v_i E[T_i(l)] \right\},$$

$$E[N_i(l)] = v_i \mathrm{TH}(l) E[T_i(l)], \qquad i = 0, \ldots, m$$

Step 3: Stop.

6.1.4. *Properties of the Throughput*

The production rate TH(n) has some useful properties in terms of the influence of the number of servers c_i at service center i, and the workload $\hat{\rho}_i = v_i/\mu_i$ assigned to service center i. To indicate this dependence, the production rate is represented by TH($\hat{\rho}$, c, n)

Property 1: TH($\hat{\rho}$, c, n) is increasing and concave in n.

Property 2: TH($\hat{\rho}$, c, n) is increasing and concave in c_i, $i = 0, \ldots, m$.

Property 3: TH($\hat{\rho}$, c, n) is decreasing and convex in each $\hat{\rho}_i$, $i = 0, \ldots, m$.

Property 4: If $c_0 = c_1 = \cdots = c_m$ then, if work load can be reallocated between service centers, the production rate is maximized by having the same work load at all service centers.

6.2. Modeling the Effects of Dedicated Material-Handling Systems

Suppose we have material-handling systems available for each link connecting any two service centers, such that no queueing delays take place during part movement. The only time expended on moving parts is the travel time. Let $1/\mu_{(i,j)}$ be the average travel time of a part on the link (i,j), $i,j = 0, \ldots, m$. Now, treating such a link (i,j) as a service center with infinitely many servers, one sees that $v_{ij} = v_i p_{ij}$ and $E[T_{ij}(n)] = 1/\mu_{(i,j)}$, $i,j = 0, \ldots, m$. Incorporating this in the MVA algorithm, we get the following algorithm to compute the system performance with material-handling effects.

6.2.1. *Algorithm 8: MVA with Material Handling*

Step 1: Let $E[N_i(0)] = 0$, $i = 0, \ldots, m$.

Step 2: For $l = 1, \ldots, n$, compute

$$E[T_i(l)] = \{E[N_i(l-1)] + 1\}/\mu_i, \qquad i = 0, \ldots, m$$

$$\mathrm{TH}(l) = l \Big/ \left\{ \sum_{i=0}^{m} v_i E[T_i(l)] + \sum_{i=0}^{m} \sum_{j=0}^{m} v_i p_{ij}/\mu_{(ij)} \right\}$$

$$E[N_i(l)] = v_i \mathrm{TH}(l) E[T_i(l)], \qquad i = 0, \ldots, m$$

Step 3: Stop.

6.3. General Single-Class Closed Queueing Network Model

Usually service times will not be exponential. We now present an approximation by which performance measures of closed queueing networks can be found. Because the approximation extends the mean value analysis algorithm, it can only be used if there is just one server at each machine center. For an approximate algorithm that can be used when there are multiple servers at a machine center, see Buzacott and Shanthikumar (1993). The extended MVA algorithm is based on the following: each arrival to service center i will see, at the instant of its arrival, the part in service, if any, requiring an average of $E[S_i^2]/2E[S_i]$ additional processing time to complete its service. This mimics the property of an $M/G/1$ queueing system. With this, and the assumption that an arrival with n parts in the system sees the time average behavior of a system with $n-1$ parts, we have

$$\begin{aligned} E[T_i(n)] = {} & \{E[N_i(n-1)] - v_i \mathrm{TH}(n-1) E[S_i] + 1\} E[S_i] \\ & + v_i \mathrm{TH}(n-1) E[S_i^2]/2, \qquad i = 0, \ldots, m \end{aligned} \tag{107}$$

The above relationship is then applied in the following algorithm.

6.3.1. *Algorithm 9: Extended Mean Value Analysis* (EMVA)

Step 1: Set $E[N_i(0)] = 0$, $i = 0, \ldots, m$; $\mathrm{TH}(0) = 0$.

Step 2: For $l = 1, \ldots, n$, compute

$$\begin{aligned} E[T_i(l)] = {} & \{E[N_i(l-1)] - v_i \mathrm{TH}(l-1) E[S_i] + 1\} E[S_i] \\ & + v_i \mathrm{TH}(l-1) E[S_i^2]/2, \qquad i = 0, \ldots, m \end{aligned}$$

$$\mathrm{TH}(l) = l \Big/ \left\{ \sum_{i=0}^{m} v_i E[T_i(l)] \right\}$$

$$E[N_i(l)] = v_i \mathrm{TH}(l) E[T_i(l)], \qquad i = 0, \ldots, m$$

Step 3: Stop.

6.4. Multiple-Class Model

An FMS is often required to process multiple part types where each part type requires a unique pallet type. Let n_s be the number of pallets for type s parts, $s = 1, \ldots, p$. Suppose the service time distribution for all part types at service center i, $i = 1, \ldots, m$ is the same for all part types and is exponential with mean $1/\mu_i$. Assume that parts are served at a service center in first-come-first-served sequence. Suppose the routing of class s parts between service centers of the FMS is described by the probability matrix $p_{ij}^{(s)}$. Let $v_i^{(s)}$ be the solution to

$$v_i^{(s)} = \sum_{j=0}^{m} v_j^{(s)} p_{ji}^{(s)} \tag{108}$$

with $v_0^{(s)} = 1$, for each $s = 1, \ldots, p$. Then $v_i^{(s)}$ is the expected number of times a class s part visits service center i during its sojourn in the system.

Then again it is possible to show that the queue length distributions are product form and is thus possible to determine the performance measures. If there is just one machine at each service center, then the mean value analysis algorithm can be adapted to find the performance measures. Define $\mathbf{n} = (n_1, n_2, \ldots, n_p)$ and $\mathbf{n} - \mathbf{e}_s = (n_1, n_2, \ldots, n_s - 1, \ldots, n_p)$. Then the expected time that a class s job spends at station i, $E[T_{i,s}(\mathbf{n})]$ and the expected number of jobs of class s at station i, $E[N_{i,s}(\mathbf{n})]$ are related by $E[T_{i,s}(\mathbf{n})] = (E[N_{i,s}(\mathbf{n} - \mathbf{e}_s)] + 1)/\mu_i$. The algorithm is as follows.

6.4.1. Algorithm 10: Multiclass MVA

Step 1: Set $E[N_{i,s}(\mathbf{l})] = 0$, $l_s \leq 0$; $s = 1, \ldots, p$; $i = 0, \ldots, m$.

Step 2: For $l_1 = 0, \ldots, n_1; \ldots; l_p = 0, \ldots, n_p$ repeat step 3.

Step 3: For $i = 0, \ldots, m$ and $s = 1, \ldots, p$, compute

$$E[T_{i,s}(\mathbf{l})] = \{E[N_{i,s}(\mathbf{l} - \mathbf{e}_s)] + 1\}/\mu_i$$

$$\mathrm{TH}_s(\mathbf{l}) = l_s \Big/ \left\{ \sum_{i=0}^{m} v_i^{(s)} E[T_{i,s}(\mathbf{l})] \right\}$$

$$E[N_{i,s}(\mathbf{l})] = v_i^{(s)} \mathrm{TH}_s(\mathbf{l}) E[T_{i,s}(\mathbf{l})]$$

Step 4: Stop.

6.4.2. Properties of the Throughput Rate

The throughput function of the multiple-class closed Jackson queueing network possesses some properties that are, at first, somewhat surprising.

Property 1: $\mathrm{TH}_s(\mathbf{n})$ is increasing in n_s for each s ($s = 1, \ldots, p$).

Property 2: $\mathrm{TH}_l(\mathbf{n})$ *need not* increase (and may *decrease*) in n_s for $s \neq l$, $s, l = 1, \ldots, p$.

Property 3: $\mathrm{TH}(\mathbf{n}) = \sum_{s=1}^{p} \mathrm{TH}_s(\mathbf{n})$ *need not* increase (and may *decrease*) in n_s, $s = 1, \ldots, p$.

Properties 2 and 3 mean that the selection of parts to be processed in an FMS requires extreme care. Note that these properties are in part due to the assumption of first-come-first-served sequence at service centers, so their effect can be reduced by more sophisticated scheduling.

6.4.3. General Service Time Distributions

It is possible to heuristically adapt the multiclass MVA algorithm for situations where the service times are not exponential. Let $E[N_{i,s}(\mathbf{l})]$ be the average number of class s parts at service center i when the total number of class s parts in the network is l_s, $s = 1, \ldots, p$. Let $\mathbf{l} + \mathbf{e}_s = (l_1, \ldots, l_{s-1}, l_s + 1, l_{s+1}, \ldots, l_p)$. Also let $E[T_{i,s}(\mathbf{l})]$ be the average flow time of a class s part through service center i and $\mathrm{TH}_s(\mathbf{l})$ be the throughput rate of class s parts. Then the rate at which parts arrive at service center i is

$$\lambda_i(\mathbf{l}) = \sum_{s=1}^{p} v_i^{(s)} \mathrm{TH}_s(\mathbf{l}), \qquad i = 0, \ldots, m$$

The basic idea is to adapt the equation describing the expected time a class s part spends at station i as follows:

$$E[T_{i,s}(\mathbf{l} + \mathbf{e}_s)] = E[S_i^{(s)}] + \sum_{\hat{s}=1}^{p} (E[N_{i,\hat{s}}(\mathbf{l})] - \lambda_i^{(\hat{s})}(\mathbf{l})E[S_i^{(\hat{s})}(\mathbf{l})])E[S_i^{(\hat{s})}] + \lambda_i(\mathbf{l})\frac{E[S_i^2(\mathbf{l})]}{2}, \qquad i = 0, \ldots, m \tag{109}$$

where

$$E[S_i(\mathbf{l})] = \frac{1}{\lambda_i(\mathbf{l})}\sum_{\hat{s}=1}^{p} \lambda_i^{(\hat{s})}(\mathbf{l})E[S_i^{(\hat{s})}], \qquad i = 0, \ldots, m$$

and

$$E[S_i^2(\mathbf{l})] = \frac{1}{\lambda_i(\mathbf{l})}\sum_{\hat{s})=1}^{p} \lambda_i^{(\hat{s})}(\mathbf{l})E[S_i^{(\hat{s})})^2], \qquad i = 0, \ldots, m$$

are the first and second moments of the service time of an arbitrary part at service center i. Since $\Sigma_{i=0}^{m} E[N_{i,s}(\mathbf{l} + \mathbf{e}_s) = \mathrm{TH}_s(\mathbf{l} + \mathbf{e}_s)\ \Sigma_{i=0}^{m} v_i^{(s)}\ E[T_{i,s}(\mathbf{l} + \mathbf{e}_s)] = l_s + 1$, one has

$$\mathrm{TH}_s(\mathbf{l} + \mathbf{e}_s) = \frac{l_s + 1}{\sum_{i=0}^{m} v_i^{(s)}E[T_{i,s}(\mathbf{l} + \mathbf{e}_s)]}. \tag{110}$$

The above equations now provide a recursive scheme to compute $\mathrm{TH}_s(\mathbf{n})$, $s = 1, \ldots, p$ starting with $\mathrm{TH}_s(\mathbf{0}) = 0$, $s = 1, \ldots, p$. The following algorithm computes the approximate performance measures.

6.4.4. Algorithm 11: Extended Multiclass MVA

Step 1: Set $E[N_{i,s}(\mathbf{l})] = 0$, $\mathrm{TH}_s(\mathbf{l}) = 0$, $-1 \le l_{\hat{s}} \le 0$, $s, \hat{s} = 1, \ldots, p$; $i = 0, \ldots, m$.
Step 2: For $l_1 = 0, \ldots, n_1$; $l_2 = 0, \ldots, n_2$; $\ldots$; $l_p = 0, \ldots, n_p$ repeat step 3.
Step 3: For $i = 0, \ldots, m$; $s = 1, \ldots, p$ and $l_s \le n_s - 1$, compute

$$\lambda_i^{(s)}(\mathbf{l}) = v_i^{(s)}\mathrm{TH}_s(\mathbf{l})$$

$$\lambda_i(\mathbf{l}) = \sum_{s=1}^{p} \lambda_i^{(s)}(\mathbf{l})$$

and $E[T_{i,s}(\mathbf{l} + \mathbf{e}_s)]$ by (109). Then compute $\mathrm{TH}_s(\mathbf{l} + \mathbf{e}_s)$ by (110) and

$$E[N_{i,s}(\mathbf{l} + \mathbf{e}_s] = v_i^{(s)}\mathrm{TH}_s(\mathbf{l} + \mathbf{e}_s)/E[T_{i,s}(\mathbf{l} + \mathbf{e}_s)]$$

Step 4: Stop.

7. PRODUCTION COORDINATION

We now consider queueing models that can be used to model the control of workflow in manufacturing and logistic systems. What is different about these models is that it is necessary to model both the flow of information and the flow of material and how information is transformed into material or parts. So although the underlying model is usually that of a multiclass open or closed queue, the models have some unusual features. We consider manufacturing and logistic systems consisting of a number m of cells or stages. We restrict our discussion to the situation where each cell produces just one type of part and where the cells are arranged in series 1, 2, . . . , m and thus part flow is $1 \rightarrow 2 \rightarrow \cdots \rightarrow m$. When cell j completes processing, it puts completed parts in store j. Store j also serves as the input store to cell $j + 1$. If cell $j + 1$ were separated geographically from cell j, then it would be necessary to add in a transport cell between j and $j + 1$. Final demand is met from store m. When store m is empty then demand can not be met immediately. We consider only the case where unmet demand is backlogged. We are interested in using queueing models to find the service level, that is, the fraction of demand met from stock p_{ND}, or the expected delay in meeting demand $E[\Delta]$. We will ignore any possibility of batching and assume that work flow and work release is controlled on a part-by-part basis.

7.1. Base Stock Control

In base stock control there are target stock levels z_j set for the store j. If a demand occurs, information about the occurrence of the demand is immediately sent to each cell. On receipt of the information, a request for a part is sent to the input store, store $j - 1$. If no parts are available, then requests would queue until a part becomes available. Once the part is removed from store $j - 1$, it is then released to the production cell for processing. On completion of processing, the completed part is put in store j. Denote by $N_j(t)$ the number of parts released to the production cell j at time t and not yet completed, $N_{j-1}^{(r)}(t)$ the number of requests for parts waiting at the input store $j - 1$, and $N_j^{(e)}(t)$ the number of parts that would be required to bring the inventory in store j up to z_j. If store j is empty and there is a backlog of waiting requests of size $N_j^{(r)}(t)$, then

$$N_j^{(e)}(t) = z_j + N_j^{(r)}(t), \qquad N_j^{(r)}(t) = 1, 2, \ldots$$

In a base stock system the immediate signaling of all demands to all cells means that

$$N_j^{(e)}(t) \equiv N_j(t) + N_{j-1}^{(r)}(t)$$

Suppose demands occur as a Poisson stream with parameter λ. Then the rate at which requests for parts will arrive at store $j - 1$, $j = 2, \ldots, m + 1$, is λ. In fact, because the requests at different stores are triggered by the same demand, these requests at different cells will be correlated. Our approximation ignores this.

The basis of the base stock model is to model the behavior of each cell and each store and to take into account the way in which they are linked.

7.1.1. Cell Model

The cell j queueing model represents the arrival of the demand at the cell, its transmittal as a request to the input store $j - 1$, the release of the part from the input store to the cell j, and the delivery of the part from the cell to the output store j. That is, we model how the arriving information on the occurrence of a demand is converted to a finished part in the output store. The queueing model consists of two queues in series, where the first queue is where the requests queue at store $j - 1$ and the second queue is where parts queue for processing in cell j. We are also interested in the arrivals of finished parts at the output store j, although parts do not queue to enter the store. Since the input stream to the first queue is Poisson with parameter λ, we will approximate its output stream of releases to the cell by a Poisson stream with parameter λ. So if the cell has single or multiple servers or some network of servers, it can be modeled as an open Jackson queueing network and its stationary queue length distribution $p\{N_j = n\}$, $n = 0, 1, \ldots$, found.

Requests that arrive at store $j - 1$ when it is not empty do not queue and the part can be immediately released to cell j. However, requests that arrive when the store is empty have to wait until a part arrives at the store from cell $j - 1$. It follows that the request queue characteristics will be determined from the inventory shortfall in the store

$$p\{N_{j-1}^{(r)} = n\} = p\{N_{j-1}^{(e)} = n + z_{j-1}\} \qquad n = 1, 2, \ldots$$

$$p\{N_{j-1}^{(r)} = 0\} = \sum_{u=0}^{z_{j-1}} p\{N_{j-1}^{(e)} = u\} \tag{111}$$

Since we assume that the queue lengths at the two queues are product form, we have that

$$p\{N_j^{(e)} = n\} = \sum_{u=0}^{n} p\{N_{j-1}^{(r)} = u\} p\{N_j = n - u\}, \qquad n = 0, 1, \ldots \tag{112}$$

At store 1 we have that

$$p\{N_1^{(r)} = n\} = p\{N_1 = n + z_1\}, \qquad n = 1, 2, \ldots$$

$$p\{N_1^{(r)} = 0\} = \sum_{u=0}^{z1} p\{N_1 = u\}$$

Thus, by considering store 1, store 2, . . . , store m, in sequence using Eqs. (111) and (112) we can determine the $p\{N_j^{(r)} = n\}$, $n = 0, 1, \ldots$; $j = 1, 2, \ldots, m$. Hence,

$$p_{ND} = p\{N_m^{(r)} = 0\}$$

$$E[\Delta] = \sum_{n=0}^{\infty} np\{N_m^{(r)} = n\} \tag{113}$$

7.1.2. Single Server in Each Cell

If each cell consists of a single server with exponential processing time having mean $1/\mu_j$, $j = 1, \ldots, m$ then it is possible to develop a very simple recursive calculation. Let $\rho_j = \lambda/\mu_j$, and we also assume that the ρ_j, $j = 1, \ldots, m$, are all different. We postulate then that

$$p\{N_j^{(r)} = n\} = \sum_{u=1}^{j} c_u^{(j)} \rho_u^n (1 - \rho_u), \qquad n = 1, 2, \ldots; j = 1, \ldots, m$$

$$p\{N_j^{(r)} = 0\} = 1 - \sum_{u=1}^{j} \rho_u c_u^{(j)}, \qquad j = 1, \ldots, m$$

It follows that

$$c_u^{(j)} = c_u^{(j-1)} \rho_u^{z_j+1} \frac{(1 - \rho_j)}{\rho_u - \rho_j}, \qquad u = 1, 2, \ldots, j-1; j = 2, \ldots, m$$

$$c_j^{(j)} = \rho_j^{z_j} \left(1 - \sum_{u=1}^{j-1} c_u^{(j-1)} \rho_u \frac{(1 - \rho_j)}{\rho_u - \rho_j}\right), \qquad j = 2, \ldots, m$$

$$c_1^{(1)} = \rho_1^{z_1} \tag{114}$$

Equations (114) define a recursive scheme by which the $c_u^{(j)}$ can be determined.

The service level measures are then given by

$$p_{ND} = 1 - \sum_{u=1}^{m} \rho_u c_u^{(m)} \tag{115}$$

$$E[\Delta] = \sum_{u=1}^{m} c_u^{(m)} \frac{\rho_u}{1 - \rho_u} \tag{116}$$

Table 4 compares the approximations with simulation results for p_{ND} and $E[\Delta]$, respectively, for a system with $z_1 = 2$ and $z_2 = 2$ for a variety of values of ρ_1 and ρ_2. The approximation tends to underestimate p_{ND} and overestimate $E[\Delta]$ because of the assumption that arrivals at the machine queue are Poisson. In fact, they are less variable than Poisson. The approximation can be extended to systems where demand is notified in advance (Buzacott et al. 1992), that is, to MRP-like systems.

7.2. Kanban Control

In kanban control, there are k_j kanban cards associated with cell j, $j = 1, \ldots, m$. A cell j kanban card waits in store j until it is triggered by the arrival at the store of a cell $j + 1$ kanban card. The cell j kanban card then moves back to store $j - 1$, where it waits until parts are available. As soon as parts are available, then the kanban card and the associated part are released to cell j for processing.

From Buzacott et al. 1992. Reproduced with permission of Springer-Verlag.

On completion of processing by cell j, the finished part and the kanban move to store j, where they will wait until the next cell $j + 1$ kanban arrives. That is, movement of a cell j kanban is from store j to store $j - 1$ to cell j to store j again. Thus the queueing model of a kanban controlled system consists of a multiclass queue with $m + 1$ classes of customers. Class j customers represent the cell j kanbans, $j = 1, \ldots, m$, and class m+1 customers represent customer demands. Class j customers circulate in the closed loop: store $j \rightarrow$ store $j - 1 \rightarrow$ cell $j \rightarrow$ store j, $j = 1, \ldots, m$; while class $m + 1$ customers enter the system, go to store m, and then leave the system. Assume that customer demand is Poisson with parameter λ. It will also be assumed that the cell consists of a single machine, and service times in the cells have exponential distributions with parameter μ_j for cell j, $j = 1, \ldots, m$.

To determine the system performance, it is necessary to model the circulation of class j customers and to model the interrelationship between the service of class j customers at store j and the service of class $j + 1$ customers at store j.

7.2.1. Store Model

Consider store j. Store inventory increases when a part and its associated stage j kanban arrive from cell j. Store inventory decreases when a stage $j + 1$ kanban arrives at the store and triggers the release of a part to cell $j + 1$. The maximum backlog of unmet demands at store j is k_{j+1} so, defining $n_j^{(e)}$ as the inventory shortfall, the inventory position at store j is $k_j - n_j^{(e)}$ with $n_j^{(e)} = 0, 1, \ldots, k_j, \ldots, k_j + k_{j+1}$. For a given $n_j^{(e)}$, the quantities $n_j^{(p)}$ and $n_j^{(r)}$ are determined by

$$n_j^{(p)} = \begin{cases} k_j - n_j^{(e)} & n_j^{(e)} = 0, 1, \ldots, k_j \\ 0 & n_j^{(e)} = k_j + 1, \ldots, k_j + k_{j+1} \end{cases}$$

and

$$n_j^{(r)} = \begin{cases} 0 & n_j^{(e)} = 0, 1, \ldots, k_j \\ n_j^{(e)} - k_j & n_j^{(e)} = k_j + 1, \ldots, k_j + k_{j+1} \end{cases}$$

Note that $n_j^{(r)} \times n_j^{(p)} \equiv 0$. $n_j^{(r)}$ is the number of stage $j + 1$ kanbans waiting at store j, while $n_j^{(p)}$ is the number of stage j kanbans waiting at the store (which is identical to the number of parts in the store).

Let $\lambda_{j:u}(n_j^{(p)})$ be the rate at which stage j kanbans arrive at store j from cell j when there are $n_j^{(p)}$ stage j kanbans at store j. Similarly, let $\lambda_{j:d}(n_j^{(r)})$ be the rate at which stage $j + 1$ kanbans arrive at store j from store $j + 1$ when there are $n_j^{(r)}$ stage $j + 1$ kanbans at store j.

It follows that, for a given $n_j^{(e)}$ such that $0 \le n_j^{(e)} \le k_j - 1$, the rate of increase to $n_j^{(e)} + 1$ is $\lambda_{j:d}(0)$ while, for $n_j^{(e)}$ such that $1 \le n_j^{(e)} \le k_j$, the rate of decrease to $n_j^{(e)} - 1$ is $\lambda_{j:u}(k_j - n_j^{(e)})$. Similarly, for $n_j^{(e)}$ such that $k_j \le n_j^{(e)} \le k_j + k_{j+1} - 1$, the rate of increase to $n_j^{(e)} + 1$ is $\lambda_{j:d}(n_j^{(e)} - k_j)$, and, for $n_j^{(e)}$ such that $k_j + 1 \le n_j^{(e)} \le k_j + k_{j+1}$, the rate of decrease is $\lambda_{j:u}(0)$.

It follows that the probability distribution of $n_j^{(e)}$ is given by

$$p_j(n_j^{(e)}) = \begin{cases} \dfrac{\prod_{v=n_j^{(e)}}^{k_j-1} \lambda_{j:u}(k_j - v - 1)}{\lambda_{j:d}(0)^{k_j - n_j^{(e)}}} p_j(k_j) & n_j^{(e)} = 0, 1, \ldots, k_j - 1 \\ \dfrac{\prod_{v=0}^{n_j^{(e)} - k_j b - 1} \lambda_{j:d}(v)}{\lambda_{j:u}(0)^{n_j^{(e)} - k_j}} p_j(k_j) & n_j^{(e)} = k_j + 1, \ldots, k_j + k_{j+1} \end{cases} \tag{117}$$

and $p_j(k_j)$ is determined by $\sum_{n_j^{(e)}=0}^{k_j+k_{j+1}} p_j(n_j^{(e)}) = 1$.

When a stage $j + 1$ kanban arrives at store j from store $j + 1$ then it will find no other stage $j + 1$ kanbans waiting if, just prior to its arrival, $n_j^{(e)} \le k_j$. However, even though it finds no stage $j + 1$ kanbans waiting, it will have to wait for a part if, just prior to its arrival, $n_j^{(e)} = k_j$. Hence $q_{j:u}$, the probability that an arriving stage $j + 1$ kanban finds no other stage $j + 1$ kanban waiting yet has to wait itself is given by

$$q_{j:u} = p_j^+\{n_j^{(e)} = k_j | 0 \le n_j^{(e)} \le k_j\}$$

where p_j^+ denotes the probabilities at instants of arrival of stage $j + 1$ kanbans. We assume that $p_j^+(n_j^{(e)}) = p_j(n_j^{(e)})$ and set

$$q_{j:u} = \frac{p_j(n_j^{(e)} = k_j)}{\sum_{u=0}^{k_j} p_j(n_j^{(e)} = u)}$$

Once there are waiting stage $j + 1$ kanbans $n_j^{(e)} > k_j$, so the rate at which they will be served will be given by $\mu_{j:u} = \lambda_{j:u}(0)$, irrespective of the number of waiting stage $j + 1$ kanbans.

Similarly, considering the arrivals of stage j kanbans at store j from cell j, the probability $q_{j:d}$ that an arriving stage j kanban finds no other stage j kanban waiting, yet has to wait itself, is given by

$$q_{j:d} = p_j^+\{n_j^{(e)} = k_j | k_j \le n_j^{(e)} \le k_{j+1}\}$$

where p_j^+ denotes the probabilities at the instants of arrival of stage j kanbans. Again we assume that $p_j^+(n_j^{(e)}) = p_j(n_j^{(e)})$ and so

$$q_{j:d} = \frac{p_j(n_j^{(e)} = k_j)}{\sum_{u=k_j}^{k_j+k_{j+1}} p_j(n_j^{(e)} = u)}$$

Since $n_j^{(e)} < k_j$ if there are waiting stage j kanbans, the rate at which waiting stage j kanbans will be served will be given by $\mu_{j:d} = \lambda_{j:d}(0)$, irrespective of the number of waiting stage j kanbans.

7.2.2. Cell Model

Assume that the cell consists of a single server who serves customers at rate μ_j. Alternatively, with minor change in the analysis, the cell can be any open queueing network with a product form solution. Then the closed queueing network representing the circulation of stage j kanbans (or class j customers) will have a product form solution with

$$p(n_j, n_j^{(p)}, n_{j-1}^{(r)}) = K.\left(\frac{1}{\mu_j}\right)^{n_j}\left(\frac{1}{\mu_{j:d}}\right)^{n_j^{(p)}}\left(\frac{1}{\mu_{j-1:u}}\right)^{n_{j-1}^{(r)}} f_p(n_j^{(p)}) f_r(n_{j-1}^{(r)}), \qquad n_j + n_j^{(p)} + n_{j-1}^{(r)} = k_j \tag{118}$$

and

$$f_p(\ell) = \begin{cases} 1, & \ell = 0 \\ q_{j:d} & \ell = 1, \ldots, k_j \end{cases}$$

$$f_r(\ell) = \begin{cases} 1, & \ell = 0 \\ q_{j-1:u} & \ell = 1, \ldots, k_j \end{cases}$$

and K is a normalizing constant

Class $m + 1$ customers only queue at store m, so we have

$$p(n_m^{(r)}) = K\left(\frac{1}{\mu_{m:u}}\right)^{n_m^{(r)}} f_r(n_m^{(r)}), \qquad n_m^{(r)} = 0, 1, \ldots \tag{119}$$

Also note that $\mu_{m:d} = \lambda$.

7.2.3. Connection between Store Model and Cell Model

Lastly, it is necessary to find the $\lambda_{j:u}(n_j^{(p)})$ and the $\lambda_{j:d}(n_j^{(r)})$. To find $\lambda_{j:u}(n_j^{(p)})$ we determine the throughput of the two service center closed queue consisting of store $j - 1$ and cell j. Hence,

$$\lambda_{jw:u}(n_j^{(p)}) = \frac{G_u^*(k_j - n_j^{(p)} - 1)}{G_u^*(k_j - n_j^{(p)})}, \qquad n_j^{(p)} = 0, 1, \ldots, k_j - 1 \tag{120}$$

where

$$G_u^*(\ell) = \sum_{n_{j-1}^{(r)}=0}^{\ell}\left(\frac{1}{\mu_j}\right)^{\ell - n_{j-1}^{(r)}}\left(\frac{1}{\mu_{j-1:d}}\right)^{n_{j-1}^{(r)}} f_r(n_{j-1}^{(r)})$$

Similarly, by determining the throughput in the closed queue consisting of cell $j + 1$ and store $j + 1$, we have

$$\lambda_{j:d}(n_j^{(r)}) = \frac{G_d^*(k_{j+1} - n_j^{(r)} - 1)}{G_d^*(k_{j+1} - n_j^{(r)})}, \qquad n_j^{(r)} = 0, 1, \ldots, k_{j+1} - 1 \tag{121}$$

where

$$G_d^*(\ell) = \sum_{n_{j+1}^{(p)}=0}^{\ell} \left(\frac{1}{\mu_{j+1}}\right)^{\ell - n_{j+1}^{(p)}} \left(\frac{1}{\mu_{j+1:d}}\right)^{\mathbf{n}_{j+1}^{(p)}} f_p(n_{j+1}^{(p)})$$

A recursive scheme can then be developed to solve the equations. Set all $\lambda_{j:d}(u) = \lambda$, then begin by observing that all $\lambda_{1:u}(v) = \mu_1$. Determine $q_{1:u}$, then $\lambda_{2:u}(v)$, $q_{2:u}$ and so on, until stage $m + 1$ is reached. Then, for stage m, determine $q_{m:d\}\text{ and }\lambda m:d}(w)$, then $q_{m-1:d}$, $\lambda_{m-1:d}(w)$, and so on. Repeat this downstream and upstream iterative process until the parameters converge.

7.2.4. Performance Measures

Define $\rho_{mu} = \lambda / \mu_{m:u}$. Then

$$p_{ND} = \frac{(1 - q_{m:u})(1 - \rho_{mu})}{1 - (1 - q_{m:u})\rho_{mu}} \tag{122}$$

and

$$\lambda E[\Delta] = \frac{\rho_{mu}}{1 - \rho_{mu}} (1 - p_{ND}) \tag{123}$$

Tables 5 and 6 compare the performance measures calculated using this approximation for a two-stage system with $k_1 = k_2 = 2$ for a variety of different values of ρ_1 and ρ_2.

CONCLUSIONS

This chapter has focused on using queueing models for performance analysis. It is largely based on the authors' book (Buzacott and Shanthikumar 1993). Other books focusing on performance models of manufacturing systems are Viswanadham and Narahari (1992) and Altiok (1997). Models can also be used for determining the optimal control and scheduling of manufacturing and service systems. See Gershwin (1994) and the papers in Yin and Zhang (1996) for numerous examples.

CHAPTER 61

Production-Inventory Systems

DAVID D. YAO
Columbia University

Production-inventory systems are one of the most established subjects in industrial engineering. The focus is on studying inventory dynamics, with inventory viewed as a buffer between supply (production/replenishment) and customer demand. Hence the emphasis is really more on inventory than on production, the latter being the primary focus of other IE subjects, such as scheduling and production planning.

Classical textbook models of production-inventory systems focus on the issue of optimality, in particular, the optimality of simple policies that are characterized by reorder points and order sizes. More recent studies have shifted the emphasis to the inventory–service trade-off (e.g., Cheng et al. 2000; Ettl et al. 2000; Glasserman and Wang 1998; Li 1992; Zipkin 2000) and to topics that are more relevant to industrial applications, such as kanban (e.g., Buzacott and Shanthikumar 1993; Glasserman and Yao 1994b, 1996) and supply chain management (e.g., Cheng et al. 2000; Ettl et al. 2000; Lee and Billington 1986). These topics are the emphasis of this chapter as well.

We start with an overview in Section 1 of several classical models, widely available in textbooks (e.g., Nahmias 1997; Silver et al. 1998). The rest of the chapter has two parts. The first part, Sections 2, 8, and 9, relates several familiar inventory control mechanisms—base-stock control, kanban control, and assemble-to-order systems—to queueing models, emphasizing steady-state results. The theme of the second part, Sections 3, 4, 5, 6, and 7, is nonstationarity, and we use a set of DRP (distribution resource planning)-like recursions as the basic model for inventory dynamics. Finally, in Section 10, the two parts converge into a unified, decomposition-based approach for modeling a supply network. Brief bibliographical notes are given in Section 11.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. OVERVIEW OF CLASSICAL MODELS

1.1. The EOQ Model

EOQ stands for economic order quantity. As its name suggests, the EOQ model emphasizes the role of inventory in achieving economies of scale—produce or replenish in batches, rather than single units. Demand is assumed to be deterministic, with rate λ. There is a fixed setup cost of C dollars for placing each replenishment order. Order lead times are zero, which, along with deterministic demand, implies that no order need be placed until the inventory level drops down to zero. The inventory holding cost is charged at a rate of h, that is, for each dollar of inventory that is kept for one unit of time, the charge is h dollars.

Suppose the (batch) size of each order is Q, the decision variable. Then the inventory level starts from the highest point of Q, immediately after an order is placed (and then received instantaneously), and then goes down to zero—depleted by demand, at rate λ. This cycle then repeats itself over the entire time horizon. Hence the average inventory level is $Q/2$ over each cycle and hence over the entire horizon as well.

The total cost—setup cost plus holding cost—per time unit is $\lambda C/Q + hQ/2$, where λ/Q is the number of orders placed per time unit. Note that we have ignored the variable cost, the cost for purchasing the units, since this term is independent of the decision variable Q. It is equal to $c\lambda$ per time unit, with c being the purchasing cost per unit. The Q that minimizes this cost objective is $Q := \sqrt{2\lambda C/h}$, which is easily derived from setting the derivative of the cost objective (with respect to Q) to zero. The square-root order quantity is often referred to as EOQ as well.

1.2. The Newsvendor Model

This is a single-period problem. Demand, D, is random, with a distribution function $F(x)$ that is known at the beginning of the period. The actual realization of the demand will not be known until the end of the period. The problem is to decide the order quantity Q at the beginning of the period, under the following cost assumptions: Each unit of demand supplied earns a profit (selling price minus cost) of p, each unit of unmet demand incurs a penalty of π, and each surplus (i.e., unsold) unit at the end of the period carries a net loss of ℓ (i.e., cost minus any salvage value). The objective is to maximize the expected net profit:

$$\max_{Q} \; [p\mathsf{E}(D \wedge Q) - \pi\mathsf{E}(D - Q)^+ - \ell\mathsf{E}(Q - D)^+]$$

where $\wedge$ denotes the min operator and $[x]^+ := \max\{x, 0\}$. The above objective simplifies to

$$\max_{Q} \; [(p + \pi)Q - (p + \pi + \ell)\mathsf{E}(Q - D)^+]$$

making use of the following identities:

$$D \wedge Q = Q - (Q - D)^+, \quad \text{and} \quad (D - Q)^+ = D - Q + (Q - D)^+$$

and ignoring the term $\pi\mathsf{E}(D)$, which is independent of Q. Hence, setting the derivative of the objective function (with respect to Q) to zero yields

$$F(Q^*) = \frac{p + \pi}{p + \pi + \ell}$$

noticing that

$$\begin{aligned} &\frac{d}{dQ}\,\mathsf{E}(Q - D)^+ \\ &= \frac{d}{dQ}\int_0^Q (Q - x)dF(x) \\ &= \frac{d}{dQ}\,[QF(Q) - \int_0^Q xdF(x) \\ &= F(Q) + QF'(Q) - QF'(Q) \\ &= F(Q) \end{aligned}$$

1.3. Deterministic Multiperiod Model

Let $k = 1, \ldots, n$ index the periods; let d_k denote the demand in period k. Demand in all n periods is deterministically known.

A production or replenishment can be ordered at the beginning of each period; the decision is the lot size—how many subsequent periods' demand this order should cover. For instance,we can decide that an order placed at the beginning of period i to have a lot size of $d_i + \ldots + d_j$, so as to cover the demand in period i through period j, for some $j > i$. That is, we run a single production at the beginning of period i, to supply the demand in all subsequent periods up to j. The cost associated with this decision is:

$$c_{ij} = C + h[d_{i+1} + 2d_{i+2} + \ldots + (j - i)d_j]$$

where C is the fixed setup cost and h is the inventory holding cost per unit of inventory, per period—applied to period-end inventory only.

Note that, as in the EOQ model, there is zero lead time and the variable cost is not included in c_{ij}, as it is independent of the lot-sizing decisions. Also, no back order is allowed, so that each period's demand must be supplied either by production at the beginning of that period or by inventory carried over from the previous periods.

This model can be solved by dynamic programming (DP). Let V_k be the optimal cost-to-go in period k, that is, the total cost to supply the demand in periods k through period n, following the optimal lot-sizing decisions. Then V_1 is the desired solution, which we can derive through the DP recursion as follows.

Clearly, in period n, where there is only a single period left, the only possible solution is to place an order of d_n units to supply the demand; hence, $V_n = C$. Recursively, for period $i = n - 1, \ldots, 2, 1$, we have

$$V_i = \min_{j \geq i} \{c_{ij} + V_{j+1}\}$$

following the DP principle of optimality. That is, the decision in period i is to pick a future period j—that is, to make a lot-sizing decision on the production so as to cover the demand in period i through period j—so as to minimize the right-hand side of the above recursion. Once j is selected, the remaining problem (i.e., the one that starts from period $j + 1$) was already solved in the earlier stages of the DP recursion, that is, to follow the optimal decision embodied in V_{j+1}.

1.4. Other Standard Models

When demand is random, a standard model is to assume that the demand stream follows a renewal process, that is, $\{D_n\}$ are independent and identically distributed (i.i.d.) random variables, where D_n denotes demand in period n. Suppose each production/replenishment order requires a lead time, denoted L, which can be constant or random.

In this context, in addition to the order size, we need a second parameter, the *reorder point*. Associated with the latter is the notion of *inventory position,* defined as the on-hand inventory minus any back orders plus any outstanding orders—orders that have been placed but have not yet arrived due to the lead time. Hence, whenever the inventory position falls below the reorder point, an order is placed. Note that since demand now fluctuates randomly and there is a lead time between placing and receiving an order, it is not desirable, in general, to order only when the inventory drops down to zero, as in the case of the EOQ model.

The above describes exactly how the so-called (Q, R) model works, with R being the reorder point and Q the order size. One way to set these parameters is to let Q take the EOQ value and let R be determined by service requirements. For instance, set the value of R sufficiently large so as to ensure that the stockout probability (i.e., the probability that the on-hand inventory is zero upon a demand arrival) is limited to, say, no more than 5%, or the fill rate (the proportion of demand that is filled from on-hand inventory) is at least 95%. (Note that in general the no-stockout probability is not equal to the fill rate.) It is also possible to set up a cost objective and then optimize it to derive the best Q and R values jointly.

Closely related, but more general, is the (S, s) model, which works as follows: whenever the inventory position falls below the lower threshold, s, place an order to bring the inventory position to the upper threshold S. When demand comes in batches, typically there will be an undershoot (of random size) when the inventory position falls below s. Hence, in the (S, s) model, the order size is random, in contrast to the constant order size in the (Q, R) model.

2. BASE-STOCK CONTROL

A widely studied inventory control mechanism is *base-stock control*, which works as follows: whenever the inventory position drops below R, a constant parameter, place an order to bring the inventory position back to R. This way, every demand will trigger the placement of an order, such that the overall inventory position is always maintained at a constant level, R, which is called the *base-stock level*.

In the case when demand always comes in unit size, then the base-stock control is a special case of the (Q, R) model, with $Q = 1$. Hence, the base-stock control is sometimes also referred to as the one-for-one replenishment rule.

2.1. The Inventory-Queue Model

The base-stock control model relates to a queueing model as follows. Consider the case of demand in single units mentioned above. (Batch demand will be discussed below in Section 2.3.) Let each unit of demand correspond to a job arrival to the queue. Each unit of demand, on arrival, is supplied by the on-hand inventory or, in the stock-out situation, joins a back-order queue. Regardless, however, a replenishment/production order is triggered.

Let the outstanding orders correspond to the jobs in the queueing system. In the inventory system, each of these orders will materialize (or ''arrive''—become available to supply demand) after a lead time. This corresponds to a queueing system with an infinite number of servers, so that any job will be served immediately on arrival. Hence, the overall cycle time of each job in the system is simply its service time, which corresponds to the lead time of orders in the inventory system.

Let N be the number of jobs in the queueing system in steady state. This, as explained above, represents the number of outstanding orders. If $N < R$, then there are $R - N$ units of on-hand inventory. If $N > R$, then we know there are $N - R$ units of back orders: R units of demand have been supplied with on-hand inventory, while the remaining $N - R$ units are back ordered. Hence, with I and B denoting the on-hand inventory and the back orders, respectively, and with $[x]^+$ denoting $\max\{x, 0\}$, we have

$$I = [R - N]^+, \quad B = [N - R]^+ \tag{1}$$

Note that the above implies

$$I - B = R - N$$

and $I \cdot B = 0$, that is, I and B cannot both be positive.

Suppose demand follows a Poisson process with rate λ, and suppose the lead time is L, the time it takes to process and finish an order. Then the queueing system in question is an $M/G/\infty$ model (see, e.g., Wolff 1989), and it is known that N follows a Poisson distribution with mean $\rho := \lambda \mathsf{E}(L)$. That is,

$$\mathsf{P}[N = n] = \frac{\rho^n}{n!} e^{-\rho}, \quad n = 0, 1, 2, \ldots$$

Combining the above with (1), we can derive the distributions of the on-hand inventory and back orders:

$$\mathsf{P}[I = 0] = \mathsf{P}[N \geq R] = 1 - \sum_{n=0}^{R-1} \frac{\rho^n}{n!} e^{-\rho}$$

$$\mathsf{P}[I = n] = \mathsf{P}[N = R - n] = \frac{\rho^{R-n}}{(R-n)!} e^{-\rho}, \quad n = 1, \ldots, R$$

and

$$\mathsf{P}[B = 0] = \mathsf{P}[N \leq R] = \sum_{n=0}^{R} \frac{\rho^n}{\mathrm{n}!} e^{-\rho},$$

$$\mathsf{P}[B = n] = \mathsf{P}[N = R + n] = \frac{\rho^{R+n}}{(R+n)!} e^{-\rho}, \quad n = 1, 2, \ldots.$$

Next, suppose that due to limited production capacity, replenishment/production orders may have to wait in queue before they can be processed. In other words, in addition to the lead time (i.e.,

processing time or ''service time''), there is also queueing time. In this case, a queueing model with a finite number of servers is more appropriate. Suppose we use the $M/M/1$ model for the corresponding queueing system. Then, N follows a geometric distribution:

$$\mathsf{P}[N = n] = \rho^n(1 - \rho), \qquad n = 0, 1, 2, \ldots$$

The distributions of I and B in the case are:

$$\mathsf{P}[I = 0] = \mathsf{P}[N \geq R] = \rho^R,$$
$$\mathsf{P}[I = n] = \mathsf{P}[N = R - n] = \rho^{R-n}(1 - \rho), \quad n = 1, \ldots, R$$

and

$$\mathsf{P}[B = 0] = \mathsf{P}[N \leq R] = 1 - \rho^{R+1}$$
$$\mathsf{P}[B = n] = \mathsf{P}\,[N = R + n] = \rho^{R+n}(1 - \rho), \quad n = 1, 2, \ldots$$

Note from (1) that in either case, while the on-hand inventory is limited to $I \leq R$, the base-stock level, there is no upper limit on the number of back orders, B.

2.2. Normal Approximations

We can also approximate the above Poisson distribution by a normal distribution, and write

$$N = \rho + Z\sqrt{\rho}$$

where Z denotes the standard normal variate, with density function $\phi(x) = (1/\sqrt{2\pi})e^{-x^2/2}$ and distribution function $\Phi(x)$. Below we shall also use $\overline{\Phi}(x) := 1 - \Phi(x)$. We can also write

$$R = \rho + k\sqrt{\rho}$$

where k is known as the ''safety factor'' in the inventory literature.

In fact, the normal approximation applies more generally; it does not have to be restricted to N following a Poisson distribution as in the inventory-queue models of Section 2.1. We can start with writing

$$N = \mu + \sigma Z \tag{2}$$

where $\mu := \mathsf{E}(N)$ and $\sigma := \mathsf{sd}(N)$; and then write

$$R = \mu + k\sigma \tag{3}$$

accordingly.

This way, we have

$$\mathsf{P}[I = 0] = \mathsf{P}[N \geq R] = \mathsf{P}[Z \geq k] = \overline{\Phi}(k) \tag{4}$$

which is the stockout probability.

To derive $\mathsf{E}(I)$ and $\mathsf{E}(B)$, we first define the following two functions:

$$G(x) := \mathsf{E}[Z - x]^+ = \int_x^\infty (z - x)\phi(z)\, dz \tag{5}$$

and

$$H(x) := \mathsf{E}(x - Z)^+ = x + G(x) = \mathsf{E}[x - Z + (Z - x)^+] = x + \mathsf{E}(Z - x)^+ = x + G(x) \tag{6}$$

We summarize below the properties of the functions $G(x)$ and $H(x)$. These properties are easily verified from first principle.

1. $G(x) = \phi(x) - x\overline{\Phi}(x)$ (note that $\phi'(x) = -x\phi(x)$); and $H(x) = \phi(x) + x\Phi(x)$. $G'(x) = -\overline{\Phi}(x)$, $H'(x) = \Phi(x)$, and $G''(x) = H''(x) = \phi(x)$.
2. For all $x \in (-\infty, +\infty)$, $G(x) \geq 0$ and $H(x) \geq 0$; $G(x)$ is decreasing and $H(x)$ increasing, and

both are convex. (Throughout, we use "increasing" and "decreasing" in the nonstrict sense.) Note in particular that $(x)^+$ is increasing and convex in x.

3. For $x >> 1$, $G(x) \cong 0$ and $G(-x) \cong x$, whereas $H(x) \cong x$ and $H(-x) \cong 0$. In fact, these approximations work very well for $x \geq 2$; for instance, $G(-2) = 2.0085$ and $G(2) = 0.0085$.

Hence, incorporating (2) and (3) with (1) and making use of the G and H functions, we can derive:

$$\mathsf{E}(I) = \sigma \mathsf{E}[k - Z]^+ = \sigma H(k), \quad \text{and} \quad \mathsf{E}(B) = \sigma \mathsf{E}[Z - k]^+ = \sigma G(k) \tag{7}$$

2.3. Demand and Demand over Lead Time

Let $D(t)$ be the demand in period t, $t = 1, 2, \ldots$. Suppose demand (per period) over time is independent and identically distributed. Let L denote the lead time to fill each replenishment order. The number of outstanding orders, as explained in Section 2.1, is equal to the number of jobs, N, in an infinite-server queueing system. In particular, if the per-period demand follows a Poisson distribution, then N also follows a Poisson distribution with mean $\mathsf{E}(N) = \mathsf{E}(D) \cdot \mathsf{E}(L)$ ($= \rho$ in Section 2.1; here D denotes the generic per-period demand). Since N follows a Poisson distribution, we know $\mathrm{Var}(N) = \mathsf{E}(N)$.

On the other hand, the total demand over the lead time,

$$D(1, L) := D(1) + \mathrm{D}(2) + \ldots + D(L)$$

has a mean

$$\mathsf{E}D(1, L) = \mathsf{E}(D) \cdot \mathsf{E}(L)$$

and a variance

$$\mathsf{Var}D(1, L) = \mathsf{Var}(D) \cdot \mathsf{E}(L) + \mathsf{E}^2(D) \cdot \mathsf{Var}(L)$$

Hence, while the lead time demand has the same mean as $\mathsf{E}(N)$, its variance is different, unless the lead time is deterministic and D follows a Poisson distribution. This distinction is important, since it is N, *not* demand over lead time, that determines the inventory performance, in terms of on-hand inventory (I) and back orders (B) via the relations in (1).

In applications, it is often more convenient to model the demand as a *batch* Poisson arrival process. Let λ be the demand arrival rate, as in Section 2.1, and let X denote the batch size associated with each arrived demand. Assume the batches are i.i.d. and independent of the demand arrival process, with $\mathsf{E}(X) \geq 1$. Then the per-period (or per-time unit) demand has the following mean and variance:

$$\mathsf{E}(D) = \lambda \mathsf{E}(X), \quad \text{and} \quad \mathsf{Var}(D) = \lambda \mathsf{E}(X^2)$$

The main advantage of this demand model is that it has (at least) three parameters: the arrival rate λ and the first two moments of the batch size X; whereas the Poisson demand model has only one parameter (the mean, or arrival rate).

Accordingly, the queue model $M/G/\infty$ of Section 2.1) now becomes $M^X/G/\infty$. Following the queueing result in (Liu et al. 1990), the mean and the variance of N are as follows:

$$\mathsf{E}(N) = \lambda \mathsf{E}(X)\mathsf{E}(L) = \mathsf{E}(D)\mathsf{E}(L) \tag{8}$$

$$\begin{aligned}
\mathsf{Var}(N) &= \mathsf{E}(N) + \lambda[\mathsf{E}(X^2) - \mathsf{E}(X)] \int_0^\infty \overline{F}_L^2(y)\, dy \\
&\leq \mathsf{E}(N) + \lambda[\mathsf{E}(X^2) - E(X)] \int_0^\infty \overline{F}_L(y)\, dy \\
&= \mathsf{E}(N) + \lambda[\mathsf{E}(X^2) - \mathsf{E}(X)]\mathsf{E}(L) \\
&= \lambda \mathsf{E}(X^2)\mathsf{E}(L) \\
&= \mathsf{Var}(D)\mathsf{E}(L)
\end{aligned} \tag{9}$$

where $F_L(y) = 1 - \overline{F}_L(y)$ denotes the distribution function of the lead time L, the inequality is due to $\overline{F}_L^2(y) \leq \overline{F}_L(y)$, and $\mathsf{E}(X^2) \geq \mathsf{E}^2(X) \geq \mathsf{E}(X)$ (since $\mathsf{E}(X) \geq 1$). Note again that the variance of N in (9) is different from the variance of lead time demand. In fact, the $\mathsf{Var}(N)$ is even smaller than the first of the two terms of the variance of lead time demand.

The generating function of N is known for the $M/G/\infty$ model (refer to Liu et al. 1990), from which the distribution of N can be derived, at least in principle. It is, however, much simpler to derive the mean and the variance of N and then approximate it by a normal distribution, as in Section 2.2.

The queueing quantity N, by definition, is nonnegative. Hence, to approximate it with a normal distribution is not always appropriate. Sometimes an adjustment to the normal distribution is needed. The same applies if we model demand D using a normal distribution.

Specifically, instead of writing $N = \mu + \sigma Z$, where Z is the standard normal variate, we should have $\tilde{N} = [\mu + \sigma Z]^+$. The mean of $\tilde{N}$ follows from (5):

$$\mathsf{E}[\tilde{N}] = \sigma \mathsf{E}\left[Z - \left(-\frac{\mu}{\sigma}\right)\right]^+ = \sigma G\left(-\frac{\mu}{\sigma}\right) \tag{10}$$

To derive the variance of $\tilde{N}$, note the following:

$$\begin{aligned}\mathsf{E}\{[(Z - x)^+]^2\} &= \int_x^\infty (z - x)^2 \phi(z)\, dz \\ &= x\phi(x) + \overline{\Phi}(x) - 2x\phi(x) + x^2\overline{\Phi}(x) \\ &= \overline{\Phi}(x) - xG(x)\end{aligned}$$

where the last equation makes use of (5). Hence,

$$\begin{aligned}\mathsf{Var}[\tilde{N}] &= \sigma^2 \mathsf{Var}\left\{\left[Z - \left(-\frac{\mu}{\sigma}\right)\right]^+\right\} \\ &= \sigma^2 \mathsf{E}\left\{\left[\left(Z - \left(-\frac{\mu}{\sigma}\right)\right)^+\right]^2\right\} - [\mathsf{E}(\tilde{N})]^2 \\ &= \sigma^2\left[\overline{\Phi}\left(-\frac{\mu}{\sigma}\right) + \frac{\mu}{\sigma} G\left(-\frac{\mu}{\sigma}\right) - G^2\left(-\frac{\mu}{\sigma}\right)\right]\end{aligned} \tag{11}$$

For moderately large x (say, $x \geq 2$), from property (c) of the G function in Section 2.2, we have $G(-x) \cong x$, and hence

$$\mathsf{E}[\tilde{N}] \cong \mathsf{E}[N], \quad \mathsf{Var}[\tilde{N}] \cong \mathsf{Var}[N]$$

from (10) and (11). Therefore, the above adjustment is *not* needed when the coefficient of variation, σ/μ, is relatively small, say, $\sigma/\mu < 0.5$.

3. NONSTATIONARY DEMAND: THE DRP FRAMEWORK

DRP stands for distribution resource planning, a class of commercial software tools that are widely used in industry for managing a firm's production/inventory/distribution systems. When demand is nonstationary, the dynamics of inventory are best captured by a set of recursive equations, which are closely related to the logic built into DRP software. Hence, we present next an overview of DRP, or more precisely, a formal abstraction of standard DRP procedures, the latter being widely available in professional references (e.g., Martin 1990; and Stenger 1994).

Time is discrete, indexed by $t = 1, 2, \ldots, n$, and referred to as periods. Suppose we are currently at the beginning of period 1 (or, the end of period 0). We are interested in the following quantities for all future periods, $t = 1, 2, \ldots, n$:

I_t = the on-hand inventory at the end of time period t
B_t = the back-ordered demand at the end of time period t
A_t = the required quantity of product needed at the beginning of period t
Q_t = the constrained (or feasible) quantity of product needed at the beginning of period t
$\tilde{Q}_t$ = the recommended order quantity at the beginning of period t

The distinction between the requirements, A_t, and the constrained order quantity, Q_t, is important. Whereas A_t represents the quantity that is needed at the beginning of period t, Q_t reflects what is feasible, taking into account lead time constraints and order quantity restrictions. For example, if $A_t = 40$ and the maximum order quantity is 30, then Q_t would be set to 30.

The following information is assumed known at the start of time period 1, for all future periods $t = 1, \ldots, n$:

D_t = the demand, in terms of its distribution, in particular $\mathsf{E}[D_t]$ and $\mathsf{sd}[D_t]$
Σ_t = the safety stock requirement, which is the portion of on-hand inventory that should be maintained in the period to protect against demand uncertainty so as to achieve a prescribed service-level requirement
I_0 = the on-hand inventory at the beginning of time period 1
B_0 = the back-ordered demand at the beginning of time period 1

In DRP, there is also the quantity of scheduled receipts, quantities that are in transit and scheduled to arrive at (the start of) each future period. Here we simply ignore these because as they can be easily netted from the inventory/back order of each period or added to Q_t.

At the beginning of each period t, the following sequence of events takes place. First, replenishment (including any scheduled receipt) arrives, that is, Q_t, the constrained order quantity (which relates to A_t and will be specified below). These units are used first to satisfy the back orders, if any, left from the previous period. Next, demand of the period, D_t, is realized and filled, which brings us to the end of the period, when I_t (on-hand inventory) and B_t (back orders) are updated.

Hence, we have the following recursive relation:

$$A_t = [B_{t-1} - I_{t-1} + D_t + \Sigma_t]^+ \tag{12}$$

which says that the replenishment requirement in each period, along with any on-hand inventory from the last period should be able to supply the demand of the current period and any backlog from the last period and still result in a surplus that is equal to the required safety stock for this period.

Next, the constrained order quantity, Q_t, is derived from A_t by applying a set of prespecified order-size restrictions, referred to as *order policies or order rules.* Several commonly used rules are listed below. Note that all of the rules below apply if and only if $A_t > 0$; otherwise, we simply set $Q_t = A_t = 0$, as $0 \le Q_t \le A_t$ by definition.

1. *Lot-for-lot:* $Q_t = A_t$, i.e., there is no restriction on the order quantity.
2. *Min-max:* With $Q_{\min}$ and $Q_{\max}$ being the (given) lower and upper limit on order quantities, $Q_t = \min\{\max(Q_{\min}, A_t), Q_{\max}\}$, becomes the order quantity planned for period t
3. *DOS* (days of supply): Q_t is equal to the (projected) demand over a given number of periods.
4. *EOQ* (economic order quantity): $Q_t = \sqrt{2C\mathsf{E}(D_t)/h}$, the classical EOQ formula (refer to Section 1.1), where C is a fixed cost for placing a replenishment order, and h is the inventory holding cost per period.

Note that all the rules above, with the exception of 1, impose some restrictions on the order quantity. In general, we can assume Q_t relates to A_t (and other parameters) via some prespecified function.

Define the *net* inventory level, Y_t, at the beginning of period t:

$$Y_t = I_{t-1} - B_{t-1}, \quad t = 1, \ldots, n \tag{13}$$

Then clearly,

$$I_t = [Q_t + Y_t - D_t]^+, \quad \text{and} \quad B_t = [D_t - Q_t - Y_t]^+ \tag{14}$$

Finally, suppose the order lead time is L (periods). Then the recommended order quantity, $\tilde{Q}_t$, in period t, corresponds to the calculated (constrained) order quantity $L + t$ periods later:

$$\tilde{Q}_t = \mathrm{Q}_{t+L}, \quad t = 1, \ldots, n - L$$

So the recommended order quantity at the start of period t is whatever the constrained order quantity is for period $t + L$.

4. LOT-FOR-LOT POLICY

Assume that the demand in period t can be expressed as

$$D_t = \mu_t + \sigma_t Z_t$$

where μ_t is the mean demand in period t, σ_t is the standard deviation of demand in period t, and $\{Z_t, t = 1, \ldots, n\}$ are i.i.d. random variables following any distribution with zero mean and unit variance. For ease of discussion, we shall focus on the case in which Z_t follows a standard normal distribution. The results extend readily to more general demand distributions.

Suppose, as before, that the lead time is L and we want to determine the requirement A_t for period t. We need to make this decision at the beginning of period $t - L$ so as to place the order in time for it to arrive in period t.

Position ourselves at the beginning of period $t - L$. What we know are the following: (a) the net inventory left from the previous period, Y_{t-L} and (b) the scheduled arrivals, $A_{t-L}, A_{t-L+1}, \ldots, A_{t-1}$, which had already been decided and ordered. What we do *not* know is the sequence of demand over the lead time, $D_{t-L}, D_{t-L+1}, \ldots, D_t$.

Denote:

$$D(s, t) := D_s + \cdots + D_t, \quad A(s, t) := A_s + \cdots + A_t$$
$$\mu(s, t) := \mathsf{E}[D(s, t)], \quad \sigma(s, t) := \mathsf{sd}[D(s, t)]$$

We claim that the right A_t value should be:

$$A_t = [\mu(t - L, t) + k_t\sigma(t - L, t) - Y_{t-L} - A(t - L, t - 1)]^+. \tag{15}$$

First, suppose $A_t > 0$, i.e., the quantity inside $[\cdot]^+$ on the right hand side above, is positive. Then, at the beginning of period $t - L$, the net inventory is Y_{t-L}, which, along with the scheduled arrivals over the lead time—a total of $A(t - L, t)$, is going to supply all the demands over the lead time—a total of $D(t - L, t)$. Hence, at the end of period t, the expected back order is:

$$\begin{aligned}
\mathsf{E}[B_t] &= \mathsf{E}[D(t - L, t) - Y_{t-L} - A(t - L, t)]^+ \\
&= \mathsf{E}[\,\mu(t - L, t) + Z_t\sigma(t - L, t) - \mu(t - L, t) - k_t\sigma(t - L, t)]^+ \\
&= \sigma(t - L, t)\ \mathsf{E}[Z_t - k_t]^+ \\
&= \sigma(t - L, t)\ G(k_t)
\end{aligned} \tag{16}$$

where the second equality follows from (15) since $A_t > 0$ as assumed:

$$Y_{t-L} + A(t - L, t) = \mu(t - L, t) + k_t\sigma(t - L, t)$$

Similarly,

$$\begin{aligned}
\mathsf{E}[I_t] &= \mathsf{E}[\,Y_{t-L} + A(t - L, t) - D(t - L, t)]^+ \\
&= \sigma(t - L, t) + \mathsf{E}[k_t - Z_t]^+ \\
&= \sigma(t - L, t)\ H(k_t)
\end{aligned} \tag{17}$$

Next, suppose $A_t = 0$ in (15). This implies

$$Y_{t-L} + A(t - L, t - 1) \geq \mu(t - L, t) + k_t\sigma(t - L, t)$$

Hence,

$$\begin{aligned}
\mathsf{E}[B_t] &= \mathsf{E}[\,\mu(t - L, t) + Z \cdot \sigma(t - L, t) - Y_{t-L} - A(t - L, t - 1)]^+ \\
&= \sigma(t - L, t)\ G(k_t')
\end{aligned} \tag{18}$$

with

$$k_t' = \frac{Y_{t-L} + A(t - L, t - 1) - \mu(t - L, t)}{\sigma(t - L, t)} \geq k_t \tag{19}$$

Hence, $\mathsf{E}[B_t]$ in (18) is no greater than $\mathsf{E}[B_t]$ in (16), since $G(\cdot)$ is a decreasing function. (Intuitively, in this case, since the available (net) inventory Y_{t-L} is higher, the effective safety factor k_t' is also higher; hence, the (projected) back order is lower.)

Similarly, when $A_t = 0$, we have

$$\mathsf{E}[I_t] = \sigma(t - L, t)\ H(k_t') \tag{20}$$

with k_t' following (19); and $\mathsf{E}[I_t]$ above is larger than $\mathsf{E}[I_t]$ of (17).

To summarize, when the order rule is lot-for-lot, that is, $Q_t = A_t$ for all t, the required quantity needed at the beginning of period t (A_t), and hence the recommended order quantity at the beginning of period $t - L$ ($\tilde{Q}_{t-L}$), should be

$$\tilde{Q}_{t-L} = Q_t = A_t = [s_{t-L} - Y_{t-L} - A(t - L, t - 1)]^+$$

where

$$s_{t-L} = \mu(t - L, t) + k_t\sigma(t - L, t)$$

Note that in this case, DRP effectively follows a base-stock control mechanism, with s_{t-L} being the base-stock level (or, reorder point) for period $t - L$. The estimates for expected on-hand inventory and back orders (for period t) follow (17, 20) and (16, 18), respectively.

Also note that the time index of the reorder point, s_{t-L}, is consistent with the time when the order is placed. On the other hand, the safety factor k_t is indexed by t since it relates more closely to the on-hand inventory and back orders in period t.

We should point out that the expression in (15) that specifies the requirement A_t can also be derived directly from the DRP logic as follows. From (13) and (14), with $Q_t = A_t$, we have

$$\begin{aligned} Y_t &= I_{t-1} - B_{t-1} \\ &= Y_{t-1} + A_{t-1} - D_{t-1} \\ &= Y_{t-2} + A_{t-2} - D_{t-2} + A_{t-1} - D_{t-1} \\ &= \ldots \\ &= Y_{t-L} + A(t - L, t - 1) - D(t - L, t - 1) \end{aligned} \tag{21}$$

Now, substituting (13) into (12), we can write the latter as:

$$A_t - [D_t + \Sigma_t - Y_t]^+$$

Substituting (21) into the above and treating demand as deterministic, which is what DRP does, we have

$$D_t + D(t - L, t - 1) = \mu(t - L, t)$$

and hence recovering (15). In other words, if DRP uses (15) directly to generate the requirements A_t, instead of going through the recursions that involve I_t and B_t, then the estimates on these requirements will be protected from the in accuracies involved in estimating I_t and B_t.

Following the expressions derived above for A_t, B_t, and I_t, the recursion can be carried over to future periods through $Y_{t+1} = I_t - B_t$. Specifically, starting from period 1, we first derive A_{L+1}, followed by B_{L+1} and I_{L+1}, and then Y_{L+1}. Continue this procedure for $t = L + 2, \ldots, 2L$, assuming that $Y_1, Y_2, \ldots, Y_L$ have all been prespecified, i.e., given at beginning of period 1. (Note that nothing in periods 1 through L can be affected by any replenishment decision, at the beginning of period 1, due to the lead time.) In return, $Y_{L+2}, \ldots, Y_{2L}$ are derived. Next, we will derive A_{2L+1}, at the beginning of period $L + 1$. At that point, we will need the value of Y_{L+1}, which has already been derived; and in return, we will derive Y_{2L+1}. The recursion then continues.

5. (*S*, *s*) POLICY

Having analyzed the lot-for-lot rule, we next want to study other rules that impose restrictions on the order quantities. It will become evident below (Section 6) that all these rules can be unified into a dynamic (S, s) control scheme—dynamic in the sense that the control parameters, S and s, in general change over time. In order to analyze the dynamic (S, s) control rule, here we first review the standard (S, s) inventory model under stationary demand and develop some simple approximations for its performance.

The (S, s) policy is known to be optimal in a quite general setting, in terms of minimizing the total costs of placing orders, keeping inventory, and paying penalty of back orders (refer to Clark and Scarf 1960; Scarf 1960). Our focus here, however, is on performance evaluation rather than cost minimization. In particular, we want to derive certain simple approximate formulas that are not only easy to evaluate but also useful in suggesting approximations in the non-stationary (i.e., dynamic) setting. More refined approximations for the stationary (S, s) systems are available in the literature (e.g., Tijms 1994), although it is not clear how they can be adapted to the nonstationary setting.

5.1. Stationary Analysis

Consider an (S, s) inventory model with periodic review. A review takes place at the beginning of each period t, at which time the inventory position is updated and a replenishment decision is made

following the (S, s) rule—order up to S if and only if the inventory position (on-hand plus on-order minus back order) falls below s.

Observe that the inventory position, X_t, as defined above, always takes values between s and S. In particular, if an arriving demand brings the on-hand inventory level to *below* s, the inventory position is immediately brought up to S through placing a replenishment order.

Suppose, without loss of generality, that we start with $X_0 = S$. Then, from standard renewal theory (Ross 1996), we know the time between two consecutive replenishment orders forms a regenerative cycle. Given x $(x = s, s + 1, \ldots, S)$, let

$$T_x = \min \{t: D_1 + \ldots + D_t > S - x\}$$

be the time, in a cycle, for the inventory position to drop from S to below x. In particular, T_s is the cycle length.

Since demands are i.i.d., we can view $T_x - 1$ as the number of renewals by time $S - x$ of a renewal process with interarrival time D_t. (Refer to Ross 1996, Section 3.4, in particular pp. 69–70.) Hence,

$$\mathsf{E}[T_x] = M(S - x) + 1, \quad \mathsf{E}[T_s] = M(S - s) + 1$$

where

$$M(x) = \sum_{n=1}^{\infty} F_{*n}(x)$$

is the renewal function, with $F_{*n}(\cdot)$ denoting the n-fold convolution of the (per-period) demand distribution, $F(\cdot)$. Furthermore, the limiting (stationary) inventory position, X, has the following distribution:

$$\mathsf{P}[X \geq x] = \lim_{t \to \infty} \mathsf{P}[X_t \geq x] = \frac{\mathsf{E}[T_x]}{\mathsf{E}[T_s]} = \frac{1 + M(S - x)}{1 + M(S - s)}$$

for $x \in [s, S]$. Alternatively,

$$\mathsf{P}[X = x] = \frac{M(S - x) - M(S - x - 1)}{1 + M(S - s)}, \quad x = s, \ldots, S - 1$$

$$\mathsf{P}[X = S] = \frac{1}{1 + M(S - s)}$$

The mean of X then follows:

$$\mathsf{E}[X] = \frac{S + sM(S - s) + \sum_{x=1}^{S-s-1} M(x)}{1 + M(S - s)}$$

To characterize the on-hand inventory and the back orders, the key is to observe that by time t all orders that are placed before or at $t - L$ will have arrived. In other words, the on-order quantities included in the inventory position at $t - L$ will all have arrived by t. As before, let $D(t - L, t)$ denote the total demand over the $L + 1$ periods: $t - L, t - L + 1, \ldots, t$. We have

$$I_t = [X_{t-L} - D(t - L, t)]^+ \tag{22}$$

where $[x]^+ = \max\{x, 0\}$. Note that in (22), $D(t - L, t)$ is independent of X_{t-L}. Similarly, we have

$$B_t = [D(t - L, t) - X_{t-L}]^+ \tag{23}$$

Letting $t \to \infty$, and denoting the limits by omitting the time index, we have

$$I = [X - D(L + 1)]^+, \quad \text{and} \quad B = [D(L + 1) - X]^+ \tag{24}$$

where $D(L + 1)$ denotes a random variable that is equal in distribution to $D(t - L, t)$ and is independent of X.

5.2. Approximations

The renewal function is known to have a linear asymptote:

$$M(x) \sim \frac{x}{\mu} + \frac{m_2}{2\mu^2} - 1 \tag{25}$$

for large x, where $\mu = \mathsf{E}(D)$ and $m_2 = \mathsf{E}(D^2)$ are the first two moments of the (per-period) demand distribution. (More precisely, the difference between $M(x)$ and the linear function on the right hand side above goes to zero when $x \to \infty$).

Since in most applications the (S, s) values are large or moderately large, we can use the linear asymptote in (25) as an approximation for the renewal function. This way, the probability distribution of the inventory position X in Section 5.1 becomes:

$$\mathsf{P}[X = x] = \frac{1}{\frac{m_2}{2\mu} + S - s}, \quad x = s, \ldots, S - 1$$

$$\mathsf{P}[X = S] = \frac{\frac{m_2}{2\mu}}{\frac{m_2}{2\mu} + S - s}$$

where $m_2/2\mu$ is the average "undershoot"—the gap between the inventory position when an order is placed (which is necessarily smaller than s) and the reorder point s. Hence,

$$\mathsf{E}[X] = \frac{(1/2)(S + s - 1)(S - s) + (m_2/2\mu)\, S}{m_2/2\mu + S - s} = \frac{\mu(S - s)(S + s - 1) + m_2 S}{m_2 + 2\mu(S - s)} \tag{26}$$

In some special cases, the above reduces to a uniform distribution over the integers $\{s, \ldots, S\}$ and $\mathsf{E}[X] = (S + s)/2$. For instance, this is the case when the (per-period) demand follows a truncated normal distribution with unit mean and unit coefficient of variation (hence, $\mu = 1$ and $m_2 = 2$). Note that for truncated normal distributions, just as for normal distributions, assuming a unit coefficient of variation loses no generality; hence, unit mean is the only significant assumption here.

Next, making use of (24), along with the normal approximation of $D(L + 1)$, we get the following approximation:

$$\mathsf{E}[B] = \sum_{x=s}^{S} \sigma\sqrt{L + 1}\, G\left(\frac{x - (L + 1)\mu}{\sigma\sqrt{L + 1}}\right) \mathsf{P}[X = x]$$

Substituting the uniform distribution of X into the above, we have

$$\begin{aligned} \mathsf{E}[B] &= \frac{1}{1 + S - s} \sum_{x=s}^{S} \sigma\sqrt{L + 1}\, G\left(\frac{x - (L + 1)\mu}{\sigma\sqrt{L + 1}}\right) \\ &\le \sigma\sqrt{L + 1}\, G\left(\frac{s - (L + 1)\mu}{\sigma\sqrt{L + 1}}\right) \end{aligned} \tag{27}$$

where the inequality follows from the fact that $G(x)$ is decreasing in x.

Once $\mathsf{E}[B]$ is derived, $\mathsf{E}[I]$ follows from (1), we have

$$\mathsf{E}[I] = \mathsf{E}[B] + \mathsf{E}[X] - \mu(L + 1)$$

For instance, from (27), taking into account $G(k) = H(k) - k$, and approximating X with a uniform distribution, we have

$$\mathsf{E}[I] = \sigma\sqrt{L + 1}\, H\left(\frac{s - (L + 1)\mu}{\sigma\sqrt{L + 1}}\right) + \frac{S - s}{2} \tag{28}$$

Alternatively, $\mathsf{E}[X]$ can follow the approximation in (26).

6. DYNAMIC (*S*, *s*) POLICY

Observe that when following any policy other than lot-for-lot, the equation in (15) governing the requirements should be modified as follows:

$$A_t = [\mu(t - L, t) + k_t\sigma(t - L, t) - Y_{t-L} - Q(t - L, t - 1)]^+ \tag{29}$$

where

$$Q(t - L, t - 1) = Q_{t-L} + \ldots + Q_{t-1}$$

replaces $A(t - L, t - 1)$ in (15). Hence, when $A_t > 0$, we have

$$\begin{aligned} A_t &= \mu(t - L, t) + k_t\sigma(t - L, t) - Y_{t-L} - Q(t - L, t - 1) \\ &= s_{t-L} - Y_{t-L} - Q(t - L, t - 1). \end{aligned}$$

That is, s_{t-L} is the reorder point, since following the DRP logic, an order ($\tilde{Q}_{t-L}$ is placed (at $t - L$) if and only if $A_t > 0$. From the above expression, A_t is the required quantity to bring the inventory position at $t - L$ back to s_{t-L}. (This is consistent with the base-stock mechanism when there are no order-size restrictions.)

Now, suppose the replenishment policy is a dynamic (S; s) rule. Specifically, when $A_t > 0$, we want to bring the inventory position to S_{t-L} ($> s_{t-L}$). Hence, an additional amount, $S_{t-L} - s_{t-L}$, is needed, and the order quantity is:

$$Q_t = A_t + S_{t-L} - s_{t-L} = S_{t-L} - Y_{t-L} - Q(t - L, t - 1) \tag{30}$$

when $A_t > 0$. (As before, $Q_t = 0$ when $A_t = 0$).

On the other hand, given any replenishment policy with a prespecified Q_t (as a function of $A_t > 0$), we can implement this policy by setting [cf. (30)]:

$$S_{t-L} = Q_t + s_{t-L} - A_t = Q_t + Q(t - L, t - 1) + Y_{t-L}$$

when $A_t > 0$. When $A_t = 0$, we set $Q_t = 0$, which results in $S_{t-L} = s_{t-L}$, from the first equation above.

We now turn to the performance evaluation under the dynamic (S, s) rule. Note that the inventory position at $t - L$ is:

$$X_{t-L} = Y_{t-L} + Q(t - L, t) \tag{31}$$

that is, the net inventory plus the on-order quantities (orders that have been placed but have yet to arrive). In particular, when $Q_t > 0$, from (30) and (31), we have

$$S_{t-L} = Y_{t-L} + Q(t - L, t) = X_{t-L}$$

that is, after the order is placed, the inventory position is brought up to S_{t-L}.

Just as in (21), we can iterate on (13) and (14) to obtain

$$Y_t = Y_{t-L} + Q(t - L, t - 1) - D(t - L, t - 1)$$

which, upon substitution back into (14), yields:

$$I_t = [Y_{t-L} + Q(t - L, t) - D(t - L, t)]^+ = [X_{t-L} - D(t - L, t)]^+$$

and

$$B_t = [D(t - L, t) - Y_{t-L} - Q(t - L, t)]^+ = [D(t - L, t) - X_{t-L}]^+$$

These are exactly the same formulas as in (22) and (23).

Therefore, we can adapt the approximations in the stationary (S, s) model. For instance, based on the back order approximation in (27), and taking into account the formulas in (16) and (18) for the lot-for-lot case, we have the following approximation:

$$\mathsf{E}[B_t] = \sigma(t - L, t) \cdot G(k_t), \quad \text{or} \quad \mathsf{E}[B_t] = \sigma(t - L, t) \cdot G(k'_t) \tag{32}$$

according to whether $A_t > 0$ or $A_t = 0$, where

$$k'_t = \frac{Y_{t-L} + Q(t - L, t - 1) - \mu(t - L, t)}{\sigma(t - L, t)}$$

which, again, can be verified as dominating k_t.

To approximate $\mathsf{E}[I_t]$, just as in the stationary case, we make use of the identity [from (22)]:

$$I_t - B_t = X_{t-L} - D(t - L, t)$$

Hence,

$$\mathsf{E}[I_t] = \mathsf{E}[B_t] + X_{t-L} - \mu(t - L, t)$$

where $\mathsf{E}[B_t]$ follows the approximation in (32), and X_{t-L} follows the expression in (31). According to the two cases in (32), and making use of the expression in (31) and the relation $H(k) = k + G(k)$, we have:

$$\mathsf{E}[I_t] = \sigma(t - L, t) \cdot H(k_t) + S_{t-L} - s_{t-L} \tag{33}$$

when $A_t > 0$ (note in this case $X_{t-L} = S_{t-L}$); and when $A_t = 0$:

$$\begin{aligned}\mathsf{E}[I_t] &= \sigma(t - L, t) \cdot H(k'_t) - k'_t) - k'_t \sigma(t - L, t) + X_{t-L} - \mu(t - L, t) \\ &= \sigma(t - L, t) \cdot H(k'_t)\end{aligned} \tag{34}$$

Approximating $H(k'_t)$ by k'_t in the above equation, we have

$$\mathsf{E}[I_t] = k'_t \sigma(t - L, t) = X_{t-L} - \mu(t - L, t)$$

The above has the intuitive interpretation that if no order is placed at $t - L$ (i.e., $R_{t_L} = Q_t = A_t = 0$), then the expected on-hand inventory at t is simply the inventory position—of which all the on-order quantities will have arrived by t—minus the demand over the lead time, period $t - L$ through period t.

To implement the above approximations requires the derivation of Y_t, which is involved in both X_t and A_t. Recursively, Y_t can be approximated by its mean:

$$\mathsf{E}[Y_t] = \mathsf{E}[I_{t-1}] - \mathsf{E}[B_{t-1}]$$

Alternatively, a cruder approximation is to forgo the distinction between the two cases $A_t > 0$ and $A_t = 0$. (Observe that this distinction is not present in the stationary case; it is averaged out in each regenerative cycle.) Specifically, ignore the k'_t case in (32), and approximate X_{t-L} by $(S_{t-L} + s_{t-L})/2$. This way, we have

$$\mathsf{E}[B_t] = \sigma(t - L, t) \cdot G(k_t) \tag{35}$$

and

$$\begin{aligned}\mathsf{E}[I_t] &= \sigma(t - L, t) \cdot H(k_t) - k_t \sigma(t - L, t) + (S_{t-L} + s_{t-L})/2 - \mu(t - L, t) \\ &= \sigma(t - L, t) \cdot H(k_t) + (S_{t-L} - s_{t-L})/2\end{aligned} \tag{36}$$

Both are consistent with the stationary approximations in (27) and (28).

To summarize, with order-quantity restrictions, the implementation of DRP can be unified into a dynamic (S, s) control rule. Under this rule, the constrained order quantity needed at the beginning of period t (Q_t), and hence the recommended order quantity at the beginning of period $t - L$ ($\tilde{Q}_{t-L}$), should be

$$\tilde{Q}_{t-L} = Q_t = [A_t + S_{t-L} - s_{t-L}] \cdot 1[A_t > 0]$$

where $1[\cdot]$ denotes the indicator function, and

$$A_t = [s_{t-L} - Y_{t-L} - Q(t - L, t - 1)]^+$$

following (29), with

$$s_{t-L} = \mu(t - L, t) + k_t \sigma(t - L, t)$$

6.1. Setting Safety Stock Levels

In the preceding discussions, the safety stock level, Σ_t, is assumed as given. Here we discuss one approach to set the safety stock levels, which is of particular importance because of its wide usage. It sets safety stock levels based on achieving a target fill rate.

For ease of discussion, here we assume stationary demand and omit the time index t wherever possible. Suppose the service requirement is that the fraction of demand back ordered should be limited to $1 - \beta$, where β is the required fill rate.

To characterize the fraction of back ordered demand, we need to pick a ''typical'' time frame. In the standard inventory literature, this is taken to be the time between two consecutive orders, known as a regenerative cycle (when demands are independent and identically distributed). The required fraction is then the ratio of the average number of back orders to the average number of demand units, both over the regenerative cycle.

In the stationary (S, s) model, the average number of back orders, following (27), is approximated by

$$\sigma\sqrt{L + 1}G\left(\frac{s - (L + 1)\mu}{\sigma(L + 1}\right)$$

whereas the average demand per cycle is

$$\left(\frac{S - s}{\mu} + \frac{m_2}{2\mu^2}\right) \mathsf{E}(D) = S - s + \frac{m_2}{2\mu}$$

where the first factor on the left hand side is the expected cycle length $\mathsf{E}[T_s] = 1 + M(S - s)$ (refer to Section 5.1) with $M(S - s)$ approximated by the linear asymptote in (25). Note that the right-hand side above is nothing but the expected order quantity; in particular, $m_2/2\mu$ is the expected undershoot.

Therefore, based on the above, under the dynamic (S, s) rule, k_t should be the solution to:

$$\sigma(t - L, t)G(k_t) = (1 - \beta)\left[\Delta_{t-L} + \frac{\mathsf{E}(D^2_{t-L})}{2\mathsf{E}(D_{t-L})}\right] \tag{37}$$

where $\Delta_{t-L} = S_{t-L} - s_{t-L}$ is assumed given.

The lot-for-lot rule is equivalent to $S_{t-L} = s_{t-L}$, or $\Delta_{t-L} = 0$. Also, since in every period an order is placed, the order quantity is simply equal to the demand. Hence, the equation in (37) is reduced to:

$$\sigma(t - L, t)\, G(k_t) = (1 - \beta)\mathsf{E}(D_{t-L}) \tag{38}$$
