Note that the equations in (37) and (38) are easily solved through Newton's method (e.g., Press et al. 1994). Write the equations in the form of $G(k) = c$. The Newton's iteration, indexed by the superscript (n), is as follows:

$$k^{(n+1)} = k^{(n)} - \frac{G(k^{(n)}) - c}{G'(k^{(n)})}$$

When demand follows a normal distribution, $G'(k) = -1 + \Phi(k)$, where Φ denotes the distribution function of the standard normal variate.

7. MULTI-STAGE MODELS

The results presented so far for the single-stage model extend to a more general distribution network. For ease of exposition, we consider a model that consists of a central stocking facility (e.g., a warehouse or depot) supplying a set of local stocking facilities (e.g., retailers or outlets), each of

which, in turn, supplies its own customer demand. As in the single-stage models, our focus here is on performance evaluation via simple approximations. We do not address the issue of cost optimization, for which many models can be found in the survey article by Federgruen (1993).

Suppose the central warehouse is numbered as stage 0 and the set of retailers, numbered as stages $1, \ldots, c$. Quantities that relate to these stages will be subscripted or superscripted (if there is already a subscript for time) by their stage indices. For instance, the demand stream to retailer i, $i = 1, \ldots, c$, is $\{D_t^i, t = 1, 2, \ldots\}$. Assume the demands are independent among the retailers, and independent over the time periods.

Suppose the lead time at each retailer i is L_i periods, a deterministic constant, for $i = 1, \ldots, c$. For instance, this can be the transportation time for a replenishment order to travel from the warehouse to the retailer; or, in the case where stage i is a plant, the cycle time to build a customer order. Suppose the lead time at the warehouse is L_0.

The analysis of each retailer i follows the same discussion as before. In particular, write

$$s_t^i = \mu_i(t, t + L_i) + k_{t+L_i}^i \sigma_i(t, t + L_i)$$

and if a set of target fill rates at each of the retailers, β_i, $i = 1, \ldots, c$, has been specified, then the safety factor $k_{t+L_i}^i$ is obtained from solving the following equation. (Refer to Eqs. (37) and (38)).

$$\sigma_i(t, t + L_i)G(k_{t+L_i}^i) = (1 - \beta_i)\left[\Delta_t^i + \frac{\mathsf{E}(D_t^i)^2)}{2\mathsf{E}(D_t^i)}\right]$$

(where $\Delta_t^i := S_t^i$ is assumed given); or, from

$$\sigma_i(t, t + L_i)G(k_{t+L_i}^i) = (1 - \beta_i)\mathsf{E}(D_t^i)$$

in the special case of i following a lot-for-lot rule.

The expected number of back orders is:

$$\mathsf{E}[B_t^i] = \sigma_i(t - L_i, t)G\left(\frac{s_{t-L}^i - \mu_i(t - L_i, t)}{\sigma_i(t - L_i, t)}\right)$$

corresponding to the k_t case in (32), that is, when $A_t^i > 0$. For the other case ($A_t^i = 0$), the expression is similar, corresponding to the k_t' case in (32). The expected on-hand inventory is where $X_{t-L_i}^i$ denotes the inventory position.

To analyze the warehouse, we follow the standard notion of echelon stock. That is, we aggregate stage 0, along with stages $i = 1, \ldots, c$, into a single system, indexed by E (for echelon). This aggregated system supplies the superposition of all c demand streams. Note that each demand process D_t^i still has its own lead time L_i. Let

$$L_{\max} = \max\{L_i, i = 1, \ldots, c\},$$

Then (22) and (23) should be modified, with L replaced by $L_E = L_0 + L_{\max}$.

Therefore, the lower threshold value for this aggregated system should be set, in period t, as follows:

$$s_t^E = \mu_E(t, t + L_E) + k_{t+L_E}^E \sigma_E(t, t + L_E)$$

where

$$\mu_E(t, t + L_E) = \sum_{i=1}^{c} \mu_i(t, t + L_E)$$

$$\sigma_E(t, t + L_E) = \left[\sum_{i=1}^{c} \sigma_i^2(t, t + L_E)\right]^{1/2}$$

As for the echelon safety factor, $k_{t+L_E}^E$, it can either be prespecified by the user or, if the safety stock levels are to be set automatically based on target fill rates specified at the retail level, it can be obtained from the solution to:

$$\sigma_E(t, t + L_E)G(k_{t+L_E}^E) = (1 - \beta_{\max})(\Delta_t^E + \gamma_t^E)$$

with $\Delta_t^E = S_t^E - s_t^E$ assumed given, $\beta_{\max} = \max\{\beta_i, i = 1, \ldots, c\}$, where β_i is the target fill rate at retailer i, and

$$\gamma_t^E = \frac{\mathsf{E}\left[\left(\sum_{i=1}^{c} D_t^i\right)^2\right]}{2\mathsf{E}\left(\sum_{i=1}^{c} D_t^i\right)} = \frac{\sum_{i=1}^{c} (\sigma_t^i)^2 + \left(\sum_{i=1}^{c} \mu_t^i\right)^2}{2\sum_{i=1}^{c} \mu_t^i}$$

That is, stage 0 should place an order at the beginning of period t if and only if the *echelon* inventory position falls below s_t^E. This echelon inventory position is the inventory position with the aggregated system considered as a single stage. It includes all the on-hand inventory at both the warehouse and all the retailers, plus any replenishment orders placed by the warehouse that have not yet arrived, minus any customer demand that is back ordered at all the retailers. Hence, this echelon inventory position will only change whenever there is a customer order arriving at a retailer and whenever the warehouse places a replenishment order. It will not change when a retailer takes supply from or registers a back order with the warehouse. When stage 0 issues a replenishment order, say at the beginning of period t, the order quantity is to bring the echelon stock position to $S_t^E = \Delta_t^E + s_t^E$. Hence, $\Delta_t^E + \gamma_t^E$ is the estimate of this order quantity.

Estimates of $\mathsf{E}[B_t^E]$ and $\mathsf{E}[I_t^E]$, like those at the retailers, follow in the same vein as those in Section 6 (refer to, in particular, the summary at the end of that section).

The relationship between Q_t and S_{t-L} follows (30); in particular, when $A_t > 0$, $Q_t = S_{t-L} - Y_{t-L} - Q(t - L, t - 1)$; and when $A_t = 0$, $Q_t = 0$ and $S_{t-L} = s_{t-L}$. The estimates on the expected on-hand inventory and back orders (for period t) follow (33), (34) and (32), respectively; or alternatively, follow (36) and (35), respectively.

8. ASSEMBLE-TO-ORDER SYSTEMS

An assemble-to-order (ATO) system is a hybrid model of build-to-stock at the component (subassembly) level and assemble-to-order for the end product. In an ATO system, typically, the components take a substantial lead time to build, whereas the time it takes to assemble all the components into the final product is often negligible. Hence, keeping stock at the component level improves response-time performance, whereas not keeping any end-product inventory reduces inventory cost and maximizes the flexibility for customization. A good example of an ATO system is the production of a PC (personal computer). Other examples include fast-food operations and many mail-order or e-commerce services.

We consider an ATO system of m different items (components) and a single end product. Let $\mathcal{I} = \{1, 2, \ldots, m\}$ denote the set of all items. Without loss of generality, assume each end product consists of exactly one unit of each item in $\mathcal{I}$. (If the end product requires multiple units from some item, simply redefine the unit for that component and adjust inventory and lead time accordingly.) Customer demand for the end product follows a stationary Poisson process, denoted $\{A(t), t \geq 0\}$, with rate λ.

Demands are filled on a first-come-first-served (FCFS) basis. If there is positive on-hand inventory for all components upon a demand arrival, the demand is filled immediately (since the time to assemble the components into the end-product is negligible). On the other hand, if there is a stockout at one or more of the component inventory, then the demand is backlogged until the stockout inventory is replenished.

For each unit of item i, we assume the production lead times are i.i.d. random variables with a common distribution function G_i, and with L_i denoting the associated random variable, and $\mathsf{E}[L_i] = \ell_i$. Assume the lead times are independent among the items.

The inventory of each item i is controlled by a base-stock policy, with R_i being the base-stock level. Since the end product consists of a single unit of each component, the base-stock policy implies that every demand will trigger *simultaneously* the production/replenishment of one unit of each component. Therefore, as in the model of Section 2.1, for each item i, the number of units in process at any time t, denoted $X_i(t)$, is equal to the number of jobs in service in an $M/G_i/\infty$ queue, for $i = 1, \ldots, m$. Note, however, that these m queues are driven by a common Poisson arrival process $\{A(t)\}$, and hence are *not* independent.

For any time t, the performance measures of interest are the on-hand inventory and the number of back orders:

$$I_i(t) = [R_i - X_i(t)]^+, \quad \text{and} \quad B_i(t) = [X_i(t) - R_i]^+ \tag{39}$$

Note that from the FCFS rule, the number of back ordered demand (for the end product) is:

$$B(t) = \max_{1 \leq i \leq m} B_i(t) = \max_{1 \leq i \leq m} [X_i(t) - s_i]^+ \tag{40}$$

Let X_i, I_i, B_i, and B denote the corresponding steady-state limits of the above quantities.

Let f_i and f denote the fill rates for item i and for the end product, respectively. Then, due to the property that Poisson arrivals see time average (PASTA) (e.g., Wolff 1989), we have

$$f_i = \mathsf{P}(I_i > 0), \quad \text{and} \quad f = \mathsf{P}(I_1 > 0, \ldots, I_m > 0)$$

Note that the item-based performance measures f_i, I_i, and B_i depend only on the marginal distribution of X_i for each i, while the product-based performance measures f and B depend on the joint distribution of X_i, $i = 1, \ldots, m$.

From standard queuing results, the marginal distribution of X_i follows a Poisson distribution with mean $\ell_i = \lambda \mathsf{E}[L_i]$, which depends on the lead time distribution G_i only through its mean. This implies that the higher moments of the lead time (variance in particular) do *not* affect the item-based performance. This is no longer true, however, for the joint distribution of $(X_i, i = 1, \ldots, m)$ as we shall see below.

Let $N(a)$ denote a Poisson random variable with parameter (mean) a, along with the following notation:

$$p(n|a) = \mathsf{P}[N(a) = n] = \frac{a^n}{n!} e^{-a}$$

$$P(n|a) = \mathsf{P}[N(a) \le n] = \sum_{k=0}^{n} p(k|a)$$

$$\overline{P}(n|a) = \mathsf{P}[N(a) > n] = \sum_{k=n+1}^{\infty} p(k|a) = 1 - P(n|a)$$

for $n = 0, 1, \ldots$ Given $R \ge 1$, an integer, we have

$$b(R|a) = \mathsf{E}[N(a) - R]^+ = \sum_{n=1}^{\infty} np(n + R|a) = \sum_{n=R}^{\infty} \overline{P}(n|a) = a - \sum_{n=0}^{R-1} \overline{P}(n|a)$$

The third equality above follows from rearranging the terms, and the fourth equality applies the identity $\Sigma_{n=0}^{\infty} \overline{P}(n|a) = a$. Note that $b(0|a) = \mathsf{E}[N(a)] = a$ and that $b(R|a)$ is decreasing in R, with $b(+\infty|a) = 0$.

Since X_i is equal in distribution to $N(\lambda \ell_i)$, we can express the item-based performance measures as follows:

$$f_i = \mathsf{P}[X_i \le R_i - 1] = \mathsf{P}(R_i - 1|\lambda \ell_i)$$

$$\mathsf{E}[B_i] = b(R_i|\lambda \ell_i)$$

$$\mathsf{E}[I_i] = R_i - \mathsf{E}[X_i] + \mathsf{E}[B_i] = R_i - \lambda \ell_i + \mathsf{E}[B_i]$$

The last equality above follows from $I_i - B_i = R_i - X_i$, which in turn follows from (39).

Next, consider the joint distribution of $\{X_1(t), \ldots, X_m(t)\}$. For ease of exposition, we start with a system of two components, that is, $m = 2$. Let $N_0(t)$ denote the number of those jobs (orders) that have arrived in $[0, t]$ and are still in service at both queues. Let $N_1(t)$ [resp. $N_1(t)$] denote the number of those jobs that have arrived in $[0; t]$ and are still in service at queue 1 [resp. queue 2], but not at queue 2 [resp. queue 1]. Hence, at time t, there are

$$X_i(t) = N_0(t) + N_i(t)$$

jobs (outstanding orders) in queue i, $i = 1, 2$.

Consider a given $t > 0$. Suppose $A(t) = n$. Then, it is well known (e.g., Ross 1996) (20) that the n (unordered) arrivals follow an i.i.d. uniform distribution in $[0, t]$ and that $(N_0(t), N_1(t), N_2(t))$ follows a multinomial distribution (of n objects, into four categories), with the following probabilities:

$$p_0(t) = \int_0^t \overline{G}_1(t - x)\overline{G}_2(t - x)(dx/t) = \int_0^t \overline{G}_1(x)\, \overline{G}_2(x)(dx/t)$$

$$p_1(t) = \int_0^t \overline{G}_1(t - x)G_2(t - x)(dx/t) = \int_0^t \overline{G}_1(x)G_2(x)(dx/t)$$

$$p_2(t) = \int_0^t G_1(t - x)\overline{G}_2(t - x)(dx/t) = \int_0^t G_1(x)\overline{G}_2(x)(dx/t)$$

(Note that $1/t$ is the uniform density over $[0, t]$.) Hence, we have

$$\begin{aligned}
&\mathsf{P}[N_0(t) = n_0, N_1(t) = n_1, N_2(t) = n_2] \\
&= \sum_{n \geq n_0+n_1+n_2} \frac{n!}{n_0!n_1!n_2!(n - n_0 - n_1 - n_2)!} [p_0(t)]^{n_0}[p_1(t)]^{n_1}[p_2(t)]^{n_2} \\
&\quad \cdot [1 - p_0(t) - p_1(t) - p_2(t)]^{n-n_0-n_1-n_2} \frac{(\lambda t)^n}{n!} e^{-\lambda t} \\
&= \frac{[\lambda t p_0(t)]^{n_0}[\lambda t p_1(t)]^{n_1}[\lambda t p_2(t)]^{n_2}}{n_0!n_1!n_2!} \cdot \exp[-\lambda t(p_0(t) + p_1(t) + p_2(t))] \qquad (41)
\end{aligned}$$

This result indicates that although $X_1(t)$ and $X_2(t)$ are driven by a common arrival process, the three underlying random variables $N_i(t)$ $i = 0, 1, 2$ have independent Poisson distributions with parameters $\lambda t p_i(t)$, $i = 0, 1, 2$, respectively. Thus, $X_1(t)$ and $X_2(t)$ are correlated only because they share a common $N_0(t)$.

Now, the joint distribution of $X_1(t)$ and X_2(,t) can be expressed through the distributions of $N_i(t)$, $i = 0, 1, 2$. Let $x_1 \wedge x_2 = \min\{x_1, x_2\}$. Then

$$\begin{aligned}
&\mathsf{P}[X_1(t) = x_1, X_2(t) = x_2] \\
&\quad = \sum_{n_0=0}^{x_1 \wedge x_2} \mathsf{P}[N_0(t) + N_1(t) = x_1, N_0(t) + N_2(t) = x_2] \\
&\quad = \sum_{n_0=0}^{x_1 \wedge x_2} \mathsf{P}[N_0(t) = n_0, N_1(t) = x_1 - n_0, N_2(t) = x_2 = n_0] \\
&\quad = \sum_{n_0=0}^{x_1 \wedge x_2} p(n_0|\lambda t p_0(t)) p(x_1 - n_0|\lambda t p_1(t)) p(x_2 - n_0|\lambda t p_2(t))
\end{aligned}$$

From (40), we have

$$\begin{aligned}
&\mathsf{P}[B(t) \leq x] \\
&\quad = \mathsf{P}[X_1(t) \leq x + s_1, X_2(t) \leq x + s_2] \\
&\quad = \mathsf{P}[N_0(t) + N_1(t) \leq x + s_1, N_0(t) + N_2(t) \leq x + s_2] \\
&\quad = \sum_{n_0=0}^{(s_1 \wedge s_2)+x} \mathsf{P}[N_0(t) = n_0]\mathsf{P}[N_1(t) \leq x + s_1 - n_0, N_2(t) \leq x + s_2 - n_0] \\
&\quad = \sum_{n_0=0}^{(s_1 \wedge s_2)+x} p(n_0|\lambda t p_0(t))\mathsf{P}(x + s_1 - n_0|\lambda t p_1(t))\mathsf{P}(x + s_2 - n_0|\lambda t p_2(t))
\end{aligned}$$

Thus, due to the special relationship between $X_i(t)$ and $(N_i(t), N_0(t))$, for $i = 1, 2$, all the performance measures of interest can be calculated by first conditioning on $N_0(t)$ and then making use of the independence of $N_1(t)$ and $N_2(t)$.

The above analysis extends readily to $m > 2$. In particular, there will be a total of $2^m - 1$ independent Poisson random variables involved: $N_{\mathcal{S}}(t)$, for $\mathcal{S} \subset \mathcal{I}$, representing the number of jobs that are still in process at time t with the queues $i \in \mathcal{S}$, but have been completed with the queues $j \in \mathcal{I} \backslash \mathcal{S}$. For each $i = 1, \ldots, m$, we can write

$$X_i(t) = \sum_{\mathcal{S}: i \in \mathcal{S}} N_{\mathcal{S}}(t)$$

That is, $X_i(t)$ can be expressed as the sum of $2^m - 1$ independent Poisson random variables. Hence, in principle, all the performance measures at time t can be exactly evaluated based on the distributions of the independent Poisson random variables via $X_i(t)$'s. The exponential growth (w.r.t. m), however, makes this impractical, even for systems with a moderately large number of components.

An exception is the special case of deterministic lead times, that is, $L_1 \equiv \ell_1$, $L_2 \equiv \ell_2$. Without loss of generality, assume $\ell_1 < \ell_2$. For any fixed t, there are three cases.

Case 1: $t > \ell_2$. In this case,

$$p_0(t) = \int_0^t 1[\ell_1 \geq s]1[\ell_2 \geq s](ds/t)$$

$$= \int_0^t 1[\ell_1 \geq s](ds/t) = \ell_1/t$$

Similarly,

$$p_1(t) = \int_0^t 1[\ell_1 \geq s]1[\ell_2 \leq s](ds/t) = 0$$

and

$$p_2(t) = \int_0^t 1[\ell_1 \leq s]1[\ell_2 \geq s](ds/t)$$

$$= \int_0^t 1[\ell_1 \leq s \leq \ell_2](ds/t) = (\ell_2 - L_1)/t$$

Since $p_1(t) = 0$, $N_1(t) \equiv 0$, we have

$$X_1(t) = N_0(t) \tag{42}$$

$$X_2(t) = N_2(t) + N_0(t) \tag{43}$$

Case 2: $l_1 < t \leq \ell_2$. In this case, we have $p_2(t) = (t - \ell_1)/t$, while $p_0(t) = \ell_1/t$ and $p_1(t) = 0$ stay the same as in Case 1; and (42) and (43) hold.

Case 3: $t \leq \ell_1$. In this case, we have $p_0(t) = 1$, and $p_1(t) = p_2(t) = 0$. So none of the arrived jobs is completed at either queue at time t. Therefore,

$$X_1(t) = X_2(t) = N_0(t).$$

Thus, in the special case of deterministic lead times, there are only $m - 1$ independent Poisson random variables involved, as opposed to $2^m - 1$ in the case of random lead times.

The steady-state performance evaluation can be conducted in a similar manner, as indicated in the next section. Denote

$$\theta_0 = \lim_{t\to\infty} tp_0(t) = \int_0^\infty \overline{G}_1(x)\overline{G}_2(x)\, dx$$

$$\theta_1 = \lim_{t\to\infty} tp_1(t) = \int_0^\infty \overline{G}_1(x)G_2(x)\, dx$$

$$\theta_2 = \lim_{t\to\infty} tp_2(t) = \int_0^\infty G_1(x)\overline{G}_2(x)\, dx$$

Let $t \to \infty$ (41), and write $N_i = N_i(\infty)$ for $i = 0, 1, 2$. We have

$$\mathsf{P}[N_0 = n_0, N_1 = n_1, N_2 = n_2]$$
$$= \frac{(\lambda\theta_0)^{n_0}(\lambda\theta_1)^{n_1}(\lambda\theta_2)^{n_2}}{n_0!n_1!n_2!} \cdot \exp[-\lambda(\theta_0 + \theta_1 + \theta_2)]$$

Thus, N_i, $i = 0, 1, 2$, are independent Poisson random variables with parameters $\lambda\theta_i$, $i = 0, 1, 2$, respectively.

Now, consider the steady-state limit of $(X_1(t), X_2(t))$, denoted (X_1, X_2). First notice the following:

$$\theta_0 + \theta_1 = \ell_1, \quad \theta_0 + \theta_2 = \ell_2$$

From the infinitely divisible property of the Poisson distribution, we can write

$$X_1 = N_0 + N_1 = N(\lambda\theta_0) + N(\lambda\theta_1)$$
$$X_2 = N_0 + N_2 = N(\lambda\theta_0) + N(\lambda\theta_2)$$

The three Poisson random variables, N_0, $N_1 N_2$, involved in the above expressions are independent of one another. Also, X_1 and X_2 are correlated through a common random component $N(\lambda\theta_0)$.

9. KANBAN CONTROL

9.1. The Basic Model

Kanban control refers to a control rule that limits the inventory level, including both WIP and finished goods to K units, with K a constant parameter. Specifically, there are K cards in the system; each card is attached to a job that is in waiting or in process, or to a job that is completed (waiting to supply demand). In other words, a card is needed to admit an order into the system. When all K cards are exhausted, there are three possibilities:

1. If all K cards are attached to completed jobs, then production is suspended.
2. If all K cards are attached to jobs in waiting or in process (i.e., there is no completed job), then any further arrival (demand) will be blocked, i.e., no more jobs are admitted into the system.
3. The situation in between is that some of the K cards are attached to completed jobs while others are attached to jobs in waiting or in process. Then, any arriving demand will be supplied by one of the completed jobs, with its card detached and given to another new job (representing the outstanding order).

This clearly relates to the base-stock control mechanism. In particular, $K = R$—any unit of demand will trigger production (or replenishment), whereas when the finished goods inventory reaches K, production will be suspended. Kanban, however, has the additional feature of blocking arrivals (of demand) when the on-hand inventory drops down to zero, that is, when all K cards are associated with outstanding orders, which is the situation in (2) above. Hence, kanban corresponds to a *finite* queueing system with K being the buffer capacity—the upper limit on the total number of jobs allowed in the system.

With this in mind, in particular, with $R = K$, the models in Section 2.1 should be modified to $M/G/\infty/K$ and $M/M/1/K$ queues (e.g., Wolff 1989). In terms of the distributions of N, I, and B, this amounts to a renormalization: dividing those probabilities in the last section by $\mathsf{P}[N \geq K]$. The inventory and back order expressions in (1) remain valid, with $R = K$. For instance, in the $M/G/\infty/K$ case, we have

$$\mathsf{P}[I = 0] = \mathsf{P}[N = K] = \frac{\rho^K}{K!} e^{-\rho} \left[\sum_{n=0}^{K} \frac{\rho^n}{n!} e^{-\rho} \right]^{-1}$$
$$\mathsf{P}[I = n] = \frac{\rho^{R-n}}{(R-n)!} e^{-\rho} \left[\sum_{n=0}^{K} \frac{\rho^n}{n!} e^{-\rho} \right]^{-1}, \quad n = 1, \ldots, R$$

and

$$\mathsf{P}[B = 0] = 1,$$

since $N \leq K$.

9.2. Generalized Kanban Control

Note that in the above kanban control mechanism, the cards control both admission (of demand arrivals) into the system and the upper limit of finished goods inventory. A more general kanban control mechanism is one that uses two types of cards. In addition to the usual type, which now (only) controls admission, there is a second type of cards controlling finished goods inventory. Let K and R, with $K \geq R$, denote, respectively, the number of cards for these two types, referred to, respectively, as kanbans and production cards. Specifically, every job within the system has a kanban attached to it. In addition, to be processed by the server, a job also requires a production card. Both the kanban and the production card stay with the completed job until it supplies a demand. At that point, the released kanban admits a new order into the system, while the released production card authorizes the service (production) of another waiting order. (Note that the above kanban control with two types of cards can be shown to be equivalent to the kanban control with three types of

cards, the so-called (a, b, k) model in Glasserman and Yao 1994b, 1996.) This way, the total number of jobs in the system is limited to K, while the total number of *completed* jobs (that are waiting for demand) is limited to R. Since now $R \leq K$, back orders are allowed, up to a limit of $K - R$.

Therefore, what is needed for this more general kanban control is the $M/G/\infty/K$ and $M/M/1/K$ models, in connection with the relations in (1)—with $R \leq K$. The earlier distributions for I and B can be modified accordingly. For instance, in the $M/M/1/K$ case, we have

$$\mathsf{P}[I = 0] = \mathsf{P}[N \geq R] = \frac{\rho^R - \rho^{K+1}}{1 - \rho^{K+1}}$$

$$\mathsf{P}[I = n] = \mathsf{P}[N = R - n] = \frac{\rho^{R-n}(1 - \rho)}{1 - \rho^{K+1}},\ n = 1, \ldots, R$$

and

$$\mathsf{P}[B = 0] = \mathsf{P}[N \leq R] = \frac{1 - \rho^{R+1}}{1 - \rho^{K+1}}$$

$$\mathsf{P}[B = n] = \mathsf{P}[N = R + n] = \frac{\rho^{R+n}(1 - \rho)}{1 - \rho^{K+1}},\ n = 1, \ldots, K - R$$

The associated expectations can be derived as follows:

$$\mathsf{E}[I] = \frac{R - (R + 1)\rho + \rho^{R+1}}{(1 - \rho)(1 - \rho^{K+1})}$$

$$\mathsf{E}[B] = \frac{\rho^{R+1} - (K - R + 1)\rho^{K+1} + (K - R)\rho^{K+2}}{(1 - \rho)(1 - \rho^{K+1})}$$

10. NETWORK OF INVENTORY QUEUES

Now consider an inventory/distribution network, also known as a supply chain. Each node in the network represents a stocking location. Suppose a base-stock control policy is followed at each node. With the discussion above, we can adapt the standard decomposition approach in analyzing queueing networks to study this inventory network.

To be specific, focus on a particular node, j, in the network. Suppose node j has a single upstream node i, which supplies any replenishment orders from j. Since base-stock control is followed throughout the network, each node is driven directly by the external demand process, which we continue to assume to be a Poisson process with rate λ.

Suppose j is modeled as an $M/G/\infty$ queue. Then, the only difference from the analysis in Section 2 is that the service time (lead time), L_j, needs to be prolonged whenever there is a stockout at node i. Hence, the modified service time is:

$$\tilde{L}_j = L_j + \tau_i, \text{ w.p. } \Phi(k_i) \tag{44}$$

While $\tilde{L}_j = L_j$ w.p. $\Phi(i_i)$. Here, τ_i is the extra delay at node i, until the next job (outstanding order) is completed. Following the analysis in Ettl et al. (2000), we can approximate τ_i as follows (provided node i is also modeled as an $M/G/\infty$ queue):

$$\tau_i = \frac{L_i \mathsf{E}(B_i)}{R_i \overline{\Phi}(k_i)} \tag{45}$$

Next, suppose both i and j are modeled as single-server queues, say $M/M/1$. Then, the only occasion in which the service time at i needs to be prolonged is when j has a stockout and server i is forced to become idle. Obviously, the probability is dominated by the stockout probability at node j, which is equal to $\rho_j^{R_j}$. In the single-server queue model, stability requires $\rho_j < 1$, hence this probability is quite negligible when R_j is reasonably large and ρ_j is not too close to 1. In this case, we can simply forgo the adjustment. Otherwise, an adjustment similar to the one in (44) is to add $\tau_i = L_i$ to L_j w.p. $\rho_j^{R_j}$. (However, this might result in overcompensation; in particular, the associated probability, $\rho_j^{R_j}$, could be too high.)

Suppose node j interacts directly with external customer demand, and follows a generalized kanban control as outlined in Section 9.2. Then a proportion of the demand will be blocked and lost when all K_j cards are occupied. This is equal to the probability $\mathsf{P}[N_j = K_j]$, where N_j follows the

$M/G/\infty/K_j$ or the $M/G/1/K_j$ model, with the adjusted service time $\tilde{L}_j$ as discussed above. Note that in this case we have a combination of back order and lost sales for external demand.

The simple Poisson demand arrival process assumed here can be readily extended to more involved processes, such as those that involve batches, like the model in Ettl et al. (2000), which makes use of the queueing results in Liu et al. (1990). The same applies to more general lead time distributions and multiple servers; approximate queueing models can be adapted; refer to Buzacott and Shanthikumar (1993).

Optimization models can be formulated based on these approximate inventory-queue models, Ettl et al. (2000) being one such example. As the basic relations in (1) serve as building blocks of the network, one should be able to establish structural properties of the objective function, based on properties of the functions in (1), which are convex in R and submodular in (R, N). These are useful properties in identifying efficient solution algorithms.

In this type of decomposition, each decomposed node is driven by exactly the same external demand processes, due to the base-stock control mechanism. This is quite different from the usual queueing network decomposition, where it is standard to assume that the decomposed queues are independent of each other, which is indeed the case in the special case of product-form networks. In the network of inventory queues, the dependence among the queues should be maximal since the queues are all driven by the same arrival processes. In this regard, the network behaves more like the ATO system in Section 8, where each unit of demand consists of a set of components; and hence, a demand arrival will simultaneously trigger the production at all component queues.

Therefore, to conclude this section, let us examine more closely the issue of stockout in the ATO system and its relation with customer order service. Consider multiple demand streams, indexed by $m \in \mathfrak{M}$. Let $\mathcal{S}_m$ denote the set of components required to assemble one unit of end product for type m demand. Let α be the required service level, defined here as the off-shelf availability of all the components required to assemble a unit of type m product, for any m. Let E_i denote the event that component i is out of stock. Then we require, for each end product $m \in \mathfrak{M}$,

$$\mathsf{P}[\cup_{i\in\mathcal{S}_m} E_i] \leq 1 - \alpha$$

From the well-known inclusion–exclusion formula (e.g., Ross 1996):

$$\mathsf{P}[\cup_{i\in\mathcal{S}_m} E_i] = \sum_i \mathsf{P}(E_i) - \sum_{i<j} \mathsf{P}(E_i \cap E_j) + \sum_{i<j<k} \mathsf{P}(E_i \cap E_j \cap E_k) - \ldots$$

we have, as an approximation,

$$\mathsf{P}[\cup_{i\in\mathcal{S}_m} E_i] \cong \sum_{i\in\mathcal{S}_m} \mathsf{P}(E_i) = \sum_{i\in\mathcal{S}_m} \overline{\Phi}(k_i) \leq 1 - \alpha \tag{46}$$

Note that $\overline{\Phi}(k_i)$ is the stockout probability of component i, using a normal approximation [c.f. (4)].

There is another way to arrive at the above inequality. Suppose we express the service requirement as follows:

$$\prod_{i\in\mathcal{S}_m} \Phi(k_i) \geq \alpha, \quad m \in \mathfrak{M} \tag{47}$$

Note that the left-hand side in (47) is, in fact, a *lower bound* of the no-stockout probability of the set of components in $\mathcal{S}_m$ that is required to assemble the end product m, that is, it is a lower bound of the desired off-shelf availability. This claim (of a lower bound) can be argued by using stochastic comparison techniques involving the notion of *association.* (Refer to, e.g. Ross 1996 for background materials.) Intuitively, since the component inventories are driven by a common demand stream $\{D_m(t)\}$, and hence positively correlated, the chance of missing one or several components must be less than when the component inventories are independent, which is what is assumed by the product on the left-hand side of (47).

Since

$$\prod_{i\in\mathcal{S}_m} \Phi(k_i) = \prod_{i\in\mathcal{S}_m} [1 - \overline{\Phi}(k_i)] \cong 1 - \sum_{i\in\mathcal{S}_m} \overline{\Phi}(k_i) \tag{48}$$

where the approximation works best when the stockout probability $\overline{\Phi}(k_i)$ is small, for all components $i \in \mathcal{S}_m$. [Note the approximation in (48) is analogous to the one in (46).] Combining (48) with (47), we arrive at the same inequality in (46).

We can now relate the above off-shelf availability requirement to the standard customer service requirements expressed in terms of response times, W_m, the time it takes to fill a customer order (of type $m \in \mathfrak{M}$). Suppose the required service level of type m demand is

$$\mathsf{P}[W_m \leq w_m] \geq \alpha, \quad m \in \mathfrak{M} \tag{49}$$

where w_m's are given data. This is the type of service requirement considered in Ettl et al. (2000).

Consider type m demand. We have the following two cases:

1. When there is no stockout at any store $i \in \mathcal{S}_m$—denoting the associated probability as $\pi_{0m}(t)$, the delay is simply L_m^{out}, the outbound lead time—time to process the order, assemble the product, and deliver it to the customer.
2. Suppose there is a stockout at a store $i \in \mathcal{S}_m$. Denote the associated probability as $\pi_{im}(t)$. Then the delay becomes $L_m^{\text{out}} + \tau_i$, where τ_i is the additional delay before the stocked-out component becomes available [cf. (45)].

Hence, we can write

$$\begin{aligned}\mathsf{P}[W_m \leq w_m] &\cong \pi_{0m}(t)\mathsf{P}[L_m^{\text{out}} \leq w_m] + \sum_{i\in\mathcal{S}_m} \pi_{im}(t)\mathsf{P}[L_m^{\text{out}} + \tau_i \leq w_m] \\ &= \left[\prod_{i\in\mathcal{S}_m} \Phi(k_i)\right]\mathsf{P}[L_m^{\text{out}} \leq w_m] + \sum_{i\in\mathcal{S}_m} \overline{\Phi}(k_i)\mathsf{P}[L_m^{\text{out}} + \tau_i \leq w_m]\end{aligned} \tag{50}$$

Note that in the approximation above, we have ignored the probability of two or more components stocking out at the same time [in the same spirit as in (46) and (48)].

In most applications, it is reasonable to expect $L_m^{\text{out}} \leq w_m$. For instance, this is the case when the outbound lead time L_m^{out} is nearly deterministic, and the delay limit w_m is set to be safely larger than L_m^{out}. Furthermore, τ_i can be estimated based on (45). Therefore, if we set the delay limit w_m such that $w_m \geq L_m^{\text{out}} + \tau_i$ with probability one, for all $i \in \mathcal{S}_m$, then the response-time serviceability in (50) can be met at nearly 100% [taking into account (48)]. In other words, aiming for a high off-shelf availability (say, 90–95%) will usually enable us to set a reasonable response-time limit (w_m), and to achieve a near-100% response-time service level.

11. BIBLIOGRAPHICAL NOTES

Buzacott and Shanthikumar (1993) is a rich source of exact and approximate queueing models of production-inventory systems, including generalizations of the models in Section 2.1 and Section 9. Kanban control is studied in detail from a discrete-event systems point of view in Glasserman and Yao (1994a, b, 1996); in particular, the dynamics are modeled as generalized semi-Markov processes, and structural properties such as monotonicity, concavity, and line reversibility (symmetry) are exploited to solve the optimal allocation of kanbans among the production stages. The PAC (production authorization cards) scheme in Buzacott and Shanthikumar (1993) provides a unified modeling framework for many production control schemes, including kanban and MRP.

The materials in Sections 3 through 7 are drawn from Feigin et al. (2000), which also contains a critique of DRP, including numerical examples.

The discussion on ATO systems in Sections 8 and 10 draws materials from Cheng et al. (2000) and Song and Yao (2000). Both papers also have extensive treatments of optimization models, with the latter focusing on queueing analysis and stochastic bounds (also refer to Song 1998; Song et al. 1999), whereas the former focuses on normal approximations and industrial (PC manufacturing) applications. Glasserman and Wang (1998) study ATO systems using a large deviations-based approach, deriving asymptotic results; also refer to Glasserman (1997).

The decomposition-based approach overviewed in Section 10 was first developed in Ettl et al. (2000) for the purpose of performance evaluation and optimization of a large-scale enterprise supply chain. (Refer to Lee and Billington 1986 for an earlier, related work on modeling supply chains.) A related network model, for semiconductor fabrication, appeared in Connors et al. (1996). Also refer to Buzacott and Shanthikumar (1993) for other network models using decomposition-based approximations.

An important topic that we have not discussed in this chapter is the incorporation of quality control into the modeling of production-inventory system (refer to Chen et al. 2000; Yao and Zheng 1999a, b), where the emphasis is on coordinating production and quality control (e.g., inspection), with quality adding a new dimension to the usual inventory-service trade-off.

CHAPTER 62

Process Design and Reengineering

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

Process design and process reengineering have received increased attention over the last decade as companies, responding to increased competition, have struggled to become more customer focused and price competitive. There has been substantial debate over precise definitions of process, business process, and process reengineering (Love et al. 1998a). There is a desire to arrive at a uniform set of definitions so that the case studies can be effectively evaluated. Aside from the debate over labels, process design and reengineering (PDR) has offered companies new ways of assessing their operations and most importantly, improving them by large orders of magnitude. While simple in concept, PDR has proven difficult to implement successfully. Some possible reasons are:

- It is not so much a scientific theory as it is a paradigm (Weicher et al. 1995).
- It ''is a messy, complex process which requires strong leadership, the application of special skills and methodologies, and an ongoing commitment to process improvement'' (Caudle 1995).
- Because companies and processes are different, seemingly similar PDR projects are vastly different in execution (Caudle 1995).
- It is not ''universally applicable'' (Coombs and Hull 1997).

However, the benefits are lucrative, and therefore companies will continue to attempt to reengineer their processes.

1.1. Definitions

A *process* may be defined as a ''sequence of pre-defined activities executed to achieve a pre-specified type or range of outcomes'' (Lee and Dale 1998) or a ''sequence of activities, which are performed across time and place'' (Bal 1998). It is a set of activities that transform a set of inputs into a set of outputs. Furthermore, a process may be classified as ''(1) the sort that starts when necessary and finished some time in the future; or (2) the sort that is constantly running'' (Bal 1998).

A *business process* is ''a collection of related, structured activities—a chain of events—that produces a specific service or product for a particular customer or customers'' (Caudle 1995). They may be classified as ''mission or external customer-facing processes, support processes, and management processes'' (Caudle 1995). There are also two critical characteristics of a business process: (1) it has external or internal customers, and (2) it crosses organizational boundaries (Malhotra 1998). A representative illustration of a business process is shown in Figure 1. Note that it spans across functions and that it has internal and external customers.

Business process redesign and *business process reengineering* are synonymous with PDR. The terms were introduced, respectively, by Davenport and Short (1990) and Hammer (1990). Each refers to ''a systematic, disciplined approach for achieving dramatic, measurable performance improvements by fundamentally reexamining, rethinking, and redesigning the processes that an organization uses

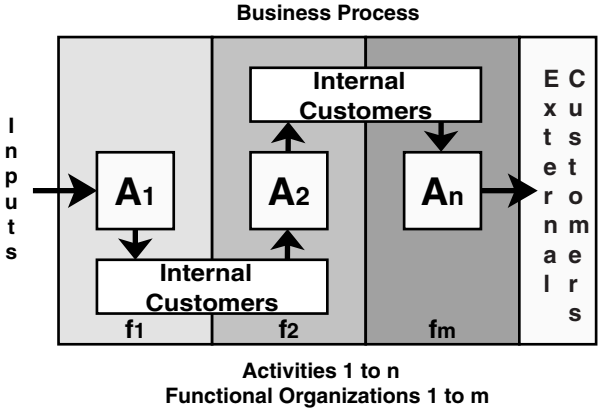

Figure 1 Business Process.

to carry out its mission'' (GAO 1995). Since that time, several additional definitions have been contributed by various authors. Because of the multiple definitions in circulation, it has been suggested that ''the reengineering label appears simply to be related to the notion of taking an organization apart and putting it back together again, more efficiently, less expensively and with fewer personnel'' (Buchanan 1998). While this statement is essentially correct, it oversimplifies the activity and challenges it involves as well as the results realized. To illustrate the different thoughts involved with PDR, consider Figure 1. Before PDR, if a person were queried about the processes present in the company, he or she would invariably answer along the lines of f1, f2, or marketing, sales, and production. Note that these are descriptions of functions within the organization and not necessarily processes. Reengineered processes are usually described in terms of the beginning and end states—for example, purchasing, which is not really a process but a function within the organization. The process would be aptly described as ''requisition to delivery.'' The difference may seem trivial, but as a starting point for PDR it forces thought towards the activities taking place between the endpoints.

In summary, the following characteristic definition regarding redesign or reengineering emerges: ''[PDR] focuses on business process, adoption of information technology, taking fundamental analysis and radical redesign, and aims to achieve dramatic improvement in a short time delivery'' (Choi and Chan 1997). It has been contrasted with TQM in that, while both center on the concept of improvement, PDR stresses radical improvement in a short time while TQM relies on incremental improvement over an indefinite period (Jarrar and Aspinwall 1999).

Finally, business process management (BPM) is the natural resultant of PDR. While some definitions include PDR as a subset of BPM, it is obvious that if processes have been radically altered, the method of managing them must be altered as well, including performance metrics, monitoring, training, and, in some cases, the organizational structure itself (Pritchard and Armistead 1999). To this end, BPM is defined as ''a systematic, structured approach to analyze, improve, control and manage processes with the aim of improving the quality of products and services'' (Lee and Dale 1998).

1.2. Assumptions

The fundamental assumptions underlying PDR are (Biazzo 1998):

1. The organization is a collection of processes that can be reengineered ''scientifically'' and systematically.
2. The nature of change is revolutionary and consists of:
   - The passage from functional units to process teams
   - A move from simple tasks to multidimensional work
   - Changes in power relations towards worker empowerment
   - Change from a ''bureaucratic'' culture to one based on customer satisfaction
   - Changes in managerial behavior from supervisors to trainers
3. Planning for this change is top-down.

1.3. Steps

There are a variety of opinions regarding the actual steps involved in process reengineering. A typical outline of the phases is listed below. It represents a consensus view from a survey of practitioners (Kettinger et al. 1997).

1. Envision:
   - Establish management commitment and vision.
   - Discover reengineering opportunities.
   - Identify information technology (IT) levers.
   - Select process.
2. Initiate:
   - Inform stakeholders.
   - Organize reengineering teams.
   - Conduct project planning.
   - Determine external process customer requirements.
   - Set performance goals.
3. Diagnose:
   - Document existing process.
   - Analyze existing process.

4. Redesign:
   - Define and analyze new process concepts.
   - Create prototype and detailed design of a new process.
   - Design human resource structure.
   - Analyze and design information systems (IS).
5. Reconstruct:
   - Reorganize.
   - Implement.
   - Train users.
   - Process cut-over.
6. Evaluate:
   - Evaluate process performance.
   - Link to continuous improvement programs.

There are critical aspects to each of the phases as well as the elements represented within. These will be discussed in the implementation section of this chapter. The six-phase process represents a logical approach to a reengineering project and is illustrated in Figure 2.

Deceptively simple, this framework implies that PDR is simply a matter of going through a sequence of steps. However, beneath this framework lies the question of how to implement the process of change. In that respect, PDR ''still remains a mystery with few rules and methods to guide firms through their endeavor'' (Crowe and Rolfes 1998). There is a great deal to be learned from the experience of others, but that experience must be continually evaluated against the culture of the firm that is considering reengineering.

Finally, the following general observations may be made about reengineering (Caudle 1995):

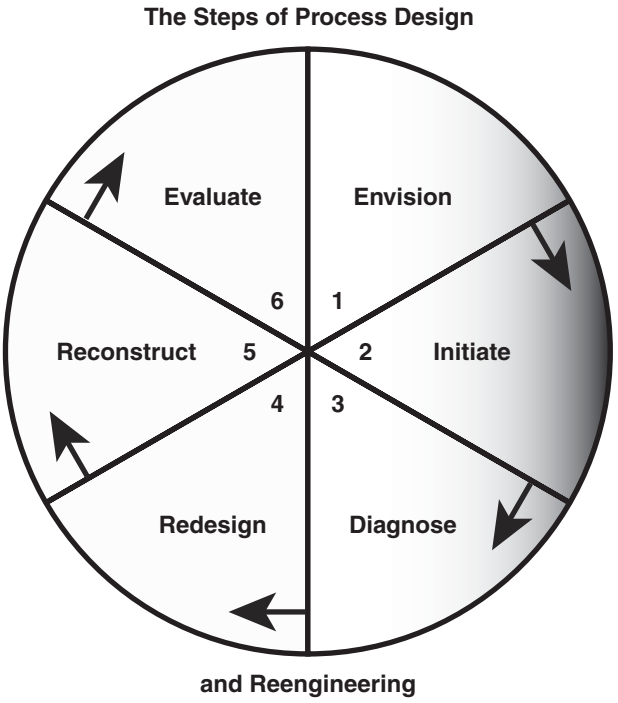

Figure 2 The Steps of Process Design and Reengineering.

1. Be aggressive about ambitions.
2. Recognize that while a lot can be done within single departments and agencies, a lot more can be accomplished through cross-departmental integration of effort.
3. Get the policy—which in private enterprise equals strategy—clear at the top.
4. Finally, always keep in mind the hidden reefs of politics.
5. Get it done fast.

2. THE EVOLUTION OF PDR

2.1. Backdrop

A variety of factors led companies to begin to experiment with changes that eventually developed into the process reengineering paradigm. Half of the Fortune 500 companies listed 20 years ago are not on that list today. The missing ones failed to see the future in terms of customer needs, evolving technology impacts, and competition (Dickie 1995). Most, if not all, were based on the management and operational structure that developed at the beginning of the twentieth century and thus had been developed for companies in stable, expanding marketplaces.

That structure performed remarkably well through the first two-thirds of the century. Unfortunately, task-oriented work required the development of functional hierarchies for supervision and control in the workplace. As the hierarchies grew, a silo mentality grew as well. Management focused on the performance of their particular function alone, making it difficult or impossible to include internal and external customers into the decision-making process. Also, efforts directed at suboptimizing the performance of a function often had little effect on the performance of the entire system. Increased competition forced companies to improve their productivity, but that effort was frustrated by the very organizational structures that once worked so well (Lucier and Torsilieri 1999). Figure 3 illustrates the inherent problems with the hierarchical structure. Note that the communication barriers that form between the functional organizations and that optimization attempts are performed vertically and do not necessarily enhance the product flow. Furthermore, as the hierarchy grows, the command-and-control nature inherent to the organization means that the distance between the decision maker and the decision point increases.

The pyramid hierarchical organization had been rendered invalid or inoperable in most cases (Love et al. 1998a). The division of labor no longer worked either (Lucier and Torsilieri 1999). TQM programs, which helped companies rediscover the customer, also introduced an incremental change paradigm, which likewise was ''no longer considered to be adequate for acquiring a competitive advantage in the marketplace'' (Love et al. 1998a). The internal workings of a company had to be redefined.

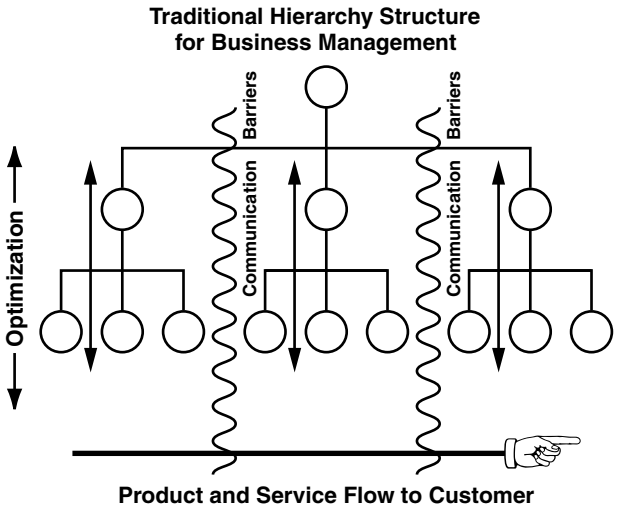

Figure 3 Hierarchical Organization Schematic.

There is now a ''perceived linkage between strategy and organizational structures'' (Coombs and Hull 1997). The advent of the concept of a business process has permitted companies to examine how they do their work, what they do, and why they do it. ''Critical business processes are the basic means to support a company's strategic objectives according to set priorities'' (Dervitsiotis 1999). The new process focus facilitates improvements that allow businesses to determine which activities are value-adding ones (Guimaraes and Bond 1996).

2.2. Implementation

The concept of process reengineering went mainstream in 1993 when Michael Hammer and James Champy's *Reengineering the Corporation* was published. The concept was eagerly embraced because it offered breakthrough changes in performance. Process reengineering held promise because it encompassed three previously unconnected components: information technology, business processes, and a greenfield or blank sheet approach to change (Davenport 1996). While none of these components was new, there were inherent dangers in using them individually. These are shown in Figure 4.

The information technology piece allowed companies to imagine previously impossible scenarios of executing work. This, in concert with a process view of work, formed the foundation for the improvement of process reengineering. The last component, which is sometimes referred to as the blank sheet concept of change, promised that there would be no legacy components from an old system unless they were critical to the new process. In theory, designers would be able to design it right the first time and overcome the inertia of status quo. Figure 5 illustrates the results of using these components in tandem.

2.3. Postimplementation

As companies began to implement process reengineering programs and data were gathered, it became apparent that breakthrough performance gains were more elusive than previously thought. Estimates of failed ''process reengineering'' programs range anywhere from 50–70%. The failures were not merely isolated to flat responses in productivity. One of the direct consequences of a reengineered process without an increase in market demand is surplus labor. Displaced workers soon began to be referred to as ''reengineered'' workers. By 1996, process reengineering had come under attack as a damaging fad with ''ruthless objectives and unclear methodology'' (Buchanan 1998). Debate continues, and four main lines of thought have emerged. The prophets continue to recommend process reengineering in its original form. The disciples strive to achieve the gains of classical reengineering with more practical implementation strategies. The revisionists declare the shortcomings of classical process reengineering to be a lack of human focus and thus try to reengineer around those shortcomings. The last group, the skeptics, attack the concepts and methodology entirely (Buchanan 1998).

2.4. Failure Reasons

Several possible reasons for the high failure rate of process reengineering have been discussed in the literature. Harrington proposes five (Harrington 1998a):

1. The methodology was misused and the reported results were misleading.
2. Process reengineering's negative impact on the organization was poorly defined and not considered in its implementation package.
3. The creative part of process reengineering was not understood.
4. The cycle time from start of project to reaping results was too long.

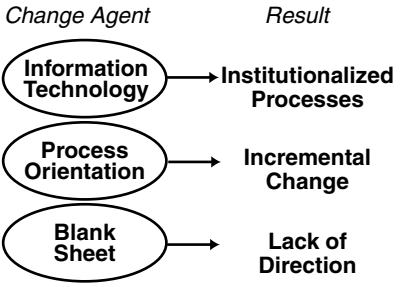

Figure 4 The Components of Reengineering: Separate.

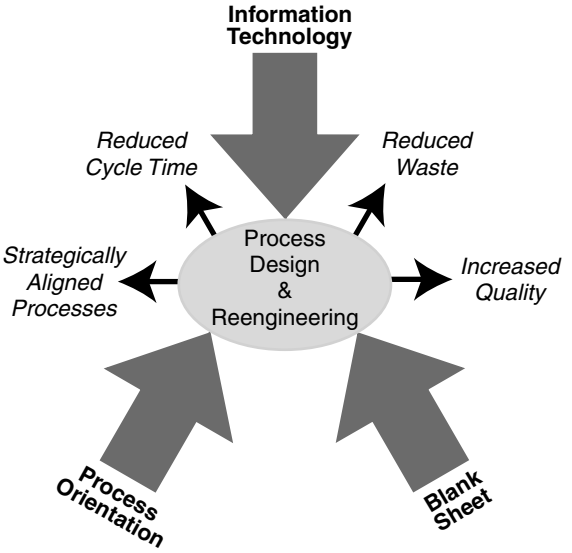

Figure 5 The Components of Reengineering: Together.

5. It produced too good a result—the methodology failed to consider anything other than performance in developing alternatives.

Another factor that contributes to less-than-desired results in process reengineering is that newly engineered processes are often implemented in traditional functional management structures (Love et al. 1998a). This can create conflict within the system (Lucier and Torsilieri 1999)—or worse, the process can revert to its old state via work-arounds (Fisher 1997). The functional management paradigm must change along with the process. The blank sheet approach has also been criticized in that it can create impractical solutions that conflict with organizational priorities (Buchanan 1998). Apparently not all of the linkage to the old process is negative. There are times when certain aspects of a given process exist for economic, political, or other good reasons, none of which may be obvious to the casual observer. These and other negative dimensions of process reengineering are changing the methodology by which it is done. The process of PDR continues to evolve as experience is gained (GAO 1995).

2.5. The Second Wave

Due in large part to the shortcomings of the original attempts at reengineering, the concept of the second wave of reengineering has developed. The companies in this wave will benefit from the experience of those who participated in the first wave. This wave will focus on ''growing the top line rather than cutting costs'' (Dickie 1995). Figure 6 illustrates this trend graphically. It has three basic principles (Moeller et al. 1996):

1. Enhance the value for cost to the customer. Rather than reengineering in order to cut or maintain the cost to the customer, attempt to increase the value to the customer.
2. Realign the processes and business systems for growth. While classical reengineering produced short-term optimization in terms of costs, the second wave will make assessments in terms of the short and long term.
3. Refocus on the soft side of capabilities development. Management vision and strategy must be transformed to reflect the values of the second wave. Measurement and reward systems will need to be revisited to ensure that they promote growth. Training and management development investments will increase, and human resource processes will need modification.

2.6. State of the Art

It appears that reengineering is poised to make a comeback (Bartholomew 1999). This wave will have the wealth of experience of the first wave to draw upon. As mentioned above, it will have significantly different goals and will attempt to shore up the weaknesses of previous attempts. While

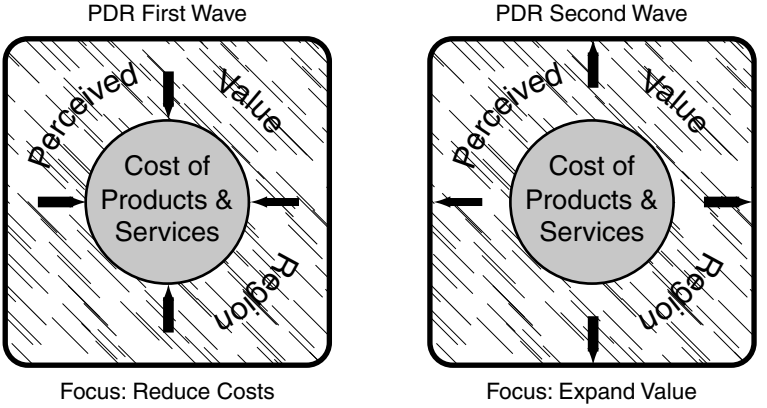

Figure 6 PDR: First to Second Wave.

IT was one of the major components of the first wave, more focus will be applied to change management in the second wave (Guha et al. 1997). The surplus problem associated with the implementation of PDR's original form drove fear into, rather than out of, the organization. As a result, people are less willing to put their heart and soul into a project that could very well cost them their jobs. As a remedy to this, some firms have implemented policies to protect personnel from layoff (Caudle 1995). The effectiveness of measures such as these remains to be seen, but the very fact that they are being attempted underscores the potential value PDR holds for companies.

3. TOOLS FOR REENGINEERING

A variety of tools are available to aid in reengineering efforts. The benefits that reengineering tools provide range from process visualization and analysis to process costing to competitive analysis. When selecting reengineering tools, it is best to give consideration to those tools that are easy to learn and easy to use. If a tool requires a long learning period, its value may be diminished. When comparing tools, proportionally discount the value of a given tool relative to the time required to learn to use it. Obtain reference data from other users about a given tool and its features. Also, consider the in-house training aspects. The rest of the reengineering team must be able to learn to use the tool effectively as well (Manganelli and Klein 1994).

A reengineering tool should have at least one of the following characteristics:

1. It must be usable by the reengineering team.
2. It must provide a return on investment (ROI).
3. It must aid in clarifying the vision.
4. It must tie top-level corporate goals to subsystem goals.
5. It must integrate into the existing infrastructure.

Reengineering tools should perform at least one of the following tasks (Roberts 1994):

1. Recording or data structuring
2. Decision support
3. Process flow diagramming
4. Flow path determination
5. Process measure determination
6. Path optimization
7. Modeling
8. Simulating
9. What-if analysis
10. Constraint isolation
11. Reporting/plotting
12. Planning/tracking

Reengineering tools include benchmarking, modeling and analysis tools, simulation, and activity-based costing.

3.1. Benchmarking

Benchmarking is defined as ''. . . the search for the best practices that will lead to superior performance of a company . . . and [that will] allow a manager to compare his or her function's performance to the performance of the same function in other companies'' (Camp 1989). The desired result of a benchmarking effort is a comparison to external but similar measures of system performance, such as quality and cost and productivity (Grover et al. 1995).

Typical benchmarking steps are:

1. Determine objectives and define the scope of the benchmark study.
2. Gain support from within the organization.
3. Select a benchmarking approach to use.
4. Determine who the benchmarking partners are.
5. Retrieve benchmark data via research, surveys, and benchmarking visits.
6. Using the results, determine the necessary practices or principles that are absent within the current system.
7. Choose the principles or practices to implement.
8. Implement.

There are four broad categories of benchmarks that provide the most valuable insight into the performance of a company: business results, cycle time, quality assurance, and asset. Business results are typically financial ratios, cycle time deals with task completion, quality assurance deals with customer-related measures, and asset benchmarks range from inventory turns to human asset measures (Schwartz, 1998).

The information necessary for benchmarking may be found in public domain, technical papers, and panel discussions, as well as, information exchange (benchmarking partnership). A benchmarking partnership allows each party to gather information about the other with the goal of creating better processes. Previous benchmarking studies of related industries, libraries, conferences, databases and suppliers are also key opportunities for gathering information for benchmarking (Stork 2000).

3.2. Modeling and Analysis Tools

Modeling tools allow the process to be diagrammed. Process modeling is crucial because it depicts the business, the relationships, and the flow of information. With this information, the impact or potential ripple effect of changes can be determined (Morris and Brandon 1993). In process modeling, activities and their connecting links are labeled and assigned to all necessary levels (Roberts 1994). Modeling tool-selection issues are methodology, alternative views, form of input, simulation, and standardization. Process modeling may be done with flowcharts, tree diagrams, fishbone diagrams, hierarchy charts, computer-simulated models, and mathematical models. One of the most popular methods is flowcharting. Flowcharts graphically illustrate the steps of an activity. Descriptive symbols are used for each step and arrows indicate the flow. The flowcharting steps are:

1. Define steps and sequence.
2. Identify all relationships and decisions.
3. Draw straight-line representation of all work steps.

Process analysis tools are used to enter, view, and track the process inputs. These tools, like modeling tools, must show different views of the results. Most process analysis tools are packaged with modeling tools. Process analysis tool selection considerations are basically the same as those of modeling tools. Typically, process modeling and analysis tools: (Yu and Wright 1997):

1. Provide system visualization through system diagrams
2. Are PC based
3. Are easy to learn to use and scalable
4. Provide analysis and performance measures of static system
5. Provide modeling of dynamic behaviors of system

3.3. Simulation

Simulation tools, while not specifically designed for PDR, provide additional methods to analyze the dynamic nature processes. ''Fundamental to the re-engineering effort is the ability to simulate the

changes that are being proposed'' (Morris and Brandon 1993). Simulation is dynamic process modeling. Simulation allows the user to predict the behavior of a system under certain circumstances without actually building the system. Simulation is just an approximation of the physical system, but it allows changes to be rapidly incorporated and tested under a variety of conditions. Through computer simulation, process fluctuations, optimal settings, and the effect of various inputs may be determined. Basic simulation inputs are task time, resources, and demand, while the outputs are cost, throughput, cycle time, utilization, and bottlenecks (Petrozzo and Stepper 1994).

3.4. Activity-Based Costing (ABC)

The need of reengineering teams for accurate information regarding the consumption of resources by processes led to renewed interest in activity-based costing (ABC). ABC is an accounting methodology in which costs are assigned to activities, as opposed to products or services. ABC more accurately distributes the applicable costs to those products and services that consume them. ''The precision of ABC is useful in establishing the true costs of the component and the compound process outputs'' (Grover et al. 1995). ABC provides necessary information as to where the money is going or where certain costs lie. An example of activity-based costing is shown in Figure 7.

In ABC, costs are assigned to activities based on resource consumption. Cost is then assigned to elements such as products or customers. This information provides the foundation for deciding on issues such as outsourcing and corporate spending. Often, when traditional accounting systems are used for costing, cost is overallocated to high-volume production and underallocated to low-volume production on a per-unit basis. To portray the value of proposed systems over current ones accurately, it is imperative that accurate methods be employed for costing.

ABC is used by reengineering teams to perform cost-benefit analysis on proposed systems including the segmented delivery of products and services. ABC will determine the cost and viability of a product/process/system, both before and after reengineering. The steps for ABC are (Maluso 1997):

1. Use a process map to identify the major business processes and key activities of the organization.
2. Attach the cost to these key activities. Financial data may be gathered from existing data, including information on labor and capital equipment expenses, budget, general ledger, and supplier invoices.
3. Link activities to processes and identify the cost drivers.
4. Summarize the total costs for each process.
5. Do this as well for the reengineering process.

4. IMPLEMENTATION

4.1. Preplanning

As mentioned in the introduction, a framework exists for conducting PDR activities. Not explicitly noted in the outline is the necessity for training and planning before any large-scale reengineering effort begins. Ultimately, the entire organization will be required to think in terms of process. This is one of the primary challenges of process management (Lee 1996). For reengineering to flow smoothly in the planning and design stages, management and staff will need to know its function,

Traditional		ABC		
Wages	$150.00		# Units	
Supplies	$ 50.00	Clean Bathroom	6	$150.00
Insurance	$ 30.24	Vacuum	3	$21.00
Transportation	$ 10.00	Dust	3	$15.00
		Change Linen	3	$12.00
Profit	$ 59.76	Empty Trash	6	$12.00
		Clean Kitchen	3	$90.00
Cost	$300.00			$300.00

Figure 7 ABC vs. Traditional Costing.

its implications, and how it fits into the scope of improvement efforts (Caudle 1995). The vision for change must be articulated over and over again. Management and staff will need to be educated in the concepts of process and reengineering. The design team should thoroughly understand the design process (Feather 1998) and be cognizant of its linkage with organizational structure (Gappmaier 1997). Spending time, effort, and money on educating people before beginning the reengineering process pays back by eliminating misunderstanding and indecision.

For most companies, the process view of work is a new one (Lee 1996). Before making the decision to reengineer along process lines, management must be firmly committed to that end as well as the necessary changes it entails (Caudle 1995). They must have in mind a target performance level that they wish the new structure to achieve (Love et al. 1998a) and a measurement system must be in place in order to let them know whether the reengineered system is, in fact, performing to expectations. This requires that employees be educated on performance measures and uses (Caudle 1995).

Lastly, management must assess the culture of the organization and determine its propensity towards change. This has proven to be a major stumbling block in a majority of the reported PDR efforts (Corrigan 1997). It is apparent from the literature that some organizational cultures have a greater capacity for accepting and processing change than others (Love et al. 1998b). Organizations that have the ability to accept change readily have been referred to as learning organizations and are ''characterized by the ability to adapt and improve, to build internal and external knowledge, and to achieve higher levels of learning that may be critical to successful [PDR]'' (Guha 1997). Communicating early and throughout can help overcome resistance to change (Feather 1998) and is viewed as a critical success factor to PDR projects (Andrews 1996a).

Figure 8 provides a summary of the steps involved in preplanning.

4.2. Envision

4.2.1. Establish Management Commitment and Vision

A prerequisite to successful implementation of a BPR project is unequivocal support from upper management (Ho 1999). The vision must be communicated to and embraced by the entire organization, but this communication is especially important in dealing with midlevel and functional managers who are affected by the changes (Guha 1997). As the implications of change are realized, risk aversion and uncertainty can develop, creating an atmosphere where less than optimal solutions are developed (Morris et al. 1999). In these cases, management's commitment is tested. The case for change and the vision of the future state must be coupled with a strategy for achieving change. Successful organizations require and practice hands-on senior management's aggressive ownership of process improvement through personal responsibility, involvement, and decision making. Most often this is seen in the use of executive committees, steering groups, and the assignment of process owners (Caudle 1995).

4.2.2. Discover Reengineering Opportunities

The breakthrough improvements available from reengineering can come in one of two forms. Reengineering a process can take away the inefficiencies present in terms of cost and time to process but leave the general value adding sequences the same. This is accomplished by removing organizational

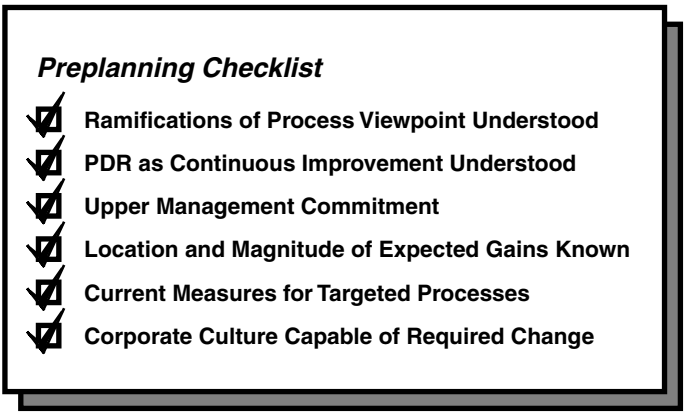

Figure 8 Preplanning Step Checklist.

issues, archaic rules, and legacy procedures that are counterproductive to the overall goal (Bartholomew 1999). Companies gain from examining their processes in this way, but not every instance will yield the same ''opportunity for dramatic breakthrough'' (Bal 1998). The most significant improvements are realized when entirely new processes are developed for bringing existing products and services to customers. The following three characteristics describe efforts of this sort (Feather 1998):

1. New opportunities in markets, products, and services where value is created in the business process are discovered and exploited.
2. New ways of thinking about the process using design principles and process benchmarks are utilized.
3. Innovative core processes that encourage people to behave differently are developed.

Being creative is one of the most demanding aspects of PDR. One of the features of PDR that has allowed companies to be more creative with their process thoughts is information technology.

4.2.3. Identify Information Technology Levers

The strategic importance of information was always known, but until recent times nothing could be done to exploit it. Modern technology, however, has served to erase the geographic barriers that once stood in the way of information flow. Likewise, it has permitted the lag time that existed between information collection, data entry, and report to be reduced. Real-time information processing is a reality. Realizing this in process design permits processes to be developed that behave and perform drastically different than their predecessors. ''Successful [PDR] involves the coalescence of 'IT' and business best practice, whereby IT plays a supportive, but not always commanding role that is linked to the business case for [PDR]'' (Guha et al. 1997).

The specific roles played by IT in PDR are many and vary from case to case. It may be used to enhance communications at the customer interface through electronic data interchange, software training systems, and distributed product/service specifications and performance data. It can facilitate the distribution of information across and outside of the organization through centralized, shared databases, networks, and wireless communications. It enables companies to provide services economically at remote locations with expert systems. The rapid increase in computing power has allowed companies to eliminate the batch mentality altogether. No longer are strategic decisions made in concentrated groups at specific points in time. Plans can update in real time and data models can provide revised forecasts instantly. Accurate snapshots concerning production and distribution data are accessible with electronic tracking and identification. Customer orders can be monitored and accurate lead times can be quoted. Internal organizational performance can be monitored as well. All of these innovations typically provide the backbone of redesigned processes. They all have the common trait of providing the necessary information to the necessary destination in a usable form at the time it is needed.

While it is generally agreed that IT is the enabler for paradigm shifts required for reengineering, it has also been pointed out that its misuse can prevent PDR projects from succeeding by institutionalizing old concepts and processes (Hammer and Champy 1993). Simply automating the old systems is not reengineering and should not be confused with it. The fundamental concept in successfully utilizing IT in PDR is that it is used to change the way things are currently done or even eliminate the need for them, not merely to optimize them.

4.2.4. Select the Process

There is much to be said about selecting a process for reengineering. To achieve the greatest gain, processes selected for reengineering must have strategic importance. ''A fact often overlooked is that processes exist to support specific strategic goals considered vital for survival and success'' (Dervitsiotis 1999). Companies should begin by evaluating their business strategy and then determining which processes are critical to the strategy (Bartholomew 1999). Failure to do this has been cited as a contributor to implementation failure (Peltu et al. 1996). All processes must be reviewed so that the interdependence among them may be fully understood (Guha et al. 1997).

Figure 9 provides a summary of the envision step activities.

4.3. Initiate

4.3.1. Inform Stakeholders

Everyone associated with the process must be informed of the need for and intent of the reengineering effort. Management, customers, suppliers, employees, and labor unions are included in this group. The sharing of information from the outset decreases the possibility of misunderstanding and increases the possibility of success (Lee 1996). From the customer's perspective, this enhances the channels of communication regarding their service level needs. From the employee's perspective, this

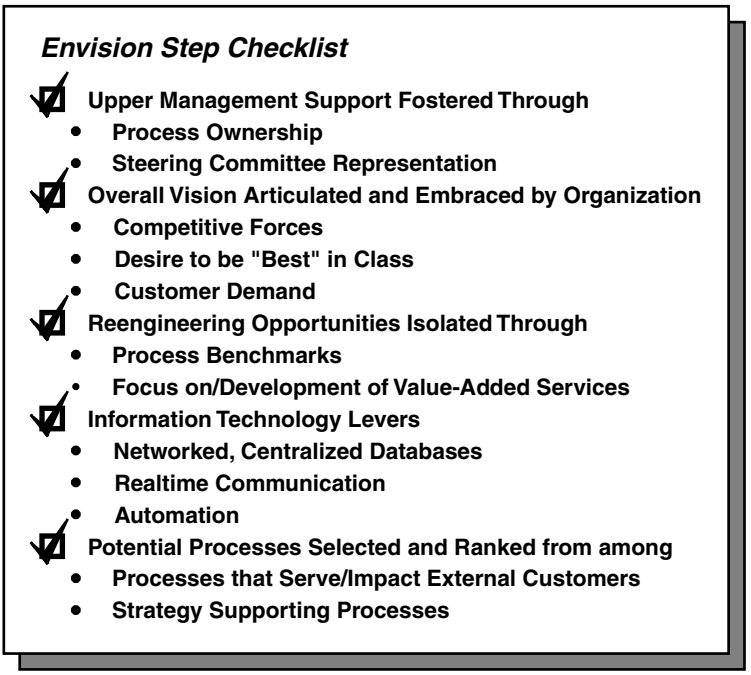

Figure 9 Envision Step Checklist.

allows them the opportunity to buy into the process as opposed to having predetermined solutions forced upon them.

4.3.2. Organize Reengineering Teams

The actual size and number of teams for a given project may vary. It is essential that the team members, especially the design members, be trained to work in a team environment. The members responsible for design must also have a background of experience or training in process design, as well as some knowledge of the current technologies available for use in reengineered processes. This is where consultants are sometimes used to add missing skills to a team. Some process reengineering experts recommend that the PDR team be split into two parts: a design team and an execution team (Weicher et al. 1995). Others have suggested that the team be split into a documentation and an analysis team. The purpose of splitting the documentation and analysis functions is to maintain objectivity in the analysis. It has been reported that documenting ''as-is'' conditions causes the practitioners to become emotionally invested in the current system, thereby reducing their ability to see opportunities for improvement (Andrews 1996b). Separating the two neutralizes the effects of this phenomenon.

4.3.3. Conduct Project Planning

The challenges facing the project planning team are similar to those facing other large-scale project management teams. Beginning and end dates must be established. Aggressive but realistic timeframes must be incorporated. Levels of measurable accomplishment must be defined for all stages. Individuals should be made accountable for specific outcomes (Feather 1998). Resources must be made available to the team as well as the project. These may be financial but will most certainly take the form of personnel and time. Inadequate staffing at critical points in the project can lead to unsuccessful attempts at reengineering (Ho 1999). Scope creep is an ever-present danger in any project. This is doubly so in reengineering efforts. Processes are complex and difficult to visualize (Bal 1998). This can lead to the inclusion of unrelated processes into the design of the process of interest. The hazard that is peculiar to reengineering efforts is cultural change. In some cases, the process concept is so new that time to assimilate and understand the concept must be factored in. In all cases, the change itself must ''proceed at a pace which can be accommodated by the organization'' (Peltu et al. 1996).

4.3.4. Determine External Process Customer Requirements

There are a variety of methods for determining customer requirements. Quality function deployment models use the voice of the customer as an integral component in process design. Focus groups and benchmark data also provide valuable insight. Placing customer representatives on the actual process design team has been done with great success. Surveys can also derive information from customers. The informal nature of surveys, however, places them in a ''general'' data-gathering category.

4.3.5. Set Performance Goals

Performance goals are frequently established using the gap between the customer requirements and the performance of the current process. Likewise, benchmarking data can provide the performance goals for the new process. The metrics depend on the process being measured, but the firm can use measures that it is already familiar with. Examples include queue time, flow days, and backlog. A key element is making sure the measures cross-over from the old process to the new (Caudle 1995). It is imperative to be able to gauge the performance of the new process against the old.

Figure 10 summarizes the initiate step activity.

4.4. Diagnose

4.4.1. Document Existing Process

Many PDR proponents suggest skipping this step because they believe it limits the vision of the design team and that there is nothing to be gained from such a task. The problem of limited vision was addressed previously. The amount of information to be gained from this step is addressed here. Practitioners have suggested that only if the processes are laid out end to end do the impacts of the process become apparent (Lee 1996). It is equally important to document the cross-departmental aspects of the process (Fisher 1997). The dynamic relationships inherent in the process yield the greatest understanding of the organization and how it functions (Ould 1997). The level of technology used for this process depends on the team itself. There are a variety of examples in the literature, ranging from ''sticky notes'' on the wall to data flow diagrams to sophisticated computer programs (Bartholomew 1999). Essentially, all of these methods describe the task, the owner and customers, and the information inputs and outputs.

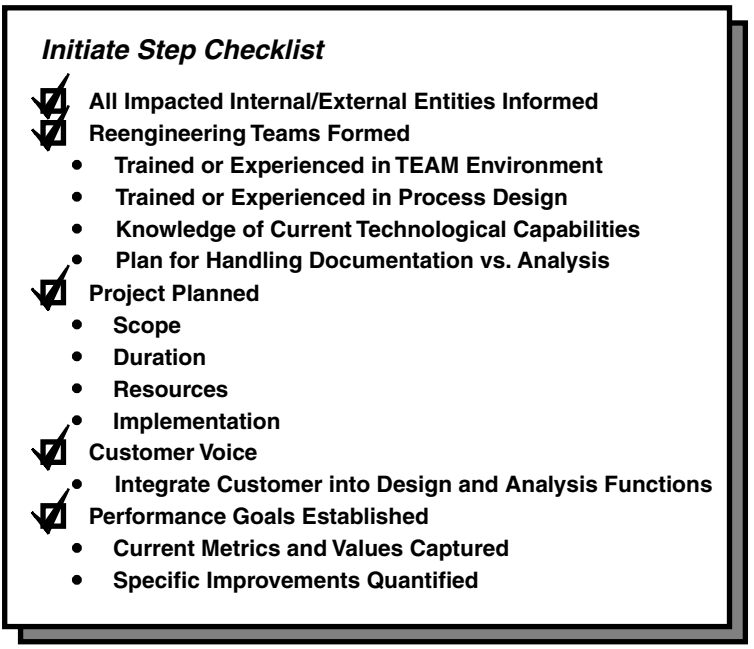

Figure 10 Initiate Step Checklist.

4.4.2. Analyze Existing Process

Two aspects of the existing process must be assessed. The first is the performance of the process as compared to customer expectations (the external performance of the process). The second is in regard to the value added/non-value added components of the current process (the internal performance of the process). This step is critical in the delivery of bottom-line benefits (Ho 1999). Much insight into the external performance of the system was gained in the initiate stage, where the performance goals were set. In the internal performance evaluation, tasks are evaluated as value adding or non-value adding. Using manufacturing terms, tasks such as transportation and rework are non-value adding, while machining and painting are value adding. What is found typically ''is that 65% to 70% of the tasks are non-value [tasks]. At the lowest level of detail, you find massive amounts of waste'' (Bartholomew 1999).

Figure 11 summarizes the activity involved with the diagnose step.

4.5. Redesign

4.5.1. Define and Analyze New Process Concepts

Much has been said about the missing element in the reengineering prescription. Establishing the future-state solution is a difficult, creative process. Hammer and Champy (1993) point this out when they say, ''[T]here are no seven or ten step procedures that will mechanically produce a radical new process design.'' They do, however, provide some characteristics of reengineered processes: (1) several jobs are combined into one, (2) workers make decisions, (3) the steps in the process are performed in a natural order, (4) processes have multiple versions, (5) work is performed where it makes the most sense, (6) checks and controls are reduced, (7) reconciliation is minimized, (8) hybrid centralized/decentralized operations are prevalent. Insight is gained in the reengineering effort when the conventional thinking is challenged. Policies and rules, whether written or not, can often be the reason a process exists in its current form (Bartholomew 1999).

4.5.2. Prototype and Detailed Design of New Process

The detailed design effort can take several months. The new process will require new skills, thinking, and behavior from those who are a part of it. The process will not exist in isolation. It will exist among all of the other processes within a company, demanding input and providing output. Many of the inputs come from shared resources. ''When designing a process there needs to be both technical and social inputs, as well as the infrastructure and architecture to support the process. If incremental, dramatic or step performance improvements are sought then the technical and social inputs must have a degree of congruence'' (Love et al. 1998a).

Whenever possible, new process concepts, if not the entire process, should be prototyped first. There is valuable information to be gained from such activity (Feather 1998). Even in the event that the process does not perform as expected, lessons gained from the experience can be applied to the next iteration of prototype design.

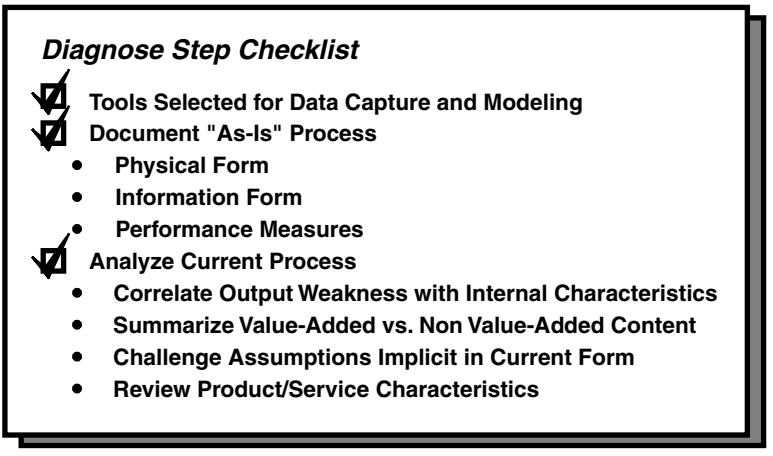

Figure 11 Diagnose Step Checklist.

4.5.3. Design Human Resource Structure

"Among the variety of reasons for the failure of reengineering processes, one of the most serious is not providing a human-performance system to support each and every performer in the organization" (Fisher 1997). "The significant factor that determines the performance of an organization is its people" (Frohman 1997). To get the people to work in concert with the new process, there is a need to develop and link reward and recognition systems to the process (Pritchard and Armistead 1999). The adage "Show me how I'm measured and I'll show you how I perform" still holds true. In order to drive home the message of process, these systems must be altered to support the new process. This may involve organizational changes (Love et al. 1998a).

Figure 12 summarizes the activities involved with the redesign step.

4.6. Reconstruct

4.6.1. Reorganize

One of the most hotly debated topics concerning reengineering is the surplus of employees that it can create. In a majority of the case studies, the employees no longer required by the new processes were laid off. Although cost cutting was arguably not one of the original primary goals of reengineering, it quickly became one as companies realized they had a surplus. Research performed since then indicates that wholesale workforce reduction may not be the correct choice of action for the following reasons:

- Stock market gains realized after the cuts are usually not long lasting (Harrington 1998b).
- Productivity either stayed the same or deteriorated after the layoff (Guimaraes and Bond 1996).
- The company cuts its capacity for future growth (Weicher et al. 1995).
- Those who are left are fearful and uncooperative (Strassman 1994).

Some companies have gone to the other extreme, guaranteeing at the outset of a reengineering effort that no jobs will be lost (Willets 1996). This is done in an effort to solidify the cooperation necessary

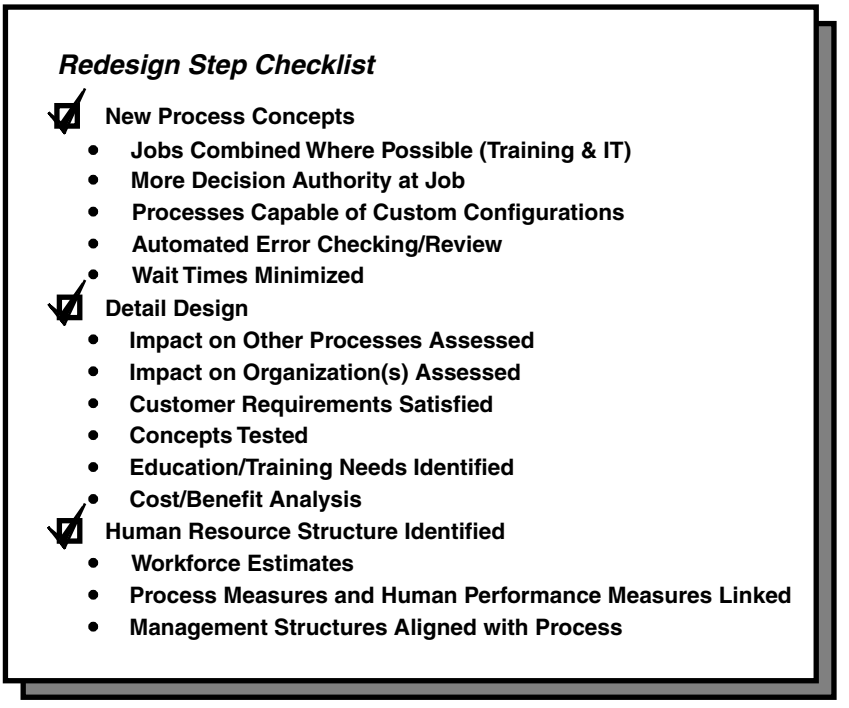

Figure 12 Redesign Step Checklist.

for genuine innovation within the workplace. While this may not be the correct answer either, there is one guiding principle to use in the event that the surplus must be reduced: Don't eliminate the full number of surplus employees provided by estimates. First, no amount of planning can accurately gauge the headcount required by the new process (Macdonald 1998). Second, the knowledge and skill lost in the workforce reduction will naturally impede the performance of the new process until those skills are reacquired. This aspect is rarely modeled in workforce estimates.

4.6.2. Implement

Implementation problems are bound to develop. The interactions are too numerous and the complexity too great for this not to be expected. While it is impossible to foresee every issue that might develop, case history does provide some clues (Guimaraes and Bond 1996). Examples include (1) communication barriers between functional areas, (2) lack of leadership, (3) strategies being formed outside the company's ability to implement, (4) difficulty having the changes accepted by the employees affected, (5) unexpected enormity of the undertaking and disruption to the company, (6) difficulty balancing the incentives of traditional performance measures against what really needs to be done, (7) faltering of some projects because nervous corporate backers pull out at the first sign of difficulty, (8) executives many times being unsure whether it is a worthwhile undertaking, (9) information systems infrastructure in most large organizations being a major impediment to achieving immediate benefits, (10) the tough problems of elimination of positions and worker anxiety over losing jobs, (11) management reluctance to commit resources, (12) major training costs to make the transition and management frustration with slow results.

4.6.3. Train Users

As mentioned previously, process thinking is new to most organizations. Users must be given the opportunity to learn the implications of process thought. They must reorient their thinking towards the customer and learn to evaluate their job in terms of how it supports the customer. Also, the process may introduce new technologies and skill requirements. The users must be given the opportunity to acquire the tools necessary to perform their new job.

Figure 13 summarizes the activities involved with the reconstruct step.

4.7. Evaluate

4.7.1. Evaluate Process Performance

The evaluation of the new process will be in accordance with the process measures developed previously. If new measures were developed, they should have been implemented while the old process was still operating. It is important to realize that early measures of the new process may not reflect its true performance potential. This can be due to the disruption caused by cut-over. In the case where new measures are being used, it may reflect the need to refine the measures.

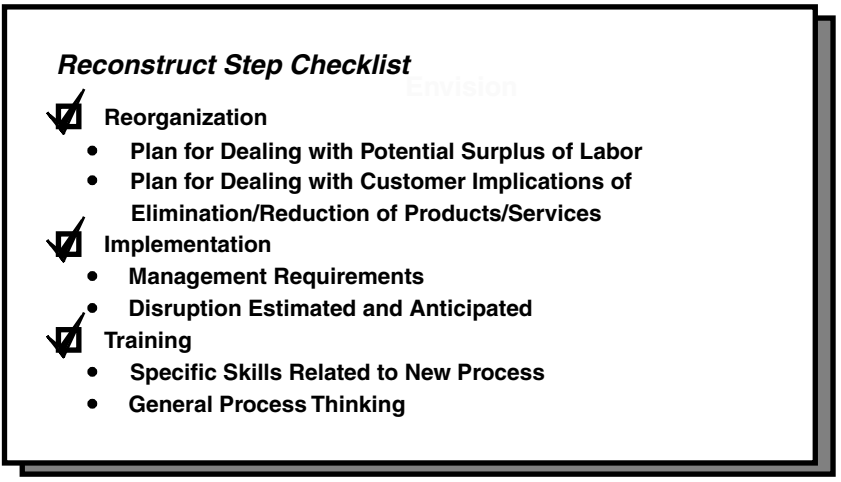

Figure 13 Reconstruct Step Checklist.

Several successful organizations are now creating assessment programs to evaluate process-improvement successes and failures and share lessons learned (Caudle 1995). This would be a system of measuring the reengineering process itself, enabling the organization to develop its own set of best practices and spread the knowledge across the organization.

4.7.2. Link to Continuous Improvement Programs

In the final analysis, PDR is an improvement program within the realm of TQM. As such, companies are compelled to constantly reevaluate themselves and their performance. The TQM framework makes the customer the absolute measure of performance and PDR makes the process the item to be measured. Including PDR in the category of improvement tools implies that the reengineering process is not a static, one-time event but rather another improvement tool that can be used as necessary to improve the products of an organization.

Figure 14 summarizes the evaluation step activities.

5. CASE STUDIES

5.1. Corning Asahi Video (Manganelli and Klein 1994)

Corning Asahi Video (CAV) is a business unit of Corning, Inc., and manufactures glass for televisions. The company had performed in the red during the period from 1987–1991. Customer dissatisfaction was high relating to lead times and order placement, and management was frustrated with its information system because the inventory and order status information was difficult to extract. To rectify this situation, the company set out to reengineer its order-fulfillment process. The overall goals of the project were to:

- Restore profitability by improving efficiency within the process
- Minimize rework and error
- Strengthen internal communications and provide process-wide access to customer information.

Initially, a cross-functional team was formed to redesign the process and implement the changes. The customer service manager was appointed as the head of this team. Customer interviews and internal studies were conducted to target inefficiencies and determine their root causes. The resulting information was shared with all of the 1200 employees at CAV.

Several changes were implemented based on study findings. To incorporate new technology, CAV adopted an existing Corning process for new product development that facilitated communication with top management to support the identification, selection, and adoption of process supporting technology. Disjointed systems of information flow were replaced with an integrated database-driven system. Customer service was consolidated into one location, and the role of customer service was expanded to allow better service. Throughout the project, employees were kept apprised of the project effort.

The project was completed in 15 months at a price of $570,000. As a result of reengineering, rework and cost overruns have been reduced by $1.6 million annually. Per order costs have decreased by 75%. Personnel costs have been reduced by $400,000 annually. Order fulfillment time has been reduced by 50% from 180 days to 90 days. The number of tasks required in the order-fulfillment process was reduced from 250 steps to 9.

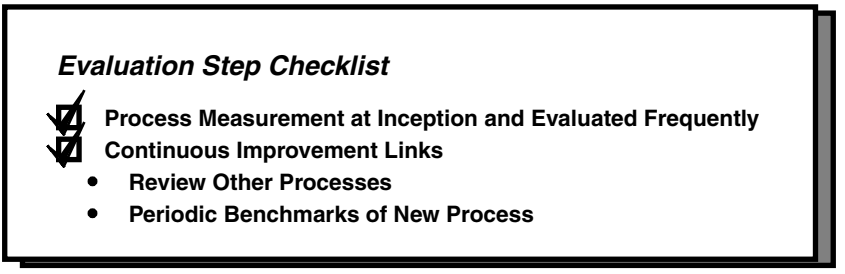

Figure 14 Evaluation Step Checklist.

5.2. Uarco, Inc. (Weston 1997)

Uarco, Inc., is a company that prints purchase order forms and other business documents. It has 14 manufacturing and service call centers located across the United States. Its annual revenues are in excess of $550 million. In 1995, the company analyzed its processes and identified $100 million in costs associated with its order-fulfillment process. This was its single most expensive process. Upon closer inspection, it found unexpected costs in their order management systems. An exorbitant amount of time was spent taking and quoting orders. Since each job is, in effect, a custom solution, each aspect of the customer specification had to be looked up to determine the cost component in order to deliver the quote to the customer. The specification components were contained in a 1000-page manual that had to be consulted for each order and change order. The process could take hours. Updating the manual was time consuming as well because change pages had to be mailed to all of the service outlets. It was determined that 60–80% of the sales force's time was spent administering orders.

As part of the solution, older mainframe units with isolated PCs were replaced with Windows NT servers and networked PCs. Client/server software was purchased along with application software that allowed the company to share database information among its geographically dispersed offices. Shared, replicated databases provided a more streamlined, real-time update process. Electronically stored specifications allowed quicker access and thus quicker order fulfillment.

With the new systems in place, the cost to provide 213,500 quotes annually has decreased from $16 million to $10 million. The capital investment by the company was $21 million. Their net profits have increased by $25 million annually. Much of the change is due to the changed nature of the workload of the salesperson. Under the old systems, a salesperson would spend 80% of his or her time administering orders and only 20% selling. Those figures have reversed under the new systems.

5.3. D2D, Ltd. (Gadd and Oakland 1995)

D2D, Ltd. is a manufacturing subsidiary of International Computers Ltd. (ICL), a systems integrator. In the mid-1980s, the IT industry underwent dramatic change. At the pinnacle of mainframe manufacturing, ICL had profit margins of over 80%. By 1994, margins were 3–4% (typical of the industry). Material costs typically accounted for 80% of the cost of finished goods. Traditional performance measures were no longer significant.

ICL faced the prospect of outsourcing its manufacturing operations in order to remain competitive. Instead, they chose to improve their operations with investments in automation, JIT, flexible assembly cells, MRP systems, EDI, and surface-mount lines. These investments enabled the company to remain competitive but put it in an under-capacity condition. Restructuring within ICL and establishing outside strategic alliances reduced the demand for goods from the manufacturing division. This provided the foundation for radical change within D2D. Extra capacity for ICL's manufacturing subsidiary, D2D, would have to be found outside the company. Given P&L accountability, the subsidiary had to transform itself from the inward-looking one it had always been into a market-led and customer-facing organization.

As a starting point, the division determined its core competencies and added a sales and marketing function. It also determined other services that were intrinsic to its culture that it could market. To help in the transformation, a customer care training program was developed. All existing employees went through the program, and all subsequent new employees now do as well. The investment in technology, particularly the manufacturing technology, enabled a flatter infrastructure with a more empowered workforce—one that was more devoted to the customer. EDI provided a connection among D2D, its vendors, and its customers that, because of its prevention-based nature, reduced order and material mistakes, thus making the supply chain more efficient. EDI created a process view that is pulled by the customer.

BPR has become an integral part of the culture at D2D. It has provided the perspective necessary to undertake the bold changes that were necessary because of the change in charter. By 1993, D2D's profits were 57% higher than in 1992. The cost associated with defects had dropped significantly as a percent of revenue. By 1995, non-ICL revenue was 50% of total revenue.

5.4. Fortune 500 Insurance Company (Feather 1998)

A Fortune 500 insurance company decided to reengineer its death claims process in order to reduce cycle time, cost, and customer dissatisfaction. Initially, a design team was formed and customer and process data were analyzed. Two important discoveries were made in this phase that would have significant bearing on the final solutions that were developed. First, a mismatch was discovered between the actual cycle time of the claim process and the cycle time deemed acceptable to the customer. Second, because of the inability of the company to provide customer data visibility to all units of the company, many opportunities—totaling hundreds of millions of dollars—were not being captured by the company.

In preparation for the reengineering effort, a design team was selected and trained in reengineering design principles. A four-stage methodology was introduced to help guide them through the effort. The methodology emphasized the discovery of new opportunities to create value in business processes, new ways of thinking in terms of process, the design of innovative, value-creating business processes encouraging different behavior, and attention to implementation details. The team used simulation exercises to familiarize themselves with design principles and encourage new thought.

The design team was separated into three subteams. The first team mapped the existing workflow. The results of their work revealed a death claims process made up of 200 steps, with only 18% of those steps deemed as value added. The second team was responsible for analyzing the cycle time of the process, while the third team conducted focus groups with beneficiaries and agents. The beneficiary focus groups provided priceless information in terms of acceptable time frames for contact, as well as typical needs of clients.

The insurance company saw tremendous opportunity in what it learned. It found that when a beneficiary needs investment counsel after receiving a death claim, it would be advantageous for the company to be able to provide options to the beneficiary coincident with the time of payout, thereby increasing the probability that the assets would be retained in the insurance company's accounts. This would effectively link the payout of benefits to the reinvestment of those benefits.

The team quickly realized that they would need to bring in technology expertise. A technology team was formed to work on information flow issues that developed through redesign efforts. It was also determined that agent and claim site personnel representation on the design team would be necessary in order to make the ideas and concepts that were beginning to develop coalesce. Design options were developed in several sessions involving all of the necessary personnel and classified into three categories: workflow, organization, and technology.

With the design options in hand, the team formed into two subteams to create the new design. This was done in order to facilitate creativity. The eventual design was a consensus design between the two teams. The features of the new design were more methods available to the beneficiary to initiate a claim and the ability to segment claims between those requiring high or low administration. The most significant change in the process was the way that company viewed it. No longer was the payment of the death claim viewed as the end of the process. With the incorporation of the correct data-recording processes and technology, the payment was now viewed as a follow-up opportunity to provide reinvestment options to the beneficiaries.

The results of the effort yielded a process with 50% fewer steps. The segmenting process at the front end of the claim permitted 65% of the claims to be processed within two days. Costs associated with handling claims were reduced by 28%, and cycle time was reduced by 56%.

6. LESSONS LEARNED

The literature points to several areas that can be considered providing advice for future practitioners. PDR is a reasoning process applied to a highly complex set of systems to produce a process. The systems include employees, customers, equipment, policies, and strategies, to name a few. The very nature of the systems—their variability—ensures that no two PDR projects will behave in the same fashion. Small differences on the input side lead to large differences on the output side (Ferrie 1995). Because of this, PDR will never be a one-size-fits-all technique. PDR, being highly situational, will require solutions to be developed on a case-by-case basis, requiring the imagination and intellect of the entire design team, if not the entire organization. As a heuristic approach, there is no one ''best'' answer. However, all actions planned or deployed must be considered in regard to their impacts and outcomes.

Another key point to remember is that the scope of reengineering should be limited. Despite the title of their book, Hammer and Champy never intended that the corporation be reengineered on all fronts simultaneously. Select the strategically important processes, rank them, and focus attention on the most critical ones. Only one or two processes should be reengineered at a time (Harrington 1998).

The people issues will continue to be a part of PDR since very few ''lights-out'' systems require reengineering. The critical aspect here is to remember to reengineer not in spite of the human aspects of the system, but in congruence with them. The key contribution of the process comes from its people rather than its hardware or systems (Frohman 1997). The first formal definition of industrial engineering, as established by the American Institute of Industrial Engineers in 1955, recognized the inseparability of people from the systems of interest to the profession. ''Successfully integrating people within a system will always be the ultimate design challenge'' (Ferrie 1995).

7. FUTURE OUTLOOK

There are diverse opinions concerning the future of reengineering. Some feel that ''knowledge management, employee empowerment, adoption of new information technology, and shared vision'' will lead to greater reengineering success (Kettinger and Grover 1995). Others feel that taxonomy will improve the success rate, while still others feel that the key is the integration of organizational theory

and control and MIS (Malhotra 1998). It is predicted that reengineering projects will be undertaken more often to keep up with a dynamic business environment and that success will be based upon how quickly a company seizes the moment. The reengineering project time will continue to decrease. Regardless of exactly how it will evolve, it is safe to assume that reengineering will continue to be used within organizations as a tool for improvement.

CHAPTER 63
Scheduling and Dispatching

MICHAEL PINEDO AND SRIDHAR SESHADRI
New York University

1. INTRODUCTION

Detailed scheduling of the various elements of a production system is crucial to the efficiency and control of operations. Orders have to be released and have to be translated into one or more jobs with associated due dates. The jobs often have to be processed by the machines of a workcenter in a given order or sequence. Queueing may occur when jobs have to wait for processing on machines

that are busy; preemptions may occur when high-priority jobs arrive at busy machines and have to proceed at once.

The scheduling and dispatching process has to interface with several other functions in the organization. On the one hand, it is affected by the production planning process, which handles medium- and long-term planning for the entire organization. Production planning takes inventory levels, forecasts, and resource requirements into account in order to do some form of optimization at a higher level. Any decision taken by this planning function may have an impact on scheduling and dispatching. On the other hand, scheduling also receives input from shop-floor control. Events that happen on the shop-floor have to be taken into account because they may have a considerable impact on the schedules.

What follows mainly focuses on the detailed scheduling of the jobs. Given a collection of jobs that have to be processed in a given machine environment, the problem is to schedule the jobs, subject to given constraints, in such a way that one or more performance criteria are optimized. Various forms of uncertainties, such as random job-processing times, machines subject to breakdown, and rush orders, may have to be dealt with.

This chapter is organized as follows. Section 2 presents some general notation as well as a mathematical framework that is used in the theory of scheduling and dispatching. The subsequent sections focus first on dispatching techniques and then on scheduling procedures. There are two reasons for following this approach: first, dispatching rules are typically easier to explain than scheduling procedures, and second, scheduling procedures often use dispatching rules as subroutines within a more elaborate framework. Understanding the workings of a scheduling procedure thus typically requires a certain knowledge of dispatching rules. Section 3 therefore gives an overview of the theory that has been developed with regard to dispatching. It covers basic dispatching rules as well as composite dispatching rules. Section 4 subsequently focuses on the main techniques applied to scheduling; it also describes a number of empirical procedures that have proven to be useful in current scheduling systems. Section 5 focuses on scheduling and dispatching problems in practice; it discusses a variety of industrial environments where scheduling is of critical importance. Section 6 first discusses the general structure of scheduling systems and then gives a description of the major trends in the development of industrial scheduling systems during the last two decades. Section 7 contains a discussion of the difficulties encountered in the implementation of these systems (see Figure 1).

Sections 3 and 4 are somewhat technical; 5 and 6 are more descriptive and basically self-contained. The less technically inclined reader may prefer to read these last two sections first.

2. FRAMEWORK AND MODELS

2.1. Models and Notation

In the past four decades, a significant amount of theoretical research has been done in scheduling as well as in dispatching. Along the way, a notation has evolved that succinctly captures the structure of most machine scheduling models studied in the literature. A short description of this framework and notation is presented here (see Lawler et al. 1989; Pinedo 1995).

The number of jobs is denoted by n and the number of machines by m. The subscript j refers to a job, while the subscript i refers to a machine. The following data are associated with job j:

p_{ij} = the processing time of job j on machine i; if job j is only to be processed on one machine or if it has the same processing times on each one of the machines it has (or is allowed) to be processed on, the subscript i is omitted.
r_j = release date of job j.
d_j = the due date of job j.
w_j = the weight (importance) of job j.

A sequencing or scheduling problem is described by a triplet $\alpha|\beta|\gamma$, where α describes the machine environment, β the processing characteristics and constraints, and γ the objective to be minimized. Examples of the possible (exclusive) entries in the α-field are:

1 = a single machine.
Pm = m identical machines in parallel; a job may be processed on any one of the m machines, it does not matter which one.
Fm = a flow shop of m machines; that is, m machines in series. A job after completion at one machine joins the queue at the next machine. All queues operate under the first-in-first-out discipline, that is, a job cannot ''pass'' another while waiting in a queue.
Jm = a job shop of m machines; in such a shop each job has its own route through the various machines and a job may visit a machine more than once.

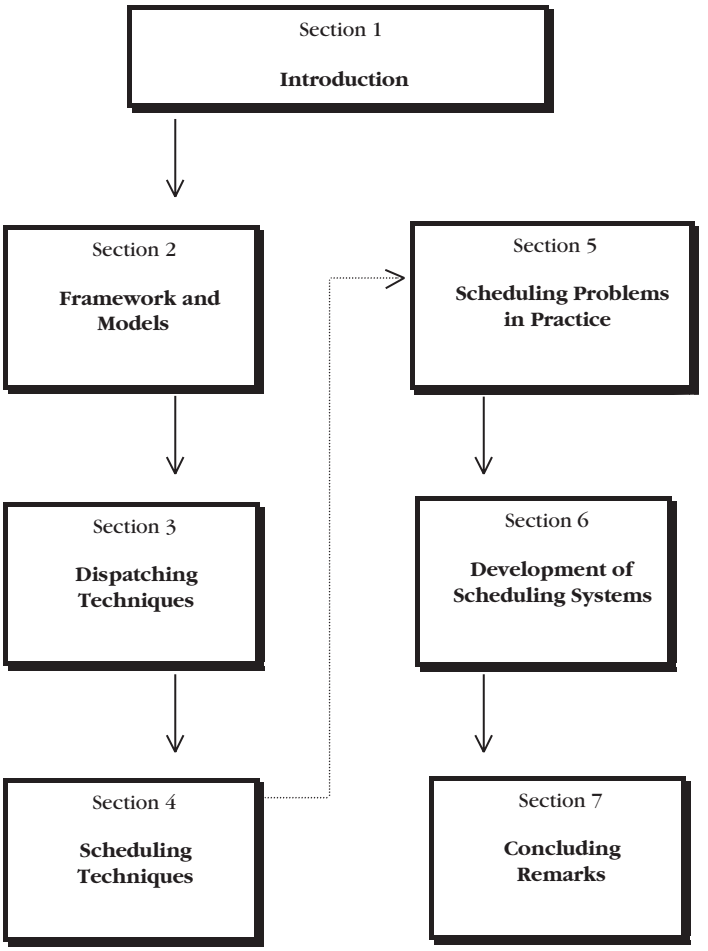

Figure 1 Outline of This Chapter.

Examples of entries in the β-field are:

r_j = the release date of job j; job j may not start its processing before this date. If no r_j appears in this field, all r_j are assumed to be *0*.

s_{jk} = the sequence dependent setup time between jobs j and k; s_{0k} denotes the setup time for job k in case job k is first in the sequence, while s_{j0} denotes the clean-up time after job j in case job j is last in the sequence (of course, s_{0k} and s_{j0} may be zero). If no s_{jk} appears in the β-field, all setup times are assumed to be 0.

prec = the precedence constraints among the jobs. If no *prec* appears, there are no precedence constraints.

prmp = preemptions are allowed. If *prmp* does not appear, preemptions are not allowed.

Most other entries that may appear in the β-field are self-explanatory. The β-field may have multiple entries or may be completely empty. Due dates, in contrast with release dates, are not specified in this field; the ojective implies whether or not the jobs have due dates.

The objective is always a function of the completion times of the jobs, which are, of course, schedule dependent. The completion time of job j is denoted by C_j. Examples of possible objective functions to be minimized are:

C_{max} = the makespan, defined as $\max(C_1, \ldots, C_n)$, which is equivalent to the completion time of the last job to leave the system. A minimum makespan usually implies a good utilization of the machine(s).
L_{max} = the maximum lateness, which is defined as $\max(L_1, \ldots, L_n)$, where L_j equals $C_j - d_j$.
$\Sigma w_j C_j$ = the sum of the weighted completion times of the n jobs.
$\Sigma w_j T_j$ = the sum of the weighted tardinesses, where the tardiness of job j, T_j, is defined as $\max(C_j - d_j, 0)$.
$\Sigma w_j U_j$ = the weighted number of tardy jobs, with U_j being 1 if $C_j \geq d_j$ and 0 otherwise.

The following examples illustrate the notation:

$1|s_{jk}|C_{\max}$ denotes a single machine with n jobs subject to sequence-dependent setup times; the objective is to minimize the makespan. It is well known that this problem is equivalent to the so-called traveling salesman problem in which a salesman has to tour n cities in such a way that the total distance traveled is minimized.

$Pm|r_j, s_{jk}|\Sigma w_j T_j$ denotes m identical machines in parallel, n jobs with different release dates, different due dates, and different weights. The jobs are subject to sequence-dependent setup times and the objective is to find a sequence that minimizes the sum of the weighted tardinesses.

$Fm|p_{ij} = p_j|\Sigma w_j C_j$ denotes a so-called *proportionate* flow shop with m machines, i.e., m machines in series, with the processing times of job j on all m machines identical and equal to p_j (which is the reason this flow shop is called proportionate); the objective is to find the order in which the n jobs go through the system so that the sum of the weighted completion times is minimized.

$Jm||C_{max}$ denotes a job shop with m machines; the objective is to minimize the makespan.

Of course, there are many scheduling models that are not captured by this framework. Many situations in the real world have machine environments that do not fit the framework. For example, various researchers have recently begun to study hybrids between flow shops and parallel machines. In one such hybrid, there are a number of stages in series, with each stage consisting of a number of machines in parallel. Jobs progress from stage to stage, and at each stage each job has to be processed on one of the parallel machines. This machine environment has been given various names in recent years: generalized flow shop, flexible flow shop, compound flow shop. Alternatively, one can consider a number of parallel flow shops, each having a single machine at every stage. When a job is assigned to a particular flow shop, it is not allowed to switch in the middle of the process to another flow shop (see Figure 2).

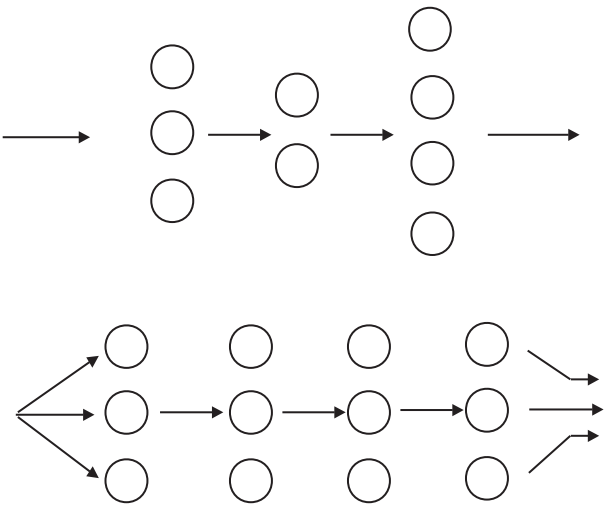

Figure 2 Hybrids of Flow Shops and Parallel Machines.

All objective functions mentioned above are so-called regular performance measures. Regular performance measures are functions that are *nondecreasing* in $C_1, \ldots, C_n$. Recently researchers have begun to pay attention to objective functions that are not regular. For example, when job j has due date d_j, there may be, besides a tardiness penalty, also an earliness penalty; the larger the deviation from the due date, in either direction, the larger the penalty. The objective may be the sum of earliness penalties and tardiness penalties.

The framework has been primarily designed for models with a single objective because most of the research has been concentrated on such models. Currently, researchers are studying models with multiple objectives as well, but a standard notation with regard to such models has not been developed yet.

Various other features in scheduling, not mentioned above, have been studied and analyzed in the past, such as finite buffers, blocking, and recirculation. A standard notation for these features still needs to be developed.

2.2. Overview of Past Research Directions

The research in deterministic scheduling problems has followed a number of different directions (see Pinedo 1995). Three areas have received considerable attention:

2.2.1. Determining Computational Complexity

For some problems so-called polynomial time algorithms are known to exist. A polynomial time algorithm implies that the number of computational steps (which is proportional to the amount of computer time) needed to find a schedule which achieves the optimum value of the objective function is a polynomial function of the parameters of the problem (e.g., the number of jobs, n and/or the number of machines, m). A polynomial time algorithm may require, for example, a number of steps that is on the order of n^3 or n^4. There are problems, however, for which no polynomial time algorithm is known to exist. These problems are the so-called NP-hard problems. The most efficient algorithms for these problems are exponential in the parameters of the problems. Such algorithms may require, for example, a number of steps that is on the order of 3^n or 4^n.

Determining whether or not a scheduling problem can be solved in polynomial time typically involves proving that the given problem is in some sense equivalent to a problem already known to be NP-hard. For example, the $1|s_{jk}|C_{max}$ problem is NP-hard because it is equivalent to the traveling salesman problem, which is known to be NP-hard.

2.2.2. Development of (Efficient) Algorithms

For problems that are solvable in polynomial time, it is usually relatively easy to find efficient algorithms. For the simplest of these problems, a simple sort is all that is required. For example, it may only be necessary to order the jobs in increasing order of their due dates (the so-called earliest due date rule [EDD]) or in decreasing order of the w_j/p_j ratios (the so-called weighted shortest processing time [WSPT] first rule. For more complicated polynomial time problems, more sophisticated techniques such as dynamic programming are required.

For the NP-hard problems, it is always significantly harder to find a good algorithm. One usually resorts to heuristics, which may give reasonably good schedules. When a more accurate solution is required, a more sophisticated technique (which also uses more computer time) such as branch and bound or lagrangean relaxation is usually employed. When only the optimal solution will do, the most likely approach would be to develop an (exponential time) algorithm based on dynamic programming or branch and bound.

2.2.3. Worst-Case Analysis of Heuristics

Solutions that are optimal for the easier problems often turn out to be good heuristics for the more complicated NP-hard problems. Examples of simple heuristics are the earliest due date (EDD) rule, the weighted shortest processing time first (WSPT) rule, the longest processing time first (LPT) rule, the shortest setup time first (SST) rule, and the critical path (CP) rule. The SST rule is of importance when the jobs are subject to sequence-dependent setup times; following the completion of a job, this rule consistently selects as the next job the one with the smallest setup time. The critical path (CP) rule is of importance when the jobs are subject to precedence constraints; following the completion of a job, this rule always selects as the next job the job that is at the head of the chain of jobs (one having to follow another) that contains the largest amount of processing.

It is of interest to know the worst-case behavior of such heuristics when applied on an NP-hard scheduling problem; that is, to have an upper bound on the ratio of the value of the objective function obtained via the heuristic divided by the true optimal value. This upper bound often, but not always, lies between 1 and 2. Besides giving an indication of how bad the result of a given heuristic may turn out to be, a worst-case analysis also gives an indication of the types of problem data for which the heuristic does not work well.

The next two sections deal, in particular, with heuristics and algorithms. At times a problem may be said to be NP-hard; however, no details will be given on how this is determined.

3. DISPATCHING TECHNIQUES

3.1. Basic Dispatching Rules

The five priority rules mentioned in the previous section, WSPT, EDD, LPT, SST, and CP, are fairly important. They provide optimal sequences in some very simple cases and serve as heuristics for more complicated scheduling models. It is useful to know the properties of these priority rules when designing a complicated computer-based scheduling system. Different modules in such a system may use at given times one of these rules to sequence a subset of the jobs. Or a composite priority rule may be constructed by combining two or more of these simple priority rules in order to minimize a mixture of various objectives. A more in-depth discussion of these five simple priority rules follows.

3.1.1. The WSPT Rule

The weighted shortest processing time first rule, which schedules the jobs in decreasing order of w_j/p_j, actually minimizes the sum of the weighted completion times on a single machine (see Smith 1956), that is, $1\|\Sigma w_jC_j$. However, for slightly more complicated problems, such as $1|r_j|\Sigma w_jC_j$, or $1|r_j,prmp|\Sigma w_jC_j$, or $Pm\|\Sigma w_jC_j$, the WSPT rule (or any variant of the WSPT rule that takes preemptions into account) does not necessarily result in the optimal solution. These three problems are actually NP-hard. The WSPT rule is nevertheless a very good heuristic. A worst-case analysis shows that for $Pm\|\Sigma w_jC_j$:

$$\frac{\Sigma w_jC_j(\text{WSPT})}{\Sigma w_jC_j(\text{OPT})} \leq \frac{1+\sqrt{2}}{2} = 1.207$$

where $\Sigma w_jC_j(\text{WSPT})$ ($\Sigma w_jC_j(\text{OPT})$) denotes the value of the objective function under the WSPT (OPT) rule (see Kawaguchi and Kyan 1986). For the special case where all jobs have equal weights, that is $w_j = 1$ for $j = 1, \ldots, n$, the WSPT rule reduces to the shortest processing time first (SPT) rule. It is well known that the SPT rule minimizes the total completion time on parallel machines ($Pm\|\Sigma C_j$).

3.1.2. The EDD Rule

The earliest due date rule, which schedules the jobs in increasing order of their due dates, minimizes the maximum lateness on a single machine (see Jackson 1955), that is, $1\|L_{max}$, as well as in a proportionate flow shop, that is, $Fm|p_{ij} = p_j|L_{max}$. However, it does not provide an optimal solution for other due date-related problems, such as $1\|\Sigma T_j$. Instances of $1\|\Sigma T_j$ with

$$\frac{\Sigma T_j(\text{EDD})}{\Sigma T_j(\text{OPT})} = n$$

can be found easily. This implies that the EDD rule at times may result in a solution that is far from optimal. The EDD rule is usually not used as a heuristic by itself, but rather as part of a composite heuristic (such as the so-called ATC rule, which is discussed later in this section).

3.1.3. The LPT Rule

The longest processing time first rule, which schedules the jobs in decreasing order of p_j, is used as a heuristic for the $Pm\|C_{\max}$ problem, which is known to be NP-hard. The importance of the makespan objective lies in the fact that a small makespan is a sign of a good job balance (partition) over the various machines. In order to find a schedule with a relatively small makespan, one orders the jobs in decreasing order of their processing times and puts the jobs on the machines, whenever one is freed, in that order. A worst-case analysis of this heuristic shows that

$$\frac{C_{\max}(\text{LPT})}{C_{\max}(\text{OPT})} \leq \frac{4}{3} - \frac{1}{3m}$$

See Graham (1969). This implies that at all times this heuristic performs reasonably well. The LPT heuristic has been used in industrial scheduling systems in order to provide a reasonable balance of the workload over the different machines. After the partition has been determined by the LPT rule, the jobs assigned to any given machine can be resequenced. Resequencing a machine clearly does not affect the balance and may be done to minimize a secondary objective.

3.1.4. The SST Rule

The shortest setup time first rule, when a machine is freed after completing job j, selects as the next job the one with the smallest setup time s_{jk}. It is used as a heuristic for the $1|s_{jk}|C_{\max}$ problem, which, as said above, is equivalent to the traveling salesman problem. The traveling salesman leaving a city for the city closest by (the nearest neighbor) is equivalent to sequencing jobs based on the smallest sequence-dependent setup time. The $1|s_{jk}|C_{\max}$ problem is known to be NP-hard even when the so-called *triangle inequality* holds. This inequality implies that $s_{jk} + s_{kl} \geq s_{jl}$ for all j, k, and l. It can be shown easily that for the $1|s_{jk}|C_{\max}$ problem, even in case the triangle inequality holds, the ratio

$$\frac{C_{\max}(\text{SST})}{C_{\max}(\text{OPT})}$$

can become arbitrarily large (see Rosenkrantz et al. 1977). The SST rule in practice is often used in composite heuristics.

3.1.5. The CP Rule

The critical path rule always selects as the next job the one that is at the head of the chain of jobs that contains the largest amount of processing. It is often used as a heuristic for the $Pm|prec|C_{\max}$ problem, which is known to be NP-hard. The heuristic actually yields the minimum makespan in case all jobs have identical processing times and the precedence constraints are in the form of a *tree* (tree-like precedence constraints imply that either all jobs have at most one sucessor or all jobs have at most one predecessor). A worst-case analysis shows that for the $Pm|prec,p_j = 1|C_{\max}$ problem with arbitrary precedence constraints:

$$\frac{C_{\max}(\text{CP})}{C_{\max}(\text{OPT})} \leq 2 - \frac{1}{m - 1}$$

See Chen and Liu (1975). The CP rule is used also when other objective functions have to be minimized. It plays an important role in composite heuristics as well.

3.2. Composite Dispatching Rules

3.2.1. The Apparent Tardiness Cost Heuristic

The problem $1\|\Sigma w_j T_j$ is of importance in many practical situations. Jobs frequently have different weights (priorities) as well as different due dates (committed shipping dates) with the sum of the weighted tardinesses as the objective to be minimized. This objective is strongly correlated with loss of goodwill. It is well known that this problem is NP-hard even with a single machine. So it is important to have a heuristic that provides a reasonably good schedule with little computational effort. Some heuristics come immediately to mind, namely, the WSPT rule (which is optimal when all release dates and due dates are zero) and the EDD rule (which is optimal when all due dates are sufficiently large and spread out). It is clear that a heuristic or priority rule is needed which in one form or another combines these two heuristics. The apparent tardiness cost (ATC) heuristic is such a priority rule (Vepsalainen and Morton 1987). Under this priority rule, the jobs are scheduled one by one; that is, every time the machine is freed, a priority index is computed for all the remaining jobs that are available for processing. The job with the highest priority index is then selected to go next. This priority index is a function of the time the current job completes, say t, as well as the p_j, the w_j, and the d_j of all remaining jobs. The index is defined as

$$I_j(t) = \frac{w_j}{p_j} \exp\left(-\frac{\max(d_j - p_j - t,0)}{K\bar{p}}\right)$$

where K is a scaling parameter which is determined empirically, $\bar{p}$ is the average of the processing times of the remaining jobs, and $\max(d_j - p_j - t,0)$ is the slack of job j. If K is chosen very large, the ATC rule reduces to the WSPT rule. On the other hand, if K is chosen very close to zero, the rule reduces to the WSPT rule among the overdue jobs when there are overdue jobs; when there are no overdue jobs, it gives priority to the job with the least slack. In order to obtain good schedules, the parameter K has to be chosen very carefully. This can be done by first making a detailed analysis of the particular scheduling instance under consideration. There are several ways to characterize scheduling instances. One is through a due date tightness factor τ, which is defined as

$$\tau = 1 - \frac{\bar{d}}{C_{\max}}$$

where $\bar{d}$ is the average of the due dates. Another way is through a due date range factor R, which is defined as

$$R = \frac{d_{\max} - d_{\min}}{C_{\max}}$$

It actually pays to evaluate the τ and the R of the instance under consideration and choose the scaling parameter K based on these values. A significant amount of research has been done that establishes the relationship between the look-ahead parameter K and the τ, the R, and the machine environment.

Thus, when one wishes to minimize $\Sigma w_j T_j$ in a more complicated machine environment, one first characterizes the particular problem instance through a number of factors. Then one determines the value of the look-ahead parameter K as a function of these characterizing factors as well as of the particular machine environment. After fixing K, one applies the rule.

Several generalizations of the ATC rule have been developed in order to take into account release dates as well as sequence dependent setup times. These generalizations require the initial computation of a number of factors. These factors, together with the particular machine environment, can then be used to determine a number of the parameters (see Lee et al. 1997).

Simple heuristics such as the five described above provide adequate results only for the simplest scheduling problems. Real-world scheduling problems usually require techniques that are significantly more sophisticated than a myopic priority rule that just orders the jobs according to a function of one or two parameters. There are various ways of formulating scheduling problems as well as various types of solution procedures. These are discussed next.

4. SCHEDULING TECHNIQUES

4.1. Mathematical Programming Formulations

Many scheduling problems can be formulated as linear programs or other forms of mathematical programs.

Scheduling problems that allow preemptions are often easier than problems that do not allow preemptions. The problems that allow preemptions can often be solved in polynomial time. Consider, for example, the problem $Pm|prmp|C_{\max}$. Job j may be processed on any one of the m machines; it may be preempted and may continue its processing on another machine at another time. A schedule that minimizes the makespan can be obtained by first solving the following linear program (LP):

$$\text{minimize} \quad C_{\max}$$

subject to

$$\sum_{i=1}^{m} x_{ij} = p_j, \qquad j = 1, \ldots, n$$

$$\sum_{i=1}^{m} x_{ij} \leq C_{\max}, \qquad j = 1, \ldots, n$$

$$\sum_{j=1}^{n} x_{ij} \leq C_{\max}, \qquad i = 1, \ldots, m$$

$$x_{ij} \geq 0, \qquad i = 1, \ldots, m, j = 1, \ldots, n$$

The variable x_{ij} represent the total time spent by job j on machine i. The LP can be solved in polynomial time, but the solution of the LP does not prescribe an actual schedule; it merely prescribes how much time job j should spend on machine i. However, with this information a schedule can easily (in polynomial time) be constructed. This LP formulation for the $Pm|prmp|C_{\max}$ problem is given for illustration purposes only. Actually, many schedules that minimize the makespan are easy to find and all these schedules result in a makespan

$$C_{\max} = \max(p_1, \ldots, p_n, \Sigma p_j/m).$$

One of the schedules that minimize the makespan is the preemptive longest remaining processing

time first (preemptive LPT) schedule. According to this schedule, at every point in time, the m jobs with the largest remaining processing times have to be processed on the m machines. This schedule requires, of course, a large number of preemptions; there are other optimal schedules that do not require as many preemptions.

The formulation described above can be generalized to include the model where the processing time of a job may depend on the machine on which it is processed. Again, job j needs processing on only one machine and any one will do. However, if job j is processed on machine i its processing time is p_{ij}.

Linear programming formulations are often possible either when preemptions are allowed or when all processing times are identical (i.e., $p_j = 1, j = 1, \ldots, n$). Scheduling problems with all processing times identical often reduce to the so-called assignment problem, for which there exists a linear programming formulation.

When a problem is NP-hard, a linear programming formulation is, of course, not possible. However, NP-hard scheduling problems can often be formulated as integer programs or other more complicated forms of mathematical programs. Consider, for example, the $Jm\|C_{\max}$ problem. Let p_{ij} denote the processing time of job j on machine i, let y_{ij} denote the starting time of this operation, and let the set N denote the set of all (i, j) operations. This set may be viewed as a set of nodes in a directed graph. Let the set A denote the set of all precedence (routing) constraints $(i, j) \prec (k, j)$ that require job j to be processed on machine i before it is processed on machine k, that is, operation (i, j) precedes operation (k, j). This set may be viewed as a set of arcs in a directed graph that has nodes N. The following mathematical program minimizes the makespan:

$$\text{minimize } C_{\max}$$

subject to

$$\begin{aligned}
y_{kj} - y_{ij} &\geq p_{ij} && \text{for all } (i,j) \prec (k,j) \in A \\
C_{\max} - y_{ij} &\geq p_{ij} && \text{for all } (i,j) \in N \\
y_{ij} - y_{il} \geq p_{il} \quad \text{or} \quad y_{il} - y_{ij} &\geq p_{ij} && \text{for all } (i,l),(i,j), \quad i = 1, \ldots, m \\
y_{ij} &\geq 0 && \text{for all } (i,j) \in N
\end{aligned}$$

The third set of constraints is often called the disjunctive arc constraints and represent the fact that some ordering must exist among operations of different jobs that are processed on the same machine. Because of these constraints, this problem is sometimes referred to as the disjunctive programming problem.

That an NP-hard scheduling problem can be formulated as an integer programming problem or a disjunctive programming problem does not imply that there is a standard solution procedure available that will work satisfactorily. For most NP-hard scheduling problems solution procedures have to be tailor made. Two general techniques are widely used, namely dynamic programming and branch and bound. In what follows, these two techniques are applied to two well-known NP-hard problems. Dynamic programming is applied to $1\|\Sigma T_j$ and branch and bound to $Fm\|C_{\max}$.

4.2. Dynamic Programming

Dynamic programming is an optimization technique that is particularly well suited for scheduling problems with makespans that are schedule independent, such as, single-machine problems without setups, proportionate flow shops, and problems with all processing times being identical. It can also be applied on scheduling problems with makespans that do depend on the sequence.

For the $1\|\Sigma T_j$ problem the *forward* dynamic programming technique is used (see Held and Karp 1962). The following observation is crucial. If the sequence $j_1, j_2, \ldots, j_n$, a given permutation of $1, \ldots, n$, is optimal for the problem under consideration, then the subsequence $j_1, j_2, \ldots, j_k$, where $k \leq n$, has to be optimal for the smaller k-job problem, which contains only jobs $j_1, j_2, \ldots, j_k$. Let S denote a subset of the n jobs and let $G(S)$ denote the minimum value of the objective function if only the jobs in S are to be scheduled. It is easy to see that the recursive relationship

$$G(S) = \min_{j \in S} \left(G(S - \{j\}) + \max \left(\sum_{l \in S} p_l - d_j, 0 \right) \right)$$

has to hold. The second term on the right-hand side of this expression represents the tardiness of job j. This recursive relationship, which in the dynamic programming literature often is referred to as the *principle of optimality,* makes it possible to solve the scheduling problem in the following manner. First, all sequencing problems that contain only a single one of the n jobs are solved. There are n

such problems. Clearly, these problems require no optimization. However, the values of the objective functions $G(S)$ still have to be computed. If such a one-job scheduling problem consists of job j, then

$$G(S) = G(\{j\}) = \max(p_j - d_j, 0)$$

After these n values have been computed, all sequencing problems containing two of the original n jobs are solved (there are $n(n-1)/2$ such scheduling problems); the optimal order as well as the values of the objective functions have to be determined. The recursive relationship and the results for the one-job problems make it possible to solve these two-job problems efficiently. That is, if $S = \{j, k\}$, then

$$G(\{j, k\}) = \min(G(\{k\}) + \max(p_k + p_j - d_j,0), G(\{j\}) + \max(p_j + p_k - d_k,0)).$$

Then all sequencing problems containing three of the n jobs have to be analyzed. Again, the recursive relationship and the results for the two-job problems make it possible to solve these three-job problems efficiently. Then all four-job problems need to be analyzed, and so on.

It is easy to see that this technique is more efficient than complete enumeration. Actually, one can reduce the amount of computation even more by using *dominance rules* or *elimination criteria* (see Emmons 1969). For the $1\|\Sigma T_j$ the following dominance rule exists: If there is a pair of jobs j and k such that $p_j \leq p_k$ and $d_j \leq d_k$, then there exists an optimal sequence with job j appearing in the sequence before job k. This rule makes it possible to reduce the amount of computation since it is not necessary to evaluate any sequence where job k appears before job j. (However, it still is not possible to find a polynomial time algorithm for this problem, since it is known to be NP-hard.)

4.2.1. Numerical Example

Consider three jobs with processing times $p_1 = 6$, $p_2 = 10$, $p_3 = 8$ and due dates $d_1 = 13$, $d_2 = 8$, $d_3 = 15$.

First, consider all sequencing problems that consist of a single job. If S consists of either job 1 or job 3, then $G(S) = 0$ because these jobs would be completed before their due dates. If S consists of job 2, then

$$G(S) = 10 - 8 = 2$$

Next, consider all problems that consist of two jobs. There are three possible sets S, namely {1, 2}, {1, 3} and {2, 3}. Each one of the three problems has to be evaluated twice (because each job has to be given the chance to be the last one of the set to be completed). If $S = \{1, 2\}$, then the last job of S is completed at $p_1 + p_2 = 16$. If job 1 is the last one of the set to be completed, then $T_1 = 3$ and

$$G(S - \{1\}) = G(\{2\}) = 2$$

If job 2 is the last one to be completed, then $T_2 = 8$ and

$$G(S - \{2\}) = G(\{1\}) = 0$$

So

$$G(\{1, 2\}) = \min(2 + 3, 0 + 8) = 5$$

The optimal order is first job 2 and then job 1. In the same way it can be determined that $G(\{1, 3\}) = 0$ and that in this case job 1 should precede job 3. The computations for set {2,3} yield $G(\{2, 3\}) = 5$ and that job 2 should precede job 3.

Now consider all problems that consist of three jobs. There is only one such set, namely {1, 2, 3}. This set has to be evaluated three times because any one of the three jobs may be the last one to finish. From the fact that $p_1 + p_2 + p_3 = 24$, it follows that if job 1 is the last one to finish, $T_1 = 11$; if job 2 is the last one, then $T_2 = 16$; if job 3 is the last one, then $T_3 = 9$. So

$$\begin{aligned} G(\{1, 2, 3\}) &= \min(G(\{1, 2\}) + T_3, G(\{2, 3\}) + T_1, G(\{1, 3\}) + T_2) \\ &= \min(5 + 9, 5 + 11, 0 + 16) = 14 \end{aligned}$$

From these computations it is concluded that the optimal order is 2,1,3 and that the minimum value of the objective function is 14.

Actually, from the elimination criteria it could have been established in advance that job 1 has to precede job 3. The use of this piece of information throughout the procedure would have reduced the number of computational steps significantly.

4.3. Branch and Bound

In the scheduling field, the branch and bound technique appears to be more widely used than dynamic programming. The technique is basically an enumeration process that attempts to eliminate, through a bounding process, as many sequences as possible from consideration. The bounding process is very problem specific. Here the technique is applied to the $Fm\|C_{\max}$ problem (see Ignall and Schrage 1965).

The branching process may be described as follows: A tree is built with a number of nodes at each level of the tree. The top level, level 1, of the tree consists of a single node, called the root. At this level the sequence is completely unspecified, that is, no job has a position in the sequence yet. This root has n branches that go down to the second level. The n nodes at the second level are characterized by the first job in the sequence, that is, at each node one particular job is assigned to the first position in the sequence and the positions of the $n - 1$ remaining jobs are still unspecified. Each node at level 2 has $n - 1$ branches emanating to the third level, with each node at the third level characterized by the jobs in positions 1 and 2 of the sequence. At each subsequent level there will be more nodes with fewer branches emanating to the next level.

The bounding process attempts to develop at any given node a lower bound on the objective functions of all sequences that start with the jobs specified at this node. A node at level $k + 1$ has k jobs specified, say jobs $j_1, j_2, \ldots, j_k$; of the remaining $n - k$ jobs the positions still must be determined. Let S denote these $n - k$ jobs and let C_{i,j_k} denote the time job j_k departs machine i in the $Fm\|C_{\max}$ example. In order to find one lower bound for all sequences which start with $j_1, j_2, \ldots, j_k$, observe that the first machine of the flow shop is always processing a job until the last job leaves the first machine. At best this last job goes through the remaining machines, after leaving the first machine, without having to wait for processing at any one of the remaining machines; thus,

$$C_{\max} \geq \sum_{j=1}^{n} p_{1j} + \min_{j \in S} \left(\sum_{i=2}^{m} p_{ij} \right) = LB_1$$

The first term of the lower bound represents the time the last job is completed on machine 1; the second term is the minimum time required for the last job to go through the remaining $m - 1$ machines. A second lower bound can be obtained by assuming that the second machine is continuously busy after C_{2,j_k} and that the last job to leave the second machine goes through the remaining machines without having to wait for processing at any one of these machines. Thus,

$$C_{\max} \geq C_{2,j_k} + \sum_{j \in S} p_{2j} + \min_{j \in S} \left(\sum_{i=3}^{m} p_{ij} \right) = LB_2$$

In this way it is possible to obtain m lower bounds. The last bound is

$$C_{\max} \geq C_{m,j_k} + \sum_{j \in S} p_{mj} = LB_m$$

The lower bound to use is the maximum of these m lower bounds.

The search for the optimal sequence now goes as follows. One starts out with an initial sequence, which has to be chosen in a somewhat intelligent way (e.g., through a heuristic) and computes its $C_{\max}$. The better the initial sequence, the faster the branch and bound technique works. The procedure requires branching down the tree until a node is hit with a lower bound that is higher than the $C_{\max}$ of the best sequence found so far. This node is ''then fathomed'' and its offspring need not be considered. The search is then resumed from another node that appears to be promising (possibly because of a low lower bound at a node somewhat close to the root). When one finds a sequence with a $C_{\max}$ that is lower than the existing sequence one already has, one retains the new sequence and discards the other. The search is terminated when all nodes of the tree have been considered explicitly or implicitly (i.e., through fathoming).

4.3.1. Numerical Example

Consider three machines and three jobs. The processing times of job 1 are $p_{11} = 8$, $p_{21} = 4$, $p_{31} = 5$, of job 2, $p_{12} = 1$, $p_{22} = 6$, $p_{32} = 3$ and of job 3, $p_{13} = 1$, $p_{23} = 9$, $p_{33} = 5$. An initial solution has to be obtained in order to have a bound to start out with. One can argue that it makes sense to

let job 3 go first because it has a very small processing time on machine 1 and a very long processing time on machine 2. Choose sequence 3,2,1 as the initial sequence. Computing its makespan yields 25. This value is used as the initial bound. There are three nodes at level 2. The first node represents all sequences that start with job 1 in the first position (i.e., node (1,.,.) in Figure 3). Computing the bounds that are associated with this node yields:

$$LB_1 = 8 + 1 + 1 + \min(6 + 3, 9 + 5) = 19$$

$$LB_2 = 8 + 4 + 6 + 9 + \min(3,5) = 30$$

$$LB_3 = 8 + 4 + 5 + 3 + 5 = 25$$

So the lower bound at node (1,.,.) is 30. Because this lower bound is higher than the makespan of our initial sequence, it does not make any sense to evaluate the offspring of this node. Node (1,.,.) is thus fathomed. Evaluating node (2,.,.) and computing in a similar way a lower bound yields a value of 25. Because a sequence with a makespan of 25 is already known it is not necessary to evaluate the offspring of this node either; node (2,.,.) is therefore fathomed as well. Evaluating node (3,.,.) and computing a lower bound for this node yields a value of 23. Because this bound is lower than the makespan of the current sequence, the offspring of this node has to be evaluated; there may be a sequence with job 3 in the first position that has a makespan that is lower than the makespan of the current sequence. Evaluation of level 3, which turns out to be the last level, reveals that there are only two nodes at this level, namely nodes (3,1,2) and (3,2,1). Computing the makespan of sequence 3,1,2 yields a makespan of 23. This sequence is therefore optimal.

4.4. Decomposition Heuristics

In this section and the next, empirical techniques are presented that have proven to be useful in practice. These empirical techniques, or at least their underlying ideas, have been used in many existing industrial scheduling systems.

The technique discussed in this section has been designed for the $Jm||C_{\max}$ problem, which has received an enormous amount of attention in the literature. One of the most successful heuristic procedures developed for this problem is the shifting bottleneck heuristic (see Adams et al. 1988). A description of the procedure requires an alternative formulation of the problem.

Consider a directed graph $G = (N, A, B)$. The nodes N correspond to all the operations to be done on the n jobs. The (solid) arcs A represent the precedence relationships between the various operations of the jobs. The disjunctive (broken) arcs B form m cliques of double arcs, one clique for each machine; the operations that are connected to one another in a clique have to be done on the same machine. *All* arcs, including the disjunctive ones, emanating from a node have as length the processing time of the operation at that node. In addition, there is a source and a sink, which are dummy nodes. The source (sink) has arcs emanating to (coming from) all the first (last) operations of the jobs. The arcs emanating from the source have length zero (see Figure 4).

A feasible schedule corresponds to a *selection* of one disjunctive arc from every pair in such a way that the resulting directed graph is acyclic. This implies, then, that each selection from a clique has to be acyclic. Such a selection, thus, determines the sequence in which the operations are to be performed on that machine. The length of such a schedule is, then, determined by the longest path

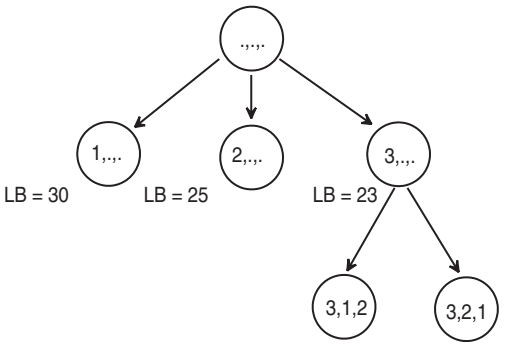

Figure 3 Branch and Bound Tree.

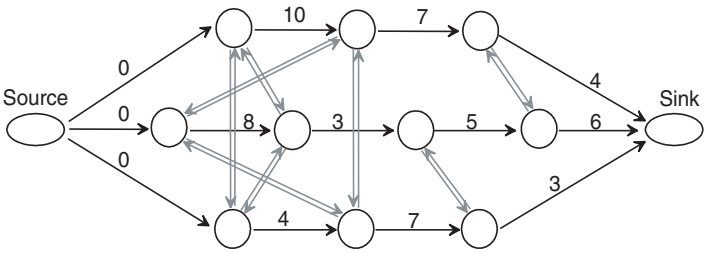

Figure 4 Disjunctive Graph of Job Shop with Three Jobs and Four Machines.

(i.e., the *critical path*) from source to sink. The problem is to find the selections of disjunctive arcs which minimize the length of the longest path. The shifting bottleneck procedure now works as follows.

Let M denote the set of all m machines. Assume that for a subset of the machines, say M_0, the selections of disjunctive arcs have been determined. That is, job sequences on these machines have been determined. An additional machine has to be added to this subset and the sequence in which the operations are to be processed on this machine needs to be specified. To determine which machine should be the next one to be included in M_0, an attempt is made to determine which machine (among the ones still to be scheduled) causes in one sense or another the severest problems. In order to do this, the original directed graph is modified by deleting all disjunctive arcs of the machines still to be scheduled (i.e., machines in the set $M - M_0$) and keeping only the relevant disjunctive arcs of the machines already in M_0 (one from every pair). Call this graph G'. Deleting all disjunctive arcs of a specific machine implies that the associated operations, which originally were supposed to be done on the machine one after another, now can be done in parallel at any point in time (as if each one of these operations has its own private machine). The graph G' has one or more critical paths as well as a makespan associated with it. Call this makespan $C_{\max}(M_0)$.

Assume now that each operation j to be scheduled on machine i, $i \in M - M_0$, has to be processed in a time window of which the release dates and due dates are determined by the critical (longest) paths in G'. Consider each one of the machines in $M - M_0$ as a separate $1|r_j|L_{\max}$ problem where the maximum lateness has to be minimized (actually, the $1|r_j|L_{\max}$ problem is NP-hard, but algorithms have been developed for this problem that perform reasonably well). After these single machine problems are solved, it has to be determined which one of these single machine problems has the *largest* maximum lateness. This machine, in a sense, is the "bottleneck" among the remaining machines still to be scheduled and therefore the one to be added next to M_0. Label this machine k, call its maximum lateness $L_{\max}(k)$, and schedule it according to the optimal solution obtained. If the corresponding disjunctive arcs, which specify the sequence of operations on machine k, are inserted in graph G', then the makespan increases by at least $L_{\max}(k)$, that is,

$$C_{\max}(M_0 \cup k) \geq C_{\max}(M_0) + L_{\max}(k).$$

Before the procedure is repeated and which machine to schedule next is decided, an additional step of resequencing each one of the machines in M_0 needs to be done. That is, a machine is taken out of the set $M_0 \cup k$, say machine l. A graph G'' has to be constructed in the same way as graph G' was constructed including now the disjunctive arcs which specify the sequence of operations on machine k and excluding the disjunctive arcs associated with machine l; machine l has to be resequenced by solving the corresponding $1|r_j|L_{\max}$ problem with the release and due dates determined by the critical paths in graph G''. After this resequencing is done for each one of the machines in the original set M_0, the entire procedure is repeated in order to add another machine to the current set $M_0 \cup k$.

The structure of this heuristic shows the relationship between the bottleneck concept and the more combinatorial concepts such as the critical (longest) path and the maximum lateness. A critical path indicates the location and timing of a bottleneck. The maximum lateness indicates the amount with which the makespan increases if a machine is added to the set of machines already scheduled.

Extensive numerical research has shown that this heuristic is extremely effective. Applied on a particular test problem with 10 machines and 10 jobs, which had remained unsolved for more than 20 years, the heuristic obtained a very good solution after only a couple of minutes of CPU time. This solution turned out to be optimal after a branch and bound approach, applied to the problem,

obtained the same result and verified its optimality. The branch and bound approach, in contrast to the heuristic, needed many hours of CPU time. The disadvantage of the heuristic is, of course, that whether an optimal solution actually has been reached can never be known for sure.

4.5. Local Search

Simulated annealing and taboo search are two techniques that can be viewed as generalizations of the iterative improvement approach to combinatorial optimization problems.

Simulated annealing originated in a different field: it was first developed as a simulation model for describing a physical annealing process for condensed matter. The application of simulated annealing to scheduling requires a certain amount of structure (see Matsuo et al. 1989). At stage k of the process, there is a solution for the scheduling problem; for a single-machine problem this solution is merely a given sequence (permutation) of the jobs, say σ_p. Let $G(\sigma_p)$ denote the value of the objective function using this solution. For this solution a *neighborhood* can be defined. If the solution is just a permutation of the n jobs, then the neighborhood could be defined as all permutations that can be obtained by interchanging a pair of adjacent jobs (which implies that the neighborhood then consists of $n - 1$ different sequences). Clearly, the structure of the neighborhood can be made more complicated and is a design issue. In order to be allowed to move from solution σ_p to solution σ_q, which is an element of the neighborhood of solution σ_p an acceptance probability

$$P_{pq}(k) = \min\left\{1, \exp\left[-\frac{G(\sigma_q) - G(\sigma_p)}{\beta_k}\right]\right\}$$

is defined, where k is the so-called stage of the search and $\beta_1 \geq \beta_2 \ldots$ The stage is a level in which the same acceptance probability is used, and β_k is a control parameter. This β_k tends to zero as k increases, which implies that the acceptance probability for a move to a worse solution is lower at a later stage in the process. From the definition of the acceptance probability, it also follows that the worse a neighbouring solution is, the lower the acceptance probability is.

The simulated annealing procedure now works as follows. At each stage a series of neighborhood searches is done. A search can be done in a random way or in a organized (possibly sequential) way. A neighbor is compared with the ''seed'' (current) solution. When the value of the objective function of the neighbor is less than the value of the objective of the seed, the neighbor is automatically accepted and becomes the new seed. If the value of the objective of the neighbor is higher than the one of the seed, the neighbor is accepted as the new seed with a probability that is determined by the acceptance probability. However, the best solution obtained so far is always being kept in memory. In practice, several stopping criteria are used for this procedure. One way is to let the procedure run for a given (prespecified) number of iterations. Another is to let the procedure run until for a given number of iterations no improvement has been obtained.

Taboo search is in many ways similar to simulated annealing. The procedure moves again from one solution to another, with the next solution being possibly worse than the preceding solution. For each solution (or sequence) a neighborhood is defined, possibly in exactly the same way as it is defined for simulated annealing. The reason for allowing a solution to be worse than the previous one is to give the procedure the opportunity to move away from a local minimum and have a chance to find a lower minimum. The mechanism that guides the moves is different from the one in simulated annealing (see Glover 1990). At any stage of the process a so-called taboo list is being kept. This list contains the moves to the neighboring solutions the procedure is *not* allowed to make. This list has a fixed number of entries (this number usually lies between 5 and 9). Every time a move is made, the reverse move is put at the top of the taboo list; all other entries are pushed one position down and the bottom entry is deleted. The reason for putting the reverse move in the list is to avoid a move back to a local minimum that has been visited before. The search for a neighbor to which the procedure is allowed to move to is a design issue. This can, just as in simulated annealing, be done in a random way or in an organized (sequential) way.

The use of simulated annealing and taboo search has its advantages and disadvantages. One advantage is that it can be applied to a problem without having to know much about the structural properties of the problem. It can be coded very easily and it gives solutions that are usually fairly good. However, the amount of computation time needed to obtain such a solution tends to be relatively long in comparison with more rigorous problem-specific approaches.

Simulated annealing as well as taboo search are often used in the following manner. First an attempt is made to find a reasonably good initial solution for a problem via a heuristic. After this has been done, either a simulated annealing or a taboo search procedure is used as a postprocessor in order to search for an even better solution. The postprocessor is then run for a given amount of time.

4.6. Multiple Objectives

Little of the theoretical research done in the past has dealt with multiple-objective models. There are, however, several approaches for dealing with such problems. We illustrate one approach here through an example (see McCormick and Pinedo 1995).

Consider the problem $Pm|prmp|\alpha_1\Sigma C_j + \alpha_2 C_{\max}$; that is, there are m identical machines in parallel with preemptions allowed and as the objective the minimization of a weighted sum of makespan and flow time. It can be shown fairly easily that the shortest processing time first (SPT) rule minimizes ΣC_j on parallel machines, while the preemptive longest remaining processing time first (preemptive LPT) rule minimizes $C_{\max}$. Because these two rules are quite different, it is not immediately obvious what type of rule minimizes a mixture of these two objectives.

The problem can be analyzed by transforming one of the objectives into a constraint; that is, consider the problem where the flow time has to be minimized subject to the makespan being smaller than or equal to a given deadline d. This problem turns out to have a fairly simple solution. Without loss of generality, it may be assumed that $p_1 \leq p_2 \leq \ldots \leq p_n$. The scheduler schedules the jobs according to SPT until time $d - p_n$. At this point in time this largest job *must* be started on one of the machines, preempting the largest job among the ones being processed at that moment. The scheduler then continues using SPT until the second-largest job must be started, that is, at $d - p_{n-1}$. At this point in time the largest job being processed, not including job p_n, is preempted by job $n - 1$, and so on. It is easy to compute the value of the objective function, given $C_{\max} = d$. Through a parametric analysis on d, one can determine the minimum flow time as a function of the makespan. This function is decreasing convex and piecewise linear with a number of breakpoints (see Figure 5).

The values of α_1 and α_2 determine at which breakpoint the optimal solution lies.

In general, when there are a number of objectives to be minimized, the following heuristic approach can be used. Select as the first (principal) objective to minimize one that is important (that is, has a large weight) as well as sensitive to the schedule. While one optimizes this objective, one continuously keeps the other objective functions (which are of lesser importance) in mind. For example, whenever a tie needs to be broken, it is broken in a way that is beneficial for a secondary objective. After having completed the optimization procedure for the first objective, one proceeds with considering a second objective, and so on.

5. SCHEDULING PROBLEMS IN PRACTICE

This section focuses on a number of application areas where dispatching and scheduling techniques are of importance.

5.1. Real-Life Scheduling Problems vs. Theoretical Models

Real-life scheduling problems usually are very different from the mathematical models studied by researchers in academia and industrial research centers. It is difficult to categorize all differences between the real problems and the theoretical models, as each real-life scheduling problem has its own idiosyncrasies. Nevertheless, a number of these differences do stand out and are worth mentioning.

Theoretical models usually assume that there are n jobs to be scheduled and that after these n jobs are scheduled the problem is solved. In real life there may be at any point in time n jobs in the system, but every day (week or month) new jobs are added. Scheduling the current n jobs has to be

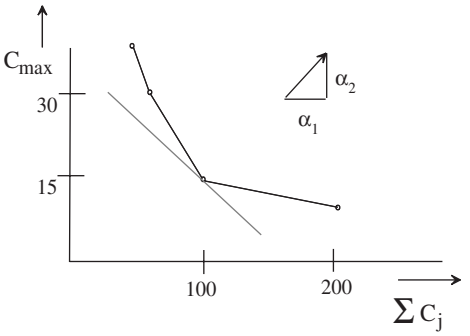

Figure 5 Trade-off Curve between Makespan and Flow Time.

done without having a perfect knowledge of what will happen in the near future. However, some provisions have to be made in order to be prepared for the unexpected. The dynamic nature of scheduling problem may therefore require, for example, slack times to be built into the schedule.

The models usually do not emphasize the *resequencing* problem. In real life the following problem often occurs. There exists a schedule that was generated based on certain assumptions; now an (unexpected) event has occurred that requires either major or minor modifications in the existing schedule. The rescheduling process, which is sometimes referred to as reactive scheduling, may have to satisfy certain constraints. For example, one may wish to keep the changes in the existing schedule at a minimum, even if an optimal schedule cannot be achieved this way.

The models usually do not consider *preferences.* In a model, a job either can or cannot be processed on a given machine. In reality, it often occurs that a job *can* be scheduled on a given machine but that there is a *preference* (for one reason or another) not to schedule it on the machine in question; scheduling it on the machine in question would only be done in case of an emergency.

Most of the theoretical research has been focused on models with a single objective. In real life there are, of course, a large number of objectives to deal with. Not only are there many objectives, but their respective weights may vary over time and may even depend on the particular person in charge.

In spite of the many differences between real-life scheduling problems and the mathematical models discussed in the previous sections, the general consensus is that the theoretical research done in the past has not been a complete waste of time. It has provided valuable insights into many scheduling problems, and these insights have proven to be useful in the development of a large number of scheduling systems.

5.2. Scheduling in the Packaging Industry

Consider a factory that produces paper bags for cement, dog food, charcoal, and so on. A scheduling system for such a factory has to be based on a flexible flow-shop model (see Adler et al. 1993). That is, there are a number of stages in series (for example, printing, glueing, and sewing) and at each stage there are a number of machines in parallel. The machines at any given stage may not be identical. Some machines may be more modern than others and may run at a higher speed or may be able to handle more complicated jobs than other machines. The main objectives are to meet the committed shipping dates as much as possible while minimizing the setup times on the machines. The algorithmic procedures adopted in such a system have to follow a number of steps.

First, the procedure goes through a bottleneck-identification process. At least one of the stages is a bottleneck. The identification of the bottleneck(s) can be done manually (specified by the user) or computed using all machine and job data. Then the procedure computes time windows during which jobs have to be processed at the bottleneck stage. The earliest time a job is allowed to start at a bottleneck stage depends on its current status upstream, while the latest time a job is allowed to be finished depends on its committed shipping date as well as on the amount of processing that is needed downstream. The current status upstream of a job may be either the stage the job currently is being processed at or the time the raw material (paper board) is expected to arrive at the facility and the job can be started at the first stage.

After this has been done, the procedure computes the various machine capacities at the bottleneck stage. For each machine it is computed how the capacity compares with the amount of processing that *has to* be done on it (that is, jobs that cannot be processed on any other machine) and with the amount of processing that *can* be done on it (that is, jobs that can be processed on other machines as well). This computation is done for various time periods (one week ahead, two weeks ahead, etc.).

Now scheduling of machines at the bottleneck stage can be done based on the information compiled in the previous steps. This schedule attempts to process all jobs within their respective windows while minimizing setup times. The procedure used here is a generalization of the ATC rule, which includes setup times. After the machines at the bottleneck stage have been scheduled, the machines at all other stages can be scheduled. The order in which the jobs go through the machines upstream and downstream of the bottleneck stage is somewhat similar to the order in which the jobs go through the bottleneck stage, with minor adjustments to improve on setup times or accommodate for machine preferences.

5.3. Scheduling in the Semiconductor Industry

In recent years a great amount of work has been done on wafer fabrication scheduling (see Hadavi and Voigt 1987). The reason for this activity is that equipment as well as products are extremely expensive. There is a great deal of randomness in the process; machines break down often and processing times are random. The machine environment can be considered as a job shop or as a flowshop with recirculation.

A system in such an environment has to create high-level production plans as well as more and more detailed scheduling plans. The timing of the generation of these detailed schedules depends on the urgency or the importance of the jobs in question.

While a large number of existing scheduling systems rely on good heuristics for solving the actual current scheduling problems (that is, *reacting* to real-time problems on the shop floor), some systems may take the more rational approach of *preventive* scheduling (that is, scheduling to avoid as many future problems as possible while at the same time optimizing the performance). In order to do so, such a system has to rely on a job-release mechanism that has a global view of the factory. Such a job-release mechanism attempts to achieve a maximal level of machine utilization and a minimal number of job delays. It may attempt to achieve this by monitoring a job parameter such as the *continuity index,* which measures how and when the job will be processed if released as proposed. The continuity index of a job is affected by bottleneck work centers, inventory shortages, tool availability, and so on. Based on these estimates, job releases are planned as much as possible to alleviate the prospective bottlenecks. This tends to minimize cycle times, which is one of the main objectives in VLSI development lines.

The sequencer and shop-floor control module of a scheduling system may track the work in progress as well as the status of the machines. It performs reactive scheduling functions based on this informtion. Such a module may be based on the axiom of *locality*, which implies that if an unexpected event occurs, an effort is made to limit, as much as possible, the number of changes in the existing schedules when correcting the problem.

The ReDS system developed by Siemens AG uses the real-time shop-floor data for another purpose as well (besides rescheduling). It uses the data in the form of a long-term feedback in order to make adjustments in the heuristics employed. This learning mechanism enables a scheduling system to mold itself over time into the shape of the factory in which it is operating.

5.4. Scheduling in the Automotive Industry

In the automotive industry, production scheduling ranges from job-shop scheduling in parts/components assembly to detailed job sequencing in automobile assembly. In automobile assembly, job sequencing and assembly line balancing are two concepts that are very closely related (see Burns and Daganzo 1987; Yano and Bolat 1990). This is largely due to two characteristics. First, most automobile assembly lines are mixed-model assembly lines with different processing time requirements for a large number of different models. In this case, different models of jobs may at times differ only in the options they carry and at other times may constitute completely different bodies. Secondly, most automobile assembly lines are paced, that is, jobs are processed at a constant rate that is determined by different model mixes and processing time requirements.

After the assembly line rate is determined, the operations with longer processing times are generally performed in sufficiently long sections of the line. This is possible because a large part of the assembly process is manually operated. However, job sequencing is now complicated because of the fact that the different operations performed on the different models require that similar jobs be adequately spaced in the sequence such that a proper balance of workload is achieved. Poor sequencing could result in reduced production and possibly quality problems. For example, suppose 10% of the jobs (cars) need a sunroof. Suppose that for a typical operation, to be done on *every* job, the processing time is p. The processing time for installing a sunroof is $3p$ since the amount of time it takes to install a sunroof is significant. The sunroof operation is designed to hold five jobs, with each job spending a total time of $6p$ in the operation (i.e., jobs are processed at a rate of $5/6p$). However, this implies that if there are three or more consecutive jobs requiring a sunroof, the operation is overloaded. An attempt is therefore made to place jobs with sunroofs as far apart as possible (i.e., approximately every tenth job) because otherwise the operation might be delayed and quality problems might occur if the workers do not have sufficient time to perform the operation properly.

Thus, the assembly line has to be sequenced in a way that more or less balances the workload at all operations, especially at those that in one form or another are critical. The operations most likely to be critical are those with a workload that tends to vary significantly from job to job.

Job sequencing is further complicated by the requirements that certain jobs be grouped together. For example, the paint process requires that each time the color of a job changes, the previous paint color must be purged from the spray gun to avoid paint overspray. Minimizing the paint purges can help reduce the paint cost, and therefore it is desirable to group jobs with the same color together in the job sequence. Also, to coordinate a better shipping schedule for finished automobiles, jobs shipped to the same destination should be grouped roughly in the same time interval.

Several large car manufacturers have developed integrated scheduling systems that take all the above requirements into account. Several systems are being used on a daily basis.

5.5. Scheduling in the Aviation Industry

In the aviation industry, many scheduling problems arise, such as crew scheduling, maintenance scheduling, and so on. In this section, a system is described that assigns airplanes to gates at an airport (see Brazile and Swigger 1988). Such scheduling systems have been developed to assign airplanes to gates at various airports in the United States, Europe, and Japan.

The problem can be viewed as a scheduling problem with machines in parallel. The gates represent the machines and the airplanes represent the jobs. The jobs have release dates that are the arrival times of the planes. These release dates are subject to random factors, such as weather and equipment failure. Any given job needs to be processed on one of the machines; the processing time is equivalent to the turnaround time of the plane. Some jobs can only be processed on a specific subset of the machines; for example, large planes can only go to specific gates while small planes may go to any one of the gates. The objective is to find a feasible assignment of jobs to machines.

Some of the systems are knowledge-based systems that attempt to find a feasible schedule through constraint satisfaction. They contain rules that guide the search and are capable of producing the trail of the rules used in reaching the conclusion. These systems may operate in one or two modes. In one mode, the static mode, it produces a daily schedule, which is followed only if everything goes as planned (which, of course, hardly ever happens). In the second mode, the dynamic mode, the system reassigns the gates in real time as information about changes in arrival and departure times becomes available.

Various different types of constraints with regard to the gate-assignment process can be formulated. There are ''hard'' constraints; for example, certain gates simply cannot accomodate 747s. There are ''soft'' constraints, which do allow exceptions; for example, domestic flights do not necessarily always have to arrive at and depart from domestic gates. There are ''convenience'' constraints; for example, planes that are scheduled to remain many hours at the terminal preferably should not be moved from one gate to another.

To arrive at an assignment, a system may search its way through two types of rules, permissive rules and conflict rules. Permissive rules determine whether it is appropiate to consider a particular gate for a particular flight. For example, when a plane is not continuing the same day, using a remote gate is acceptable. Conflict rules basically embody in the program the hard constraints mentioned before.

Systems may use a number of priority rules in their assignment of flights to gates. They first assign flights and gates that are the most constrained and the hardest to assign. Because only a small number of gates are capable of handling 747s, the wide-bodied aircraft are assigned first. Certain gates are so close to one another that planes cannot taxi in but have to be towed in. These gates have the lowest priority in the assignment.

Gate assignments are made when no rules are violated. If a feasible assignment is obtained in one pass, the process terminates. If the system does not find a feasible assignment in one pass, it automatically deactivates certain optional rules and tries again.

A system's second mode (the reassignment mode) operates as follows. It receives the most recent data concerning the current status of arriving and departing flights from the airline's database. When deviations are larger than given treshold values, the system checks whether the changes are creating conflicts. If there is a conflict, the system attempts to create a new schedule with a minimum number of changes. At times it may invoke the help of the scheduler.

6. DEVELOPMENT OF SCHEDULING SYSTEMS

6.1. General Structure of Scheduling Systems

During the last decade, numerous computer-based scheduling systems have been developed, many of which are currently controlling the scheduling operations in a variety of industries. For a number of reasons, the implementation of such systems usually turns out to be at least as difficult as the actual development. The development of these systems has taken place at R&D centers of industrial corporations as well as at universities (see Kanet and Adelsberger 1987; Adelsberger and Kanet 1989). Computer-based scheduling systems often consist of three modules:

1. A database management module
2. A schedule-generation module
3. A user interface module

See Figure 6.

All three parts play a crucial role in the functionality of the system. In practice, a significant amount of effort is usually required to make a factory's database suitable for input to the system. Making the database accurate, consistent, and complete often involves the design of a series of tests the data must pass before they can be used. This module may also have capabilities of manipulating the data, performing various forms of statistical analysis, and enabling the scheduler to see data in the form of bar charts or pie charts. The schedule-generation module involves the formulation of a suitable model, the formulation of objective functions and/or constraints, and (possibly) the development of the algorithms. The user interface module is very important, especially with regard to the implementation process. Without a good user interface, there is a good chance that, regardless of its

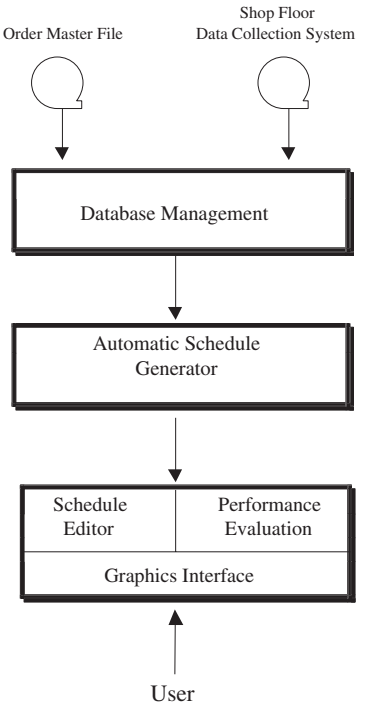

Figure 6 Configuration of a Scheduling System.

scheduling capabilities, the system will never be used. This user interface often takes the form of an electronic Gantt chart with tables and graphs that enable the scheduler to edit the schedule generated by the system and take last-minute information into account (see Figure 7). When the scheduler edits the schedule generated by the system, he or she is usually able to follow the impact of his or her changes on the various measures of performance as well as compare several schedules with one another and perform an extensive what-if analysis.

6.2. Schedule Generation

There are several schools of thought with regard to schedule generation. Two of these deserve further discussion. One, which is predominantly used by industrial engineers and operations researchers, could be called the *algorithmic* approach. The other, which is often used by computer scientists and artificial intelligence experts, is usually called the *knowledge-based* approach (see Kanet and Adelsberger 1987). Recently, these two approaches have started to converge towards one another and the differences have become more blurry. Some hybrid systems developed in the recent past use a knowledge base as well as fairly sophisticated heuristics.

The first approach usually requires a mathematical formulation of the problem, which includes objectives and constraints. The algorithm could be based on any one of the techniques or combination of techniques presented in Sections 3 and 4. The ''goodness'' of the solution is based on the values of the objectives and performance criteria under the given schedule. This form of schedule generation often may consist of three segments. In the first segment a certain amount of *preprocessing* is done. In this segment the problem instance is analyzed and a number of statistics are compiled, such as the average processing time, the maximum processing time, the due date tightness. The second segment consists of the actual algorithms and heuristics. The structure of the algorithm or heuristic may depend on the statistics compiled in the first segment (for example, in the way the look-ahead parameter K in the ATC rule may depend on the due date tightness and due date range factors). The third segment may contain a *postprocessor*. The solution that comes out of the second segment is fed into a procedure such as simulated annealing or taboo search in order to see whether any improvements can be obtained. This type of schedule generation is usually coded in a procedural language such as Fortran, Pascal, or C.

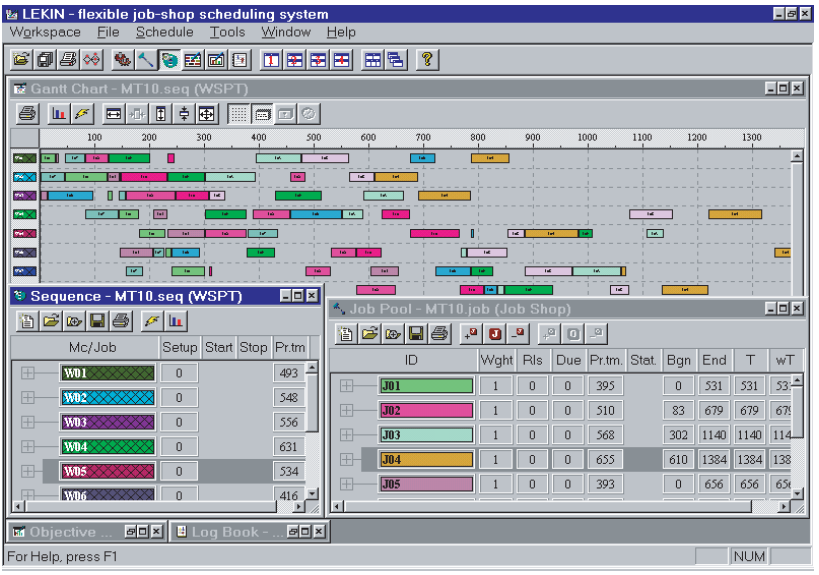

Figure 7 The Gantt Chart Interface of the Lekin System.

The second approach is different from the first in various respects. This approach is often more concerned with underlying problem structures that cannot easily be described in an analytical format. In order to incorporate the scheduler's knowledge into the system, so-called rules and objects are used. This approach is used often when it is only necessary to find a *feasible* solution given the many constraints or rules; however, because some schedules are ranked "more preferable" than others, heuristics are used at times in order to obtain a "preferred" schedule. Through an *inference engine* the approach attempts to find sequences that do not violate prescribed rules and satisfy stated preferences as much as possible. Whenever a satisfactory solution does not appear to exist or when the scheduler judges it to difficult to find, the scheduler may reformulate the problem through a relaxation of the constraints. The relaxation of constraints may actually be done automatically by the system itself. The programming style used in the development of such systems is usually different from the ones used under the first approach; systems are usually coded in languages that have so-called object oriented extensions, such as LISP and C++. These languages emphasize user-defined functions, which promote a modular programming style.

Both approaches have their advantages and disadvantages. The algorithmic approach clearly has an edge if (1) the problem allows for a crisp mathematical formulation, (2) the number of jobs involved is large, (3) the amount of randomness in the environment is minimal, and (4) some form of optimization has to be done frequently and in real time (it is very common that schedulers have neither the patience nor the time to wait more than 30 seconds for a schedule to be specified). One disadvantage of the algorithmic approach is that if the scheduling environment changes (for example, certain preferences on assignments of jobs to machines), the reprogramming effort may be substantial. The knowledge-based approach may have an edge if only a *feasible* schedule is required. Some system developers believe that changes in the scheduling environment or rules can be incorporated more easily in a knowledge-based system than in a system that is based on the algorithmic approach. Others, however, believe that the effort required to modify any system is mainly a function of how well the code is organized and written; the effort required to modify does not depend that much on the approach used. One disadvantage of the knowledge-based approach is that obtaining a reasonable schedule may take a substantial amount of computer time.

6.3. Software Development and Implementation

The last three decades have seen the design and implementation of many scheduling systems. Some of these systems were application specific and others were generic. Some were developed for research and experimentation and others were commercial.

A number of scheduling systems have been designed and developed in academia over the last three decades. Several universities developed research systems or educational systems that were often

based on ideas and algorithms that were quite novel. An example of such a system is the Lekin system, which can be downloaded free of charge from the Web. Some of the academic systems have been handed over to industry and have led to the start-up of software companies.

The last two decades have witnessed the development of scores of commercial scheduling systems. There were a few major trends in the design and development of these commercial scheduling systems.

One trend started in the 1980s when a number of companies began to develop sequencing and scheduling software. Most of these companies tended to focus in the beginning only on sequencing and scheduling. They started out with the development of generic scheduling software that was designed to optimize flow lines or other types of machine environments. Some of these companies have grown significantly since their inception, such as ILOG, I2, and Manugistics.

These companies, whenever they landed a contract, had to customize their software to the specific applications. Because they realized that customization of their software customization is a way of life, they usually tried to keep their schedule generators as generic as possible. The optimization methodologies they adopted often included:

1. Shifting bottleneck procedures
2. Local search procedures
3. Mathematical programming procedures

These companies, which at the outset were focusing primarily on sequencing and scheduling, began to branch out in in the 1990s; they started to develop software for supply chain management. This diversification became necessary because clients typically had a preference for dealing with vendors that could provide a suite of software modules capable of optimizing the entire supply chain; clients did not like to have to deal with different vendors and face all kinds of integration problems.

A second major trend in the development of sequencing and scheduling software had its source in another corner of the software industry. This second trend started to take place in the beginning of the 1990s. Scheduling software started being developed by companies that at the outset specialized in ERP systems, such as SAP, Baan, J.D. Edwards, and PeopleSoft. These ERP systems basically are huge accounting systems that serve as a backbone for all the information requirements in a company. This backbone can then be used to feed information into all kinds of decision support systems, such as forecasting systems, inventory control, and sequencing and scheduling. The software vendors that specialized in ERP systems realized that it was necessary to branch out and develop decision support systems as well. A number of these companies either bought a scheduling software company (e.g., Baan bought Berclain), started their in-house scheduling software development (e.g., SAP), or established partnerships with scheduling software vendors.

Currently there are more than a hundred scheduling software vendors. Most of these are relatively small. The bigger players are I2, Cybertec, and Manugistics, all of them offering software for the entire supply chain. The main ERP vendors, such as SAP, Baan, PeopleSoft, and J.D. Edwards, all offer sequencing and scheduling packages. Some of their scheduling modules had been developed internally, whereas other modules were developed through acquisitions of smaller software companies specializing in scheduling. The algorithmic approaches differ considerably from company to company. Some companies specialize in local search procedures, while others specialize in mathematical programming techniques, and again others in decomposition techniques. Even the preferences for user interfaces may differ. However, the most popular user interface tends to be the Gantt chart.

7. CONCLUDING REMARKS

During the last two decades, with the advent of the personal computer in the factory, a large number of scheduling systems has been developed. Currently, many more scheduling systems are under development. This developmental process has made it clear that a large proportion of the theoretical research done during the decades past is of limited use in real-world applications. The system development that is currently going on in industry is fortunately encouraging theoretical researchers to tackle scheduling problems that are more relevant to the real world. At various universities in Europe, Japan, and North America, research is being focused on the development of algorithms as well as on the development of systems; significant efforts are being made in the integration of these developments (see McKay et al. 1989).

Even though during the last decade many companies have made large investments in the development and implementation of scheduling systems, not that many systems appear to be used used on a regular basis. Systems, after being implemented, often remain in use only for a limited time; after a while they are often, for one reason or another, ignored altogether.

In those situations where the systems are in use on a more or less permanent basis, the general feeling is that the operations do run more smoothly. A system in place usually does *not* reduce the time the scheduler spends on the scheduling process. However, a system usually does enable the

scheduler to produce better schedules. Using an interactive schedule editor, the scheduler is able to compare different schedules and easily monitor the various performance measures. Actually, there are other reasons for smoother operations besides simply better schedules. A scheduling system imposes more ''discipline'' on the operations. There are compelling reasons now for keeping an accurate database. Schedules are printed out neatly and are visible on monitors. This apparently has an effect on people, encouraging them to actually even obey the schedules.

It would be interesting to know the reasons why some systems have never become implemented or are never used. In some cases databases are not sufficiently accurate. In other cases the way in which workers' productivity is measured is not in agreement with the performance criteria the system is based upon. User interfaces may not enable the scheduler to resequence quickly in the case of unexpected events. There may also be an absence of procedures that enable resequencing when the scheduler is absent (for example, if something unexpected happens during third shift). Finally, systems may not be given sufficient time to settle or stabilize in their environment (this may require many months, if not years).

Nevertheless, it appears that in the decade to come an even larger effort will be made in the development of such systems and that such systems will play an important role in computer-integrated manufacturing.

CHAPTER 64

Personnel Scheduling

RICHARD N. BURNS
BCW Consulting Limited

1. INTRODUCTION

Personnel scheduling involves two stakeholders: management, who need to have the work done, and workers, who need to have working conditions that contribute positively to their quality of life. In recent years, management has recognized that the objectives of the two groups need not be mutually exclusive. Good working schedules help to make happy employees and increase the length of time a person stays with the employer.

Personnel scheduling problems can be separated into different categories, based on the types of shifts to be worked, the employment contract working conditions clauses, and the pattern of the quantity of work needing to be done. The objective of this chapter is to give an overview of the types of personnel scheduling problems that arise and an introduction to some of the solution methods available.

2. BASIC STEPS FOR PERSONNEL SCHEDULING

Generally, there is a definite set of steps to complete the process of personnel scheduling. These steps will be discussed in more detail in this section, but the first step is to determine what work needs to be done.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

2.1. The Quantity of Work to Be Done

The quantity of work to be done must be defined by the appropriate time period, which could be by as little as a 15-minute interval for cashiers and as long as a day for paper mills. For continuous process industries, such as chemical plants and some mining processes, the definition of what is needed is relatively easy to determine. Even so, the work must be defined by the hour and day of the year to allow for maintenance and shutdowns for holidays. There are many other industries that also have a well-known stable demand for work profile—for example, prisons, long-term health care facilities, and many manufacturing systems, such as assembly lines. At the other end of the scale are situations such as retail outlets and telephone operators, that have a demand that varies constantly during the day, and from day to day, and from season to season. Many of the organizations with such a fluctuating demand pattern have a detailed data bank of historic data, usually by the 15-minute interval. These data can be used to predict the work requirements for future time periods.

Hospitals have an expected amount of work for each day. However, many hospitals apply a patient classification system to all patients daily to calculate the actual amount of work needed for that day. This last-minute determination of the work requirement is necessary and unavoidable, even though it makes personnel scheduling very difficult.

Managing the demand to try to smooth out the fluctuations in work required is an important part of personnel scheduling. Examples of such efforts are visible in the reduced prices for matinees at theaters, early-bird specials at restaurants, and discounted long-distance calls for off hours. In manufacturing, longer, less complicated tasks are often done at night to reduce the number of supervisory and support staff needed. It is this ability to manage or alter the work required that can make the scheduling steps iterative. If the current demand proves too difficult to schedule, then this first step can be revisited to try to alter the demand. Once the concept of managing demand is acknowledged, the organization will often find suitable ways of making the demands change to match the ability to satisfy the demand.

2.2. Determining Staffing Requirements

Even when the work required is known, the process of determining how many people are needed can be very difficult. The first step is to break down the work required into shifts, with the number of people needed for each shift. The whole process depends on several factors and will be discussed in some detail in the subsequent sections. The criteria involved are as follows: what shift lengths are to be considered, what contract conditions apply, how many part-time workers are to be used, what sickness rate can be expected, what vacation and statutory holiday conditions apply, and what are the capabilities of the staff available. This last point illustrates that the process may be iterative because the worker availability may necessitate a change in the number of workers needed.

2.3. Determine Personnel Availability

There are, of course, the obvious categories of workers, such as full-time workers, regular part-time workers, casual workers, temporary workers, and labor pools. These categories can be expanded. For example, there may be full-time workers who only work weekends. There can be other full-time workers who only work specific shifts such as nights. In the part-time worker category, there may be two workers doing job sharing so that they are scheduled as if they were one full-time worker. In most cases, regular part-time workers are associated with specific jobs and times of availability. Casual workers also are often associated with specific jobs, while others can do many jobs. Maternity leave, long-term sick leave and other leaves, as well as vacations and requests for time off that have been granted must be acknowledged in determining who is available to work. In the last few years, many industries have employed more part-time employees to reduce costs and increase flexibility in scheduling. For example, the prison systems and schools now use more part-time staff that before. The availability of all the people must also include the number of hours of work available, the shifts, and the days of work available.

2.4. Developing Work Schedules

There is one fundamental approach to scheduling that needs to be considered when developing work schedules. In the past, many of the approaches have been to determine how many workers are needed in each time period and then assign people to the jobs. The emphasis has been from the management point of view of ensuring that there are enough people available to get the work done. This is not the best point of view or the approach that should be taken. The workers are at work, on average, 40 hours per week, even if they get paid for 37½ or some other figure. This leaves 128 hours of off time in each week for the workers. To the workers, the time off is the most important time. This is the time that they have to spend with family and friends, to indulge in hobbies, and just to relax. In developing schedules, the whole approach should be to make the time off for the workers the best time possible. A secondary goal, and one that is relatively easy to achieve, is to ensure that the right number of workers is available at all times.

For example, a worker does not like to have a weekend off to spend with the family, where they work the night shift Friday night which starts at 11:30 p.m. Friday and ends at 7:30 a.m. Saturday. By the time they get home from work on Saturday morning, have something to eat, and get at least seven hours of sleep, the day is gone. Although the shift schedule might show Friday night working, Saturday and Sunday off, and return to work on the day shift Monday, it is not a desirable time off.

Once the schedule has been built, it is relatively easy to assign workers to different lines of the schedule.

3. TYPES OF PERSONNEL SCHEDULING PROBLEMS

There are many ways of categorizing shift scheduling problems. Some of the choices are based on the demand patterns, such as stable demand during a shift vs. variable demand during a shift, or demand only during a single shift or multiple shifts. Another way of considering problems is by the way workers are scheduled, such as scheduling individuals vs. crew scheduling. Within each category there are numerous subcategories, and recent research has made progress on these problems.

3.1. Single Shift

For the most basic single shift problem, where there is only demand for the day shift for five days a week, the problem does not generally create difficulties. All workers can be scheduled to work Monday to Friday with every weekend off. Recently, many companies have changed this system to have flexible hours for the workers, providing that they spend at least a given number of hours in a specified time period, such as between 10 a.m. and 4 p.m. Again, no difficulty arises, and the same holds for summer hours, where people work 10-hour shifts for four days a week.

The more difficult problems occur when the daily demand for workers extends over a longer period than eight hours. In most retail stores, banks, and service outlets, such as clinics and repair depots, the hours of operation may be as many as 14 or 16 hours per day. Even operating rooms in major hospitals are used from early in the morning to 6 or 7 in the evening. A second condition that adds a whole new level of difficulty, is if the daily demand is for more than five days per week. Now the problem involves giving workers suitable weekends off with a required frequency.

Most retail outlets have developed sophisticated databases that track the historic sales. These stores are usually open long hours, seven days a week, and have a demand for workers that varies both by the day and by the 15-minute interval within a day. Although this is still a single-shift problem, the increased difficulty is shown when building schedules for these cases. Fortunately, part-time workers are used extensively, but even so, experience has shown that there is a great deal of discontent with the final weekly schedules that are posted. Section 4 of this chapter will address how to improve schedules for the time-varying demand problem.

3.2. Multiple Shifts Required

Multiple-shift scheduling problems have many added difficulties:

- Limiting the number of shift changes in a given time period
- Having a given amount of time off between shift changes
- Preceding weekends off and vacations with a suitable shift
- Balancing the less desirable shifts among workers
- Limiting the number of successive days that some shifts are worked
- Using worker seniority when assigning shifts if required by the contract
- Choosing the mix of shifts, such as 8-hour, 10-hour, and 12-hour shifts
- Balancing the paid hours worked

3.2.1. Crew Scheduling

In many continuous process industries, such as mines, steel, and chemical companies, the workers are scheduled by crew. The author has completed many consulting contracts for such companies, but has also turned down many more contracts for the very simple reason that one recurring problem could not be solved. The problem that arises time and again, but that is not solvable, is the request to help with the scheduling to reduce the amount of overtime being paid. Consider the mathematics of the situation. A crew is needed to be working continuously, seven days a week. This means that there are 7 days of 24 hours for a total of 168 hours of work needed. The company will have four crews rotating shifts to provide the coverage. Each crew provides 40 hours of work for a total of 160 hours. The shortfall of 8 hours each and every week is made up by the same four crews, so there must be 8 hours of overtime each week, which is an average of 2 hours of overtime each week for every crew. The mathematics seems obvious, but the request for help in removing this overtime arises a startling number of times. For most continuous process companies, there is no help in

reducing this overtime, but in a later section a set of suggested solutions for mining companies will be discussed.

3.2.2. Shift Scheduling for Individuals

Police, hospital workers, prison workers, all emergency systems, telephone workers, and many other seven-day-a-week operations schedule individuals rather than crews. These are the situations allowing for the most flexibility in scheduling, and also requiring complicated methods. They are also the source of most of the discontent with schedules because the workers expect better schedules than they receive, or better than may be possible. The following are some of the features not already mentioned above that make for discontent:

- Working too many days in a row too often
- Having too many single days off
- Perceiving inequities in schedules among workers
- Having too few shifts if a part-time worker
- Not having requested time off
- Not having a fair share of statutory holidays off

3.3. Hierarchical Workforce Requirements

Examples are perhaps the best way of illustrating these problems. For example, a prison system may require 20 guards for a shift, and at least one must be a qualified dog handler. In a hospital unit there may need to be eight nursing staff on the day shift, with at least six of them being four-year graduate nurses. The balance can be either nurses, nurse's aides, or nursing assistants.

Calculating the number of people needed and scheduling them is a little more difficult if there is a shortage of qualified people in some categories. Scheduling can be made easier by hiring the right mix of people or by training the people to achieve a desirable mix of worker skills. In recent years, many contract concessions have been given by unions to assist with this cross-training of workers.

3.4. Part-Time Workers

Part-time workers have become the mainstay for many industries. Various reasons exist for having part-time workers, only some of which pertain to scheduling, as can be seen in the following list:

- The full-time complement allowed is not enough to cover all the required workers, so part-time workers are scheduled into the master schedule to make up the deficit.
- People call in sick, so part-time workers are called at the last minute to fill the vacant spot in the schedule.
- A statutory holiday occurs and some full-time workers are given the day off; part-time workers are scheduled in advance for this holiday.
- Vacations, training time, business trips, long-term sickness, and other reasons for using a part-time worker are known in advance when the schedule is created.
- There is a fluctuation in demand during the day, or during the week that needs to be accounted for using part-time workers. In many cases, the need for part-time workers is known in advance, but in others, additional people will need to be called at the last minute.

Regular part-time workers are staff that are associated with the employer and used on a regular basis. In many instances these employees will fall under a union or employer contract. Some of the conditions prevailing in contracts are as follows:

- The person must be available for a given number of hours per week.
- The person must work at least a required number of weekends.
- The person must have at least a specified frequency of weekends off.
- The person cannot be required to work more than a specified number of days in a row.
- When part-time workers are needed, they are to be asked if they are available in some specified order, such as seniority, or equitably with the others.
- When called to work, the shift length must be at least as long as a specified time.

Many of the conditions above drive the way a schedule can be built. Very good records must be kept to ensure that the conditions are satisfied, as penalties often apply. The contacting of part-time

people to get them to commit to a specific job assignment is very time consuming and costly. For nurse scheduling, software packages are available on the Internet that will assist in this task.

Casual part-time workers are not usually employed under a set of contract conditions. For example, in nursing, a hospital will have a list of nurses who would like some work but who are not on the regular part-time list. These nurses are called only after the list of regular part-time nurses has been exhausted. They will work a full shift, in one of a short list of units that depends on the person's skills and experience. Retail stores and fast-food outlets use many casual workers, including a large number of students. This scheduling also takes a lot of time because of the information base that must be referred to when scheduling and updated as a schedule is used. Some of the information required is similar to that of the regular part-time workers. The following is a partial list:

- The person's usual available hours
- The number of hours desired by the person
- The skills that the person has and the jobs he or she qualifies for
- The seniority of the person
- The number of hours that the person has worked in a rolling window of time
- The person's immediate past schedule record
- The means of contacting the person
- How many recent requests to work were refused or not answered
- Any short-term unavailability times requested by the person for personal reasons
- The average number of hours given to people in the same category of workers to ensure equitable assignment of work time

Many grocery stores and fast-food stores leave the scheduling of part-time workers to be done manually by administration. While they try to do a good job, it is time consuming and inequitable schedules can inadvertently arise. Such schedules can lead to discontent and employee unrest. A good system must be set up for this task.

Temporary workers are only part-time in that they are not permanent workers. They will usually be summer students or people hired to fill a job that is being reserved for someone who will be absent for a longer period of time. Long-term sickness and maternity leaves are simple examples of the need for temporary workers. Temporary workers will be scheduled just as if they are full-time workers, subject to all the rules for the full-time workers they are replacing. In seasonal situations, the temporary workers may be the bulk of the people being employed.

There is one more class of workers who appear as part-time workers to the scheduler but are in fact full-time workers. The name for this class differs from industry to industry and changes with time within an industry. ''Relief labor pool'' and ''float pool'' are names for a group of full-time people who are available to work in different jobs in the organization. The scheduler for one group of workers will use these people as needed. Essentially, the group scheduler is only assigning a job to the relief worker, who is already working to a predeveloped schedule. The person responsible for developing the relief pool schedule and for maintaining it for requests for changes for personal reasons, holidays, and vacation days is another issue. Someone must also be responsible for assigning jobs to the relief pool people who have not been requested to work by a specific unit.

4. CREATING SCHEDULES

Schedules have an important effect on employees' lives. A good schedule for one person may be considered a poor schedule by another person. There are no absolutes, but there are guidelines. If the schedules are good, worker performance and worker retention will improve, which is good for the organization as a whole. For example, in a major city hospital with 21 operating theaters, there was a 30% turnover of nurses. Changing the schedules made the turnover rate drop to the hospital average. A schedule can be considered optimal in the sense that it only reduces labor cost to the minimum, but an optimum schedule will minimize overall costs by reducing labor costs while improving performance and keeping workers satisfied with their schedules. As mentioned earlier, the goal of scheduling should be to develop optimum schedules, not just locally optimal schedules.

Much has been done in recent years to understand the personnel scheduling problem. As with most research, progress is made by making simplifying assumptions and solving the resulting problem. Insights are gained and the problem is then expanded slightly. By this iterative approach to research, problems resembling the real-world situation are finally attained. In personnel scheduling, many of the real-world problems have not yet been solved, but much of the insight obtained in the process of doing the research helps the scheduler to develop workable schedules. In the next few

4						X	X			X				X

sections, some of the more useful facts will be presented, along with suggested ways of using them when scheduling.

4.1. Single Shift

Single-shift scheduling is still used in many situations. The shift is called a day shift, whether a person starts at 7 a.m. or 3 p.m. Schedules can be made for people and the time of starting can be determined later. The more interesting situation is a seven-day-a-week operation, with people being scheduled to work eight-hour shifts for an average of five shifts per week.

Cyclic scheduling was one of the first analytic approaches to single-shift scheduling. The situation can have a variable demand for the seven days and a requirement that all workers have two successive days off. This problem can be solved by mathematical programming, as shown in Baker (1974, 1976) and Tibrewala et al. (1972). The final schedules will have each person working five consecutive days followed by two days off. If a person has Tuesday and Wednesday off in one week, then he or she will always have the same two days off and will never have a weekend off. This type of schedule, while useful in some situations, is optimal from the short-term point of view of the employer but may in the long run cause a higher turnover of employees as they move in order to have some weekends off.

Burns (1978) introduced three very interesting facts to the process of scheduling. The first was that the definition of a work week should be Sunday to Saturday, not Monday to Sunday, as will be shown below. The second was that a simple analytic formula could be used to calculate how many workers were needed, and the third was that a simple polynomial time method could be used for developing optimal schedules without using mathematical programming. These three facts have formed the basis of many research papers and doctoral theses since that time, and they are useful in practice. Burns and Carter (1985) generalized the problem to allow for any frequency of weekends off.

Consider the problem of building a schedule that has one person working each day of the week, and the week is defined as Monday to Sunday. The schedule is to have each person working five days a week, with the maximum work stretch six days, and each person is to have every second weekend off. The difficulty arises in the week before a person has the weekend off. Once a person has Saturday and Sunday off in a week, he or she must work the five weekdays in order to have five working days per week. This means that in the week before, he or she must have either Sunday or Saturday off in order to restrict the work stretch to a maximum of six days. In Table 1, the schedule necessary to have at least one person working every day is given.

In order to have one person working each day, it is necessary to hire four people. To have n people each day, the requirement will be $4n$ workers. The schedule can be presented in a cyclic form, as shown in Table 2, with one person starting on each of the four lines and working that week before going to the next line. The person working the last line goes to the first line next. Notice that in order to have one person working on the weekend, there will be up to four people working on a weekday.

Changing the definition of the week to be from Sunday to Saturday means that the schedule can be constructed with only two people. Table 3 is an example of a cyclic schedule for a scheduling

TABLE 2 Week as Monday to Sunday, Cyclic Schedule

totals	1	2	1	2	2	1	1

problem with cyclic demand. Start one person on each line and have the person go to the next line after Saturday, where the first line is next after the second line.

In a cyclic scheduling problem, the demand on each day of the week is the same for each week. However, the demand may vary from day to day within a week. There are two basic types of schedules for the cyclic problem. The first is a cyclic schedule, such as the one in Table 3. In a cyclic schedule, the schedule itself repeats over some defined period, thereby giving a ''master rotation.'' The second type of schedule is an iterative schedule, where an algorithm is given that schedules the first week of the schedule, and then another part of the algorithm shows how to generate week $i + 1$, given week i of the schedule. An iterative schedule might never repeat, and no ''master rotation'' is available.

The following is the statement of the scheduling problem that can be solved using the methods of Burns and Carter (1985):

W is the minimum number of workers required to cover a seven-day-a-week operation with the following primary constraints satisfied:

1. The demand per day n_j, $j = 1, 2, \ldots, 7$; n_1 being Sunday's demand.
2. Each worker is given at least A out of B weekends off.
3. Each worker works exactly five out of seven days each week.
4. Each worker works no more than six consecutive days.

In Burns (1978), the requirement was for every second weekend off.

This last constraint is added because a person could work the last five days of one week, followed by up to five more consecutive days of the next week, unless the restriction were in place. In Brown et al. (1976) over 50% of the schedules produced had work stretches of 10 consecutive days. Even as late as 1994, papers have appeared where the work stretch is as long as 10 days. Such schedules are not of much practical use.

The algorithm of Burns and Carter (1985) is an iterative scheduling method. The basic approach of the algorithm for the problem in this section is simple.

Ignore some of the constraints to get an absolute lower bound on the number of people required to complete the schedule. It will be a lower bound because if more constraints were incorporated, some schedules might not be feasible and more people might be needed.

Build a schedule for this lower bound number of people by first assigning the weekends off so that the required frequency of weekends off will be met for everyone.

Then assign the remaining days off for each worker to satisfy the work stretch constraint and ensure that everyone has exactly two days off per week.

Note, as outlined in the previous section, that the method does not assign workers to work specific days, but does concentrate on the workers' time off, which will produce better schedules for the individual. Following the detailed steps of the algorithm ensures that the schedule for just the lower bound number of people will, when completed, satisfy the total requirements for workers in each time period. The schedule is then optimal because no other schedule could be produced using fewer people.

Lower bounds for the number of workers needed will now be given. There are three bounds that are used:

1. *The weekend constraint:* The total number of employees' shifts available for the B weekends must be sufficient to meet the maximum weekend demand for the B weekends. In B weeks, each employee is available for $(B - A)$ weekends. Hence, $(B - A)W \geq Bn$, where $n = \max(n_1, n_7)$ is the maximum weekend demand.

$$L_1\colon W \geq \left\lceil \frac{Bn}{(B - A)} \right\rceil, \text{ where } \lceil x \rceil \text{ is the upper integer part of } x.$$

2. *The total demand constraint:* The total number of employees' days worked per week must be sufficient to meet the total weekly demand for shifts. Since each employee works exactly five days per week:

$$L_2\text{: } 5W \geq \sum_{i=1}^{7} n_i \text{ or } W \geq \left[\frac{1}{5}\sum_{i=1}^{7} n_i\right]$$

3. *The maximum daily demand constraint:* The number of employees must be sufficient to meet the maximum demand on any day.

$$L_3\text{: } W \geq \max_i(n_i),\ i = 1, 2, \ldots, 7$$

The algorithm uses a workforce equal to the maximum of the three constraints. The paper proves that if the algorithm is used, then the W employees will be sufficient to satisfy all the problem constraints, including the ones not used in calculating W.

In scheduling the weekends off, the algorithm assigns a number from 1 to W to each employee. Since n people are required to work each weekend, $(W - n)$ can have the weekend off. Assign the first weekend off to the first $(W - n)$ people. Assign the next $(W - n)$ weekends off to the next $(W - n)$ people. This process is continued cyclically with employee 1 being next after employee W.

For each week of the schedule, every employee must have exactly two days off. In any given week, there are already $(W - n)$ Sundays off at the beginning of the week and $(W - n)$ Saturdays off at the end of the week. An additional $2n$ days must be given off so that all W people have two days off and the algorithm constructs n off-day pairs for this task.

Denote the surplus workers for day j by S_j.

For Monday to Friday $S_j = W - n_j$ for $(j = 2, 3, 4, 5, 6)$
For Sunday $S_j = n - n_1$
For Saturday $S_j = n - n_7$

Iteratively, construct a list of n pairs of off days, numbered from 1 to n, as follows:

1. Choose day k such that $S_k = \max(S_j)$.
2. Choose any $i \neq k$ such that $S_i > 0$. If $S_i = 0$ for all $i \neq k$, set $i = k$.
3. Add the pair (k, i) to the list and decrease S_k and S_i by 1.
4. Repeat this procedure n times.

Pairs of the form (k, k) are called nondistinct off-day pairs and will be at the end of the list.

The next step is to assign the off-day pairs in week 1. Employees will fall into one of four categories, depending on the weekends off at the beginning and end of the week. Table 4 illustrates the categories.

There are n people working on each weekend. Therefore, $|T3| + |T4| = n$ from weekend 1 and $|T2| + |T4| = n$ from weekend 2, for $|x|$ = the cardinality of the set x. Each employee of type $T2$ is paired with one of type $T3$.

Assign the n pairs of off-days from the top of the list, first to the employees of type $T4$ and then to employees of type $T3$. The $T3$ get the earliest day of the pair, and the latest day is assigned to their associated type $T2$ employee. The paper proves that nondistinct pairs of off-days always get assigned to type $T3$ workers and then split. Hence, the algorithm will not assign two days off to a worker where the two days are the same day.

The next step is to assign the off-day pairs in week i for $i > 1$. Assume that weeks 1 up to week $(i - 1)$ have been scheduled. In week i, categorize the workers into the four types $T1$, $T2$, $T3$, $T4$. The critical problem of this step is to ensure that no employee has a work stretch longer than six days. The assignment of off-days for week i falls into two cases:

TABLE 4 Worker Categories

Category	Weekend 1	Week 1	Weekend 2
Type $T1$	off	no off-days needed	off
Type $T2$	off	one off-day needed	on
Type $T3$	on	one off-day needed	off
Type $T4$	on	two off-days needed	on

Case 1: If the list of off-day pairs contains nondistinct pairs of the form (k, k), for some day k, then week i is scheduled in precisely the same way as week 1 and is independent of week $(i - 1)$.

Case 2: If all off-day pairs are distinct, of the form (j, k) where $j \neq k$, then all employees of type $T3$ and $T4$ in week i are associated with the same pair of off-days that they received in week $(i - 1)$. The type $T4$ are given both days off and the type $T3$ get the earliest day of the associated pair. The $T2$ employees get the remaining days of the $T3$ pairs. In this instance, the maximum possible work stretch will be five days.

Example 1:

day j	1	2	3	4	5	6	7
	Sun.	Mon.	Tue.	Wed.	Thu.	Fri.	Sat.
required:	4	4	5	5	7	7	5

where each person requires one out of three weekends off. $A = 1$; $B = 3$, and $n = 5$. Then:

$$L_1 = \left[\frac{3 * 5}{(3 - 1)}\right] = 8; L_2 = \left[\frac{37}{5}\right] = 8; L_3 = 7$$

The minimum workforce is $W = 8$. $(W - n) = 3$, which is how many workers are assigned off each weekend. The schedule after assigning the weekends off looks like Table 5.

After the weekends off are assigned, there are eight people available to work each weekday and five on the weekends. The surplus is:

day j	1	2	3	4	5	6	7
surplus S_j	1	4	3	3	1	1	0

Because of ties in the surplus, there are many different ways to make the pairs of off-days. The following is one list of pairs that would be generated using the algorithm as stated:

List 1: (Mon., Tue.), (Mon., Wed.), (Mon., Tue.), (Mon., Wed.), (Tue., Wed.)

Two features of the pair-choosing algorithm are incorporated in its design. The first is that the surplus workers on any one day, when the selection is completed, will be made as even as possible. The second feature is that, if at all possible, nondistinct pairs will be avoided. As far as the proofs of the optimality of the algorithm are concerned, only the second feature is necessary. This means that any other algorithm for choosing the pairs is acceptable as long as it does not unnecessarily create nondistinct pairs. The quality of the schedules can be improved by modifying the step of the algorithm that chooses the pairs of off-days. If list 1 above is used, the resulting schedule will have two features that are considered to be bad in schedules. The first is that there will be single-day work stretches where a person has a day off followed by a working day followed by a day off (on–off–on). Such a feature is not wanted by either management and the workers. The second poor feature is there are type 4 workers who work both weekends of a week and who will receive nonadjacent days off. If at all possible, this should be avoided.

TABLE 5 Example 1: Assigning the Weekends Off

Employee	S	S M T W T F S	S M T W T F S	S M T W _ _ _
1	X	X		X	X
2	X	X			
3	X	X			
4			X	X		
5			X	X		
6			X	X		
7					X	X
8					X	X

Some published research papers suggest that using heuristics after the schedule is built can minimize the single-day work stretch. It is often possible to choose a different set of pairs of days off, before creating the schedule, that will result in no single day work stretches or split days off for the type 4 workers. We will improve the schedule of this example, but first it should be clear that it is not always possible to remove all the single day work stretches.

Selkirk (1999), a doctoral student of Burns, published a thesis that shows that for some problems, a new bound that increases the size of the workforce needs to be introduced to ensure that the single-day work stretches are avoided. He gives very complicated, optimal polynomial time algorithms for different subsets of the single shift scheduling problems. These algorithms are beyond the scope of this article but are mentioned here to show that heuristics cannot always be used to eliminate single-day work stretches.

The quality of the schedules can be improved if the cause of the poor schedules can be avoided when creating the off-day pairs. By applying the method for choosing pairs by Burns and Carter (1985), it is ascertained that nondistinct pairs can be avoided. The example has two type 4 workers each week. A type 4 worker who just becomes a type 4 worker in week i must have worked the weekend in the previous week and had one other day off, and therefore was a type 2 worker in the previous week. In the algorithm, this person gets both days of the associated pair off in week i. If all the pairs were adjacent pairs, then there would be no problem. Therefore, one goal in picking the pairs is to have as many pairs of adjacent days as is possible when type 4 workers are required.

The single-day work stretches are caused by two types of pairs. The first are the pairs (Mon., Tue) and (Thu., Fri.). In the algorithm the person who has Sunday at the beginning week off gets the latest day of the pair. This means that for the pair (Mon., Tue.) they would receive the Tuesday off after having the weekend off, thus creating a single-day work stretch. Similarly, the person having the weekend off at the end of the week receives the earliest day of the pair off, which for the pair (Thu., Fri.) will give him or her Thursday and Saturday off, which creates a single-day work stretch. The algorithm used for choosing the pairs of days off should avoid creating these two troublesome pairs.

The second cause of single work stretches is having a type 4 worker receive both days of a pair off, where the days in the pair are separated by only one day. This pairing should be avoided when type 4 workers exist in the schedule.

There are other quality of work schedule considerations. For example, if the demand on Saturday is different from the demand on Sunday, then it is possible to give days off on one of the weekend days. Workers prefer to have weekend days off. The pair (Mon., Fri.) is also useful because it can be exchanged in the schedule for any pair and still maintain a maximum work stretch of six days.

A new list of off-day pairs can now be prepared for example 1, taking into consideration the quality considerations just discussed.

List 2: (Sun., Mon.), (Tue., Wed.), (Tue., Wed.), (Tue., Wed.), (Mon, Fri.)

In week 1, the algorithm will assign adjacent pairs from the beginning of the list. In subsequent weeks the type 4 workers will either receive a pair of adjacent days or will receive the pair (Mon., Fri.). With a little thought, it is easy to see that this pair can be exchanged with any other pair of type 3 and type 4 workers without violating the work stretch constraint of any of the three people involved in the switch.

The final schedule is shown in Table 6.

In week 2, worker 3, a type 4 person, would have received the pair of off-days (Mon., Fri.), but this can always be switched with any paired workers of type 2 and type 3 receiving days off from

TABLE 6 Example 1: Assigning the Weekdays Off

Employee	S	S M T W T F S	S M T W T F S	S M T W _ _ _
1	X	X X	X X	X
2	X	X X	X X	
3	X	X X	X X	
4		X X	X X	
5		X X	X X	
6		X X	X X	
7		X X	X	X
			X	
8		X X	X X	X
surplus		1 0 0 0 1 1 0	1 0 0 0 1 1 0	

the pair (Tue., Wed.), so the first and fourth workers were used for the switch. The final schedule has no single workday stretches, and all type 4 workers have pairs of adjacent days off.

The bounds for the minimum number of workers required can be used for other purposes. For example 1 above, if a part-time worker is hired for Saturday, the variable n is reduced to 4. Bound L_2 still requires that 8 workers be hired, but the frequency of weekends off can be increased to every second weekend off without hiring more workers. For $A = 1$, $B = 2$, $n = 4$, the bound L_1 will still be 8. An interesting result will be that in the final schedule, the surplus workers on the weekdays will be increased because more days off will be given on the weekend for the same 8 people. The employer will need to find work for these surplus people, if possible.

One way of eliminating surplus workers in the final schedule is to hire part-time workers for the weekend, and for the weekdays to have the bounds given by L_1 and L_2 equal. Extra part-time workers would be hired to ensure that the bound L_2 is divisible by five.

The bounds given are very general and can be used for much more complicated scheduling problems. For example, Burns (1981) showed that the same bounds are sufficient for the problem having multiple eight-hour shifts with different demands on the shifts, and with the restriction that there must be at least 24 hours off between shift changes. As mentioned above in the reference to Selkirk (1999), enforcing no single-day work stretches may necessitate increasing the size of W by using a new bound.

Adjacent days off is another restriction that has drastic implications when the maximum work stretch is restricted to six days. The six-day work stretch restriction is the key factor. Burns and Koop (1984) explored this case and found the following:

- There are very few possible schedules.
- It is no longer possible to have each worker work exactly five days per week as is shown in Table 7. Instead, the number of days worked averages five days per week over the B week period of the cycle.
- The number of workers will need to be increased drastically from the same problem where single days off are allowed.

Consider the lower bound L_1, based on the weekend constraint. In most practical problems, the weekend constraint will be tight because it is desirable to give as many weekends off as is possible with the current work force. If the work stretch is limited to six days and all days off must be adjacent, then for each string of weekends off, a worker must have either the Saturday off in the week preceding the string of weeks or the Sunday off after the string. Table 7 illustrates this by giving the only two possible schedules, each with two work stretches of six days, and one of three days, for the example of one weekend off in three weeks.

A new weekend bound needs to be calculated. The bound is constructed as before, using the obvious fact that the weekend shifts available from W workers over B weeks must be greater than or equal to the shifts needed on weekends in B weeks. If all the weekends off are given sequentially, followed by all the weekends worked, each worker will only need one extra weekend day off. If the weekends off are separated by worked weekends in the B week cycle, then more single weekend days off will be needed, which might require more workers.

$L_{1\,\text{paired}}$: Available weekend shifts $\geq$ required weekend shifts

$$[2(B - A) - 1]W \geq 2Bn$$

$$W \geq \left\lceil \frac{2Bn}{2(B - A) - 1} \right\rceil$$

Table 8 gives the values of the new and old bounds for some of the frequencies of weekends off found in practice.

The most startling result is for every second weekend off, where the number of workers needed in the schedule must have all paired days off doubled! Even for the other two cases, the number of

TABLE 7 Paired Days off, $A = 1$, $B = 3$

S	S M T W T F S	S M T W T F S	S M T W T F S	S
X	X X	6 days	X X 6 days	X X
X	X 6 days	X X 6 days	X X	X X

TABLE 8 All Paired Days Off Compared to Some Single Days off

Frequency of Weekends Off A	Cycle Length B	L_1 paired	L_1
1	3	$2n$	$3n/2$
2	5	$2n$	$5n/3$
1	2	$4n$	$2n$

workers needed increases by a large percentage. To reduce the surplus workers that would be scheduled for weekdays, the demand for workers on weekends would need to be reduced by hiring part-time workers for weekend shifts and hiring fewer full-time workers.

Shift scheduling is like job shop scheduling in that a small change in the problem statement results in an entirely new algorithm being needed. Since Burns and Carter (1985) solve the most general problem available with variable demand, why produce special algorithms for more restricted cases? The answer is that for more restricted cases, better schedules can be guaranteed. Several cases, such as constant demand each day, or a fixed demand of N for the weekdays, and a demand of n for both weekend days, have been addressed in the research literature. The algorithms presented for the case where $N \geq n$ are easier to implement and to prove that they are optimal. One the main differences is in picking the list of paired days off. However, the Burns Carter (1985) method, with the paired-off list modified, as suggested in this article, will solve all of these cases.

A second class of single-shift scheduling problems occurs when the demand pattern changes by shortened time intervals within a day. The demand for telephone operators and cashiers in retail stores may vary by the hour or half hour or by even less time. In some cases it is also necessary to build schedules that give the workers lunch breaks and coffee breaks while ensuring that the demands are met by the workers not on breaks. Most retail stores are closed for several hours a day. It is not necessary to consider shift rotation times from one day to the next, which makes it a single-shift problem, even though there will be many different shifts during the day. There are the same three steps with this type of scheduling as with the problems where the demand is constant over a shift: determining the demand; creating the schedules that meet the demand at the lowest cost possible; and meeting the scheduling needs of the people who work the schedule.

Many of the big chain stores have a database and computer software that can predict the requirements for the days to be scheduled, based on annual history and recent history that will account for trends. Exponential smoothing, running averages, or other methods can be used to predict the daily demand. Adjustments must be made based on weather conditions in the past, special promotions, or other predictable influences.

There are several methods reported in the literature dealing with creating the schedules, given the demand. One way is to use mathematical programming methods such as linear or integer programming. Other approaches such as Segal (1974), using network flows, Henderson and Berry (1976), using heuristics, and Glover and McMillan (1986), using a taboo search, have addressed the problem of determining the shifts to be worked on one day. But why are these methods not used extensively in practice? One of the reasons is that the demand is not cyclic. The daily demand continues to change each day of the year and from year to year. The scheduling problem needs to be solved every day, for every company location, and in some instances, for different groups of workers in each location. What is done in practice? Many retail stores are given the demand pattern expected for the next scheduling period by a central computer system, while others create the demand pattern locally. Some stores are given schedules from a central location, but in many cases these have not proven to be very useful. Management in the store usually create the schedules manually. The task is time consuming and unrewarding because workers are often unhappy with their schedules.

The methods currently used for this time-varying demand problem do not address the assigning of full-time workers to have a maximum work stretch of six days, or weekends off with a given frequency, or any constraints on the pairing of off-days, or, in fact, any conditions linking one day to the next. Research for the fixed-shift requirement, cyclic demand work, and research for the time-dependent, noncyclic demand case have been developed in parallel with little if any crossover. There is no need for this separation. The following is an outline of a method for creating the shifts needed and the schedules that will satisfy the full-time workers' requirements for good schedules, followed by a method of creating shifts for the part-time workers to complete the total schedule.

The suggested methods presented below are extracted from the retail shift scheduling algorithms used in Burns (1999). In a commercial computer package, there are many small details and specifics of the particular installation built into the algorithms. For example, the third step below would be modified based on how many hours the operation is open and on the number of peaks in the demand pattern. While important to the scheduling efficiency, these specific features are not necessary to the understanding of the method.

In any particular location, there will be a core of W full-time staff and many part-time staff. The full-time staff will have a set of conditions that need to be incorporated into their schedule, such as A out of B weekends off, a maximum work stretch of six days, and five days per week of work. Schedules for the full-time workers will be considered first.

Step 1. Calculate the demand pattern to be satisfied by the W full-time workers.

Shifts available on the weekend $= (B - A)W$

Shifts required $= Bn$, where n is the demand to be satisfied by full-time employees

Therefore, $Bn \leq (B - A)W$, or

Weekend shifts available from full time workers is given by

$$n = \left\lfloor \frac{(B - A)W}{B} \right\rfloor$$

where $\lfloor x \rfloor$ is the largest integer contained in x.

Assuming at least N shifts per weekday are to be satisfied by full-time people, the average number of shifts per weekday from full-time workers is given by

$$N = \left\lfloor \frac{5W - 2n}{5} \right\rfloor$$

If rounding down was done to create N, then let k be the number of eight-hour shifts rounded down, which is given by $k = (5W - 2n) \bmod (5)$. k weekday shifts will need to be created in the schedule, in addition to the N shifts each weekday.

The k shifts will be added to the N shifts on weekdays, requiring the most number of workers while ensuring that the maximum required per day does not exceed W, or will be distributed evenly so that the final demand pattern will be as follows:

Sunday $= d(1) = n$. Saturday $= d(7) = n$. The weekdays have demand of either $d(i) = N$ or $d(i) = N + a$, where $a =$ the number of extra shifts, from the k shifts, that have been allocated to day i, $i = 2, 3, 4, 5, 6$.

Step 2. Use the Burns and Carter (1985) method with the list of off-day pairs, as modified above, to schedule the W full-time workers to the next week. Since the method is iterative, the starting position, after the first time that the algorithm has been used, will be from the previous week, using the list of off-day pairs in existence. After step 1, the number of full-time shifts required per day is known, and after step 2, who will work the shifts is known; but when the full time shifts will actually start within a day has not been determined.

Step 3. Create the shifts to be worked on each day of the schedule, using the part-time workers as well as the full-time workers.

Let $s(j)$ be the number of people needed in each time period of the day being considered. The time period could be an hour, a half hour, or just 15 minutes. Let d be the requirement for eight-hour shifts on the day being considered. The algorithm will try to schedule the eight-hour shifts first and then five-hour part-time shifts. The selection of five hours is arbitrary and could be changed depending on the installation. The algorithm may need to complete the first pass at allocating part-time shifts by using shifts as short as three hours. Then the method will assign lunch breaks and coffee breaks. The final pass will be to add shifts where needed, and reduce shift lengths where needed.

Creating the eight-hour shifts: Start at period $k = 1$.

If $s(k) > 0$, let m be the minimum of $s(k)$ and d. Create m eight-hour shifts, starting at period k. Set $d = d - m$ and $s(j) = s(j) - m$ for the eight-hours, starting with period k.

If $s(k) \leq 0$, set $k = k + 1$. Repeat this step to create eight-hour shifts until $d = 0$.

Creating part-time shifts: Start with period k from the previous step.

If $s(k) > 0$, check to see if there is enough time left for a part-time shift. If the time left is at least five hours, assign the shift length L to be five hours. If the time left is greater than or equal to three hours but less than five hours, assign the shift length L to be the time left. If the time left is less than three hours, set L equal to three hours and set F equal to the period that starts three hours before the end of the day. If F was set in this step, start at period F and create $s(k)$ shifts of length L and set $s(j) = s(j) - s(k)$ for all periods from period F until the end of the day. If F was not set in this step, start at period k and create $s(k)$ shifts of length L. Set $s(j) = s(j) - s(k)$ for the L hours starting with period k. Set $k = k + 1$ and repeat this step until all $s(k) \leq 0$.

TABLE 9 Weekly Eight-Hour Shifts for Time-Dependent Workers

Worker	S	M	T	W	T	F	S	S	M	T	W	T	F	S	S	M	T	W	T	F	S
1	X						X	X			X						X				X
2	X			X						X				X	X						X
3			X				X	X						X	X		X				

The final steps are straightforward in principal but complicated in detail. Assign all the break times needed, using the surplus workers wherever possible, that is, where $s(k) < 0$. Then either add part-time shifts where $s(k) > 0$ or increase the length of a part time shift to reduce $s(k)$ to zero. Finally, try to reduce the length of part-time shifts to increase $s(k)$ to 0 wherever $s(k) < 0$.

The entire algorithm is repeated for all the days that are to be scheduled. An important output from the algorithm is the printed reports giving the schedules and who is to work each shift. The full-time people have been assigned using the method as outlined in this section. The part-time people will be assigned using the work of Section 3.4.

The algorithm is easy to computerize or to do manually and is very fast because the amount of work is polynomial.

Example 2: Time-variant, single-shift scheduling:

Consider a retail store that is open from 9 a.m. to 9 p.m. There are three full-time employees requiring every second weekend off, a maximum work stretch of six days, and five days of work per week. The required number of people is given in Table 10 in half-hour intervals. All eight-hour shifts must have a lunch period of a half hour; coffee breaks will not be scheduled but will be given during the day as time is available. The part-time shifts must be at least three hours long and can be up to five hours long.

From the facts given, $A = 1$, $B = 2$, $W = 3$ and from step 1 of the algorithm,

$$n = 1, N = \left[\frac{15 - 2}{5}\right] = 2, k = 3$$

There will be three weekdays with three workers required and two with two required. At this point, looking ahead to step 2 of the algorithm is useful. The modification to selecting the paired off-days above suggests that (Mon., Tue.) and (Thu., Fri.) pairs should be avoided to eliminate one-day work stretches for the full time workers, and we need $n = 1$ pairs of off-days. If the three extra working days are given to Wednesday, Thursday, and Friday, the only pair of off-days would be (Mon., Tue.), which is undesirable. To help make better schedules, the three extra workdays will be assigned to Monday, Thursday and Friday leaving (Tue., Wed.) as the pair of off-days for step 2 of the algorithm. Sunday $= d(1) = 1$, $d(2) = 3$, $d(3) = d(4) = 2$, $d(5) = d(6) = 3$, $d(7) = 1$.

In step 2 of the algorithm $(W - n) = 2$ people are given the weekend off each week. Table 9 gives the schedule for the eight-hour full-time workers.

Because there are no choices of days off when creating the schedule, the schedule is cyclic, with a period of three weeks; that is, the schedule is the first week repeated. For step 3 of the algorithm, completing one day will be sufficient to illustrate the algorithm. Consider a Thursday, with the requirement for workers given in Table 10.

Step 3 first assigns the following shifts:

Eight-hour shifts starting at periods 1, 3, and 4

Five-hour shift starting at period 5

Three-and-a-half hour shift starting at period 18

Two three-hour shifts starting at period 19

Lunch breaks can be assigned to several places. Choose the half hour lunch break for the eight-hour worker number 1 to start at period 7, worker 2 at period 8, and worker 3 at period 9 and start a new three-hour shift to start at period 7 to cover for the lunch breaks. The current status of the worker requirement table is given in Table 11.

Using the last part of the step 3, the five-hour shift starting at period 5 would be reduced to a three-hour shift, and the three-and-a-half-hour shift starting at period 18 would be reduced to a three-hour shift. The final schedule would have the following shifts:

Eight-hour shifts starting at periods 1, 3, and 4

Three-hour shift starting at period 5

Three-hour shift starting at period 7

Three-hour shift starting at period 18

Two three-hour shifts starting at period 19

The final status of the worker requirement table is given in Table 12.

For the problem requirements and scheduling restrictions, the schedule is optimal. Two of the extra shifts could be removed if the minimum part time shift is reduced to two-and-a-half hours from three hours.

4.2. Multiple Eight-Hour Shift Crew Scheduling

As discussed in Section 3.2.1, a continuous operation working four complete crews has 2 hours of overtime per week per crew. Switching to 12-hour shifts or 8-hour shifts will not remove the problem. Later in this section, some special schedules for the mining industry are presented where the work to be done is reduced for short periods of time and no overtime occurs. In continuous operations, one industry standard is to have no single days off and to allow seven-day work stretches. Because the demand is constant, 24 hours a day for every day, it is possible to have as goals the following: a good schedule will have shift rotations always moving forward, that is, day to evening to night shift; a good schedule will also have three days off after the night shift, if possible, and will not start a weekend off after working the night shift on Friday, because the worker would need to sleep most of the Saturday. Tables 13 and 14 are two different schedules for four crews, each having the desired properties. In the schedules d, e, n are 8-hour shifts for the day, evening, and night respectively. As with the single-shift schedules, a crew (person) starts on each line and when a line is finished moves to the next line, with the first line being next after the last line.

Crew schedule 1 is the more standard type of shift rotation, whereas crew schedule 2 has the fast rotation of shifts that some places like to work. Note that, as expected, each crew only has seven days off in four weeks, which means they work eight hours overtime in four weeks.

If a maximum work stretch of six days is required, then a 24-week cyclic schedule can be made. An 8-week schedule forms the basis for the schedule and is repeated three times, with the starting shift changed each time. The starting shift will be determined by just continuing on the shift that was being worked at the end of the cycle. Table 15 gives the basic schedule that is worked by all four crews, starting the cycle with one crew on each of weeks 1, 7, 13, and 19.

Over the years, the author of this article has worked on numerous consulting projects for personnel scheduling. Repeatedly, the consulting has been initiated because a company signed a new contract with the union and then found that they either could not create any schedules to match the contract conditions or could not create schedules without a considerable increase in labor costs. The motive

for moving the start of the week in single-shift scheduling to be Sunday rather than Monday was one such instance, and the analysis of the cost of having paired off days, with a maximum work stretch of six days, was another. Multishift crew scheduling presented a third case of having an impossible contract signed. A mining company agreed that all overtime would be voluntary and all workers would work exactly 40 hours each week (lunch and other breaks occurred within the 40 hours). The company thought that they could change to 12-hour shifts to solve the problem. Although scheduling with extended length shift will be discussed in Section 4.4, for the sake of completeness, crew scheduling using 12-hour shifts will be included in this section. In particular, schedules for the mining industry will be discussed because it is often possible to work partial crews for a short period of time and still keep the above-ground processes working. The goal in doing this is to eliminate the overtime for the workers. When there is a partial crew working, other workers can do maintenance on the mine tunnels not in use. The methods presented are abstracted from Burns (1983).

With 12-hour schedules, the problem of working an average of 40 hours per week is difficult because 40 hours for one week, and even 80 hours for two weeks, are not divisible by 12. There are many ways of resolving this issue, and for the following examples the schedules will have six shifts of 12 hours, and one shift of 8 hours every two weeks, which has all workers average 40 hours per week every two weeks. As before, d and n are used for 8-hour day and night shifts. D and N are used for the 12-hour day and night shifts respectively. A new piece of notation is needed.

$[x/y]$ means that the crew is divided in half and the first half works shift x and the second half works shift y. If $x = d$ and $y = D$, then the first half of the crew will work an 8-hour shift and have 4 hours off while the other half of the crew is working a 12-hour shift. Table 16 is just one of many schedules that can be created for the mining industry. Each crew (person) works exactly 80 hours in each two-week schedule. On Monday, Tuesday, Friday, and Saturday there is a 4-hour period with only half a crew working.

The times of the 8-hour shifts can be moved to have two maintenance shifts of eight hours each by giving one day in every second week where there is an 8-hour shift for both halves of the crew at the same time, instead of where it is in Table 16.

The 12-hour schedule in Table 16 solves the overtime problem for the mine, but not the condition that each worker must work exactly 40 hours per week. It is possible to use 8-hour shifts and to have one full maintenance shift every Monday where no regular crew is working. In this case, everyone works exactly 40 hours per week and the overtime can be voluntary. The essence of the solution is that the reduced production happens on only one of the 21 shifts in a week. Table 17 illustrates this schedule, which is a slight modification to the schedule in Table 13. Note that on Monday there is no crew scheduled to work on the day shift. Voluntary overtime could happen on that shift.

4.3. Multiple Eight-Hour Shift Scheduling for Individuals

In addition to the requirements of the single-shift scheduling problem, there are the difficulties outlined in Sections 3.1 and 3.2.2. With the crew scheduling problems the goals included having shifts rotate forward and having three days off after completing night shifts. The methods of this section do not include these goals, because the need for workers is different for different shifts. In the research literature there are two approaches to the problem. The first, by Burns (1981), is an iterative algorithm for a very general shift scheduling problem involving eight-hour shifts. This paper presents an optimal, linear time algorithm to schedule the following problem:

- There are P shifts of length eight hours each day and the start times may overlap.
- The demand N_j per shift j, for weekdays Monday to Friday, is met and the demand n_j per shift j, for weekends Saturday and Sunday, is met, with $N_j \geq n_j \geq 0$ for all shifts $j = 1, 2, \ldots P$.
- Each employee is given at least A out of B weekends off.
- Each employee works exactly five out of seven days in each week, with the week defined as Sunday to Saturday.
- Each employee works no more than six consecutive days.
- Each employee who works two consecutive weekends has a pair of consecutive days off during the week.
- Each employee has at least one day off when changing shifts. Because shifts can have overlapping start times, the algorithm yields at least $(24 - t)$ hours off between shift changes, where, if the completion time of the last shift on one day is less than or equal to the start time of the first shift on the next day, t is the negative of the number of hours difference, otherwise t is just the difference in hours.

After the algorithm is described, ways of extending the use of the algorithm to more problems will be presented.

The first steps of the algorithm are almost identical to the modified Burns and Carter (1985) algorithm of Section 4.1. Since the demand pattern has been restricted to being the same for each weekday and the same, but of a different value, for each weekend day, rather than totally variable, the extra condition of having pairs of adjacent days off for the type $T4$ workers can be incorporated. Surprisingly, no change in the size of the workforce is required for the multiple shift problem, and the same bounds can be used.

Step 1. Compute the minimum workforce size. Set

$$n = \sum_{j=1}^{P} n_j, \text{ and } N = \sum_{j=1}^{P} N_j$$

and use n as the demand on weekends and N as the demand on weekdays to calculate the bounds on the workforce W as in the Burns and Carter (1985) algorithm.

Step 2. Schedule the weekends off. Schedule the weekends off as in the Burns and Carter (1985) algorithm.

Step 3. Determine the additional off-day pairs. Select n pairs of off-days cyclically from the list (Mon., Tue.), (Wed., Thu.), (Thu., Fri.), (Tue., Wed.), (Mon., Fri.).

Step 4. Assign off-day pairs in week 1. Use the categories of workers from the Burns and Carter algorithm. Assign $|T4|$ pairs of adjacent off-days to employees of type $T4$. Associate each employee of type $T3$ with an employee of type $T2$. From the list of pairs of off-days not yet assigned, assign the earliest day of each pair to a type $T3$ employee and the latest day to the associated type $T2$ employee.

Step 5. Assigning shifts in week i, ($i \geq 1$). For each week of the schedule, a total of n shifts are required on the weekends and N shifts on the weekdays. These requirements are met by forming n chains [Sun.–Sat.] and N–n chains [Mon.–Fri.] that are pair-wise distinct. A [$d1$–$d2$] chain, for $d1 < d2$, is a sequence of $d2 - d1 + 1$ workdays, taken from one or more employees. Two chains are pair-wise workday disjoint if no employee workday is a member of both chains. A [$d1$–$d2$] chain is formed by starting with an employee who works on day $d1$. This employee's workdays are assigned to the chain until either day $d2$ is reached or the employee has a day dk off, ($d1 < dk < d2$). In this latter case, the chain is transferred to a new employee who works on day dk but had day $dk - 1$ off. This new employee's workdays are then assigned to the chain. This process is continued until day $d2$ is reached.

Construct the (N–n) chains [Mon.–Fri.], first using employees of type $T1$ and pairs of type $T2$ and $T3$ employees who are associated with adjacent off-days. The type $T1$ employees form a [Mon.–Fri.] chain by themselves, while a [Mon.–Fri.] chain started with a type $T2$ employee can be completed by its associated $T3$ employee.

The n chains [Sun.–Sat.] are constructed once the current schedule has been temporarily modified so that exactly n workers are available each day, where ''available'' means an employee does not have the day off and has not already been assigned to a [Mon.–Fri.] chain. Sunday and Saturday already have exactly n workers available, but the weekdays may have more than n. Remove the excess workers for each weekday, starting with Monday, by temporarily giving an employee an extra day off as needed, if that employee would have started working that day. An employee would have started working on a particular day if he or she is not scheduled to have the day off and if, on the previous day, he/she had an actual day off or a designated extra day off. Then form the n chains [Sun.–Sat.], starting with any employee who is scheduled to work on Sunday, in the same way that [Mon.–Fri.] chains were formed.

The chains must now be assigned to shifts. Prior to this, however, it is necessary to associate the extra days off with chains so that they will also be assigned to shifts. Start with any extra days off that are immediately followed by a workday that is assigned to a chain. Associate this extra day off and any extra days off that precede it, back to an actual day off, with that chain. Once this is done, the only extra days off remaining are those that fall between two actual days off. Associate these extra days off with any [Sun.–Sat.] chain at random.

The (N–n) chains [Mon.–Fri.] and the n chains [Sun.–Sat.], with any extra associated workdays, must now be assigned to shifts. If it is week 1, assign the [Sun.–Sat.] chains to the P shift types according to n_j, the number of employees required for each shift of type j. If it is week i, ($i \neq 1$), assign the [Sun.–Sat.] chains to the same shift as the Saturday preceding the Sunday. In either case, assign the [Mon.–Fri.] chains to the shifts required to make the N_i–n_i weekday chains.

Step 6. Assigning off-day pairs in week i, ($i \neq 1$). Assume that weeks 1 up to ($i - 1$) have already been scheduled. As in step 4, each employee can be categorized into one of four types $T1$, $T2$, $T3$, and $T4$.

For each employee who is type $T4$ in week i, who was of type $T4$ in week ($i - 1$), assign the same pair of off-days that he or she received in week ($i - 1$).

For each employee who is of type $T4$ in week i, who was of type $T2$ in week ($i - 1$), and who was associated with a pair of adjacent off-days, assign both days of that pair in week i.

For each employee who is of type $T4$ in week i, who was of type $T2$ in week $(i - 1)$, and who was associated with a pair of nonadjacent off-days in week $(i - 1)$, trade pairs of off-days with an employee who was of type $T4$ in week $(i - 1)$ but is of type $T3$ in week i.

For each employee who is of type $T3$ in week i, assign the same pair of off-days that he or she received one off-day from in week $(i - 1)$, or the interchanged pair from above. The type $T3$ employees get the earliest day of the pair, while the type $T2$ employees get the remaining latest days off.

Go to step 5.

Example 3: Multiple-Shift Eight-Hour Schedules:

A company has a seven-day-a-week operation with four shifts working each day, with the following demand for workers.

Shift	Time	Weekdays	Weekends
1	Midnight to 8 a.m.	1	1
2	8 a.m. to 4 p.m.	2	2
3	1 p.m. to 9 p.m.	3	2
4	4 p.m. to midnight	1	1

Each worker is to receive at least one weekend off every three weeks; the maximum work stretch is to be six days; any worker working both weekends of a week will have a pair of adjacent days off in the week.

Step 1: $N = 7$ the daily demand on a weekday, and $n = 6$ the daily demand on the weekends.

$$L_1 = \left\lceil \frac{3 * 6}{2} \right\rceil = 9,\ L_2 = \left\lceil \frac{5 * 7 + 2 * 6}{5} \right\rceil = 10$$

Therefore, $W = 10$.

Step 2: Table 18 shows the results of step 2.

Step 3: Choosing six pairs of days from the list gives the following pairs: (Mon., Tue.), (Wed., Thu.), (Thu., Fri.), (Tue., Wed.), (Mon., Fri.), (Mon., Tue.).

Step 4: There are two type $T4$ workers every week (workers 9 and 10 in week 1). Assign the first two pairs from the list to workers 9 and 10. Associate workers 5&1, 6&2, 7&3, and 8&4, assigning the next four pairs from the list to get the weekday assignment for week i in Table 18.

Step 5: In this example, N is one bigger than n so one chain [Mon.–Fri.] needs to be constructed. Fill in this chain with a string of the letter A in Table 19 and then fill in the extra shifts with the letter Y to get the result in Table 19.

Completing step 5 using the letters B, C, D, E, F, G for the six chains, starting with workers 5–10, yields Table 20. The shifts assigned would be $B = 1$, $C = 2$, $D = 3$, $E = 4$, $F = 2$, $G = 3$, and $A = 3$, and the extra shifts would be removed to give the schedule after week 1.

In step 6 for week 2, the new type $T4$ workers are workers 3 and 4. Worker 3 is associated with worker 7 and assigned to the off-day pair (Mon., Fri.), so he or she must be interchanged with worker

9, who became a type $T3$ worker. The new associations are: workers 9&7 assigned to pair (Mon., Fri.), worker 3 assigned to pair (Mon., Tue.), worker 4 assigned to pair (Mon., Tue.), and worker 8, who was associated with worker 4, joins the association 10&8 assigned to pair (Wed., Thu.). Table 21 gives the completed schedule for the first two weeks.

The algorithm works for situations where the shift demand on Monday to Friday is at least as big as on the weekends. For situations where the weekend demand is larger, the algorithm can still be used if part-time workers are hired to reduce the weekend demand to the required level. Any problem where the frequency of weekends off is greater than or equal to one off in two weeks will have no type $T4$ workers. Step 4 of the algorithm illustrates that clearly. Hence, for these cases the need for adjacent pairs disappears. One would think that the list could be modified, as was done above for the single-shift Burns and Carter (1985) algorithm, in order to reduce the number of single-day work stretches. Unfortunately, the proofs of optimality and feasibility require the existing list. All is not lost, though. Since the demand is constant for the week, it is relatively easy to modify the algorithm to ignore the list of off-day pairs and dynamically assign the days off to the type $T4$ workers as needed. Then assign the type $T3$ workers days off from Monday to Wednesday, and then assign days from Wednesday to Friday to the type $T2$ workers. A computer program can do this, along with the necessary checks to assure feasibility.

A second, completely different approach to the eight-hour scheduling problem was presented by Burns and Koop (1987). In this approach a master rotation is created rather than using an iterative algorithm. The method is optimal and works for the situation where there are three shifts a day, the weekday demand is at least as large as the weekend demand, the maximum length work stretch is six days, and each worker must have at least A out of B weekends off. A library of minischedules called modules is given, and the complete schedule is created by combining the modules. There are many situations where master shift rotations are either preferred or required; for example, in Canada, all nurse schedules and all prison guard schedules must be master rotations.

Rather than the methods of Burns and Koop (1987), a slightly different method that also uses modules to build optimal master schedules will be presented. In Burns (1985) the modules have two extra properties: the number of shift rotations is controlled and the workers receive exactly A out of B weekends off rather than the maximum number off that is possible. These modules have been used extensively to create schedules in hospitals and prisons.

The module library is separated into different categories, such as 8-hour vs. 12-hour shift. Even greater separation is created. Some modules are for people who rotate shifts, and some are for people who work a fixed shift. Within a workplace both types of schedules are often needed. In addition, there may be a group of people that want specific characteristics for their schedule, and these characteristics may differ for other groups.

The whole library of modules is too extensive to give in this work, but a sample will be given, along with enough information to show how to create modules. Having seen a sample, the reader should find it relatively easy to begin creating his or her own modules for different situations.

The reason that modules work so well in practice is that given a specific situation, there are often only a very small number of possible schedules. In addition, constructing the modules as outlined below means that the whole system works like building blocks for the complete schedule.

Consider situations such as nurse scheduling. The following is a set of basic requirements that apply in many hospitals: employees are to have one weekend off in three weeks; the maximum work stretch is six days; shift rotations to a shift that starts at an earlier time than the current one are to be done only after at least one day off; weekends off cannot start after an evening or night shift on Friday, where the night shift is the last shift of the day; employees are to work at least 50% of their time on day shift; there must be no single-day work stretches; there must be at least two days off after working a stretch of night shifts. The last restriction is necessary because if someone worked the night shift on a Tuesday, which ended, say, at 7:30 Wednesday morning, then had Wednesday off during which he or she spent most of the day sleeping, and then returned to work on the next day at 7:30 a.m. on Thursday, he or she would not really have had a very useful day off. As shown in Section 4.1, having all adjacent days off increases the number of nurses needed and reduces the possible schedules to two, which is not much choice.

The first example uses all the basic requirements, plus allowing only one single day off in the three-week cycle. The expectation is that there should be more feasible schedules than when the restriction is to have all paired off-days, but in fact there are only two possible ways of giving the days off. Table 22 shows the two basic schedules, and Table 23 shows the four possible schedules for the day (d) and evening (e) shift. Since there are only two possible ways of giving the days off, Table 22 also shows that it is not possible to give anyone a Wednesday off. This fact should be kept in mind when negotiating or promising schedules. Note that if module 1 is followed by module 2, it should be possible to have two people working on each shift every day of the week, with the extra two people on Wednesday as expected. Table 24 gives a six-week cycle with the shift assignments that give the even coverage for the two shifts.

d	1	2	2	2	0	1	1

For the modules with day and evening shifts, d/e modules 1, 3, and 4 can be converted to the d/n modules 1, 3, and 4, with the evening shift replaced with a night shift. Because of the one day off at a shift change, d/e module 2 cannot be converted to a d/n module. When a schedule is made, the different building blocks can be used. If the nursing unit required one nurse on night shift, and two on evening shift, with all nurses working all three shifts, then module d/e 5 would be followed by a d/n module. The nine nurses required would each start on a different line of the schedule and rotate in the usual way. Even if there were only seven or eight nurses available, the same schedule would be used because there is no other feasible schedule, and in this case, as the schedule was worked from week to week, part-time nurses would need to be used to fill in the missing shifts. Because all modules start with a Sunday off and end with a Saturday off, the modules can be put together in any order without violating the scheduling criteria. If there are more people required for the shifts, more modules will be used. If there are people who only work days and nights and others who only work days and evenings, the modules can be separated into two different master rotations for the unit.

A different module library can be built for the same basic requirements but allowing two single days off in a three-week schedule. The technique is the same as before, with the modules beginning with the Sunday off and ending with the Saturday off. In between, the four remaining off-days are placed as one adjacent pair of days off and two single days off. Each day off should be on a different day from the others to give even worker coverage, and no one-day work stretches should be allowed. As with building the chains in the iterative method, the last day of the adjacent pair off and one of the single days off should be in different weeks but adjacent days so that a chain of evening shifts is formed. There are only four basic modules that lead to only a few d/e and d/n modules for this case. A schedule can be built using modules from both the one-single-day-off library and the two-single-days-off library to give different schedules.

The iterative schedules given before can be easily computerized. The modular scheduling is much more complicated and involves using a rule-based expert system in the computer program, but the modular system is easy to do manually.

4.4. Multiple Mixed Shift Length Scheduling For Individuals

In the 1990s there were several papers published that dealt with four day work weeks, and work weeks that had either three or four days. As is usual with research, the first set of papers gained some ground with the problem but were not of much practical use. The papers by Hung (1991, 1993, 1994a,b), ignored the length of work stretch and often had work stretches much longer than six days. In addition, some of the work by Hung applies only when the frequency of weekends off is greater than or equal to one out of two, which means that there are no workers of type $T4$ requiring pairs of adjacent days off. Burns et al. (1998) give an algorithm for the single-shift problem that restricts the work stretch to be at most five days and uses a mix of three- and four-day weeks. Burns and Narasimhan (1999) give an iterative method for optimally solving the multiple-shift scheduling problem with a restricted length of work stretch and with either four- or three-day work weeks. The algorithm is easy to understand and implement.

In this work, we will address the much more usual case of scheduling 12-hour shifts. In Burns (1985) there are many different modules given for the 12-hour scheduling problem. Only a few are needed to illustrate both the method of scheduling and the difficulties that can arise. The first difficulty is how to balance the number of hours worked. As explained in the crew section earlier, a common way of balancing the hours is to have one 8-hour shift every two weeks. Table 25 illustrates two basic modules giving every second weekend off, having a maximum work stretch of three days, having no single days off unless in a module having two weekends in a row off, where a single day off is necessary, and having a minimum work stretch of two days. The 8-hour shift replaces one of the 12-hour shifts in the module. By using two modules, with an 8-hour day shift in one and an 8-hour night shift in the other, it is possible to hire a part-time worker for an eight-hour evening shift. Many hospitals use this type of schedule for nurse schedules.

For D/N module 1, any shift can be the 12-hour N, but for D/N module 2, the Friday of the second week cannot be a N shift and still have a ''good'' weekend off. For this reason, many places only use the D/N module 1. Depending on the preferences of the employees, the schedule can have two weeks of nights whenever needed, followed by two or more weeks of days or the day and night shifts can be interspersed within the module.

There is an inherent problem if only module 1 is used to create a schedule. The employees working the schedule are essentially divided into two subgroups: the first working the odd-numbered weeks in the schedule and the second working the even-numbered weeks. These two groups will never work together, as they are never scheduled to work on the same day, let alone the same shift. To avoid this separation of the work force, introducing some of module 2, (or some of module 3 if needed) into the schedule will ensure that the groups see each other.

If fewer people are needed on the weekends than on the weekdays, then as many of the D/N module 3 as are required should be used.

Example 4:

The following are the requirements for workers: two people on night shifts and four people on day shift on weekdays, and two on night shift and two on day shift on the weekends. Because six people are needed each weekday, six modules will be needed. Choosing D/N1 with all the shifts D followed by D/N 1 with all the shifts N, followed by D/N module 3 on days, gives the complete schedule when two people are started on each line.

Carefully placing the 8-hour shifts allows the schedule to be created as in Table 26, with no part-time workers required. Two people are started on each line of the schedule, and each person works exactly 80 hours in every two-week period.

A second type of module can be used where no 8-hour shifts are used. In this type, an extra 12-hour shift is given off every six weeks, rather than 4 hours off every two weeks. Any of the modules can be used to do this, as long as the 12-hour shift given off is at the start or end of a three-day

TABLE 26 Example 4, Schedule 1

X	X	X	D	D	D	X

work stretch. For module 3 above, the single day off would be moved to Thursday and the Friday given as the extra day off, thus creating an off-day stretch of six days. Table 27 gives the schedule for example 4, using only 12-hour shifts. In practice, the hours worked balance over a six-week period but not over the two-week pay periods. Some agreement on overtime rules needs to be negotiated before this approach can be used.

4.5. Hierarchical Workforce Scheduling

Consider the situation where there are m different categories of workers with a definite ranking. Type i workers can do the work of any worker at a lower level j but the reverse is not true. It can be assumed that workers of type i are paid at least as much as, and probably more than, workers of type j for $i > j$. There is a demand for a minimum number of each type of worker on each shift and a cumulative demand for the number of workers of type 1 to type k for each shift. In the hierarchical problem, the requirement is to calculate the minimum number of workers in the most economical mix of types and to give each worker two days off per week and A out of B weekends off. A schedule is to be created with a maximum work stretch of six days for all values of A and B. Workers who must work two consecutive weekends should have two adjacent days off in the week.

Emmons and Burns (1991) solved the case for a single shift and a constant demand for each day of the week. Other papers were published trying extend the work, but they either did not adhere to the six-day maximum work stretch or only worked with the easier case where A of B was greater than or equal to one out of two.

Narasimhan (1993) solved several very interesting problems. He extended the work of Emmons and Burns (1987) to the case where the demand for each category of worker is constant for the weekdays and has a different constant value for the weekend. His work did not require a restriction that the weekday demand be greater than or equal to the weekend demand, and there was no restriction of the frequency of weekends off.

In the same work, Narasimhan also solved the multiple 8-hour, hierarchical workers shift problem for any number of shifts, with the weekday demand greater than or equal to the weekend demand, and he also solved the 10-hour, four-day-a-week problem for the same labor demands.

The algorithms and calculations are complicated but can be computerized. They will not be presented here because they would take too much space and because in practice they are often not applicable. For example, in the health care industry there are different categories of employees that can provide different patient needs. These categories, and the number of workers of each type required per shift, usually fall into a hierarchy that would fit the requirements of this section. However, in many cases the workers belong to different unions and have different scheduling rules in the hours of work clauses of their contracts. Since a single schedule, using one set of rules, could not be used in these instances, separate schedules are made for each category of worker. In some situations, the schedules are made sequentially, with the remaining needs for employees in the next category re-

TABLE 27 Example 4, Schedule 2

flecting the schedules already constructed. Generally, the schedules are done independently, using one of the methods described in this work for the single category of workers.

5. COMPUTER SYSTEMS

Despite the all-pervasive use of computers in society today, computers are not used frequently for shift-scheduling methods. There are notable exceptions in airline crew scheduling and some other industries. However, many health care companies and most retail companies still do manual scheduling. One of the reasons for this situation is the separation of institutional functions by the use of different third-party software packages, each custom-built for one function only. The merging of these companies to integrate such systems has not occurred as it has in the case of personnel records, payroll, and shift scheduling. All three systems must be integrated in a major company to have the shift scheduling work well.

5.1. Personnel Interface

Personnel systems have much of the key information about employees that is needed by a shift-scheduling computer package. The unique identifier to be used, such as a Social Security number or an employee number, is just one such item. Other needed information is a person's seniority and qualifications. Employees often take courses to upgrade their qualifications and are then eligible for a higher-paying position, and this information must be transmitted to the scheduling system on a timely basis. If someone leaves a scheduling group of employees and a new employee replaces that person, the seniority of members in the group changes and hence the schedules may need to be changed. For example, in a hospital, a change in staff may mean that a nurse may be able to move from a schedule of straight night shifts to a day shift schedule.

In industries such as pulp and paper, employees are offered chances to fill in for a higher-paying position whenever an open shift becomes available. If the person refuses the position more than once, he or she is no longer eligible for the position. The status of each employee regarding each position is required by the scheduling system.

5.2. Contract Regulations

When contracts are being negotiated, analysis using the methods of this chapter is very valuable. Calculating the required workforce size for increases in the weekend-off frequency and for any decrease in the work stretch can be done along with the related costs. If changes, such as having all pairs of days off with a work stretch maximum of six days, are contemplated, the increase in cost can be calculated and the paucity of possible scheduling modules can be illustrated.

The bounds given by Burns and Carter (1985) give the workforce size as the maximum of the bound on the total shifts required and the weekend-off bound. If a contract is being negotiated that will increase the frequency of weekends off and the new bound for this increase is higher than the bound on the total shifts required in the old contract, extra employees will be working on the weekdays. What may happen is that the employer will reduce the number of people required on the weekend until the two bounds are equal and then will hire part-time workers for the weekends. Each time the weekend requirements are reduced, the total shift requirements for full-time employees are reduced by two shifts. When the adjustments are done to balance the two bounds, the result may mean that fewer full-time employees are required under the proposed contract changes and more part-time employees will be used, which may not be what the employees want or expect.

5.3. Payroll Interface

Any computer scheduling package needs an extensive database to keep the necessary information to transmit to the payroll program. One copy of the schedule should be posted the required number of weeks in advance, usually six weeks. The employees can then trade shifts with other employees and request the scheduler to allow these changes. If the requested changes violate the contract, they may still be granted, but extra premiums, such as overtime, will not apply. The schedule, as modified with requested and granted changes, will then be saved. Up until a fixed time, say two weeks before the schedule is actually worked, management can make some types of changes without incurring a payable penalty. The final schedule, as it is to be worked, is then saved. The actual schedule worked will be saved, along with any last-minute changes made by management to satisfy unexpected needs or absenteeism. The information transferred to the payroll package will come from this final schedule, with the pay premiums calculated based on when, and by whom, the changes were made. All the information must be archived for later reference.

6. MANUAL SYSTEMS

Manual shift scheduling systems are widely used and for the most part are time consuming and frustrating. No matter how good the schedule, some employees will express discontent. This basically

arises from the fact that all employees want to be home with family and friends at the same time and from the fact that different people have different ideas as to what makes a good schedule. Since many of the people creating the schedules have other tasks to do, the scheduling often gets done at home, on personal time, which is not a good situation for creating good schedules. Computer scheduling would free up the time of the person doing the scheduling and would help divert any unavoidable discontent of personnel to a machine and away from the scheduler.

An interesting result of linking the payroll and the scheduling system arose when Burns first computerized nurse scheduling in the 1980s. The head nurses were able to receive reports on the total hours worked by their full-time and part-time employees. Several nurses were discovered to be working seven days a week by doing part-time shifts in different units. This was deemed to be an unsafe work situation and changes were made to put a stop to the practice. Other work patterns can be detected once the information is put into a general payroll system rather than in a unit-by-unit shift-scheduling system.

Manual systems have a manual entry of data from the schedules worked into the payroll system. Because of the large amount of information that needs to be processed and transferred, as outlined in Section 5.2, errors are inevitable. In addition, extra people are employed just to do the data entry, an expense that can be eliminated with a computer system that is integrated with the payroll system.

For companies that will continue to use a manual system, several things can be done to improve the situation. The people doing the scheduling can be educated and trained to understand the complications of scheduling. The methods outlined in this chapter can be introduced to improve the schedules and decrease the time required to create the schedules.

1. INTRODUCTION

On the surface, companies from industry sectors such as mining, construction, manufacturing, and service would appear to be very different. Certainly, the physical activities involved and the resulting products are different. At a conceptual level, however, each of these companies can be viewed as a

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

complex system trying to utilize its resources to maximize its performance. The ability of managers and workers to control and monitor the operations within such a system has a great impact on its performance.

This chapter addresses three issues related to controlling and monitoring operations in such a system: architectures to organize those operations; artificial intelligence techniques for scheduling those operations; and commercial software to implement monitoring and control. The principal application focus of this chapter is manufacturing, but the ideas can be applied to a wide range of complex systems.

2. CONTROL ARCHITECTURES

Decisions, decisions, decisions—factory managers make them and factory workers implement them everyday. Some decisions impact events immediately; others impact events months or years into the future. Industry, academia, government agencies, and standards bodies have expended considerable effort to develop architectures that (1) organize and integrate these decisions in some meaningful way and (2) specify the information required to make those decisions monitor their execution, and control their implementation. This section describes two such architectures.

2.1. The Purdue Enterprise Reference Architecture (PERA)

A tree structure, hierarchy, is one of the most common ways of organizing functions and activities. Many such hierarchies have been proposed for decision-making and control within manufacturing systems (Jones 1990). The Purdue Enterprise Reference Architecture (PERA), which was developed by a collection of industrial and academic representatives, is one such organization of the factory that includes the control functions and information requirements (Williams 1992). Originally aimed at the process industry, it has been developed so that it can be used across all types of manufacturing. The material in the following sections is taken from Annex D and Section 5.1 of ANSI/ISA-S95.00.01-2000, *Enterprise-Control System Integration Part 1: Models and Terminology* (ANSI/ISA 2000).

2.1.1. Control Hierarchy

Figure 1 shows three levels of the PERA functional hierarchy model at which decisions are made: business planning and logistics, manufacturing operation, and control. Level 4 and level 3 deal with plant production scheduling, operation management, and plant floor coordination. Levels 2, 1, and 0 decompose control functions for three types of manufacturing: batch, continuous, and discrete. This decomposition defines the cell or line supervision functions, operations functions, and process control functions. There are several different execution methods for these functions, which are based on the actual production strategy used.

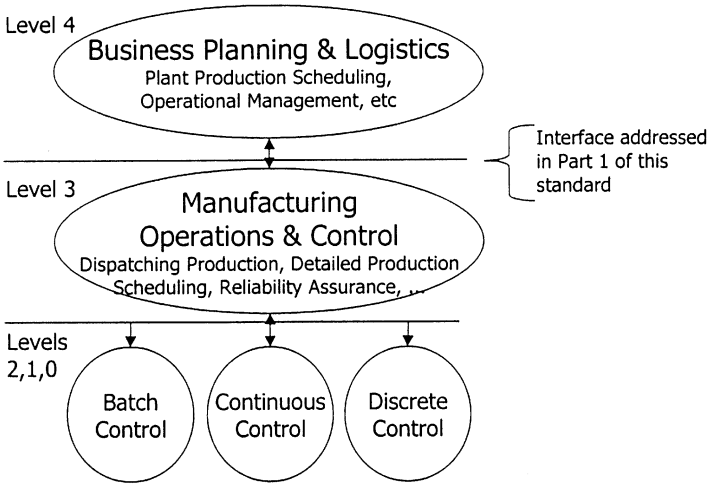

Figure 1 Decision-Making and Control Hierarchy.

Level 4 performs the following major functions: capacity planning, plant production scheduling, materials requirements planning, and all manufacturing-related purchasing. It establishes and modifies the basic plant production schedule for orders received, based on resource availability changes, energy sources available, power demand levels, and maintenance requirements. It develops preventive maintenance and equipment renovation schedules in coordination with the basic production schedule. It determines the optimum inventory levels of raw materials, energy sources, spare parts, and in-process goods. Finally, it collects, maintains, and provides data on a large number of items. These items include raw material and spare parts usage, overall energy use, goods in process, inventory, control files as they relate to customer requirements, machinery and equipment utilization and history files, and manpower use data for transmittal to personnel and accounting.

Level 3 is the principal level of interest in this chapter. Therefore, we provide detailed descriptions of the major activities performed at this level.

- *Resource allocation and control:* Manage those resources directly associated with control and manufacturing. These resources include machines, tools, labor skills, materials, and other equipment, documents, and entities that must be available for work to start and be completed. The management of these resources may include local resource reservation to meet production-scheduling objectives, the assurance that equipment is properly set up for processing, the responsibility for providing real-time, resource status and a history of resource use.
- *Dispatching:* Manage the flow of production in the form of jobs, orders, batches, lots, and work orders by dispatching production to specific equipment and personnel. The flow is governed by the sequence of operations, which determines the order the work is done, and the time that work starts and stops. It is possible to change the sequence or times in real time as events occur on the factory floor; however, those changes are made within agreed upon limits, based on local availability and current conditions. Dispatching of production includes the ability to control the amount of work in process through buffer management and management of rework and salvage processes.
- *Data collection and acquisition:* Manage the operational production and parametric data that is associated with the production equipment and production processes, provide real-time status of the equipment and processes, and keep a history of production and parametric data.
- *Quality management:* Provide real-time measurements collected from manufacturing and analysis in order to ensure proper product quality control and identify problems requiring attention. This includes SPC/SQC tracking and management of off-line inspection operations and analysis in laboratory information management system (LIMS). This activity may recommend actions to correct the problem, including correlating the symptoms, actions, and results to determine the cause.
- *Process management:* Monitor production and provide decision support to operators who correct and improve in-process functions. These functions may be intraoperational (focusing specifically on machines or equipment being monitored and controlled) or inter-operational (tracking the process from one operation to the next). It may include alarm management to alert factory personnel of process changes that are outside of acceptable tolerances.
- *Production planning and tracking:* Provide the status of production and the disposition of work. Status information may include personnel assigned to the work, component materials used in production, current production conditions, and any alarms, rework, or other exceptions related to the product.
- *Performance analysis:* Provide up-to-the-minute reporting of actual manufacturing operations results, along with comparisons to past history and expected results. Performance results include such measurements as resource utilization, resource availability, product unit cycle time, conformance to schedule, and performance to standards. Performance analysis may include SPC/SQC analysis, and may draw from information gathered by different control functions that measure operating parameters.
- *Operations and detailed scheduling:* Generate sequences that optimize some objective (such as minimize set-up time) based on priorities, attributes, characteristics, and production rules associated with specific production equipment and specific product characteristics. This activity is carried out using the current estimate of unused capacity and recognizing alternative and overlapping/parallel operations.
- *Document control:* Control records and forms that must be maintained with the production unit. The records and forms include work instructions, recipes, drawings, standard operation procedures, part programs, batch records, engineering change notices, shift-to-shift communication, as well as the ability to edit ''as-planned'' and ''as-built'' information. This activity is responsible for providing data to operators and recipes to device controls, and for maintaining the integrity of regulatory, environmental, health and safety regulations, and SOP information such as corrective action procedures.

- *Labor management:* Provide status of personnel in real time. This activity includes time and attendance reporting, certification tracking, as well as the ability to track indirect functions such as material preparation or tool room work as a basis for activity-based costing. It may interact with resource allocation to determine optimal personnel assignments.
- *Maintenance management:* Maintain equipment and tools. This activity ensures the availability of equipment and tools for manufacturing, and manages a history of past events or problems to aid in diagnosing problems.

2.1.2. Equipment Organization

The hierarchy described above deals with the decision making, control, and information needed to manage the physical assets of a manufacturing enterprise. Those assets are usually organized in a tree structure such as the one described in Figure 2. Lower-level groupings are combined to form higher-level entities. In some cases, a grouping within one level may be incorporated into another grouping at that same level. In the following section, we define the areas of responsibility for the different levels defined in the hierarchical model and some of the objects used in the information exchanged within and across those levels.

- *Enterprise:* A collection of one or more sites. The enterprise is responsible for determining the products to be manufactured, where they will be manufactured, and in general how they will be manufactured. Level 4 functions are generally dealing at the enterprise and site levels. However, enterprise planning and scheduling may involve areas, cells, lines, or units within an area.
- *Site:* A physical, geographical or logical grouping determined by the enterprise. It may contain areas, production lines, process cells, and production units that have well defined manufacturing capabilities. The level 4 functions at a site include local site management and optimization. Sites are often used for rough-cut planning and scheduling, which may involve cells, lines, or units within the areas.
- *Area:* A physical, geographical, or logical grouping, which may contain process cells, production units, and production lines. The main production capability and geographical location within a site usually identify areas. Areas generally have well defined manufacturing capabilities and capacities that are used for planning and scheduling at levels 3 and 4. An area is made up of lower-level elements that perform continuous manufacturing operations, discrete (repetitive and nonrepetitive) manufacturing operations, and batch manufacturing operations. An area may have several of these elements in varying combinations, depending upon the manufacturing requirements. For example, a beverage manufacturer may have an area with continuous mixing equipment that feeds a batch process cell for batch processing that feeds a bottling line for discrete bottling process. Depending on the planning and scheduling strategy selected, the level 4 func-

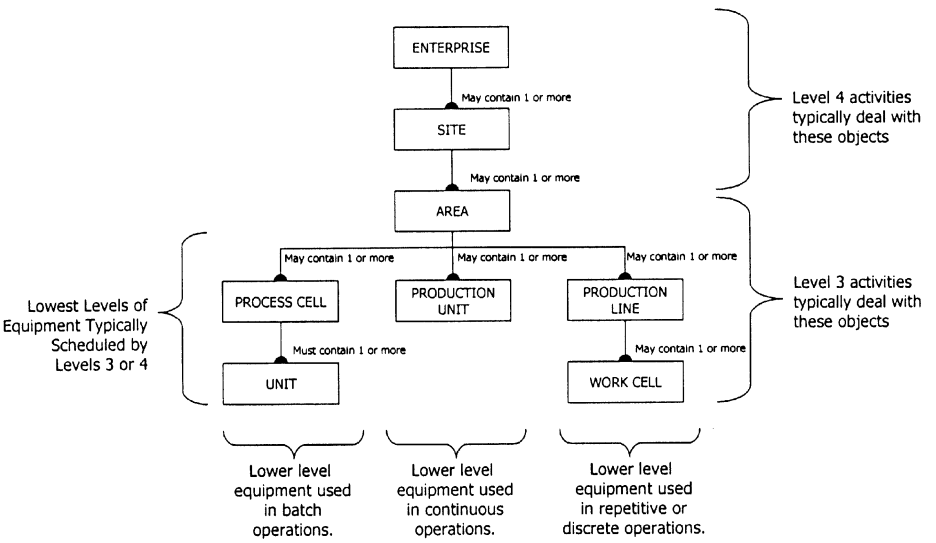

Figure 2 Typical Equipment Organization.

tions may stop at the area level, or they may schedule the functions of the lower-level elements within the areas.

- *Production units:* The lowest level of equipment typically scheduled by the level 4 or level 3 functions for continuous manufacturing processes. Production units are composed of lower level elements, such as equipment modules, sensors, and actuators. Production units have well-defined processing capabilities, and throughput capacities, and these are used for level 3 functions. The capacities and capabilities are also often used as input to level 4 scheduling, even if the production units are not scheduled by the level 4 functions.
- *Production lines and work cells:* The lowest levels of equipment typically scheduled by the level 4 or level 3 functions for discrete manufacturing processes. Work cells are usually only identified when there is flexibility in the routing of work within a production line. Production lines and work cells may be composed of lower level elements. Production line and work cells have well defined manufacturing capabilities and throughput capacities and these are used for level 3 functions. The capacities and capabilities are also often used as input to level 4 scheduling, even if the production lines and work cells are not scheduled by the level 4 functions.
- *Process cells and units:* The lowest level of equipment typically scheduled by the level 4 and level 3 functions for batch manufacturing processes. Units are usually only identified at levels 3 and 4 if there is flexibility in the routing of product within a process cell. The definitions for process cells and units are contained in the IEC 61512 and ISA S88.01 standards. Process cells and units have well-defined manufacturing capabilities and batch capacities, and these are used for level 3 functions. The capacities and capabilities may also be used as input data for level 4 scheduling, even if the process cells or units are not scheduled by the level 4 functions.

2.1.3. Status

The PERA plays a critical role in two standards, one being developed by SP95 of the ISA (Instrument Society of America) and the other by TC 184/WG 1 of the ISO (International Standards Organization). SP95 seeks to create standards for the interfaces between control functions and other enterprise functions (http://www.isa.org/sc/committee/1,1512,145,00.html) based upon the PERA. The interface initially considered is the interface between levels 3 and 4 of that model. Additional interfaces will be considered, as appropriate. WG 1 has published the PERA as an annex (http://www.nist.gov/sc5wg1/gera-std/15704fds.htm) to ISO 15704, *Requirements for Enterprise Reference Architectures and Methodologies,* which is a final draft international standard (http://www.nist.gov/sc5wg1/gera-std/15704AB.htm). From the WG1 perspective, PERA is an example of a generalized enterprise reference architecture, GERAM. A GERAM defines a toolkit of concepts for designing and maintaining enterprises for their entire life history and is meant to organize existing applications in all types of enterprises. An advantage is that previously published reference architectures can keep their own identity while identifying through GERAM their overlaps and complementing benefits compared to others.

2.2. SEMATECH CIM Framework

The CIM Framework, developed by SEMATECH, defines a standard component architecture and application component interfaces for manufacturing information and execution systems (MIES) software (Doscher 1998)—the following material is taken largely from (Hawker 1999). The CIM Framework is not hierarchical in nature; rather, it leverages distributed, object-oriented computing technology. Additionally, it uses middle-ware standards from the Object Management Group (OMG) (http://www.omg.org) to enable integration of the applications.

The CIM Framework software architecture was designed to enable the following capabilities:

- *Integration:* Applications can cooperate by exchanging data, providing services (client/server method invocation), publishing service exceptions, and publishing and subscribing to events.
- *Interoperability:* Applications from one supplier or source can be replaced easily with a functionally equivalent application (conformant to standard interface and behavior) from another source.
- *Flexibility:* Components and applications can be configured in a variety of ways that meet specific needs.
- *Reuse:* New systems can be implemented from standard components or applications more quickly, at lower cost, and with higher quality.

The major benefit of this framework is a significant reduction in the cost and time involved in building, modifying, and enhancing MIES software in response to changing business needs. Adherence to the framework allows semiconductor manufacturers to integrate applications from multiple suppliers with their legacy systems and to replace or upgrade these applications and systems over time.

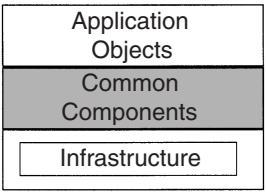

Figure 3 CIM Framework Architecture Layers.

2.2.1. CIM Framework Component Architecture

The CIM Framework architecture is a layered system that enables distributed, object-oriented applications assembled from common software components to interoperate as a single, integrated system.

The integration infrastructure is based on specifications in the Object Management Architecture (OMA) from the OMG (OMG 1995, 1996, 1997a). These specifications define standard services for distributed object communications, persistence, transactions, name services, and so forth. On top of the infrastructure, the CIM Framework architecture defines common application components. Components are software building blocks that implement some collection of functions. Typically, each MIES application will be composed of many such components. The CIM Framework common components layer defines standard models for application components that are common across MIES applications. Examples include a machine management component, a product management component, and a person management component. The machine management component includes machine resources, sensors, process capabilities, and relations to material and recipes. The product management component includes product material, lots, and relations to product and process specifications. The person management component includes persons, qualifications, and relations to skills and skill requirements. This common application model, defined in terms of common software components, is the *framework* for building integrated MIES applications.

The application objects layer of the CIM Framework architecture provides additional functionality, extending the common components to make a complete MIES. This layer, which is identified but not specified, enables MIES suppliers and users to define product-specific and site-specific application objects and components that use and extend the CIM Framework common components to implement MIES functions that meet business needs.

A given MIES application, as shown in Figure 4, implements some common components and application objects and interoperates (via the infrastructure) with other common components and

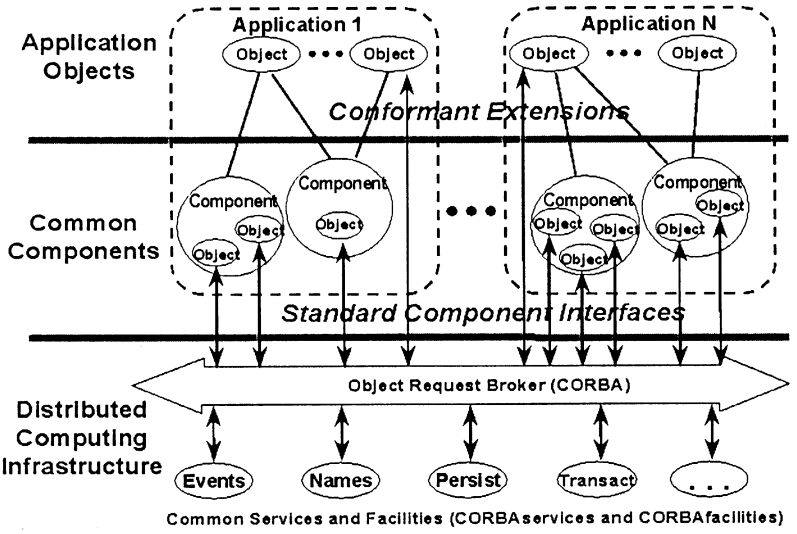

Figure 4 CIM Framework Component Architecture.

application objects implemented in other MIES applications. The collection of interoperating MIES applications provides a complete, integrated, MIES solution.

2.2.2. Component-Specification Methodology

The key to the CIM Framework is the specification of components. The CIM Framework uses the following modeling methods to specify components:

- Component relationship models showing interaction between "medium-grained" components (larger than an object, smaller than an application)
- Component information models showing object interfaces and relationships in the form of OMT (object modeling technique) diagrams (Rumbaugh et al. 1991)
- Object interface definitions using OMGs Interface Definition Language (IDL)
- Published and subscribed events using an extension to OMG IDL
- Component interaction diagrams showing scenarios that trace messages and events between components
- State transition diagrams as Harel state charts (Harel 1987) and state definition tables

These modeling methods go far toward specifying components that MIES implementers can "plug-and-play" into integrated systems. SEMATECH is also working in the OMG Business Objects Domain Task Force to define and standardize additional methods for even richer semantic models, including the specification of method preconditions and postconditions, roles, rules, and dependencies (http://www.omg.org/homepages/bodtf/).

2.2.3. Shop-Floor Application Modules

The CIM Framework specifies application components for manufacturing information and execution systems (MIES). MIES perform factory operations functions in the context of enterprise information and control systems and systems that automate material processing, storage and movement. Figure 5 shows the MIES functional groups in the CIM Framework.

Each functional group defines a collection of related application components. Table 1 lists the CIM Framework components in each functional group. The functional groups are a convenient mechanism to organize the CIM Framework components; they are not rigid partitions, and suppliers can deliver applications that span functional groups or that implement only some of the components of a group. In contrast, the component is the smallest-grained entity that suppliers can deliver. A supplier must implement all the interfaces and behaviors of a component in order to claim conformance to that component specification.

The value and power of the CIM Framework is the application model, which specifies medium-grained components common to MIES applications. The SEMATECH CIM Framework Specification Version 2.0 (Doscher 1998) has almost 300 pages of detailed component models specified using the

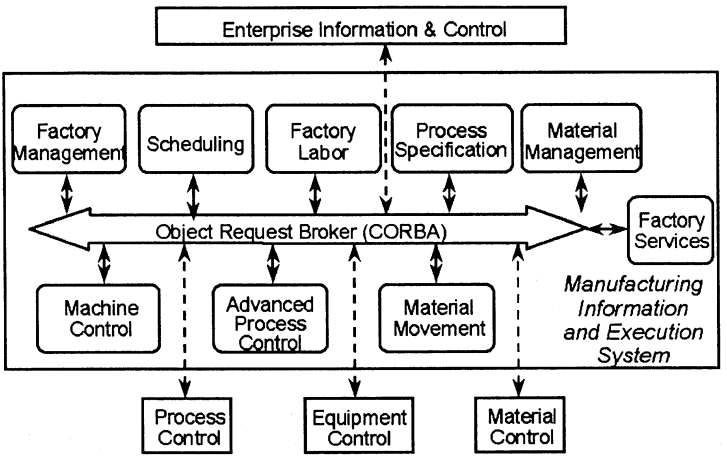

Figure 5 Functional Groups for MIES.

TABLE 1 CIM Framework Application Components

Factory Services	Material Management	Process Specification Management
Document management	Product management	Process specification
Version management	Durable management	Process capability
History management	Consumable management	
Event broker	Product specification	*Schedule management*
	Bill of material	Dispatching
Factory management		
Factory	*Advanced process control*	*Machine control*
Product release	Plug-in management	Machine management
Factory operations	Plug-in execution	Recipe management
	Control management	Resource tracking
Factory labor	Control execution	
Person management	Control database	*Material movement*
Skill management	Data collection	Material movement

methodology of Section 2.3. Section 4 presents a portion of the CIM Framework Product Management component to illustrate the style and detail of the specification. By developing industry-wide consensus on these component definitions, SEMATECH has enabled manufacturers quickly and cost effectively to build, modify and enhance MIES by assembling standards-conformant components from multiple suppliers.

2.2.4. Status

Six of the CIM Framework specifications have become SEMI (Semiconductor Equipment and Materials International) standards (http://www.semi.org/web/wstandards.nsf/). These standards were developed with the cooperative efforts of both users and suppliers of semiconductor MES software systems. Active efforts were underway to add another standard for the CIM Framework Scheduling Component by the end of 2000, and there is interest in working on factory operations and production machine components (Hodges 2000). While there may be few instances of fully compliant MES products being shipped, we believe that vendors are using the standards in their product-development process and plans. The customers of these MES products are also using the adopted standards in integration efforts that combine best-in-class components into working factory systems.

3. AI APPROACHES TO SHOP-FLOOR SCHEDULING AND CONTROL

In the preceding section, we described two architectural approaches for organizing functions related to shop-floor scheduling control. One of the most important of these functions is scheduling. Another chapter reported on two major approaches to solving these problems: mathematical programming and heuristics. In this chapter, we describe a number of AI (artificial intelligence) techniques.

3.1. Knowledge-Based Systems

Expert and knowledge-based systems were quite prevalent in the early and mid-1980s. They have four main advantages. First, and perhaps foremost, they can use both quantitative and qualitative knowledge in the decision-making process. Second, they are capable of generating heuristics that are more complex than the simple dispatching rules described in an earlier chapter. Third, the selection of the best heuristic can be based on information about the entire shop, including current jobs, expected new jobs, and the status of all resources. Fourth, they capture complex relationships in elegant, new data structures and contain special techniques for manipulation of these data structures. They are, however, time consuming to build and verify, difficult to maintain and change, and generate only feasible solutions that can be quite far from the optimum.

3.1.1. Generating the Required Knowledge Base

Formalizations of the knowledge that human experts use—rules, procedures, heuristics, and other types of abstractions—are captured in the knowledge base. Three types of knowledge, procedural, declarative, and meta, are usually included. Procedural knowledge is domain-specific, problem-solving knowledge. Declarative knowledge provides the input data that defines the problem domain. Metaknowledge is knowledge about how to use the other knowledge to solve the actual problem. Several data structures have been proposed to represent the knowledge, including semantic nets, frames, scripts, predicate calculus, and production rules. The inference engine implements a strategy

to apply to the knowledge to obtain a solution to the problem at hand. It can be forward chaining (data driven) or backward chaining (goal driven).

The first step in developing a knowledge base is knowledge acquisition, which is a two-step process: get the knowledge from knowledge sources and store that knowledge in digital form. Knowledge acquisition, such as protocol analysis, machine learning, and interactive editing (Shaw et al. 1992), has been an active area of research. Knowledge sources may be human experts, simulation data, experimental data, databases, and documents. In scheduling problems, the knowledge sources are likely to be human experts or simulation data. To extract knowledge from these two sources, any technique that learns from examples (data) becomes a promising tool. Inductive learning, which is a state classification process, is one such technique. If we view the state space as a hyperplane, training data (consisting of conditions and decisions) can be represented as points on that hyperplane. The inductive learning algorithm seeks to draw lines that divide the hyperplane into several areas within which the same decision (conclusion) will be made.

Quinlan (1986) developed an algorithm, which implements the inductive learning paradigm, called Iterative Dichotomister 3 (ID3). ID3 uses examples to induce production rules (e.g., if-then) that form a simple decision tree. Decision trees are one way to represent knowledge for the purpose of classification. The nodes in a decision tree correspond to attributes of the objects to be classified, and the arcs are alternative values for these attributes. The end nodes of the tree (leaves) indicate classes to which groups of objects belong. Each example is described by attributes and a resulting decision. To determine a good attribute, which is the basis for an object-class partitioning, entropy is employed. Entropy is a measure of the information content of each attribute. Rules are derived through a repetitive decomposition process that minimizes the overall entropy.

The attribute with the minimum entropy value will be selected as a node in the decision tree. The arcs out of this node represent different values of this attribute. If all the objects in an arc belong to one class, the partition process stops. Otherwise, another attribute will be identified using entropy values to partition further the objects that belong to this arc. This partition process continues until all the objects in an arc are in the same class. Before this algorithm is applied, all attributes that have continuous values need to be transformed to discrete values.

In the context of job shop scheduling, the attributes represent system status and the classes represent the dispatching rules. Very often the attribute values are continuous. Yih (1990) proposed a trace-driven knowledge-acquisition (TDKA) methodology to deal with continuous data and avoid the problems that occur interviewing human experts. TDKA learns scheduling knowledge from expert schedulers without resorting to an interview. There are three steps. In Step 1, an interactive simulator is developed to model the system of interest. The expert will interact with this simulator and make decisions. The entire decision-making process will be recorded in the simulator and can be repeated for later analysis. The pair, system information and scheduling decision, is called a trace. Step 2 analyzes the trace and proposes classification rules to partition the trace into groups. The partition process stops when most of the cases in each group use the same dispatching rule (error rate is below the threshold defined by the knowledge engineer). Then the decision rules are formed. The last step is to verify the generated rules. The resulting rule base is used to schedule jobs in the simulator. If it performs as well as or better than the expert, the process stops. Otherwise the threshold value is increased and the process returns to Step 2. This approach was applied in an electroplating process line and the rule base system outperforms the users. Later, Yih (1994) developed a prolog-based controller that handles the time-window problems in the same manufacturing environment.

3.1.2. Applications to Scheduling and Control

ISIS (Fox 1983) was the first expert system aimed specifically at job shop scheduling problems. ISIS used a constraint-directed-reasoning approach with three constraint categories: organizational goals, physical limitations, and causal restrictions. Organizational goals specified five objective functions based on due date and work-in-progress. Physical limitations specified the processing capability of each resource. Casual restrictions included all procedural constraints and resource requirements. Several issues related to these constraints were considered, such as conflicts among constraints, relative importance of constraints, and interactions of constraints. ISIS used a three-level, hierarchical, constraint-directed search. Orders were selected at level 1. Capacity analysis was performed at level 2 to determine the availability of the resources required by the order. Detailed scheduling was performed at level 3, to assign times to the resources identified at level 2. ISIS utilized its constraint knowledge to maintain the consistency of the schedule and identify scheduling decisions that would result in poorly satisfied constraints. It also included the capability to construct and alter schedules interactively. Chiu and Yih (1995) proposed a learning-based approach for dynamic scheduling in a distributed manufacturing system. An incremental approach to training a decision tree is proposed in this study. Each training sample consists of system attributes as inputs and a dispatching rule as its output. In their work, simulations are conducted first to collect some scenarios, and then the genetic algorithm

is performed to search a good dispatching rule for each scenario. The learning algorithm is then applied to obtain a decision tree for dynamic selection of scheduling rules.

Chang (1996) proposed a fuzzy-based methodology to control the number of kanbans in a generic kanban system. In this approach, the simulated annealing algorithm is employed to find the near-optimal number of kanbans for different system status, and thereafter a training instance is generated. Then the proposed fuzzy system will be generated for dynamic kanban control. Other work in developing a control system includes Huang and Chang (1992), Gupta et al. (1989), Chandra and Talavage (1991), and Talavage and Shodhan (1992).

Adachi et al. (1988) proposed a pattern-recognition-based method for controlling a multiloop production system. In their proposed approach, a state table is constructed for the control-decision support system (CDSS) based on the simulation results. After the user indicates the desired level and importance weight for each performance measure, the one with shortest distance to the desired pattern will be selected by the control system and the associated performance level will be displayed. These procedures are repeated until the user is satisfied with the expected performance levels. The authors further constructed a rule-based decision support system (RBDSS) to control the same production system and compared the performance of CDSS and RBDSS (Adachi et al. 1989).

Several researchers have attempted to use the knowledge-based approach to model the shop-floor control problem (Farhoodi 1990; Pluym 1990; Adachi et al. 1989). Under this approach, a central database with several production rules handles scheduling and monitors system status. Each production rule consists of a condition part and an action portion with a form of an if-then clause. Typically, these rules are based on the simulation results from different scenarios or the knowledge from the experience of schedulers. When a decision-making point is encountered, the database is scanned to find the condition that could match the current situation and the associated action is then executed. However, it is not easy to generate a database consisting of every possible situation for a system. Besides, if this database is large or the production rules are complex, it will take a long time to search the database and it is impractical for real-time implementation.

O'Grady and Lee (1988) proposed a cell control system, called PLATO-Z, by using a rule-based expert system and a multiblackboard/actor model. In the proposed control system, the major functions are performed by four blackboard subsystems: scheduling, operation dispatching, monitoring, and error handling. Adequate messages are passed between blackboard subsystems in order to achieve the control requirements. This control framework was further implemented by an object-oriented programming technique (O'Grady and Seshadri 1992).

Wu and Wysk (1988, 1989) also proposed a multipass, expert control system for flexible manufacturing cells. Under their proposed system, some candidate rules are selected by a knowledge-based system and then the performance of each candidate rule is evaluated through simulation. Weighted objective values are compared in order to achieve the multicriterion objective. Cho and Wysk (1993) then refined it by using a neural network instead of the knowledge-based system for selecting the candidate rules in the initial stage.

3.1.3. Agents to the Rescue?

It is difficult to use expert and knowledge-based systems to solve large, real-world scheduling problems because of their limited knowledge and problem solving abilities. To address this, AI researchers have used the "divide and conquer" approach to develop distributed scheduling approaches (Parunak et al. 1985). This requires a technique to decompose the scheduling problem and a collection of associated knowledge-based systems that cooperate to solve the overall problem (Zhang and Zhang 1995). Cooperation is handled through an agent paradigm. Each agent is a complete knowledge-based system with its own long-term knowledge, solution-evaluation criteria, languages, algorithms, and hardware requirements. A multiagent system is created by integrating agents selected from a "library" of agents.

For example, one such multiagent system could involve two types of agents: tasks and resources. Each task agent might schedule a certain class of tasks, such as material handling, machining, or inspection, on those resources capable of performing such tasks. The schedule is generated using any task-related performance measure, such as minimize tardiness. The schedules generated by task agents become goals for the resource agents (Daouas et al. 1995). Each resource agent schedules tasks for its assigned resource(s) using resource-related performance measures, such as maximize utilization. Each resource agent will use its schedule to decide whether it can meet the scheduling goals set by the task agents. Clearly, a situation can arise where no resource will accept a given task; coordination mechanisms must be developed to avoid this situation.

While there is promise for these types of agent-based approaches, there are no general guidelines for the design and implementation of such approaches.

3.2. Artificial Neural Networks

Neural networks, also called connectionist or distributed/parallel processing models, have been studied for many years in an attempt to mirror the learning and prediction abilities of human beings.

Neural network models are distinguished by network topology, node characteristics, and training or learning rules. They are important because they can match current shop status and the desired performance measures to near-optimal scheduling strategies and they can learn (Yih and Jones 1992).

Among the many network topologies and learning algorithms, the Hopfield network and the multilayer perceptron are preferred by several researchers for scheduling problems. Therefore, in the following sections, these two networks will be briefly discussed, and the related works on scheduling problems will be reviewed.

3.2.1. Hopfield Networks

A Hopfield network consists of nodes that are fully connected to each other bidirectionally. Instead of a continuous value, this network takes only the binary or bipolar value as its input. In addition, it is also regarded as a symmetrically weighted network because the weights on the links between nodes are the same in both directions. When an input pattern is applied, the Hopfield network will adjust the weights until it converges to a stable state. This happens when the output value of each node is no longer changed. In other words, the network will reduce its "energy" until it stabilizes in a hollow of the energy landscape.

Foo and Takefuji (1988a, b) used the Hopfield network to solve job shop scheduling problems. The scheduling problem was first mapped into a two-dimensional matrix representation. Feasibility constraints and performance measures were then formulated as the energy function, named cost function. The characteristic of this energy function is that it will result in very large value when the schedule is not feasible or the performance is far from expectations. The solution is obtained by reducing the energy in the network. The authors concluded that this approach could produce near-optimal solutions, though the optimality was not guaranteed. In addition, it was claimed that the proposed approach would not be feasible in a large-scale problem.

Zhou et al. (1991) modified this approach by using a linear cost function and concluded that this modification not only produced better results but also reduced network complexity. Other works related to using the Hopfield network for the scheduling problem include Zhang et al. (1991) and Arizono et al. (1992).

3.2.2. Supervised-Learning Neural Networks

Through exposure to historical data, supervised-learning neural networks attempt to capture desired relationships between the inputs and the outputs. Back-propagation is the most popular and widely used capture procedure. Back-propagation (Rumelhart et al. 1986, Werbos 1995) applies the gradient-descent technique to change a collection of weights so that some cost function can be minimized. The cost function, which is dependent on weights and training patterns only, is defined by:

$$C(W) = \tfrac{1}{2}\Sigma\ (T_{ij} - O_{ij}) \tag{1}$$

where the T is the target value, O is the output of the network, i represents the output nodes, and j represents the training patterns.

After the network propagates from the input layer to the output layer, the error between the desired output and actual output will be back-propagated to the previous layer. In the hidden layers, the error for each node is computed by the weighted sum of errors in the next layer's nodes. In a three-layered network, the next layer means the output layer. The activation function is usually a sigmoid function with the weights modified according to (2) or (3).

$$\Delta W_{ij} = \eta\ X_j\ (1 - X_j)(T_j - X_j)\ X_i \tag{2}$$

or

$$\Delta W_{ij} = \eta\ X_j\ (1 - X_j)\ (\Sigma\ \delta_k W_{jk})\ X_i \tag{3}$$

where W_{jk} is weight from node i to node (e.g., neuron) j, η is the learning rate, X_j is the output of node j, T_j is the target value of node j, and δ_k is the error function of node k. If j is in the output layer, (2) is used. If j is the hidden layers, (3) is used. The weights are updated to reduce the cost function at each step. The process continues until the error between the predicted and the actual outputs is smaller than some predetermined tolerance.

Rabelo (1990) was the first to use back-propagation neural nets to solve job shop scheduling problems. He allowed several job types, with different arrival patterns, process plans, precedence requirements, and batch sizes. Examples were generated to train the neural network to select those characterizations of the manufacturing environments suitable for various scheduling policies and applied to the target manufacturing system. The neural networks were trained for problems involving

3, 4, 5, 8, 10, and 20 machines. To carry out this training, a special input-feature space was developed. This space contained information on both job characteristics (such as job types, number of jobs in each type, routings, due dates, and processing times) and shop characteristics (such as number of machines and their capacities). Neural networks were tested on numerous scheduling problems with a variety of performance measures. For each test, the output of the neural network represented a relative ranking of the available dispatching rules. The one with the largest ranking was selected. Rabelo showed that the same rule did not always minimize a specified performance measure under all input conditions. For example, SPT does not always minimize mean flow time. In addition, he showed that the rule selected by the neural network never performed worse than the presumed optimum.

3.2.3. Multilayer Perceptrons

A multilayer perceptron is a fully connected feed-forward network consisting of an input layer, an output layer, and several hidden layers in between. Each layer is composed of nodes that are fully connected with those in the succeeding layer by weights. Each node computes a weighted sum of the elements in the preceding layer, subtracts a threshold, and then passes the result through a nonlinear function, called an activation function. Typically, the activation function is a sigmoid energy function and the learning algorithm employed to adjust weights is the Backpropagation algorithm (Rumelhart et al. 1986).

When an input pattern in training data is fed into the network, the error between the desired output and actual output values will be back-propagated to the previous layer and the weights will be adjusted accordingly. This procedure is called training and it is done to obtain the proper weight matrices so that the total is minimized. Yih et al. (1993) conducted a three-phased experiment to quantify the benefits of training. Schedules were generated by a human expert, an untrained neural network, and a neural network with training data refined by a semi-Markov decision model. The results indicated that the untrained neural network performed worse than the human expert did. However, the trained neural network outperformed both. This implies that good training data will significantly improve network performance.

Several works have used multilayer perceptrons with the Backpropagation training algorithm in scheduling or in candidate rules selection. Potvin et al. (1992) modified the network structure but still used the Backpropagation learning algorithm to build up the dispatcher for automated vehicles. Rabelo et al. (1993) used modular neural networks to serve as a candidate rule selector. In 1996, Chen and Yih discussed the impact of the network input attributes on the performance of the resulting control system.

As mentioned above, Cho and Wysk (1993) utilized the multilayer perceptron to take the place of the knowledge-based system in selecting candidate scheduling rules. In their proposed framework, the neural network will output a ''goodness'' index for each rule based on the system attributes and a performance measure. Sim et al. (1994) used an expert neural network for the job shop scheduling problem. In their approach, an expert system will activate one of 16 subnetworks based on whether the attribute corresponding to the node (scheduling rules, arrival rate factor, and criterion) is applicable to the job under consideration. Then the job with the smallest output value will be selected to process.

Yih and Jones (1992) proposed using multilayer perceptrons in selecting some candidate rules for further evaluation of their performance. In their proposed approach, a multilayer perceptron will take the attributes describing the system configuration and the performance measures and will output a proper matching score for each dispatching rule. They also used this approach for multiple-criterion objectives.

Sun and Yih (1996) adopted their idea to develop a neural network-based controller for manufacturing cells. In their approach, a neural network was trained to serve as decisionmaker that will select a proper dispatching rule for its associated machine to process the next job. Based on their results, the controller performs well under multiple criterion environments. In addition, when the production objectives change, the controller can respond to such change in a short time.

3.2.4. Unsupervised Neural Networks (Competition Based)

Competition-based neural networks, which are good at classifying or clustering input data, can also be applied to scheduling problems. Since the classes or clusters are not known in advance, the network must discover them by finding correlation in the input data. Multidimensional data sets are presented to the network, which adaptively adjusts its weights. This input presentation process is repeated until the network reaches stability—each output unit is activated only for a particular subset of the input patterns. Variations of these neural networks have been used to solve scheduling problems. For example, Bourret et al. (1989) applied some of these principles to develop a neural network that was able to schedule optimal time periods of low-level satellites to one or several antennas. The neural network was able to take into account that each satellite has a given priority and several other

operational constraints. Min et al. (1998) adopted this concept and developed a methodology in a multiobjective scheduling problem. Kim et al. (1998) integrated the network with inductive learning module to develop a real-time controller for flexible manufacturing systems.

3.2.5. Reinforcement Learning

We noted above that supervised learning neural networks attempt to capture desired relationships between inputs and outputs through exposure to training patterns. For some problems, the training period may be too short to find those relationships. When the desired response is obtained, changes to the neural network are performed by assessing penalties for the actions previously decided by the neural network. As summarized by Tesauro (1992), "In the simplest form of this paradigm, the learning system passively observes a temporal sequence of input states that eventually leads to a final reinforcement or reward signal (usually a scalar). The learning system's task in this case is to predict expected reward given an observation of an input state or sequence of input states. The system may also be set up so that it can generate control signals that influence the sequence of states." For scheduling, the learning task is to produce a schedule that minimizes (or maximizes) the performance measure. Several procedures have been developed to train neural networks in a variety of generic cases.

One of the popularly adopted reinforcement learning algorithms is called Q-learning. In this approach, an action-value function, which assigns an expected utility to take a given action in a given state, is defined. The output of this function is called Q-values. The relation between Q-values and the utility values is as follows:

$$U(s) = \operatorname*{Max}_{a} Q(a, s)$$

where $U(s)$ = the utility value at state s
$Q(a, s)$ = the Q-value of taking action a in state s

The learning process in Q-learning is to find an appropriate Q-value associated with each action in each state that the decision can be based on.

Rabelo et al. (1994) utilized a procedure developed by Watkins (1989), called Q-learning, to solve dynamic scheduling problems. The procedure followed trends in the shop floor and selected a dispatching rule that provided the maximum reward according to performance measures based on tardiness and flow time. Zhang and Dietterich (1996) utilized a procedure developed by Sutton (1988) called TD(λ) to schedule payload processing of NASA's space shuttle program. The scheduling system was able to outperform an iterative repair scheduler that combined heuristics with simulated annealing.

Kim and Lee (1995) formulated the machine-scheduling problem as a reinforcement learning problem and then developed a learning-based heuristic, called EVIS, for solving the scheduling problem. The EVIS, implementing reinforcement learning with the genetic algorithm, was then applied to a few deterministic scheduling problem instances. The results show that the proposed heuristic has good average-case performances for most of the problem instances.

Another alternative in reinforcement learning involves using the CMAC network. A CMAC network can be regarded as an associative memory system which stores the appropriate output in the associated memory cells. As mentioned by Miller et al. (1990), the CMAC network is an alternative to the back-propagated, multilayer, neural network because it has the advantages of local generalization, rapid training, and output superposition. Several researches have been involved in applying the CMAC network to develop a controller. Miller et al. (1990) demonstrated the application of CMAC networks in real-time robot control without providing any initial knowledge, in character recognition, and in signal processing. Lin and Kim (1991) constructed a CMAC-based controller and demonstrated its capability in the inverted pendulum problem. Moody (1989) proposed a multiresolution CMAC (MRC) that combines some CMAC networks with different resolution to increase the accuracy and generalization ability. The proposed approach shows good performance and online learning ability in prediction of a time series.

3.3. Genetic Algorithms

Genetic algorithms (GA) provide an optimization methodology based on a direct analogy to Darwinian natural selection and mutations in biological reproduction. In principle, genetic algorithms encode a parallel search through concept space, with each process attempting coarse-grain hill climbing (Goldberg 1988). Instances of a concept correspond to individuals of a species. Induced changes and recombinations of these concepts are tested against an evaluation function to see which ones will survive to the next generation. The use of genetic algorithms requires five components:

1. A way of encoding solutions to the problem—fixed length string of symbols
2. An evaluation function that returns a rating for each solution
3. A way of initializing the population of solutions
4. Operators that may be applied to parents when they reproduce to alter their genetic composition, such as crossover (i.e., exchanging a randomly selected segment between parents), mutation (i.e., gene modification), and other domain-specific operators
5. Parameter setting for the algorithm, the operators, and so forth

A number of approaches have been utilized in the application of genetic algorithms (GA) to job shop scheduling problems (Davis 1985; Goldberg and Lingle 1985; Starkweather et al. 1992):

1. Genetic algorithms with blind recombination operators have been utilized in job shop scheduling. Their emphasis on relative ordering schema, absolute ordering schema, cycles, and edges in the offsprings will lead to differences in such blind recombination operators.
2. Sequencing problems have been addressed by mapping their constraints to a Boolean satisfiability problem using partial payoff schemes. This scheme has produced good results for very simple problems.
3. Heuristic genetic algorithms have been applied to job shop scheduling. In these genetic schemes, problem specific heuristics are incorporated in the recombination operators (such as optimization operators based).

Starkweather et al. (1992, 1993) were the first to use genetic algorithms to solve a dual-criteria job shop scheduling problem in a real production facility, a beer plant. Those criteria were the minimization of average inventory in the plant and the minimization of the average waiting time for an order to be selected. These criteria are negatively correlated: as the inventory increases (decreases), the wait decreases (increases). To represent the production/shipping optimization problem, a symbolic coding was used for each member (chromosome) of the population. In this scheme, customer orders are represented by discrete integers. Therefore, each member of the population is a permutation of customer orders. The GA used to solve this problem was based on blind recombinant operators. This operator emphasizes information about the relative order of the elements in the permutation because this impacts both inventory and waiting time. A weighted sum of the two criteria was utilized to rank each member of the population. That ranking was based on an online simulation of the plant operations. This approach generated schedules that produced inventory levels and waiting times that were acceptable to the plant manager. In addition, the integration of the genetic algorithm with the online simulation made it possible to react to plant dynamics.

These applications have emphasized the utilization of genetic algorithms as a ''solo'' technique. This limits both the complexity of the problems solved and levels of success. Recent research has demonstrated the sensitivity of genetic algorithms to the initial population. When the initial population is generated randomly, genetic algorithms are shown to be less efficient that the annealing-type algorithms but better than the heuristic methods alone. However, if the initial population is generated by a heuristic, the genetic algorithms become as good as or better than the annealing-type algorithms. In addition, integration with other search procedures (e.g., taboo search) has enhanced the capabilities of both. This result is not surprising, as it is consistent with results from nonlinear optimization.

3.4. Fuzzy Logic

Fuzzy set theory has been utilized to develop hybrid-scheduling approaches. Fuzzy set theory can be useful in modeling and solving job shop scheduling problems with uncertain processing times, constraints, and set-up times. These uncertainties can be represented by fuzzy numbers, which are described by the concept called interval of confidence. These approaches usually are integrated with other methodologies (e.g., search procedures, constraint relaxation). For example, Slany (1994) stressed the imprecision of straightforward methods presented in the mathematical approaches and introduced a method known as fuzzy constraint relaxation, which is integrated with a knowledge-based scheduling system. Chang (1996) and Chang and Yih (1998, 1999) proposed a machine learning methodology to develop a fuzzy rule-based system for controlling a kanban system. Grabot and Geneste (1994) use fuzzy logic principles to combine dispatching rules for multi-criteria problems. Krucky (1994) used fuzzy logic to minimize setup times for a production line with a medium-to-high product mix by clustering assemblies into families of products that share the same setup. The clustering was achieved by balancing a product's placement time between multiple-high-speed placement process steps. Tsujimura et al. (1993) presented a hybrid system, which uses fuzzy set theory to model the processing times as triangular fuzzy numbers (TFNs). Each job is defined by two TFNs,

a lower bound and an upper bound. A branch and bound procedure is utilized to minimize makespan through the shop based on these estimates.

3.5. Commercial Systems

A number of university software systems use these techniques to do scheduling. A few commercial software systems use expert systems and genetic algorithms. Commercial hardware and software systems are available that implement neural networks, but none have been designed specifically for scheduling.

4. MANUFACTURING EXECUTION SYSTEMS (MES)

During the 1990s a new category of software system, manufacturing execution system (MES), emerged that consolidated and automated a number of functions involved in the management and operation of a production facility. An MES is a collection of hardware/software components that enables the management and optimization of production activities from order launch to finished goods. While maintaining current and accurate data, an MES guides, initiates, responds to, and reports on plant activities as they occur. An MES provides mission-critical information about production activities to decision support processes across the enterprise (MESA 1997; Wallace 1999). The term *order launch* is to be interpreted as initiation of physical production activities, typically beginning with materials preparation or machine preparation. Activities relating to planning and scheduling physical production operations are included within the scope of MES, but activities related to defining physical operations are not. The word ''component'' is used in a generic way to mean a separable portion of a larger whole.

Wallace (1999) provides a list of 12 major functions, derived from the original list in MESA (1997). These functions are similar to those found in the PERA model described in Section 3.

1. Resource allocation and tracking
2. Operations/detailed scheduling
3. Production unit dispatching
4. Specification management
5. Data collection/acquisition
6. Labor management
7. Quality management
8. Process management
9. Maintenance management
10. Product tracking
11. Performance analysis
12. Material management

The relationship between these functions and software products that call themselves MES is not clear. Some MES products can be purchased prepackaged as a single unit that performs all of these functions. Many other products provide only a subset of these functions; some call themselves MES, some do not. Standard interfaces would facilitate the integration of components into an overall MES and facilitate the integration of that MES with other enterprise software applications such as ERP (enterprise resource planning). No viable standards are emerging to fulfill this need, but there are four organizations looking at the problem: ISO, ISA, SEMI, and OMG.

Within the International Organization for Standardization (ISO), the Manufacturing Management Data Exchange (MANDATE) work in TC184/SC4/WG8 is focusing MES (http://www.iso.ch/meme/TC184SC4.html). Within ISA, MES-related work is being done in SP95 (http://www.isa.org/sc/committee/1,1512,145,00.html), see **2.1**. Within SEMI, MES-related standards are being generated as part of the standardization of CIM Framework specifications, (http://www.semi.org/web/wstandards.ns), see **2.2**. Within OMG, the MES-related work is being done by the Manufacturing Execution Systems/Machine Control group (http://www.omg.org/homepages/mfg/mfgmesmc.htm). Most of the remaining material in this section is based on work done in the OMG working group.

4.1. A More Detailed Look at MES Data

MES functions create, collect, modify, analyze, react to, and manage a great deal of data. These data are summarized below:

Dispatch data: job/operation dispatch list, or commands to operators and equipment

Equipment resource data: resource state, staffing, setup, current operations and assignments, and job usage history

Labor resource data: personnel availability and tracking information, and job assignment history

Maintenance data: machine availability data, maintenance history, and usage data

Material location data: location and state of materials with respect to active resources and material-handling components

Order data: units of a particular product to be manufactured, including status and associations with particular material groups

Performance, cost, and usage data: cost of operations performed, materials and resources used, idle time

Process control data: process control parameters

Product data (WIP): the amount, state, and disposition of materials in production and their relationship with manufacturing orders

Quality analysis data: data resulting from the quality analysis function, that is, interpreted measurements of process and product

Quality data: product and process measurement data, which can include such data taken from process operations

Resource description data: characteristics of labor and equipment resources such as capabilities, skills, types, and assigned cost

Schedule data: allocation of resources to jobs and processes per time period

Shop-floor data: raw data collected by data collection systems that can be used to derive product (WIP) data, resource data, performance data, and so on

Specification data: specifications for how to perform a manufacturing process, including sequence of operations to be performed, equipment, tooling and skills requirements, and materials to be used

Tooling resource data: usage, location and allocation information, which may be used for tracking, scheduling, and maintenance of tools

Table 2 shows the nature of the data usage by the MES functions. The numbers in each cell correspond to the numbers assigned above. The designations HRM, ERP, and PPE refer to non-MES systems of the enterprise that use some of the same data. HRM refers to human resource management systems, ERP refers to enterprise resource planning systems, and PPE refers to product and process engineering systems.

4.2. MES Object Models

An analysis of the MES functions and the data in Table 2 led to the development of the two MES object models shown in Figure 6 and Figure 7. These models, which are based on the work in Ray and Wallace (1995) and OMG (1997b), organize the functions and data in a way that facilitates the implementation of MES components based on object or component middleware technology. They also provide an implementor or integrator with an organization of a distributed MES architecture that simplifies integration with other manufacturing information systems.

The partitions that we have shown with dotted boxes in Figure 6 are groupings of model entities that are closely coupled or functionally similar. Coupling between these partitions should be supported via domain specific names or keys. Each partition in the model is described in detail below. While all these partitions are important to MES, they need not all be supported directly within an MES. We make special note below of those that we consider to be core MES partitions. The tags, shown in italics above or below each partition box in the figures, are general characterizations of the resource entities within the corresponding partition. These are further elaborated in the text below:

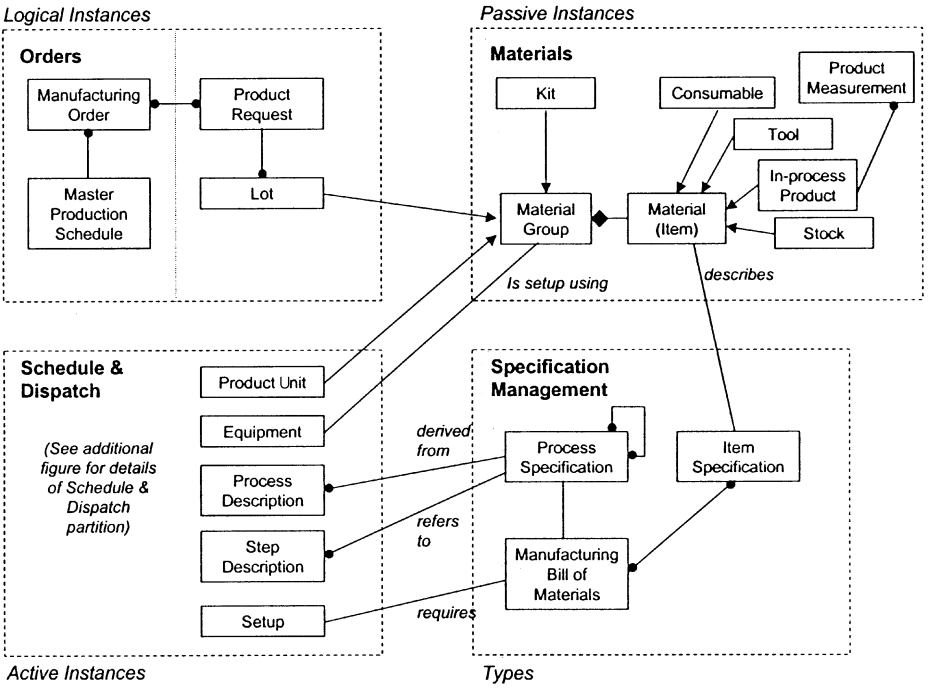
Orders: The orders partition contains two planning entity classes: those that are created by ERP systems and those that may be MRPII entities. This distinction is made here since it is not clear whether MRPII is considered an ERP or MES function. We have tagged this partition ''logical instances'' in the diagram to indicate that the entities within it are logical resources, which merely represent groups of physical resources or planned physical resources that are modeled in other partitions.

Schedule and dispatch: This partition is at the heart of MES operations, containing the primary entities involved in scheduling and dispatching. If the MES supports reactive scheduling, then the internal components must be able to share a common understanding of process description. Therefore, the model has a separate entity for process description, which is distinct from (and an instance of which is derived from a) process specification. We note with the tag ''active instances'' that unlike the entities in the other partitions, many Schedule and Dispatch entities can initiate actions.

Specification management: The entities in this partition have similar access characteristics but only a loose coupling. This means that some efficiency may be gained by putting all these entities into one component. Nevertheless, as long as all access requirements shared by these entities are met, these entities could be stored in multiple components. We note with the tag ''types'' that this partition contains information resource entities that provide type information used to instantiate or describe other entities.

TABLE 2 Relationship of Data to MES Activities

	Collects	Creates	Changes	Manages	Analyzes	Reacts To	Delivers	Displays	Derived From
Dispatch data		3	3, 8			8, 10, 12 Control	3	3, 10	
Equipment resource data	5		5, 9	1	9	2, 3			
Labor resource data	6		10	6, HRM	11	2, 3			
Maintenance data	5	9	9	9	9, 10	2, 3, 9	9		
Material location data	5, 12	12	12	12		3, 10		12	Shop-floor data
Order data	ERP		10	ERP		2, 3, 10	ERP	2, 10	Product data
Performance data		11		11		ERP, P/PE	11	11	Resource data, Schedule data, Shop-floor data, Process data, Product data
Process control data		P/PE	8			Control	8		
Product data (WIP)	5		7, Control	10	11	2, 10, ERP		10	Shop-floor data, Process data
Quality analysis data		7		7, 10		3, 9	7	7	Quality data
Quality data	5?, 7	Control		7	7, 10	?			Product data, Process data
Resource description data		ERP, HRM, P/PE		6, HRM, ERP, P/PE		2, 3			
Schedule data		2	2	2	11	2, 3			
Shop-floor data	5			5	2, 10	2, 3	5		
Specification data	P/PE	P/PE	4	4		3, 7	P/PE		
Tooling resource data	12	12	Control	1, 10		2, 3, 10			



*The graphic notation used in this figure and subsequent object models, is a simplified version of the object modeling technique (OMT) notation described in Rumbaugh (1991).

Figure 6 Simplified Object Model.*

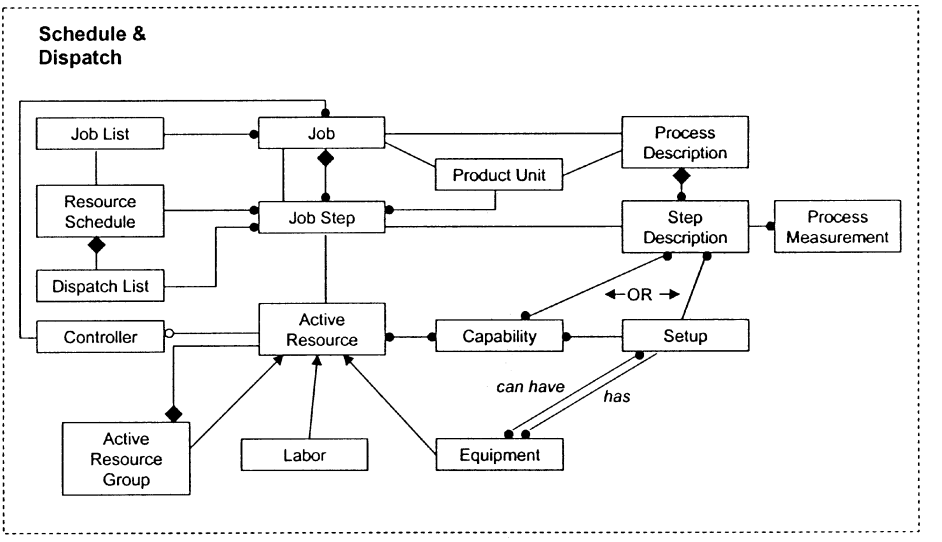


Figure 7 Detailed View of Scheduling and Dispatching.

Materials: The entities in this partition are related to material instances such as material status, history, and genealogy data. It may also provide inventory information. We note with the tag ''passive instances'' that the entities in this partition represent physical resources that are manipulated or acted upon by active resources represented in other models.

The entities of the MES Object Model shown in Figures 6 and 7 are described in detail below:

Active resource: a physical resource, or a logical grouping a resources, that can perform process operations and supports specified capabilities during manufacturing activities—people and equipment such as machines, robots, storage devices, transport devices, etc.

Capability: the ability of a resource to perform a specified operation. For human resources, a capability is sometimes called a (certified) skill. For equipment resources, this potential may be dependent on setup and on having an appropriately skilled operator.

Consumable: a unit of material that is used and expended during manufacturing or support processes.

Controller: a software system, or human agent, that provides the intelligence needed by an active resource to perform all or part of a process operation automatically.

Item specification: the complete description of a kind of material item including its shape, weight, handling characteristics, image, etc.

Job: a unit of work assigned to an active resource. At the schedule/dispatch level, the unit of work is a lot; at lower levels, the unit of work is a process operation, transport operation, or operation step.

Job step: an instantiation of a step description. Depending on its granularity, a job step becomes a job for the active resource to which the step execution is assigned.

Kit: a physical collection of material items that is handled as a unit.

Labor: a human active resource (employee or contractor or group) who performs certain jobs directly or in collaboration with a machine. The ability of a human resource to perform a specific kind of process with specific kinds of equipment is called a certified skill.

Lot: the unit of product into which a manufacturing order is decomposed for scheduling, dispatching, and tracking. A lot is a conceptual material group. The actual corresponding product units on the factory floor may be decomposed and regrouped, depending on production policies and needs.

Manufacturing bill of materials: a list of the types and quantities of all materials needed to manufacture a unit of product or to perform a particular process.

Manufacturing order: a quantity of a particular product to manufacture as specified by an ERP system.

Master production schedule: A long-term schedule created and maintained by enterprise planning systems that defines quantities of particular products to be produced in particular time frames based on customer demands, manufacturing capacity, and resource availability.

Material item: a physical resource that is acted upon or used by an active resource in the performance of a manufacturing activity. It is characteristic of most material items that they can be moved around the factory floor, and it is often the case that their location is tracked in some way.

Material group: a logical or physical collection of material instances.

Process description: a breakdown of a process into subtasks or steps, expressing the requirements for each step and its relationship to other steps in the recipe. Every process description has an associated active resource that is responsible for planning and executing the process described. Process descriptions come in many forms: NC programs, routings, operation sheets, recipes, etc.

Process specification: archival form of a process description, usually a document. An information resource is targeted for a particular type of active resource. It is copied as needed to create process descriptions for individual resources.

Product in-process: a material item, which becomes part of a final product.

Product request: a unit of product that is the basis for planning/scheduling activities at the highest level of a manufacturing execution system.

Product unit: a quantity of product (or a group of in-process product items) that undergoes manufacturing activities together.

Resource schedule: a collection of assignments of active resources to job steps at specific times.

Setup: a particular configuration of an equipment resource that results in a set of active capabilities for that resource.

Step description: a part of a process description that identifies a job step to be performed, resources necessary to perform the job step, other information needed to plan the job step, and, usually, the process specification that the active resource will use to perform the job step activity.

Stock Material: a kind of material that is the starting point for, or an ingredient in, a unit of product.

Tool: a material item used by an active resource in the performance of some manufacturing activity. A tool is a material item that is needed during the manufacturing process but is not (usually) consumed and does not become part of the finished goods. Tools are used to set up an equipment resource, or augment a workstation setup, in order to enable the workstation to perform a particular process operation.

4.3. Market Trends and Future Directions

Originally predicted to be a strong new market area, the MES product category had only grown about $218 million in 1998 (Callaway 1998). This has been attributed to such diverse factors as manufacturing management's preoccupation with higher-level enterprise systems such as enterprise resource planning (ERP) and supply chain management (SCM) and resources being diverted for Year 2000 projects. No matter what the cause, MES has not become a ubiquitous system across all manufacturing domains.

However, the functionality it targeted remains important as the changing marketplace for manufactured goods forces manufacturers to respond more quickly to market opportunities and participate in more dynamic supply chains. An MES provides the higher level of integration needed to support rapid access to data, as well as the means to respond rapidly to new production tasks or priorities. Because this need still remains, vendors in other product categories have expanded their product line to include many of the MES functions described in Section 2.2, with mixed success. This encroachment has come from above with ERP systems and from below with open control systems. While it is certain that the functionality and data described in this section will be available in the factory of the future, it is difficult to predict what systems will be managing it. This underscores the importance of developing standard interfaces and data models for this area so that manufacturers can make use of this technology no matter what the products are called or where the lines are drawn between them.

5. SUMMARY

This chapter has addressed three subjects related to the control of shop-floor operations: control architectures, AI-based scheduling, and manufacturing execution systems (MES). The ideas discussed in this chapter are applicable to many different types of manufacturing and service industries. To date, very few of the advanced scheduling techniques have been incorporated into commercial MES software packages, and little or no effort has been put into integrating these packages into an open architecture for shop-floor control. We expect this situation to change dramatically over the next few years as companies push more toward Internet-based electronic commerce.

CHAPTER 66
Total Quality Leadership

JOHNSON A. EDOSOMWAN
Johnson & Johnson Associates, Inc.

1. INTRODUCTION AND KEY DEFINITIONS

Global competition and customer demands for competitive quality products and services require that both public- and private-sector organizations implement results-driven continuous performance improvement approaches and systems. According to Hiam (1993), between 75 and 80% of large companies adopted quality management approaches within the last decade. Malhotra et al. (1994) also point out that quality continues to be a top-ranked strategic issue among top manufacturing executives.

The terms *total quality* (TQ), *total quality management* (TQM), *total quality improvement process* (TQIP), and *total quality leadership* (TQL) have been used interchangeably in the literature and in organizations embarking upon a comprehensive quality-driven performance improvement process. Evans (1992) defines total quality as a people-focused management system that aims at continual increase of customer satisfaction at continual lower real cost. Total quality is a total systems approach (not a separate area or program) and an integral part of high-level strategy; it works horizontally across functions and departments; involves all employees, top to bottom; and extends backwards and forwards to include the supplier and the customer chains. Practitioners and researchers agree that when all the elements of total quality are fully implemented with leadership support and commitment, there are bound to be positive business results. Edosomwan (1994, 1998a) defines total quality lead-

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

ership as a systematic, continuous improvement process that involves measuring, planning, evaluating, and improving all aspects of an organization's performance. It involves a customer- and people-driven process that is led by senior management vision and commitment, with full participation from organizational stakeholders to produce error- and defect-free products and services for end users. The TQL process utilizes quantitative, qualitative, behavioral, technological, technical, and managerial tools and techniques to improve organizational structures, work processes, policies, procedures, products, and service-delivery systems. Edosomwan (1994) points out that total quality leadership encompasses all aspects of the total quality management and improvement process. It is also important to point out that the definition of quality varies quite widely. As shown in Table 1, Edosomwan (1998d) documented 10 approaches and major definitions of quality appearing in the literature.

Various critical dimensions of TQM, TQL, and TQIP are identified in the literature. For example, Whitney and Pavett (1998) note that management support for the improvement process is the genesis, without which little else will happen. Almaraz (1994), Edosomwan (1990, 1998a), Crosby (1979), Juran (1974), Deming (1981), Hackman and Wageman (1995), and Westphal et al. (1997) discuss other important dimensions that are critical to the successful implementation of the total quality

TABLE 1 Ten Key Approaches and Major Definitions of Quality

Approaches	Authors	Definitions
Customer based	Juran 1974	"Quality is fitness for use."
	Edwards 1968	"Quality consists of the capacity to satisfy wants."
	Edosomwan 1988	"Quality is conformance to customer requirements."
Product based	Crosby 1979	"Quality is conformance to requirements."
	Deming 1981	"Quality is durability of product."
Performance based	Edosomwan 1999	"Quality is a measure of product and service delivery system performance."
Management based	Deming 1981	"Eighty percent of the quality problems are caused by organization management system."
	Edosomwan 1998d	"The quality of management drives performance."
System based	JISC 1981	"[Quality is] a system of means to economically produce goods or services which satisfies customers requirements."
Transcendent	Pirsig 1974	"Quality is neither mind nor matter, but a third entity independent of the two, even though quality cannot be defined, you know what it is."
Process based	Deming 1982	"Quality is controlling process variation."
	Edosomwan 1994	"Quality is a measure of process performance."
Value based	Feigenbaum 1983	"Quality means best of certain conditions: (a) the actual use, and (b) the selling price."
Prevention based	Edosomwan 1994	"Quality is preventing errors and defects."
Technology and culture based	Sashkin and Kiser 1993	"Quality means that the organization's culture is defined by and supports the constant attainment of customer satisfaction through an integrated system of tools, techniques and training."

Source: Edosomwan 1998d.

improvement process. These dimensions include, but are not limited to: (1) management practices, (2) customer focus, (3) supplier quality and performance, (4) employee development and training, (5) performance incentives, (6) technology, (7) cultural and relationship factors, (8) workforce attitude, (9) process management, (10) performance measures, (11) strategic planning, (12) problem-solving process, (13) product and service-delivery systems, and (14) labor and management relations. However, implementing the total quality leadership process definitely requires the commitment, support, and dedication of the organization's senior managers and leaders.

2. TOTAL QUALITY LEADERSHIP SYSTEM ELEMENTS

According to Almaraz (1994), implementing the total quality improvement elements and process requires a transformation in the organization's culture, processes, and strategic priorities and in individual attitudes, beliefs, work ethics, and behavior. Edosomwan (1995, 1998a) identifies four total quality leadership (TQL) system areas: the management system, the social system, the technical system, and the behavioral system (see Figure 1).

1. *The management system* encompasses the way that policies, procedures, practices, protocols, and directives are established, enforced, and maintained. The leadership systems of the organization set the tone and vision and provide indicators of what should be done, how it should be done, and what should be accomplished. The management system carries into effect strategies, processes, and project management, and it encompasses the vision, mission, and values of the organization.
2. *The social system* has a significant impact on motivation and the ability to implement new ideas; it addresses organizational culture, structure, rewards, teamwork, values, and the creativity of individuals and groups. The social system is influenced by the values of the founders, leaders, families, peers, and supervisors, as well as group behaviors. Before transformation, the state of the organization is usually influenced by rigid rules and lack of focus on customer requirements, constancy of purpose, and continuous improvement.
3. *The technical system* includes the tools, techniques, and mechanisms necessary to produce excellent products and services. The technical system also involves work processes, technol-

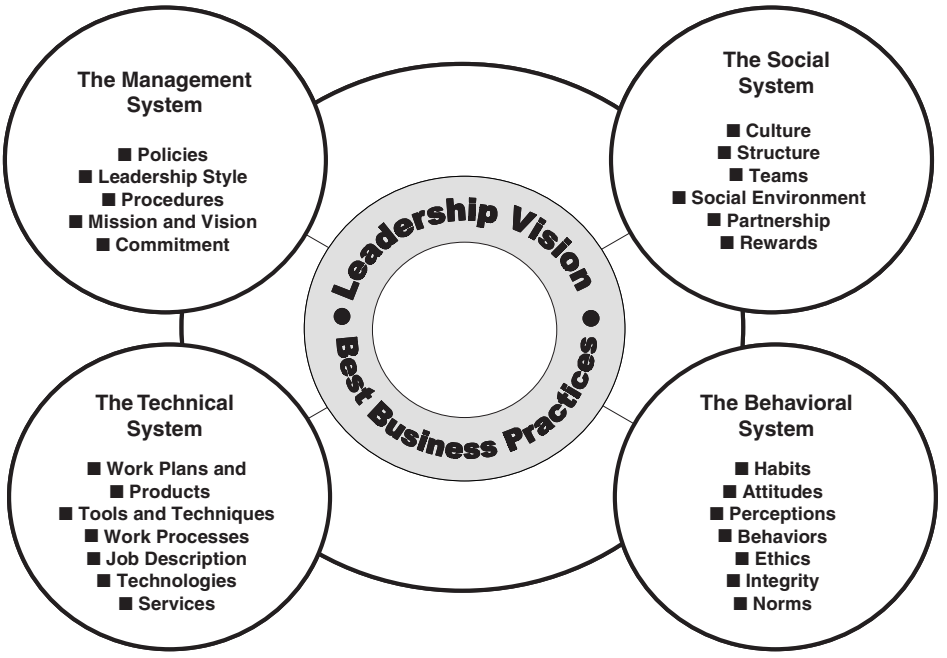

Figure 1 Total Quality Leadership System Areas (From Edosomwan 1995).

ogies, and systems that are utilized in transforming organizational inputs to outputs and outcomes. The job and task descriptions are part of this system. The technical system pertains to measures, which serve as the basis for improvement and planning.

4. *The behavioral system* relates to the fundamentals of the human side of quality, as characterized by the habits, attitudes, work patterns, and behaviors of individuals and groups. Through modification of the elements in the behavioral system, it is possible to implement changes that can lead to significant breakthrough in performance. The behavioral elements are often difficult to change, and when a change is made, it positively influences the speed of organizational process transformation.

3. TOTAL QUALITY LEADERSHIP: EIGHT PILLARS OF QUALITY

Edosomwan (1995, 1998a) identifies eight pillars of quality, as shown in Figure 2 and described below. The eight pillars of quality must be continuously improved throughout the TQL process.

1. *Quality of management* pertains to the quality of organizational policies, procedures, values, and the resource-allocation system. It also addresses the quality of leadership and management decisions, supervision, and guidance provided to the workforce as it relates to the delivery of products and services.
2. *Personal quality* pertains to the quality of personal attributes, trust, and characteristics that enable individuals to maintain excellent work ethics and performance. The critical factors in this area include personal attitude, skills, abilities, work habits, behaviors, integrity, trustworthiness, loyalty, dedication, and commitment to the successful achievement of organizational and personal mission and priorities.
3. *Quality of service* involves several tangible and intangible factors, such as the degree of courtesy provided to internal and external customers. It also includes other factors, such as the appearance of the products and services being offered, responsiveness, and the extent to which customers receive adequate value-added service.
4. *Process quality* pertains to the quality of primary, secondary, and auxiliary work processes that are required to transform organizational inputs to outputs and outcomes. Primary work pro-

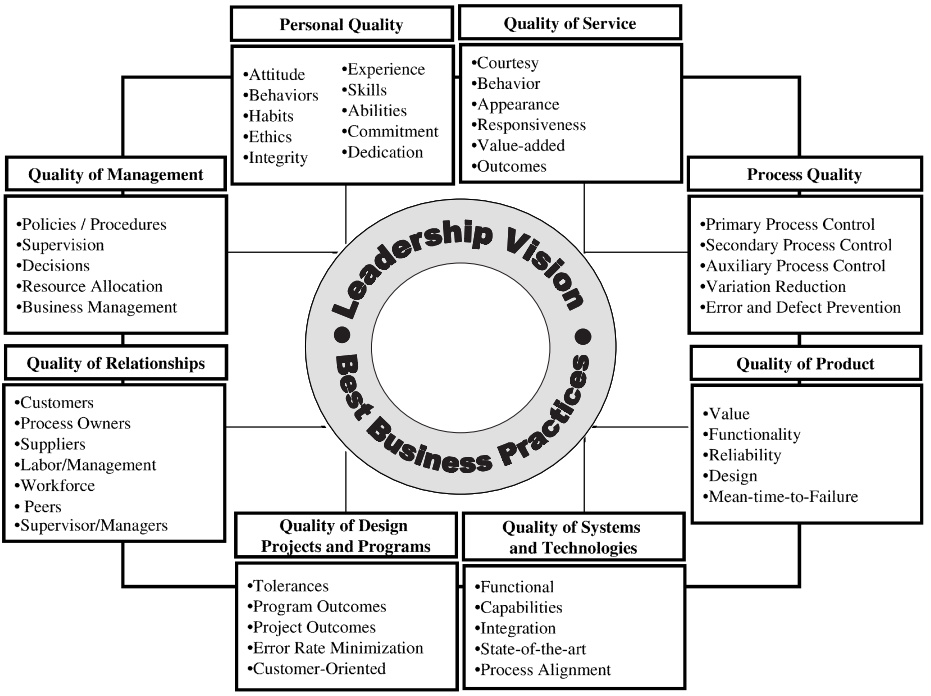

Figure 2 Eight Pillars of Quality (From Edosomwan 1998d).

cesses have impact on the external customers, while secondary processes have impact on the internal customers. Auxiliary work processes have impact at the job and task levels. Process quality also pertains to how well variation in process variables is managed, controlled, and improved continuously to ensure that the final products and services delivered to the end users are error and defect free.

5. *Quality of relationships* pertains to the quality of interaction and relationship among suppliers, process owners, customers, teams, work units, labor and management, and functional business areas. It also involves the quality of outputs and outcomes produced as a result of a defined relationship among suppliers, process owners and customers.
6. *Quality of design projects and programs* pertains to the quality of products and services at the design, program and project management, and delivery stages. It takes into account design specifications, tolerances, and quality of task outputs and outcomes involved in the design and development cycle of a product or service.
7. *Quality of systems and technologies* pertains to the functional quality of production and service delivery systems and technologies. It addresses the quality of the technology life cycle as well as the operational measures of system and technology performance. Measures such as mean-time-to-design, mean-time-to-failure, mean-time-to-service and -repair, and reliability are utilized to assess the quality of systems and technologies. It also addresses how well state-of-the-art systems and technologies are integrated to deliver error- and defect-free products and services to end users.

TABLE 2 Traditional Organizations vs. Customer-Driven Organizations

Area	Traditional Organizations	Customer-driven Organizations
Product and Service Planning	■ Short-term focus ■ Reactionary management ■ Management by objectives	■ Long-term focus ■ Prevention-based management ■ Customer-driven strategic planning process
Measures of Performance	■ Bottom-line financial results ■ Quick returns on investment	■ Customer satisfaction ■ Market share and profitability ■ Quality and total productivity
Attitudes Toward Customers	■ Customers are irrational ■ Customers create problems ■ Customer concerns are bottleneck to profitability	■ Identify and respond to the voice of the customer ■ Professional treatment and attention to customer needs
Quality of Products and Services	■ Provided according to organizational requirements	■ Provided according to customer needs and priorities
Marketing Focus	■ Seller's market ■ Careless about loss of customers	■ Long-term focus ■ Prevention-based management ■ Customer-driven strategic planning process
Process Management Approach	■ Focus on error and defect detection and risk management	■ Focus on error and defect prevention and total process management
Product and Service Delivery Attitude	■ It is fine for customers to wait for product and services	■ It is best to provide fast-time-to-market products and services just-in-time
People Orientation	■ People are the source of problems and are burdensome to the organization	■ People are the greatest asset and resource to the organization
Basis for Decision Making	■ Product-driven ■ Management by opinion	■ Customer driven ■ Management by facts and data
Attitudes Toward Customers	■ Hostile and careless ■ "Take it or leave it" attitude	■ Courteous and responsive ■ Empathetic and respectful
Improvement Strategy	■ Crisis management ■ "If it is not broken, don't fix it"	■ Continuous process improvement ■ Total performance management
Mode of Operation	■ Career-driven independent workers ■ Short-term planning and profitability	■ Management-supported improvement ■ Teamwork among customers, suppliers, and process owners

Source: Edosomwan 1994.

8. *Quality of product* pertains to product reliability, value, functionality, and dependability. End users also utilize mean-time-to-failure, mean–time-to-repair, and maintenance cycle time and costs to evaluate the quality of products.

The continuous improvement of the eight pillars of quality and the implementation of the TQL system and process enable organizations to move from a tradition-based culture to a customer-driven organization culture. Table 2 summarizes the major differences between traditional and customer-driven organizations.

4. TOTAL QUALITY LEADERSHIP TOOLS AND MODEL

Several models, tools, and techniques are available for improving the quality of products and services and managing the total quality leadership process. Greene (1993) reviewed quality practices in Japan and the United States and claims to have identified about 24 dimensions of total quality management (TQM). Edosomwan (1998a) identified several TQL tools summarized in Table 3 for improving quality and performance at the individual, work-unit, and organizational levels.

The Malcolm Baldrige National Quality Award performance excellence criteria have been widely used as a model for total quality leadership and a tool for achieving performance excellence. The Baldrige criteria and model focus on leadership as a driver of quality. Other aspects of the model include information and analysis, strategic planning, process management, human resource management and development, customer and market focus, and business results. Edosomwan (1998a, b, c, d) developed a more comprehensive performance excellence model, shown in Figure 3, that has been utilized by both public- and private-sector organizations for improving all aspects of performance.

This model is based on augmented, expanded performance criteria, an expanded scoring system, and a defined implementation methodology. The categories and key components of EPEM, described below, retain the components of the Baldrige criteria while providing a more comprehensive, universal criteria and performance-improvement system for both public- and private-sector organizations. There are 10 EPEM categories, as described below:

1. *Leadership* examines how the organization's senior leaders address and communicate the organization's vision, mission, values, and performance expectations, as well as their focus on employees, customers and other stakeholders, empowerment, innovation, learning, organizational direction, and coordination of tasks. Also examined is how the organization addresses its societal responsibilities and community involvement.
2. *Strategic planning* examines the organization's strategy development process, including how the organization develops strategic, tactical, and operational business plans that are aligned with organizational vision, mission, values, resources, budget, measures, and stakeholders' requirements.
3. *Customer and market focus* examines how the organization determines customer requirements, expectations, and preferences of customers and segments. Also examined is how the organization builds relationships with internal, external, and self-unit customers; determines satisfaction levels; and uses information to determine priorities.
4. *Information and analysis* examines the organization's process and approach for collecting, analyzing, and using performance data and other core information across the organization. It also includes the organization's performance measurement system, technology capabilities, data transfer, and information management system.
5. *Human resource development and management* examines how the organization trains and enables employees to develop and utilize their full potential, aligned with the organization's objectives. It also addresses the organization's efforts to build and maintain a work environment of empowerment and a culture and climate conducive to performance excellence, full participation, and personal and organizational growth, providing appropriate recognition and reward.
6. *Process management* examines key aspects of the organization's ability to define, manage, and continuously improve primary, secondary, and auxiliary work processes, including customer-focused design, product and service delivery, and process variation management.
7. *Culture systems and relationship management* examines the organization's ability to create an integrated, cohesive working environment of teamwork and cooperation that is sensitive to the needs and requirements of a diverse employee population. Also examined are the organization's policies, procedures, and actions that are deployed to ensure fair and equitable treatment of stakeholders and the employee population. It examines the organization's culture, environment, and relationships among labor leaders, managers, and labor and their ability to work together in partnership to meet and exceed the organization's goals and objectives.
8. *Technology integration and management* examines the organization's commitment to identification and evaluation of emerging technology related to new products and services, primary

TABLE 3 Selected Examples of Total Quality Leadership Tools

Plan Do Check Act Technique	Provides a methodology to assist individuals and teams in problem solving, planning, work analysis, and implementation of solutions
Personal Performance Improvement Model	Provides a model for assisting individuals in developing and implementing performance-improvement goals
Quality Error-Removal Technique	Provides a team-based approach for analyzing and removing error and defect sources
Statistical Process Control Technique	Provides statistical techniques and tools for controlling managing process variation
Force Field Analysis Tool	Provides a graphical means of understanding, quantifying, and balancing the positive and negative impacts related to goal achievement for individuals and teams
Brainstorming Technique	Provides a process for a group to quickly generate, clarify, and evaluate ideas, suggestions, problems, and issues to stimulate the creativity of individuals in a participative, group problem-solving process
Benefit Energy Dots Tool	Provides a structured process for multivoting and subjective prioritization of ideas and suggestions in a team problem-solving environment
Job Requirement Mapping Tool	Provides an approach and a working tool for defining and understanding the requirements of the job
Problem-Solving Approach	Provides the key steps for successfully resolving any problem by testing, defining and implementing solutions
Process Analysis Technique	Provides a technique for defining the steps of work processes and analyzing them to identify non-value-added steps and opportunity areas
Group Ideas Management Technique	Provides a methodology for generating ideas, solving problems in a team environment, and prioritizing the ideas for the optimal solution
Cause-and-Effect Diagram	Provides steps for constructing a cause-and-effect diagram for identifying root causes of a problem
Pareto Analysis Technique	Provides a graphical representation of identified causes presented in descending order of magnitude or frequency
Error Mapping Technique	Provides an approach for analyzing quantitative error data to identify the sources of errors and defects in work elements, tasks, and processes
Problem Statement Impact Definition Tool	Provides a comprehensive description of the actionable item and stratifies the items which an individual or team intends to analyze for performance improvement; helps individuals specify data and information relevant to a specific problem
Problem-Containment Model	Provides a framework for containing problems from irate individuals, teams, and the work environment
Complaint-Resolution Model	Provides a step-by-step process for resolving internal and external customer complaints
E-Alarmo Technique	Provides an approach for identifying and resolving breaks in customer service and handling irate customers
Process Reengineering Technique	Provides a methodology for reengineering and transforming organizational structures and work processes
Process Element Mapping Technique	Provides a step-by-step approach for mapping process steps, elements, requirements, and owners
PADER Technique	Provides a five-dimension scoring system for evaluating an organization's performance with focus on plan, approach, deployment, evaluation and results

Source: Edosomwan 1998a.

and support process performance, and people management. It assesses the organization's technology utilization, systems integration, and connectivity elements.

9. *Supplier performance management* examines the organization's commitment to and process for ensuring a high-performance supplier base capable of meeting and exceeding specifications and requirements for all goods and services procured by the organization.

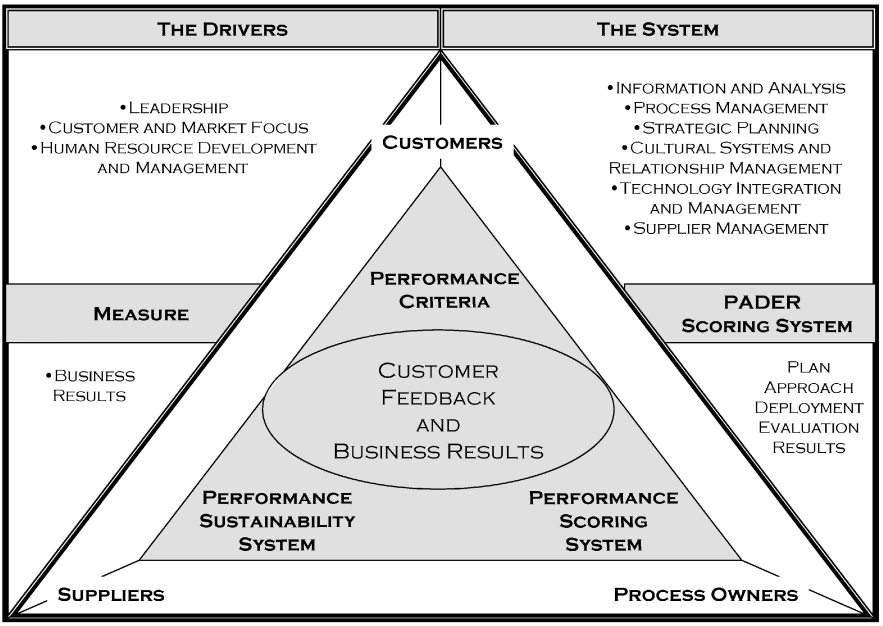

Figure 3 Edosomwan Performance Excellence Model (EPEM). (From Edosomwan 1998a, b, c, d)

10. *Business results* examines the key results and trends related to the organization's performance in key business areas: customer satisfaction, employee satisfaction, product and service performance, financial management, marketplace performance, mission accomplishment, human resource results, supplier and partner results, and operational performance. Also examined are performance levels relative to world-class organizations.

4.1. PADER Scoring System

Edosomwan (1995, 1998a, b, 2000), developed the Plan, Approach, Deployment, Evaluation, and Results (PADER) scoring system, shown in Figure 3. The system has five performance-evaluation dimensions. The PADER system is utilized for continuous measurement, evaluation and scoring of the categories of the EPEM model. Each component of the PADER scoring system is described below:

1. *Plan* considers the existence of strategic, tactical, and operational thinking, covering long-range, medium-range, and short-term time horizons, respectively. The success of all aspects of a comprehensive continuous performance improvement system depends heavily on a sound, results-driven plan.
2. *Approach* examines the methods used in the organization. Factors used to evaluate the approach dimension include appropriateness of the methods to the requirements; effectiveness of the methods; degree to which the approach is systematic, integrated, consistently applied, embodies evaluation and improvement cycles, and is based on reliable data and information; and evidence of innovation and effective adaptations of approaches used in other types of applications or organizations.
3. *Deployment* refers to the extent to which the organization's approach is implemented across the organization. The factors used to evaluate deployment include the use of the approach in addressing business requirements and the use of the approach by all appropriate work units.
4. *Evaluation* examines the mechanisms, processes, methodologies, and measures used for evaluating, monitoring, and tracking organizational performance for all category elements on a regular basis.
5. *Results* addresses organizational outcomes. The factors used to evaluate the results dimension include current performance; performance relative to appropriate comparisons to world-class

results or benchmark organization; rate, breadth, and importance of performance improvements; and demonstration of sustained improvement over an extended period of time.

5. IMPLEMENTATION OF THE TOTAL QUALITY LEADERSHIP PROCESS

The successful implementation of TQL requires leaders and managers to possess the characteristics and attributes shown in Table 4. *Leading* TQL involves the thought process and act of creating a quality-driven, executable vision or agenda in a systematic manner for the purpose of achieving desired performance results and outcomes. Organizational leaders create, choose, convince, inspire, direct, cause, and make things happen. *Managing* TQL involves the thought process and act of planning, organizing, directing, evaluating, maintaining, supervising, and producing desired quality results and outcomes through people to accomplish the leadership vision and agenda. Organizational managers implement, administer, supervise, and maintain the process of making this happen. Quality results do not happen by accident. The process must be led, managed, and implemented by customers, process owners, suppliers, and the workforce.

The eight steps shown in Figure 4 and described below are recommended for implementing the TQL process in both public- and private-sector organizations:

5.1. Step One: Provide Leadership and Vision for Performance Excellence

Organizational senior leadership must provide the vision, values, culture, and environment for performance excellence. Senior managers need to be trained on the tools, techniques, and principles for leading an organizational performance improvement process. Comprehensive world-class data and information should be utilized to convince top management of customer-driven performance improvement needs and benefits. Do a thorough analysis of the market requirements. Use competitive data on products and services, market share, cost profile, customer, quality, and performance improvement. Explaining the role of the customer, quality, and successful and unsuccessful customer performance improvement examples from other companies also provides a quick way of helping executives see the benefits of adopting the customer-driven performance improvement philosophy. The message to top management is that improvement of quality, productivity, customer satisfaction, and performance are key to achieving competitive advantage, profitability, efficiency, growth, and effectiveness.

5.2. Step Two: Communicate the Continuous Performance Improvement Philosophy

Once senior management support has been achieved, the next step is to communicate and demonstrate management's commitment to the TQL process. Communication regarding the TQL philosophy should emphasize that everything begins with the customer; that is, the sole purpose of the business

TABLE 4 Attributes of Effective Leaders and Managers

Leaders	Managers
1. Create the vision, agenda, purpose, goals, and objectives	1. Implement goals, objectives, policies, and procedures
2. Lead programs and processes for continuous improvement	2. Administer programs for continuous improvement
3. Ask what and why the organization is now and will be in the future	3. Ask how and when—focused on details
4. Are developers of people and organizations	4. Educate people and motivate them to do their best
5. Lead change, are pace setters and risk takers	5. Recognize and reward in a timely manner
6. Provide trust, hope, results, compassion, and constancy of purpose	6. Appraise and counsel to improve performance
7. Remind people of what is important	7. Maintain the process of getting things done
8. Develop customer- and people-driven agendas and results	8. Are proactive rather than reactive
9. Set policies, procedures, and results	9. Implement policies, procedures, and rules
10. Create and build relationships and trust	10. Maintain positive relationships and trust
11. Innovate new productive systems	11. Maintain new and existing systems
12. Use data- and fact-driven, prevention-based strategies and solutions	12. Use data- and fact-driven, prevention-based management

Source: Edosomwan 1999b.

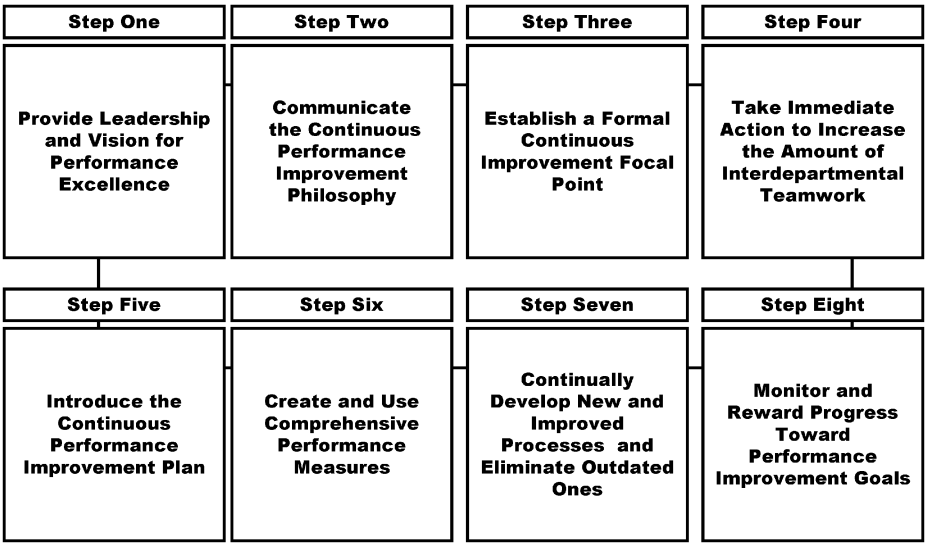

Figure 4 Eight Steps for Implementing Total Quality Leadership Process.

is to attract, serve, and exceed customer's expectations. The commitment to performance excellence means that a total quality culture exists in which everyone constantly considers the quality of their work and how it is reflected in the final output. This also requires that workers be given control, responsibility, and decision latitude for a variety of activities, such as maintenance, information control, quality, process analysis, service, production, and resource allocation. Adopting a TQL philosophy also means focusing on management using facts and data, quality first, proper planning, and effective utilization of human resources.

5.3. Step Three: Establish a Formal Continuous Performance Improvement Focal Point

Recruit seasoned and talented individuals to develop quality-driven performance improvement programs. Individuals charged with this program development must also be given the authority and resources required to institutionalize the program elements. The organization should benchmark successful quality practices implemented in other organizations to avoid potential sources of failure.

5.4. Step Four: Take Immediate Action to Increase the Amount of Interdepartmental Teamwork

People should be trained to work together toward common performance and quality goals while sharing ownership of the final work output. Individuals and work teams should be encouraged to participate in group problem solving, decision making, and incentive systems for rewarding quality excellence. Organizational barriers that hinder teamwork should be eliminated. The method of working should focus on cooperation, not contention. Everyone can make a difference in the quest for continuous performance improvement. Both management and employees should be encouraged to take greater responsibility for their work processes and provide ideas for improving the total process. Managers and supervisors should use a participative management approach to encourage innovative ideas from everyone and put them to work. The environment should allow managers and employees to share in decision making and problem solving and recognition, which are essential for error prevention and innovative improvements.

5.5. Step Five: Introduce the Continuous Performance Improvement Plan to the Team

The organization's quality, productivity, and customer satisfaction strategy should describe the framework, approaches, goals, and objectives that the organization will pursue to achieve continuous performance improvement. At every level of the organization, it is important to have a performance improvement strategy consistent with customer requirements, market demands, operating principles, procedures, and policies. The performance improvement strategy should be the responsibility of the

senior management team. Senior management in each operational unit should work with its team to define tactical and operational strategies. The performance improvement strategy should address performance planning, measurement, evaluation, and improvement management. Continuous performance planning involves defining the specific strategies for understanding the market and maintaining an awareness of customer needs, wants, and desires. The plan should define opportunities for supplier and customer involvement in formulating performance improvement needs. This element of the strategy will define the process for continuous improvement and people improvement. Other requirements that may be included in the strategy include updated product specifications such as those for hardware and software; equipment for enhanced measurement, inspection, and testing; process control; and resource management tools. The performance management element should define the strategy for developing the skills and knowledge required by management and employees to do the job right the first time. Plans for education and training should include technical and managerial courses, seminars, and workshops. This element should define communication channels for quality and performance improvement throughout the organization. Such channels of communication should ensure that customers, suppliers, employees, and stockholders are informed about quality goals, objectives, policy, direction, guidance, and performance. The performance management plan should also define specific direction and procedures for monitoring compliance to the organization's quality policy, ensuring successful implementation of the quality goals and objectives. Once developed, the integrated master performance strategy for the organization should be reviewed and revised annually by the organization's senior management committee. This committee should be composed of representatives from all the functional areas of the business, including research and development, manufacturing, marketing, services, and support groups. Once developed, the performance improvement plan should be communicated to everyone with specific milestones and measurements for assessing performance.

5.6. Step Six: Implement Comprehensive Performance Measures at All Levels

Develop and implement comprehensive performance measures for managers and nonmanagers, as well as suppliers and process owners. One of the essential elements of developing a quality-driven organization is deciding how the performance of managers and nonmanagers is evaluated and rewarded. Performance measurements should be more than sales volume, short-term profitability, and rate of return on investment. The focus in developing performance measures for both managers and nonmanagers should include but not be limited to the following areas: short-and long-term profits, customer satisfaction indices, quality and productivity improvement indicators, organizational development, market share profile, rate of return on investment, and product reliability measures. Impediments to successful management of information and measures of performance include poor channels of communication and inadequate data collection processes. Communication channels, such as meetings and electronic data exchange, are recommended at all levels of the organization.

5.7. Step Seven: Develop New, Improved Processes to Eliminate Outdated Ones

Identify the products and services to be provided; define the process sources of variation; and define non-value-added steps with ongoing focus on process measurement, evaluation, control, and improvement. Develop new processes that provide defect-free output and satisfy customer requirements. TQL should encourage broad ownership and total participation by everyone, as well as accountability for results. The commitment from everyone should also include willingness to change unproductive work habits and adopt the attitude of doing the job right the first time. To achieve expected customer satisfaction and quality results, individuals and work teams should be provided with the right training and education. Quality education is essential because it prepares everyone to perform well by providing the knowledge needed to make logical, intelligent decisions. If the right skills are provided, people develop efficient work habits and positive work ethics and attitudes that lead to performance excellence. Training should focus on basic orientation to quality, techniques, and tools for quality improvement, quality leadership, technical skills, process involvement, and teamwork.

5.8. Step Eight: Monitor and Recognize Progress toward Performance Improvement Goals

Publicize successful pilot projects. Reward heroes and consistently performing individuals who have made a difference. A management system that recognizes and encourages ongoing quality improvement efforts must be developed and implemented. In rewarding quality success, place emphasis on accomplishments of teams as well as individuals. Provide recognition and reward in a timely manner. Promotions, pay increases, awards, additional responsibilities, and thanks for a job well done should recognize the accomplishments of teams and individuals. Utilize comprehensive performance measures to evaluate progress of projects, individual and team performance, and overall organizational effectiveness. Continue to build pockets of success through the promotion of successful performance improvement projects.

6. SELECTED TQL KEY SUCCESS FACTORS AND CONCLUSIONS

Edosomwan (1994) presents selected key TQL foundation factors for public- and private-sector organizations aspiring to become benchmarks in performance excellence (see Figure 5). These factors focus on the foundational elements, the key players, the philosophy, the implementation process and levels, the scorecard, and the achievement of desired goals and deliverables. The implementation of the TQL process requires teamwork between all key organizational stakeholders, the philosophy of continuous improvement, an implementation process that focuses on strategic, tactical, and operational issues with ownership for results at the individual, team, work-unit, and organizational levels. Other TQL implementation success factors and lessons learned from world-class organizations by Edosomwan (1994, 1998a, b, c, d) include the following:

1. *Defined leadership expectations:* An organization's senior leaders and managers must ensure the existence of clear quality values, vision, goals, and expectations with defined measures. Systems for achieving organizational goals must be clearly defined. These systems must guide all tasks; activities of the organization to enable all stakeholders contribute to the achievement of the quality goals and objectives.
2. *Employee training, empowerment, and participation:* In world-class quality organizations, employees are partners with management in making decisions about how work is done. People are empowered with the right training, tools, techniques, and authority to deliver error and

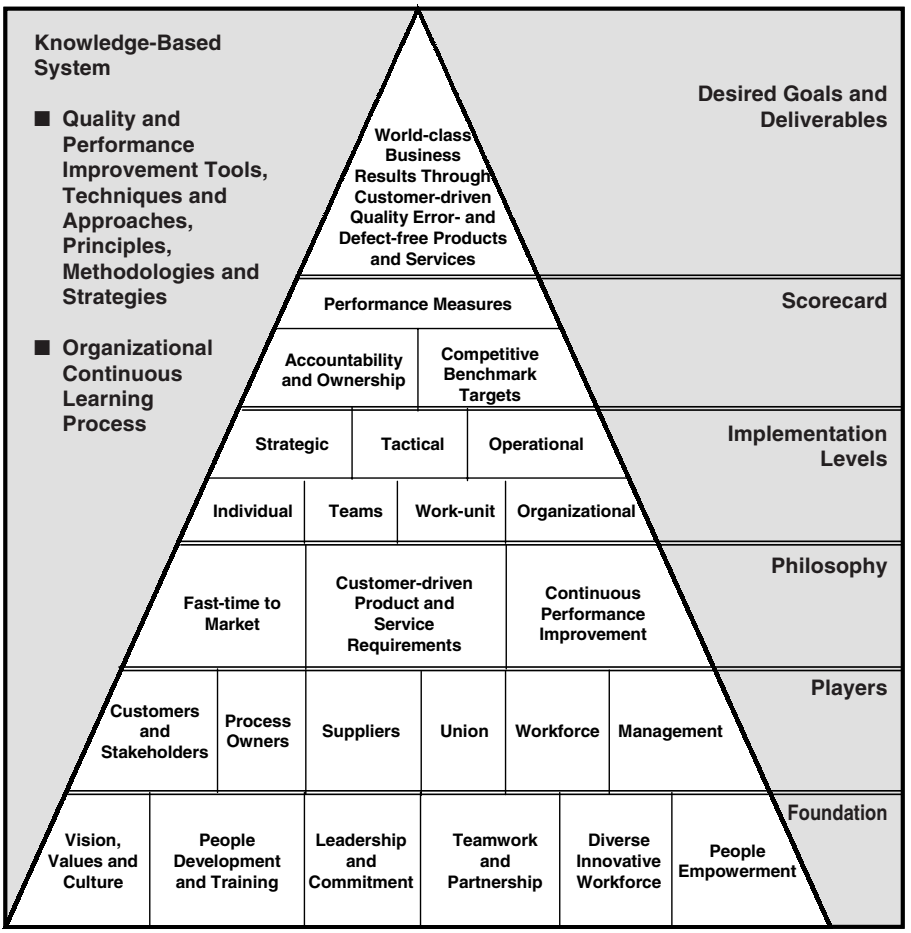

Figure 5 Selected Key TQL Factors. (*Source:* Edosomwan 1994, 1998a, b, c, d).

defect free products and services to customers. The organization leadership creates an environment conducive to employee participation in the TQL process.

3. *Continuous improvement and benchmarking:* In world-class quality organization, quality results from a well-executed approach to continuous improvement and learning. The term *continuous improvement* refers to both radical, incremental and breakthrough improvement. The term *learning* refers to adaptation to change, leading to new goals and results-oriented approaches for delivery of products and services to customers. World-class quality organizations also benchmark and implement best business practices to improve performance at the individual, team, work unit and organizational levels.
4. *Partnership for progress and teamwork:* World-class quality organizations promote and implement methods, approaches, and systems for cooperation and suppliers, process owners, and customers. Internal partnering arrangements are also utilized to help individual employees and the workforce achieve defined quality goals and objectives. Also, strong emphasis is placed on team-based problem solving, team-based product design process, self-directed work teams for production, and service-related functions and activities.
5. *Innovation and fast response:* Successful quality organizations promote innovation and risk taking that produces new ideas, suggestions, and breakthrough technologies for performance excellence. They are very responsive to customers. There is continuous focus in product and service-cycle time reduction at all product and service life-cycle stages.
6. *Facts and data-improvement process:* World-class quality organizations utilize reliable data and facts for decisions. Significant investment in information and data gathering systems and tools is made to enable those participating in the quality process to analyze and solve problems with accurate data and information.
7. *Long-range view of the future:* Successful quality organizations usually have a strong orientation toward the future and a willingness to make long-term commitments to customers, suppliers, stakeholders, and employees. They anticipate challenges and put the right strategic, tactical, and operational plans in place to achieve success.
8. *Prevention-based management:* World-class quality organizations utilize highly effective systems and tools to build quality into products and services and the processes through which they are produced. The focus is on error and defect prevention and not on crisis management of problems that could have been prevented through appropriate planning.
9. *Customer-driven quality results:* World-class organizations operate on the philosophy that customers judge quality. Customers' requirements and specifications therefore drive all products and service features that contribute value to customers and lead to customer satisfaction, preference, loyalty, and retention. These organizations also focus on achieving world-class results through defined process for customer segmentation, anticipating demands, problem solving and analysis, performance planning, measurement, evaluating, and improvement.
10. *Diversity as a strength:* World-class quality organizations utilizes the skills, talents, and abilities of a diverse workforce to achieve quality goals and objectives. Employing people of different genders and abilities and with rich variety of educational, cultural, ethnic, linguistic, and physical characteristic enables these organizations to serve diverse customer segments and populations effectively. Diversity is seen by quality organizations as a strength in individual and team capabilities to innovate, solve problems and deliver error and defect-free products and services.

There are enormous benefits from implementing the quality improvement process in an organization. One of the outcomes of the process is a radical shift from a traditional to a customer-driven organization. The new customer-driven organization is responsive and competitive and able to address new market demands and challenges. The customers benefit from improved products and services, and the employees benefit from full-time employment, better wages, job satisfaction, and improved morale. The organizational suppliers and stakeholders benefit from financial gains and business growth.

CHAPTER 67

Quality Tools for Learning and Improvement

LLOYD PROVOST
Associates in Process Improvement

1. MODEL FOR IMPROVEMENT

Improvement comes from the application of knowledge to relevant problems or opportunities. This knowledge may be knowledge of engineering, operations, complex theories, or simply experience of the way some activity is currently done. Generally, the more complete the appropriate knowledge, the better the improvements will be when applying the knowledge to making changes. Therefore, improvement must be based on building and applying knowledge. This view leads to the model for improvement in Figure 1 (Langley 1998). The model consists of three fundamental questions that define the opportunity and a method (the PDSA cycle) to increase the requisite knowledge.

This model provides a framework for a trial-and-learning approach to improvement. The word ''trial'' suggests a test of a change. The word ''learning'' implies that some criteria exist by which to study and learn from the trial. The focus on the questions accelerates the building of knowledge by emphasizing a framework for learning, the use of data, and the design of effective tests or trials. Learning from testing changes on a small scale is encouraged, rather than from extensive study of the problem before any changes are attempted. The PDSA (Plan, Do, Study, Act) cycle in the model provides the framework for an efficient trial-and-learning methodology. We refer to this cycle as the cycle for learning and improvement. The cycle begins with a plan and ends with action being taken based on the learning gained from the Plan, Do, and Study phases of the cycle.

Many improvement efforts can be successfully completed using only subject matter knowledge to answer the three questions of the model for improvement. In other cases, additional knowledge is needed to develop a change. What are some ways to obtain this knowledge? A number of different tools and methods are described in this Handbook and are summarized in this chapter. These methods and tools for improvement in this chapter are organized into five use categories:

1. Viewing Systems and Processes
2. Gathering Information
3. Organizing Information

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

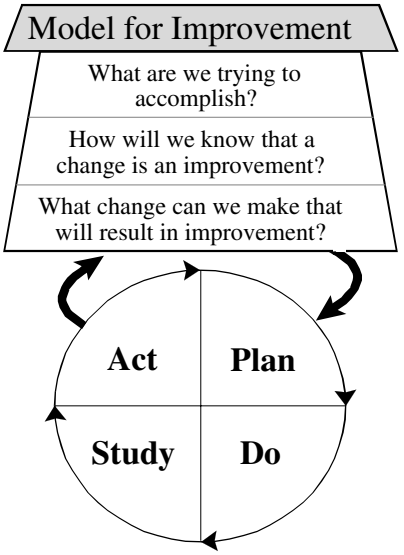

Figure 1 The Model for Improvement. (Copyright 1980–1998 Associates in Process Improvement)

4. Understanding Variation
5. Understanding Relationships

The 19 improvement tools and methods described in this chapter are summarized in Table 1. Note that these tools are sometimes called by slightly different names in other references.

Figures 2 through 20 show pictorial examples of these tools/methods. Each tool or method is considered in light of five questions about the tool:

1. *What* is this tool?
2. *Why* would someone choose to use this tool?
3. What are important considerations when *planning* to use this tool?
4. What *other tools* might be useful in conjunction with this tool?
5. What are the basic *mechanics* of using this tool?

A case study at the end of the chapter illustrates the use of the tools in an improvement project.

2. TOOLS FOR VIEWING SYSTEMS AND PROCESSES

- *What?* The flow diagram (often called flowchart) is a graphic representation of a series of activities that define a process.
- *Why?* This tool is useful when there is a need to describe how a process is being carried out or should be carried out. In particular, the flow diagram is very useful when a team needs to understand how the process works.
- *Planning:* The scope of the process (beginning and end) must be defined. The developers of the flow diagram must agree on the use of symbols and the level of detail needed. These choices will be guided by the purpose of the flowchart.
- *Other tools:* The flow diagram can help plan where to collect data. Use of the flow diagram may help initiate using the tools for organizing information, such as the cause-and-effect diagram.
- *Mechanics:* Decide on the process stop–start points, level of detail, and symbols. Have those knowledgeable about the process construct the chart. There are a number of special versions of

TABLE 1 Overview of Methods and Tools for Improvement

Use Category	Method or Tool	Typical Use of Method or Tool
Viewing systems and processes	1. Flow diagram	Develop a picture of a process. Communicate and standardize processes.
	2. Linkage of processes	Develop a picture of a system composed of processes linked together.
Gathering information	3. Form for collecting data	Plan and organize a data-collection effort
	4. Surveys	Obtain information from people.
	5. Benchmarking	Obtain information on performance and approaches from other organizations.
	6. Creativity methods	Develop new ideas and fresh thinking.
Organizing information	7. Affinity diagram	Organize and summarize qualitative information.
	8. Force field analysis	Summarize forces supporting and hindering change.
	9. Cause-and-effect diagram	Collect and organize current knowledge about potential causes of problems or variation.
	10. Matrix diagram	Arrange information to understand relationships and make decisions.
	11. Tree diagram	Visualize the structure of a problem, plan, or any other opportunity of interest.
	12. Quality function deployment (QFD)	Communicate customer needs and requirements through the design and production processes.
Understanding variation	13. Run chart	Study variation in data over time; understand the impact of changes on measures.
	14. Control chart	Distinguish between special and common causes of variation.
	15. Pareto chart	Focus on areas of improvement with greatest impact.
	16. Frequency plot	Understand location, spread, shape, and patterns of data.
Understanding relationships	17. Scatterplot	Analyze the associations or relationship between two variables; test for possible cause and effect.
	18. Two-way table	Understand cause and effect for qualitative variables.
	19. Planned experimentation	Design studies to evaluate cause-and-effect relationships and test changes.

flow diagrams (for example, complexity flow diagram, deployment flowchart, and top-down flow diagram).

- *What?* The linkage of processes (LOP) is a method to describe a system composed of processes linked together to accomplish a common purpose.
- *Why?* The LOP can be used to develop a systems view of an organization or a group of processes. A LOP can be used to explore the interdependencies and complexities in a system or subsystem.
- *Planning:* The boundaries of the system must be defined; the level of process detail should be uniform. This will be determined by the purpose of the LOP. People knowledgeable about the entire system will be needed to build a LOP.
- *Other Tools:* The linkage can be used as a data collection form. Parts of a LOP can be expanded using flow diagrams. The LOP provides a structure for using the tools to organize information.
- *Mechanics:* Decide on purpose and system boundaries; define processes at a uniform level of detail (initially target about 20-80 processes); assemble related processes and show linkages between processes.

3. TOOLS FOR GATHERING INFORMATION

- *What?* The form for collection of data provides an organized method to record observations or measurements to be used in the process of analysis.

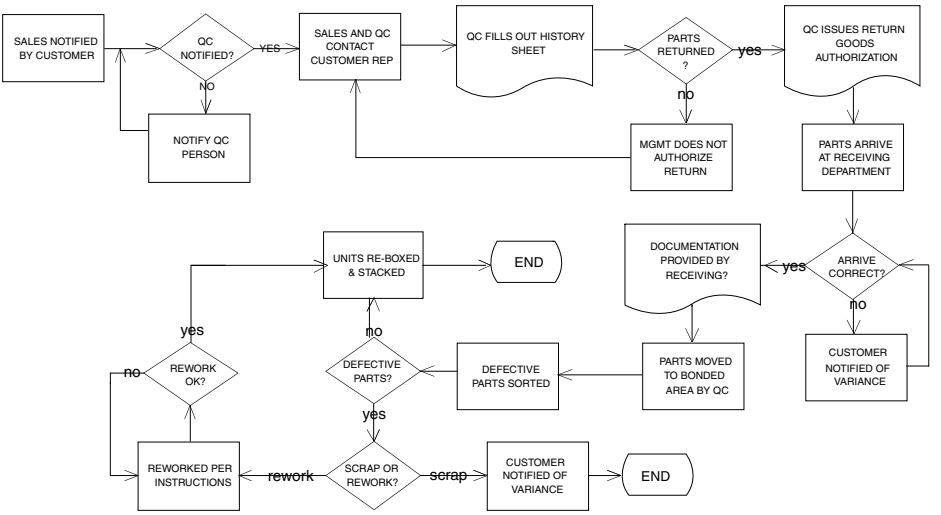

Figure 2 Flow Diagram. (Copyright 1980–1998 Associates in Process Improvement)

- *Why?* This tool is used to facilitate the recording of data and, in some cases, begin the analysis of data.
- *Planning:* It is important to have a clear understanding of what we want to learn from the data and who will collect and analyze it. The process of planning the form may force a more thorough consideration of the issues. Two types of forms are the check sheet and the recording form.
- *Other tools:* A form for collecting data is often built into other data analysis tools such as a control chart. All of the other data analysis tools will require some sort of data collection form for capturing observations or measurements.
- *Mechanics:* Decide on the questions to be answered. Decide on exactly what observations or data will be recorded and what format will be most useful. Operational definitions of terms can be important on a form for data collection.
- *What?* A survey is a method of collecting information directly from people about their feelings, motivations, plans, beliefs, experiences, and backgrounds.
- *Why?* As part of a PDSA cycle, a survey is a type of data-collection process that focuses on getting information from people to answer a question(s) posed in the planning phase of the cycle.
- *Planning:* Determine the objective of the survey. Consider why a survey is the most appropriate method for obtaining the desired information. Determine what questions are to be answered by the survey.
- *Other tools:* Any of the data-analysis tools may be used with data from surveys. Benchmarking is a special kind of survey. Surveys are required for a QFD analysis.
- *Mechanics:* Surveys can be administered in a number of ways: written surveys, personal interviews, group interviews, observations, and trading places.
- *What?* A process of measuring products, services, and business practices against the toughest competitors or those companies recognized as industry leaders.
- *Why?* Benchmarking, in its simplest form, is merely looking around at how others are doing things and trying to learn new approaches and possibilities. We can all benefit from doing this, and most organizations are already doing this on an informal basis. Benchmarking provides a formal method, with some structure, for making these observations and then using this information for improvement.
- *Planning:* Successful benchmarking efforts are organized using the PDSA cycle. A typical benchmarking exercise would be organized into four or five learning cycles.
- *Other tools:* Benchmarking is a type of survey. All of the other methods and tools can be used to organize and analyze data from benchmarking studies.
- *Mechanics:* The 10-step benchmarking process can be organized using the Model as a series of PDSA Cycles.

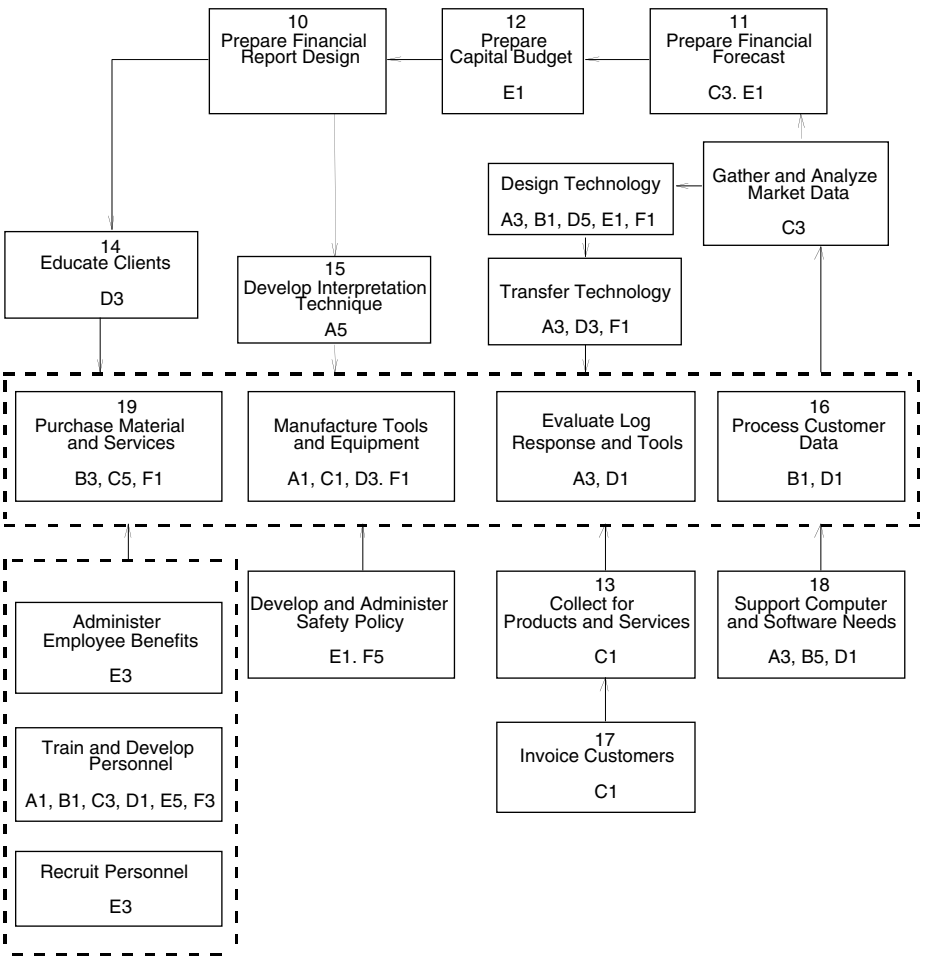

Figure 3 Linkage of Processes. (Copyright 1980–1998 Associates in Process Improvement)

- *What?* A collection of tools and methods (provocations, random entry, six thinking hats, concept triangle, etc.) based on creative thinking that fit with traditional quality improvement methods. The methods are serious, deliberate, and systematic; they do not rely on acting crazy or pure natural talent.
- *Why?* Based on theory and knowledge of how the brain works as an active, self-organizing information system, the lateral (creative) thinking tools are designed to allow people to deliberately produce thoughts that are outside their normal thinking patterns. This in turn greatly increases the chances of producing new ideas, new concepts, and new perceptions from old situations.
- *Planning:* The tools should be used when new ideas or concepts are required to accomplish the improvement initiative.
- *Other tools:* The creativity methods provide a refreshing alternative to the other methods to gather information. Tools for organizing information can be used with information collected using the creativity methods.

Problem	Occurrences				
	Monday	Tuesday	Wednesday	Thursday	Friday
Out of paper					
Out of toner					
Copies too light					
Sorter problems					
Document feeder					
Transparency feed					
Other:					
Copier stopped					
Panel won't clear					
No power					

Figure 4 Forms for Collection of Data. (Copyright 1980–1998 Associates in Process Improvement)

- *Mechanics:* Provocations seek to jolt us or start us outside of these mainstream patterns so that we can then increase the probability of connecting with other patterns to produce new ideas, concepts and perceptions.

4. TOOLS FOR ORGANIZING INFORMATION

- *What?* The affinity diagram is a method to summarize qualitative data into groups with common themes.
- *Why?* The affinity diagram should be used when there are large amounts of qualitative data that must be summarized before proceeding. An example is the answers to open ended questions on a survey.
- *Planning:* Much will depend on the type of qualitative data. There may be many useful ways to group the data, so being creative and open-minded is helpful.

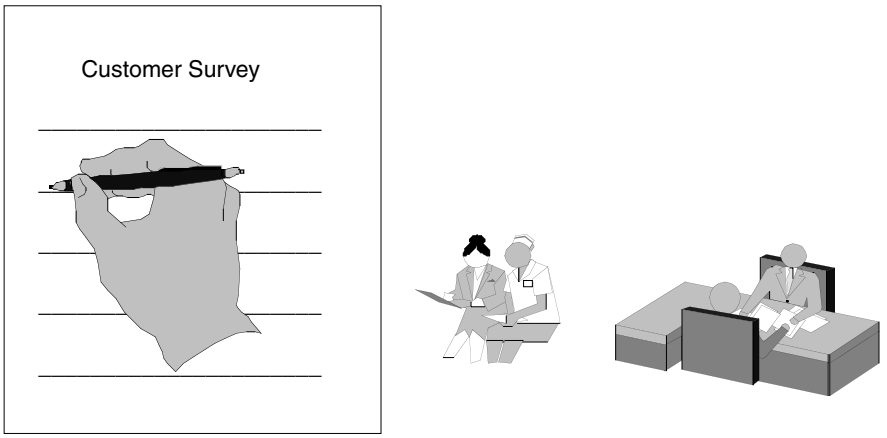

Figure 5 Surveys. (Copyright 1980–1998 Associates in Process Improvement)

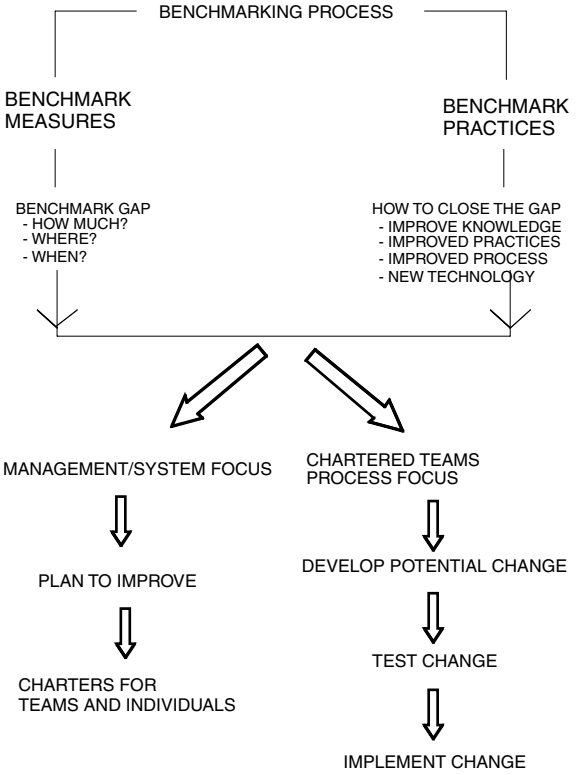

Figure 6 Benchmarking. (Copyright 1980–1998 Associates in Process Improvement)

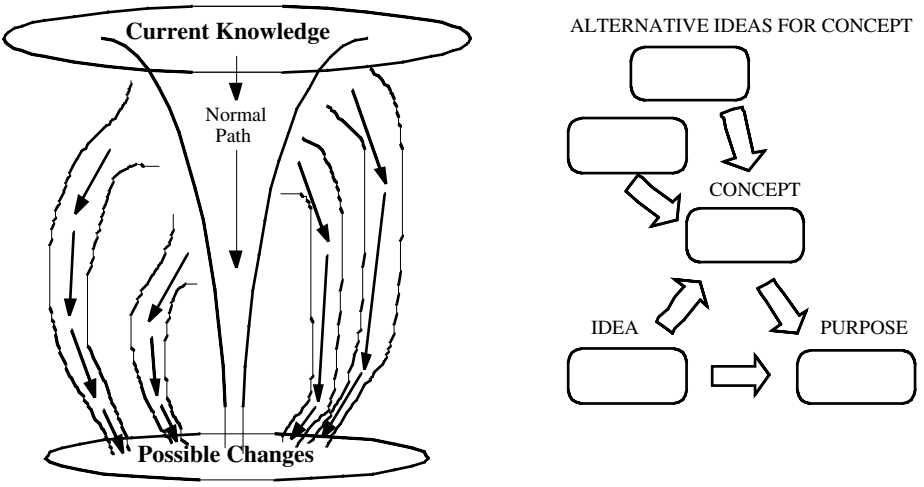

Figure 7 Creativity Methods. (Copyright 1980–1998 Associates in Process Improvement)

Each manager is doing the next level job	Products routinely miss the market window	Customer complaints about product consistency
Managers are task oriented	Increase in unprofitable products	Customer complaints about product consistency
Employee grievances have increased 14%	Change over from one product campaign to another is difficult and time consuming	Product variability causes downtime of equipment & maintenance PM time increase
Turnover rate is high - 23%	Costs associated with product introduction are typically 30% over estimates	Customer inspection results do not match our documented results
Decision making process is cumbersome		
Globalization of market requires managers that appreciate other cultures		

Figure 8 Affinity Diagram. (Copyright 1980–1998 Associates in Process Improvement)

- *Other tools:* Tools for gathering information that result in qualitative data can lead to an affinity analysis. After constructing an affinity diagram, the results may be summarized in a Pareto chart. Categories developed during an affinity analysis can be used for stratification with the other tools.
- *Mechanics:* Make a clear statement of the issue to be considered; record the qualitative data on cards; sort into related groups; create the main subgroup themes.
- *What?* The force field analysis is a method to analyze situations that support and inhibit a planned change.
- *Why?* The force field analysis is typically used in planning to overcome restraining forces and reinforce driving forces when implementing a change.
- *Planning:* Develop a clear definition of the planned change. The group will need knowledge of the organization as well as its outside environment.
- *Other tools:* The force field analysis is a planning tool. Information to do the analysis can come from any of the methods to gather information.

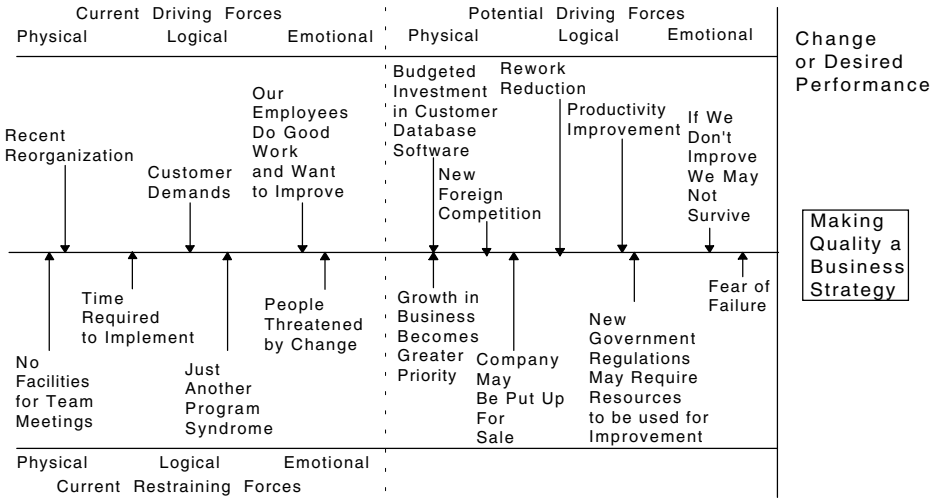

Figure 9 Force Field Analysis. (Copyright 1980–1998 Associates in Process Improvement)

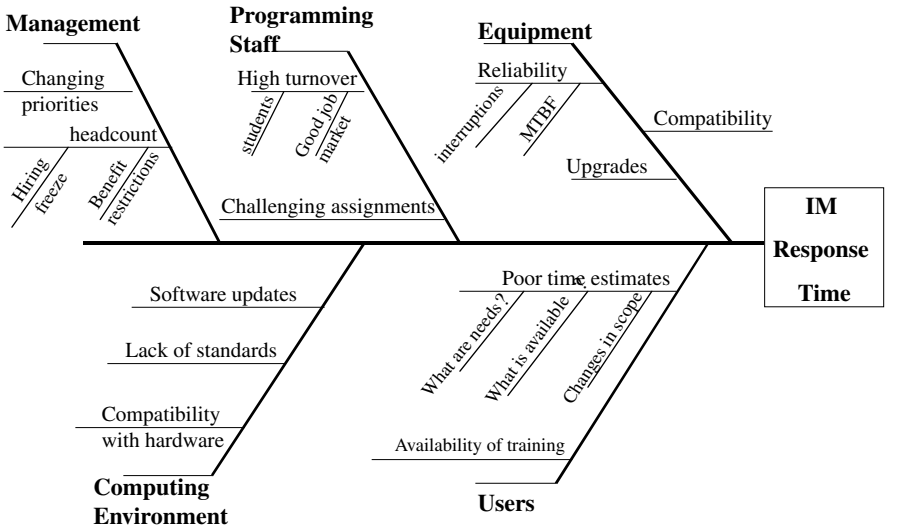

Figure 10 Cause-and-Effect Diagram. (Copyright 1980–1998 Associates in Process Improvement)

- *Mechanics:* Develop a clear statement of the change to be considered, brainstorm restraining, and reinforcing forces. Place these into categories, if useful.
- *What?* The cause-and-effect diagram (C&E) is a tool for organizing a group's current knowledge about causes of a problem or variation in a quality characteristic. The tool is also called a fishbone diagram or an Ishikawa diagram.
- *Why?* It is useful for a group to share knowledge when each member has a different perspective on a problem, e.g., management, operations, maintenance, and accounting. The C&E diagram can be updated and serve as a method to organize a team's current knowledge.
- *Planning:* It is important to define the problem or issue clearly. Putting the diagram together requires people with all of the knowledge relevant to the situation working together and sharing ideas.
- *Other tools:* Any of the data-analysis tools might be useful after it is decided what should be measured using the C&E diagram. Causes on the C&E are likely to show up on a flowchart as

	Criteria for Selection						
Computer Type	Disk size	Memory size	Processing speed	Features	Standard software	Costs	**Total Score**
Brand A	1	2	4	3.5	1	2.5	14
Brand B	4	4	3	3.5	3	2.5	20
Brand C	2	1	1	2	2	1	9
Brand D	3	3	2	1	4	4	18

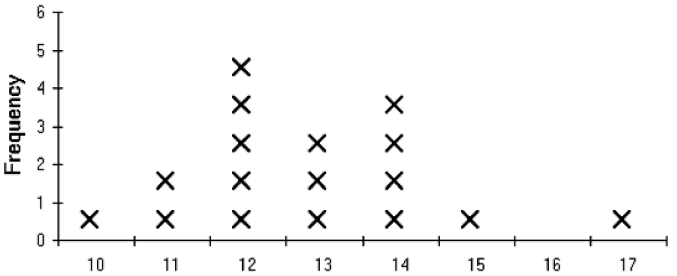

Figure 17 The Frequency Plot. (Copyright 1980–1998 Associates in Process Improvement)

complexity or awkward stages of a process. A C&E diagram is useful when planning an experiment to identify factors and background variables.

- *Mechanics:* Define the issue, brainstorm the causes, and organize the causes into categories. Display the categories on a diagram.
- *What?* A matrix diagram is a method used to arrange data to help the user understand important relationships. The diagram displays the relationship between two groupings (e.g., steps in a process and departments, customer needs and features offered with your service, vendors and selection criteria).
- *Why?* The matrix diagram has many uses in improvement efforts. It is especially useful for developing a change and deciding where to test it. Some of the typical uses include showing the changes planned for a process and where in the organization they will have an impact; summarizing information to help make a decision; and showing the relationship between factors and measure of quality in a planned experiment.
- *Planning:* Understand the information available and the relationships that are important.
- *Other tools:* Information from any of the methods for gathering information can be summarized using a matrix diagram.
- *Mechanics:* Establish lists of items whose relationship is under study. Place one list across the top of the matrix and the other down the side. Draw the matrix. Pick the data or relationship

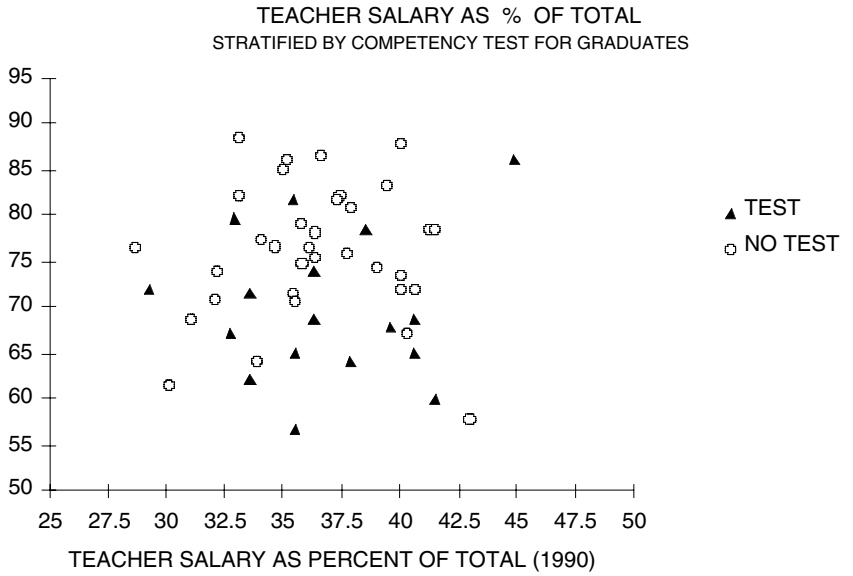

Figure 18 Scatterplot. (Copyright 1980–1998 Associates in Process Improvement)

	New System	
Current System	**on-time**	**late**
on-time	**28**	**2**
late	**16**	**4**

Figure 19 Two-Way Table. (Copyright 1980–1998 Associates in Process Improvement)

symbols to be used. Place the relevant symbols or data on the matrix that corresponds to the proper relationship.

- *What?* A tree diagram is used to visualize the structure of a problem, a plan, or any other opportunity of interest. The diagram helps you think systematically about each aspect of the problem. It has also been called a systematic diagram. The tree diagram allows the graphical view of different level of details about a problem.
- *Why?* The diagram allows a system of strategies for solving a problem or means of achieving an objective to be developed systematically and logically, making it less likely that any essential items will be omitted. The diagram facilitates dialogue and agreement among group members. Tree diagrams are convincing in presentations because they identify and clearly display the details of complex issues.
- *Planning:* Understand the information available and which of the many varieties of tree diagrams is appropriate for the opportunity of interest.
- *Other tools:* Information from any of the methods for gathering information can be summarized using a tree diagram. A tree diagram is similar to a cause-and-effect diagram when causes of an event are being evaluated. Standard symbols are used with tree diagrams for applications like fault tree analysis or failure mode and effects analysis (FMEA).
- *Mechanics:* A tree diagram is simple and natural to construct and thus is a common tool used to organize information. This is done by developing the branches on the tree into different levels of detail. The tree can be developed either horizontally or vertically on the page.
- *What?* Quality function deployment (QFD) is a tool for organizing information when designing a process or product.
- *Why?* QFD is especially useful as an interdisciplinary method that takes customer-centered marketing information and translates this into choices for the organization.
- *Planning:* The group developing the QFD will need marketing information on quality characteristics with customer weights. Also, operations knowledge will be needed to relate quality characteristics to process choices.
- *Other tools:* QFD is typically a jumping-off point for a new product or other major change. Often QFD will establish the need for planned experimentation or customer surveys.
- *Mechanics:* Create a matrix; enter quality characteristics on one side. Enter process choices on the other side; weight the effects. Identify interrelationships. Note where tests and new information are needed.

5. TOOLS FOR UNDERSTANDING VARIATION

- *What?* The run chart is a graphical record of a quality characteristic measured over time.
- *Why?* The run chart is useful when it is important to study variation over time. Studying the order of the data enables important information to be learned from measurements.
- *Planning:* Scale the chart appropriately for the variation of interest. Choose a useful interval of time.
- *Other tools:* A run chart can be converted into a control chart after sufficient data have been collected. A run chart can be collapsed into a frequency plot to study the spread and shape of the data.
- *Mechanics:* Scale the chart such that the expected variation will take up about 75% of the chart. (Sometimes this will not be possible on the first try if not much is known about the variation in the process.) Record the measurements directly on the chart in the time order they are generated.
- *What?* A control chart is a tool for studying variation in data, distinguishing between common cause and special cause variation.
- *Why?* To decide on a course of action for improving a process and learn about the extent of variation and its degree of predictability; to evaluate the effectiveness of a change; and study dynamic complexity of a system.
- *Planning:* What subgrouping strategy will help us to learn the most about a process? How often should measurements be made? What is our reaction plan for out-of-control points?
- *Other tools:* A frequency plot would yield useful information about the spread and shape of the data. The flowchart might be helpful in understanding where the measurement was taken, and for what purpose. The cause-and-effect diagram of the process might help in understanding causes of variation. A scatter plot can be used to study measurements from different control charts.
- *Mechanics:* Define the variable and subgrouping; collect and plot the data; calculate control limits; identify special causes and learn from them.
- *What?* The Pareto chart is a tool for helping to focus our efforts by identifying the relative importance of certain categories of events.
- *Why?* This tool should be used when we want to focus an improvement effort on those areas that will have the greatest impact.
- *Planning:* Develop useful definitions for the categories of observations. Select the number of occurrences of each category or another useful measure (time, cost, etc.) of importance.
- *Other tools:* The cause-and-effect diagram may give useful information regarding which categories to measure. A Pareto chart is often used to analyze further a characteristic evaluated using an attribute control chart.
- *Mechanics:* The *X*-axis categories of the chart need to be well defined and useful. The *Y*-axis should be a measure of what is most important. Often this is frequency of occurrence, but it may be time, cost, or other meaningful measures.
- *What?* The frequency plot (or histogram) is a tool to display data. It presents to the user basic information about the location, shape, and spread of a set of data. The frequency plot is similar to the Pareto chart. The frequency plot displays quantitative data, while the Pareto chart displays categorical data.
- *Why?* This tool should be used when there is a need to understand the spread, location, and/or shape of the data. It is useful for summarizing a large amount of data.
- *Planning:* Have a clear objective for constructing the plot. What is the likely spread of the data? Is your scale appropriate?
- *Other tools:* A control chart provides important information about the stability of the process and should always be used when interpreting a frequency plot.
- *Mechanics:* The scale for the horizontal measure needs to be developed. Sometimes groupings of the values need to be determined. Individual values can be recorded or bars can be used to represent the frequency.

6. TOOLS FOR UNDERSTANDING RELATIONSHIPS

- *What?* The scatterplot is a tool for analyzing associations or relationships between two quantitative variables.
- *Why?* If a cause-and-effect relationship exists between the variables, the scatter plot will show this relationship.

- *Planning:* Which two variables may be associated? What is the range of data for both variables? Consider whether there might be a third variable causally related to one or more variables on the chart. Are the processes delivering the data stable?
- *Other tools:* Run charts and control charts would be important to determine whether the data is stable or trending. The cause-and-effect diagram could give insights as to which variables should be plotted together.
- *Mechanics:* Select the two variables. Record pairs of measures. Plot the data on a scale such that the range of variation takes up the full range of data. The axes should be of approximately equal length for each variable.
- *What?* The two-way table is a tabular representation of the relationship between pairs of variables or categories. (Similar to scatter plot.)
- *Why?* If a cause-and-effect relationship exists between the variables, the two-way table will show this relationship.
- *Planning:* Which two variables are associated? What are the levels of the two variables? Consider whether there might be a third variable causally related to one or both variables on the chart. Are the processes delivering the data stable?
- *Other tools:* The scatterplot can be used instead of a two-way table when quantitative data are available. Run charts and control charts would be important to determine whether the data are stable or trending. The cause-and-effect diagram could give insights as to which variables should be on a table together.
- *Mechanics:* Select the two variables. Record events. Develop range of the data or categories for the table. Place the data into the table. Evaluate the ratios across the tables.
- *What?* Planned experimentation is a set of tools for understanding the causes of variation in a variable of interest. It is of particular interest when there are several factors that all contributed considerably to the variation under study.
- *Why?* To study the important common causes of variation in a process. Planned experimentation is most effective when we want to learn about the effects of numerous factors in a study.
- *Planning:* What subject matter knowledge is available? How much time and expense can we devote to the study? Are the processes that are part of the study stable? How will the various variables in the process be treated during the study?
- *Other tools:* Control charts, cause-and-effect diagrams, scatter plots, matrices, run charts, and frequency plots are used to analyze data from planned experiments.
- *Mechanics:* Variables are classified as response variables, factors, or background variables. A design matrix is created for the factors. Background variables are held constant or grouped in blocks. Randomization and replication are used to minimize the impact of unknown variables. Graphical methods are used to summarize the response variables.

7. INTEGRATION OF THE TOOLS FOR IMPROVEMENT

When working with the tools used in improvement, it should be kept in mind that they form a set of tools. Sometimes a single tool will answer all of the important questions, but more often several tools may be needed together. It is a common mistake to reach for the ''favorite tool'' and expect it to be useful in all situations. One of the particularly useful aspects of using the model for improvement to guide the improvement effort is that it will encourage the careful consideration of the questions to be answered. Choosing the correct tool or tools to use will follow naturally from asking the right questions.

It may be helpful, when learning the tools and methods, to consider not only what each tool tells us but also how another tool might give us information that would complement that given by the first tool. For example, a flow diagram can give us useful information about how a process works and may suggest where improvements can be made. It may also show us where complexity in the process might be causing difficulties. We may see more clearly where data could be collected to learn about the process. This is all very useful information, but what other types of information might be helpful? The flowchart gives us no quantitative information from which we might learn. If it were important to understand the variation in a process, we might need to make use of control charts, scatter diagrams, histograms, or Pareto charts. One or several of these might be useful to answer questions about the performance of the process.

Stratifying the data may also enhance the tools of data analysis—that is, separating the data according to some logical grouping, such as by machine, shift, supplier, or method of operation.

There are some particularly strong connections between some of the tools that deserve special mention. The Pareto diagram should only be used with adequate knowledge about the stability of the characteristic being measured. If the process is stable, the Pareto diagram displays the important

failure modes or problem classifications produced by the common cause system. If the process is unstable, then stratification of the data should be performed to separate the data obtained when special causes were present from data produced by common causes.

A similar issue arises with histograms. Adequate knowledge of stability is necessary to interpret the histogram. It is a common misuse of a histogram to display data that have a symmetric ''normal'' shape and imply that the data came from a stable process. An unstable process can also appear as a ''normal'' distribution on a frequency plot.

As you gain experience using the tools, it will become clear that the tools actually just formalize ways of thinking that we often use in ordinary life. For example, we all have some idea of how we go about a task, such as coming to work in the morning. If we were to write down the steps, using some agreed-upon symbols, we would have a flowchart. A similar statement could be made regarding each of the tools presented, even those requiring calculations. A control chart could be used to chart your arrival time at work. Special causes could be learned from, and the extent of common cause variation could be seen. Yet you probably already have some mental estimate of these, along with some reaction plan.

By using the tools, we will apply some formality and will be more effective in learning and making changes. Also, we will have a ready means to share the information with others. This is one of the great benefits of using the improvement tools, particularly in combination; they put information into a form that can be effectively shared and acted upon.

8. CASE STUDY: USING THE TOOLS TO IMPROVE

The following example illustrates how several of the tools can be used together, along with stratification, to improve a process. The ABC Distribution Company delivered several different types of products mostly within a five-state region. Discussions with the customers showed that on-time delivery and complete orders were their main concern. On-time generally meant that the delivery should arrive on the agreed-upon day. If, for some reason, the delivery could not be made as scheduled, the customers wanted to know ahead of time, if possible. One major customer was a grocery store that expressed a desire for the shipments to arrive within a window of ± two hours. This standard had not been met consistently. At the company's planning session, management decided that improving arrival time would be a way of differentiating themselves from competitors.

Using the model for improvement as a guide, the team decided to try to improve the processes affecting delivery. To find out how the delivery processes had performed in the past, they gathered some historical data from recent shipments and constructed the frequency plot shown in Figure 21. From this chart it can be seen that although most of the shipments were close to the target time, there are nonetheless a considerable number of deliveries that strayed from target. The frequency plot gives the following information about the historical performance: (1) average, (2) spread, and (3) shape. This chart gives only a summary of what happened in the past.

The next question that the team asked was: How had the delivery performance at ABC varied over time? There was quite a lot of disagreement among the team members over this. Some remembered a day when ''everything seemed to work better.'' Others thought the problems had always been there but had just floated from one place to another. Fortunately, time order of the

Figure 21 Frequency Plot of Time from Target. (Copyright 1980–1998 Associates in Process Improvement)

recent data used to construct the frequency plot had been retained. A run chart (Figure 22) was constructed using the same data as in the frequency plot from both warehouses over the last 46 deliveries.

There seemed to be a slight trend, and some of the team members thought there might be some increase in variation. In deciding what to do next, the team asked the question: What are some factors that could be contributing to variation in delivery performance?

The ABC business consisted of two warehouses located about 200 miles apart. Each carried about the same line of products, although there were some differences and some seasonal variations. Some of the team members thought the locations might be performing a little differently. It was decided to construct a run chart of the data but to stratify the data by warehouse 1 and 2. This run chart with stratification is shown in Figure 23.

A trend upward is visible from warehouse 2. The team decided to construct control charts to answer the question: Are the deliveries stable? The team was fairly sure about the trend in warehouse 2, but there was considerable uncertainty about warehouse 1. Control charts were constructed for each location. These are shown in Figures 24 and 25.

The trend seen in the run chart is clearly visible with the special cause signal, while warehouse 1 appears to be stable. The center lines for the two warehouses are also different. The team also constructed a scatterplot to see whether the results from the two warehouses on any particular week were related. The scatterplot in Figure 26 showed no relationship in results.

The team then more thoroughly considered the factors that might be affecting the delivery performance. There were several opinions that generally reflected the experience of the individual drivers and shipping personnel. One interesting theory was that the minor sideline-type products were a major source of delay in getting off on a run. When the run started late, more problems were likely to creep into the delivery, such as traffic delays and slow unloading. These sidelines were deliveries that were not part of the main customer deliveries and were things shipped only on some trips. These included some types of machinery, special building materials, and some clothing. The team decided to use a two-way table to investigate whether these deliveries might be tied to the late deliveries in a systematic manner. Figure 27 shows these data.

From this two-way table, it can be seen that these sideline deliveries are strongly associated with late deliveries. This can be seen by looking at the ratios across the table. For the on-time deliveries, 1 out of 16 were associated with special deliveries; for the late deliveries, 19 out of 30 were associated with special deliveries. Furthermore, the team looked into the portion of these deliveries from each warehouse and saw that location 2 had experienced an increase in these kinds of shipments, while location 1 had seen no change recently.

The team was now ready to make, develop, and test some changes. Management agreed that generally these sideline items were less time sensitive than the mainstay deliveries. This was verified in discussions with these customers. It was decided to split these types of deliveries into separate, smaller deliveries to be made in smaller trucks. For the test cycle, these trucks would be rented to try out this system. A month after the change was implemented, an updated control chart of the ABC delivery performance was constructed. Figure 28 shows the impact of these changes.

From this example, it can be appreciated that we need to be very careful about falling into the habit of trying to use only one tool to answer all questions. There should be no great difficulty

imagining situations in which practically any combination of the tools would be used together. It is your subject matter knowledge of your business, along with knowledge of the tools, that will guide you to select the best tool for your situation. Using the model for improvement will also provide a helpful discipline and assist in selecting the best tool when help is needed to answer the three fundamental questions for improvement.

CHAPTER 68
Understanding Variation

LLOYD PROVOST
Associates in Process Improvement

1. VARIATION IN DATA

Data from observations or measures will vary over time or location, and analysis of this variation is often used as a basis for action on the process. Sometimes this action is inappropriate or counterproductive because of a lack of understanding of the concept of common and special causes of variation.

One approach to analyze the performance of a process is to compare measures to an established standard, set of specifications, or customer requirements. The outcomes of the process can then be classified as acceptable or unacceptable. The unacceptable product is then scrapped, reworked, repaired, blended, or sold at a lower price. An unacceptable service usually requires rework, as well as management of an unhappy customer. This approach to the analysis of a process is an application of inspection. Inspection is useful to sort the good product or service from the bad, but without further analysis of the data, it provides no help in determining what should be done to improve the performance of the process.

A fundamental concept for the study and improvement of processes, due to Walter Shewhart (1931), is that variation in a measure of quality has its origins in one of two types of causes:

1. *Common causes:* those causes that are inherent in the process over time, affect everyone working in the process, and affect all outcomes of the process

2. *Special causes:* those causes that are not part of the process all the time or do not affect everyone but arise because of specific circumstances*

For example, the variation in cycle time in an assembly process is affected by causes common to the process and to all the workers in the process. Some possible examples of common causes of variation in cycle time are line speed, equipment reliability, staffing levels, complexity of orders, and supplier performance. If a high cycle time is due to these common causes, changes in the system by management will be required to reduce the times. If the high cycle times are due to special causes (e.g., broken belt, an absent worker, a fire in a supplier's plant), reduced cycle time will require specific actions by process workers and managers to remedy these issues. This example illustrates the importance of knowing whether the process is dominated by common or special causes before assigning responsibility for improvement. This example is used only to illustrate the concept. In practice, the distinction between common and special causes must be made with the aid of a control chart.

A process that has only common causes affecting the outcomes is called a *stable process,* or one that is in a state of statistical control. A stable process is one in which the cause system for the variation remains essentially constant over time. This does not mean there is no variation in the outcomes of the process, the variation is small, or the outcomes meet the requirements. A stable

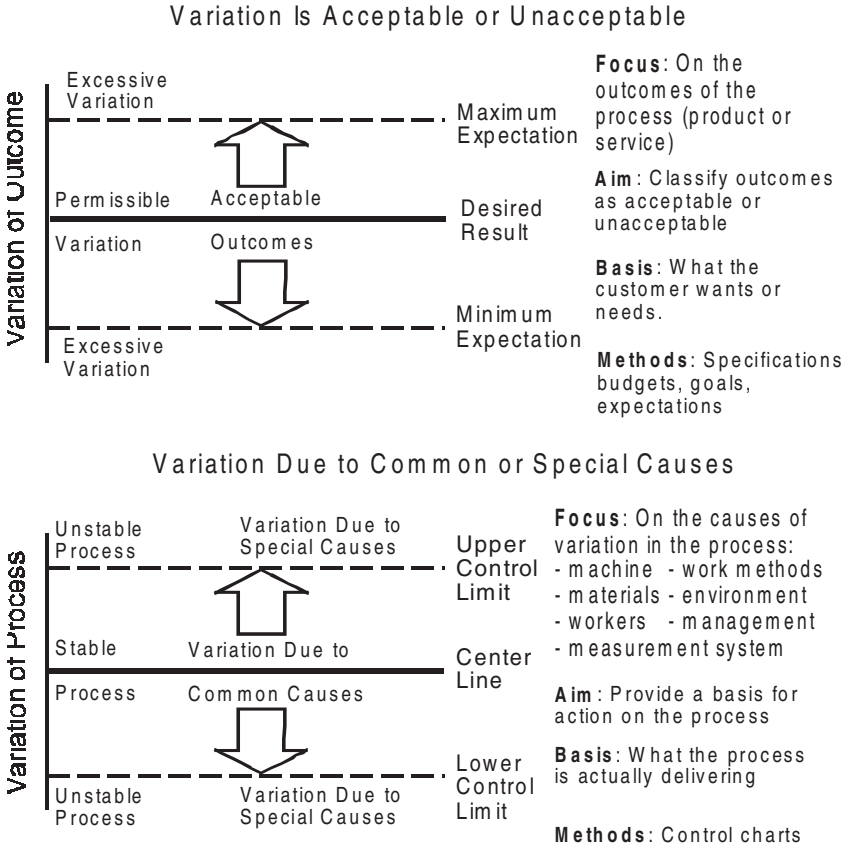

Figure 1 Two Views of Variation. (Copyright 1980–1998 Associates in Process Improvement)

*Shewhart (1931) used the terms *assignable* and *chance* rather than *special* and *common* to describe these two types of causes. Deming (1986) popularized the latter two terms.

process implies only that the variation is predictable within statistically established limits. A process whose outcomes are affected by both common causes and special causes is called an *unstable process*. An unstable process does not necessarily mean one with large variation. It means that the magnitude of the variation from one time period to the next is unpredictable. The two views of variation are contrasted in Figure 1.

As special causes are identified and removed, the process becomes stable. Deming (1986, p. 340) gives several benefits of a stable process. Some of them are:

- The process has an identity; its performance is predictable.
- Costs and quality are predictable.
- Productivity is at a maximum and costs at a minimum under the present system.
- It is relatively easy to evaluate the effect of changes in the process.
- Stability provides a solid basis for altering specifications that cannot be met economically.

Besides providing the basic concepts, Shewhart also provided a tool, the Shewhart control chart, for determining whether a process is dominated by common or special causes. The control chart is the means to operationally define the concept of a stable process. There are many different types of control charts. The appropriate chart to use in a particular application depends in part on the type of data obtained from the process or product.

2. APPLICATION OF THE CONCEPTS OF COMMON AND SPECIAL CAUSES

Although Shewhart focused his initial work on manufacturing processes, the concepts of common and special causes and of stable and unstable processes have implications in many areas, including:

- Operation of processes
- Management of processes
- Improvement of quality
- Supervision and leadership

2.1. Operation of Processes

In manufacturing processes, it is often easy to make adjustments to the average of a process. It is a mistake to make these adjustments on the basis of inspection results without the aid of a control chart. For example, if a dimension of a machined part is inspected and is found to exceed the upper specification, an adjustment is made to the machine so that the average dimension of future parts is lowered. If a batch of a particular chemical is outside of specifications, an adjustment is made by changing the amount of catalyst added to the next batch. In both of these cases, there are circumstances in which the adjustments described will improve the performance of the process and circumstances in which the adjustment will result in even worse performance. It is vital that both managers and operators be able to distinguish between these two sets of circumstances. Fortunately, there is a simple way to do this.

Adjustment to reduce the variability of a stable process, that is, one whose output is dominated by common causes, will make the performance worse. Improvement of a stable process is achieved through a fundamental change in the process that results in the removal of some of the common causes. If a special cause is found and will persist for some time, for example a lot of raw material, an adjustment of the process to counteract the special cause may be helpful in the short term. The control chart is an important tool to help the operator know when an adjustment to the process is needed.

2.2. Management of Processes

Tools such as specifications, standards, forecasts, and budgets are useful for planning, pricing of product, and other functions of management. They are used to communicate what the customer or manager expects or wants from the process. It is important to keep in mind that they do not communicate reality, that is, they do not communicate how the process is doing or what it is capable of doing.

A control chart of important measures such as costs, material usage, volume of production, sales and profit, and an analysis of the capability of the process (if the process is stable) communicates a realistic view of the performance of the process. Without the aid of a control chart and an understanding of the concept of common and special causes of variation, the tools for planning are mistaken for reality or the capability of the process. Workers or other managers are often asked to conform to that ''reality.'' If the salesman does not meet the forecast, his performance is unacceptable. When the production worker does not achieve the production standard, his performance is unacceptable.

When a manager compares a measure of performance of the process, such as costs or sales to a planning tool such as a forecast or standard, and uses this comparison as a basis for action, his actions are analogous to the operator adjusting the machine on the basis of specifications. Sometimes his actions will be appropriate, other times they will not. Just as in the case of the operator, there is a simple way to know which set of actions is appropriate.

If the process is stable with respect to a particular measure of performance such as costs, then a fundamental change in the process, the responsibility of management, will be needed to reduce cost. Exhortations to lower-level managers or workers in the process to meet the forecast or standard will make things worse. Deming (1986) calls this type of action "tampering." Webster's dictionary defines "tamper" as follows:

- To interfere so as to weaken or change for the worse
- To alter for an improper purpose or in an improper way

It is vital in managing processes that planning tools are kept in their proper place and tools such as control charts and capability analysis are used as a basis for action on the process.

2.3. Improvement of Quality

To improve the quality of a process, it is useful to recognize whether the process is dominated by common causes or special causes. This will determine who is responsible for specific steps of improvement, what resources are needed, and what statistical tools will be useful (Figure 2). Since

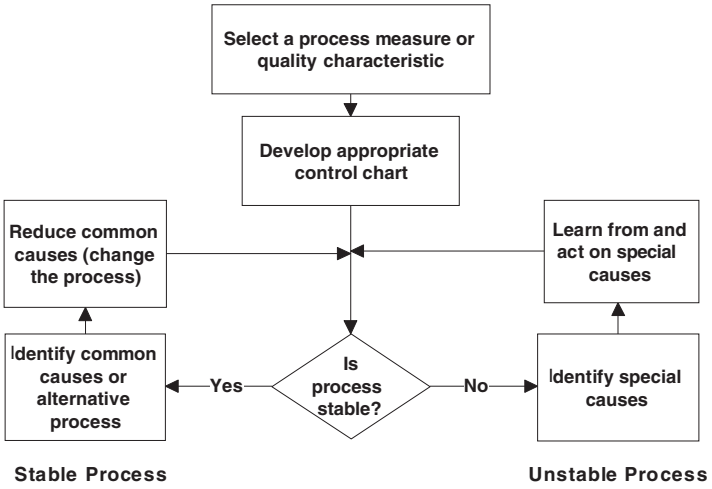

Figure 2 Using the Concepts of Variation to Guide Improvement. (Copyright 1980–1998 Associates in Process Improvement)

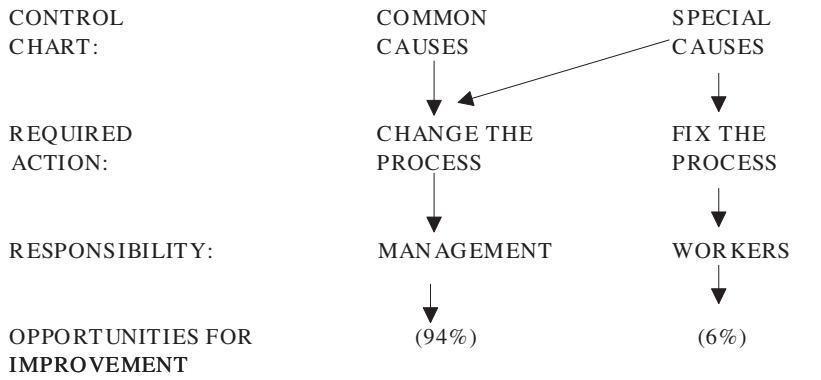

Figure 3 Opportunities for Improvement. (Copyright 1980–1998 Associates in Process Improvement)

unacceptable product or service can result from either common or special causes, the comparison of quality characteristics to requirements (product inspection) is not a basis for action on the process. Product inspection is useful to sort good products or services from bad and to set priorities on which processes to improve.

Activities to improve quality include the assignment of various people in the organization to work on common causes and special causes. The appropriate people to identify special causes are usually different than those needed to identify common causes. The same is true of those needed to remove causes. Removal of common causes is the responsibility of management, often with the aid of experts in the process such as engineers, chemists, and systems analysts. Special causes can frequently be handled at a local level by those working in the process, such as supervisors and operators. Without a knowledge of the concepts of common and special causes, it is difficult to allocate human resources efficiently to improve quality.

Many leaders of quality improvement have emphasized that most of the improvements in quality will take action by management. For example, Deming (1986) states that in almost all cases the removal of common causes will take a fundamental change in the process initiated by management. Some special causes can be removed by operators or supervisors. Others will require action by management in another process, possibly one of management or administration. For example, a special cause of variation in a production process may result when there is a change from one supplier's material to another. To prevent the special cause from occuring in the particular production process or other production processes, a change in the way the organization chooses and works with suppliers is needed. Figure 3 contains a summary of these concepts.

2.4. Supervision and Leadership

Another area in which the knowledge of common and special causes of variation is vital is in the supervision and leadership of people. A frequently made mistake is the assignment of faults of the process (common causes) to those working in the process, such as operators and clerks, rather than to those in charge of the process, management. It is obviously important for a supervisor or manager to know whether problems, mistakes, or rejected material are a result of common causes, special causes related to the system, or special causes related to the people under his or her supervision. Again, the use of a control chart will help the supervisor and manager accomplish this. For a thorough explanation of the role of statistical thinking in supervision, see Deming (1986).

3. TOOLS FOR LEARNING FROM VARIATION IN DATA

Some tools for learning from the variation in data are presented in Chapter 67. The primary tools are shown in Figure 4. Each of these tools looks at a particular aspect of the variation:

1. *Run charts:* View variation in data over time; study the impact of changes on measures.
2. *Control charts:* Distinguish between special and common causes of variation.
3. *Pareto charts:* Focus on areas of improvement with greatest impact.
4. *Frequency plots:* Understand location, spread, shape, and patterns of data.
5. *Scatterplots:* Analyze the associations or relationship between two variables.

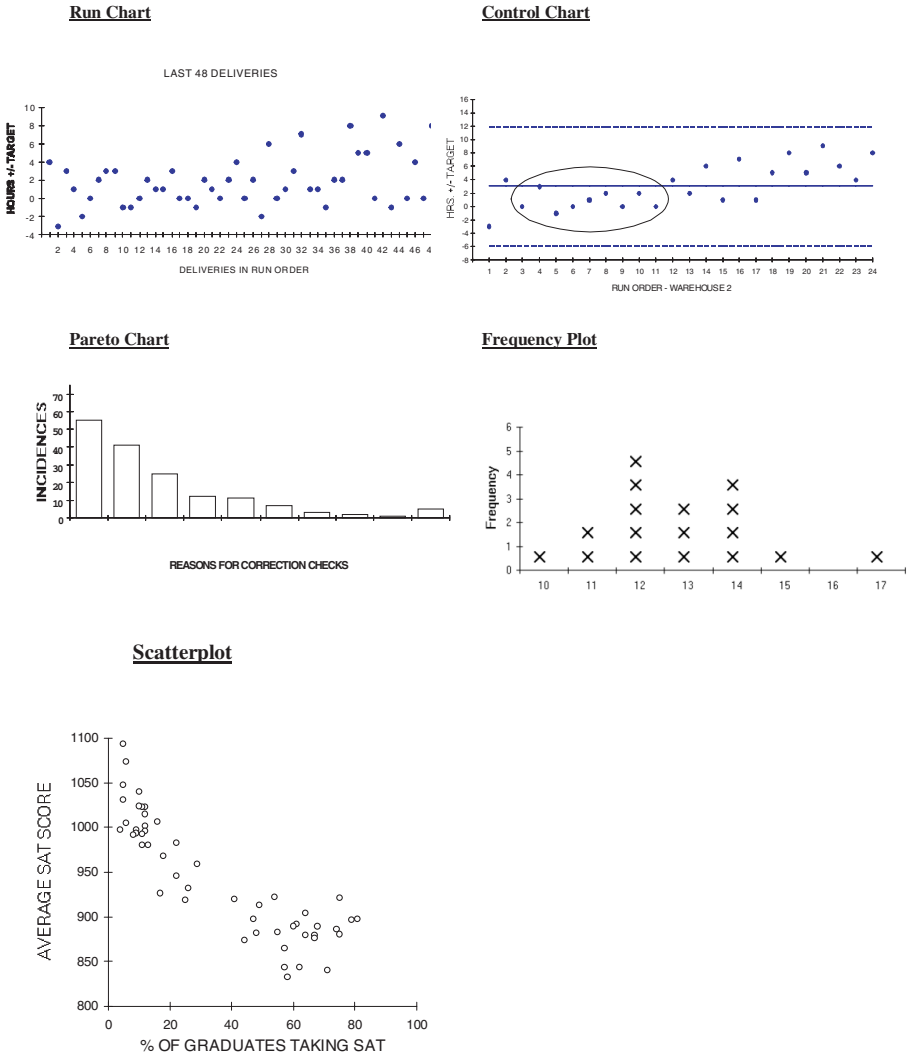

Figure 4 Tools to Learn from Variation. (Copyright 1980–1998 Associates in Process Improvement)

The run chart is simply a graphical record of a measure or characteristic plotted over time. Some type of run chart should always be a part of the study of variation in a process or system. The run chart focuses on dynamic complexity in a system (complexity over time) as well as the detail complexity of specific measures. The very simplicity of the chart is what makes it so powerful (Deming 1986). Everyone connected with the process can use and understand a run chart. Run charts are commonly used in business and economic documents.

The control chart (discussed extensively below) is an extension of the run chart. The control chart method provides a more formal way to learn from variation and guide the development of changes for improvement. The Shewhart control chart is a fundamental tool to guide improvement of processes.

The Pareto chart is a tool to help focus quality improvement efforts. It is useful whenever general classifications of problems, errors, defects, customer feedback, and so on can be classified for further study and actions. Often a few (the ''vital few'') classifications dominate the problem of interest while all the rest (the ''useful many'') contribute only a small proportion. To improve a process, it is important to find out which are the vital few problem areas.

A frequency plot is a tool to display data. It presents to the user basic information about the location, shape, and spread of a set of data. The frequency plot is widely used as a tool to help one understand variability. The frequency plot should only be used with adequate knowledge of the stability of the characteristic being measured. If the process is stable, the frequency plot serves as a prediction of the performance of the process in the future. If the process is unstable, then the frequency plot is simply a summary of what the process has done in the past. A basic type of frequency plot is the histogram, which is constructed by putting the scale for the characteristic of interest on the horizontal axis and the number of occurrences on the vertical axis.

A scatterplot is a tool used to study such relationships between possible causes and effects. It can also be used to study the association (or correlation) between different quality characteristics. A scatterplot is a graphic representation of the association between pairs of data. This pairing of data is the result of associating different measurements of a certain cause (e.g., pressure) with the corresponding measurement of the quality characteristic (e.g., paint thickness). The paired data could also be the measurements of two causes (e.g., pressure and temperature) or two quality characteristics (thickness and glossiness). Each pair becomes one point of the scatterplot.

4. SHEWHART CONTROL CHARTS

The control chart method provides an operational definition of the two types of causes of variation in a measure: common and special causes. Besides providing a new theory of variation, Shewhart also provided the method, the Shewhart control chart, for determining whether a system is dominated by common or special causes. The control chart is a statistical tool used to distinguish between variation in a measure of quality due to common causes and variation due to special causes. The name used to describe the chart (''control'') is misleading because the most common uses of these charts are to learn about variation and to evaluate the impact of changes. A better name might be ''learning charts.'' But Shewhart's name has persisted. Figure 5 shows an example of a typical control chart.

The construction of a control chart typically involves:

- Plotting the data or some summary of the data in a run order (time is the most common order)
- Determining some measure of the central tendency of the data (such as the average)
- Determining some measure of the common cause variation of the data
- Calculating a centerline and upper and lower control limits (see Figure 5)

In developing the control chart method, Shewhart emphasized the importance of the economic balance between looking for special causes when they do not exist and overlooking special causes that do exist. It is also necesssary to develop rules that will give an acceptable economic balance for all types of measures in a variety of systems, processes, and products. Figure 6 illustrates the impact of these two mistakes.

4.1. Rationale for Shewhart Control Limits

Shewhart called the control limits three-sigma control limits and gave a general formula to calculate the limits for any statistic. Let T be the statistic to be charted, then:

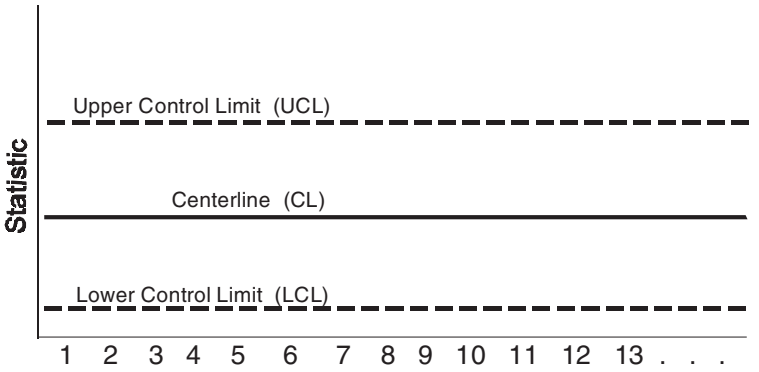

Figure 5 Illustration of a Control Chart. (Copyright 1980–1998 Associates in Process Improvement)

MISTAKE 1: To react to an outcome as if it came from a special cause, when actually it came from common causes of variation.

MISTAKE 2: To treat an outcome as if it came from common causes of variation, when actually it came from a special cause.

	ACTUAL SITUATION	
ACTION TAKEN	**NO CHANGE**	**CHANGE**
Take action on individual outcome (special)	**– $**	**+ $**
Treat outcome as part of system; work on changing the system (common)	**+ $**	**– $**

Figure 6 Mistakes Made in Attempts to Improve. (Copyright 1980–1998 Associates in Process Improvement)

$$\text{The centerline: } CL = U_t$$

$$\text{The upper control limit: } UCL = U + 3 * \sigma_t$$

$$\text{The lower control limit: } LCL = U - 3 * \sigma_t$$

where U is the expected value of the statistic and σ_t is the standard deviation of the statistic. Shewhart emphasized that statistical theory can furnish the expected value and standard deviation of the statistic, but empirical evidence justifies the width of the limits (the use of "3" in the control limit calculation).

The challenge for any particular situation is to develop appropriate estimates of the expected value and standard deviation of the statistic to be plotted. Appropriate statistics have been developed for control charts for a wide variety of applications.

The rationale for the use of Shewhart's three-sigma limits is:

- The limits have a basis in statistical theory.
- The limits have proven in practice to distinguish between special and common causes of variation.
- In most cases, use of the limits will approximately minimize the total cost due to overreaction and underreaction to variation in the process.
- The limits protect the morale of workers in the process by defining the magnitude of the variation that has been built into the process.

4.2. Interpretation of a Control Chart

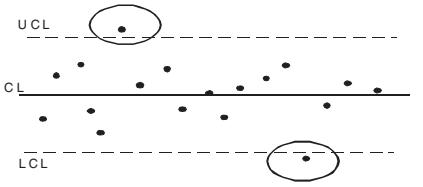
The control chart provides a basis for taking action to improve a process. A process is considered to be stable when there is a random distribution of the plotted points within the control limits. For a stable process, action should be directed at identifying the important causes of variation common to all of the points. If the distribution (or pattern) of points is not random, the process is considered to be unstable and action should be taken to learn about the special causes of variation.

There is general agreement among users of control charts that a single point outside the control limits is an indication of a special cause of variation. However, there have been many suggestions for systems of rules to identify special causes that appear as nonrandom patterns within the control limits. Figure 7 contains five rules that are recommended for general use with control charts. These rules are consistent in the sense that the chance of occurrence of rules #2 through #5 in a stable process is close to the chance of rule #1 occurring in a stable process.

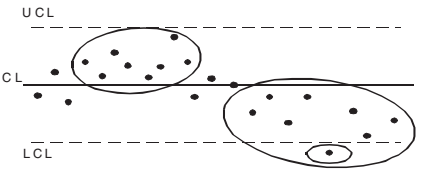
When applying the rules, the following guidelines will help with consistent interpretation of charts:

- Ties between two consecutive points do not cancel or add to a trend (rule 3).
- A point exactly on a control limit is not considered outside the limit (rule 1).

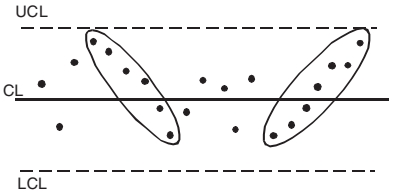
1. A single point outside the control limits.



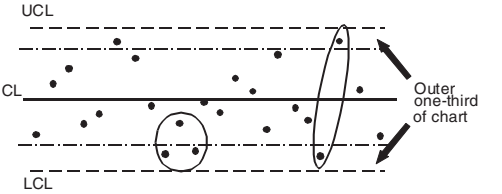
2. A run of eight or more points in a row above (or below) the centerline



3. Six consecutive points increasing (trend up) or decreasing (trend down).



4. Two out of three consecutive points near (outer one-third) a control limit.



5. Fifteen consecutive points close (inner one-third of the chart) to the centerline

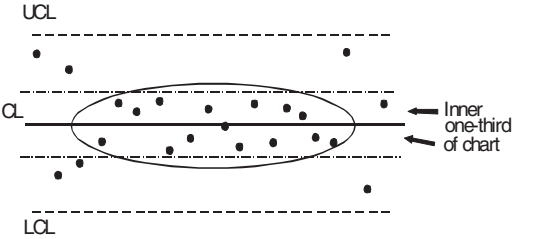


Figure 7 Rules for Determining a Special Cause. (Copyright 1980–1998 Associates in Process Improvement)

- When control charts have varying limits due to varying numbers of measurements within subgroups, rule 3 should not be applied.
- A point exactly on the centerline does not cancel or count towards a run (rule 2).
- When there is not a lower or upper control limit (for example, on a range chart with less than seven measures in a subgroup or on a P chart with 100% as a possible result for the process), rules 1 and 4 do not apply to the missing limit.

Rule 5 is especially useful in detecting a reduction of variation with an individual chart or for detecting improper subgrouping with an X-bar chart. Special circumstances may warrant use of some additional tests given by Nelson (1984). Deming (1986) emphasizes that the most important issue is the necessity to state in advance what rules to apply to a given situation.

4.3. Control Charts for Different Data Types

The different kinds of control charts are based on two groupings of types of data: attribute data and variable data. Attribute data includes classification, count, and rank data. Variable data refers primarily to continuous data, but rank data are often analyzed using a variable-control chart (realizing that the arithmetic functions are not theoretically valid). Otherwise the ranks can be converted to classification data and analyzed using attribute charts. Figure 8 contains examples of each of these categories of data.

Type of Data	Quality Characteristic	Recorded Data
Classification	Delivery Performance	On-time/late delivery
	Rework	OK the first time/rework
	Scratches	OK/excessive scratches
Count	Changes	Number of changes/design
	Accidents	Number of accidents/month
	Scratches	Scratches/surface
Continuous	Time	Minutes early or late
	Weight	Grams using a laboratory scale
	Scratches	Length in cm of each scratch

Figure 8 Examples of Types of Data. (Copyright 1980–1998 Associates in Process Improvement)

As can be seen from Figure 8, data for some characteristics can be recorded as any one of three types. For example, for a part with a large number of dimensional characteristics, the data could be recorded in the following ways:

- Classification: part meets or does not meet specification
- Count: number of dimensions not meeting specification
- Continuous: measured value for selected dimensions

Continuous data can be converted to attribute data by applying an operational definition for the count or classification. A recorded dimension can be classified as meeting or not meeting the specification; however, this conversion does not work in reverse. The measured dimensions are unknown for a part that is recorded as not meeting specifications.

For classification data, quality attributes are recorded in one of two classes. Example of these classes are conforming units/nonconforming units, go/no-go, and good/bad. To obtain count data, the number of incidences of a particular type is recorded: number of mistakes, number of accidents, or number of sales leads. For continuous data, a measured numerical value is recorded: a dimension, physical attribute, or calculated number.

Examples of continuous data include height, weight, density, elapsed time, viscosity, and costs. Continuous data can be converted to attribute data by applying an operational definition for the count or classification. In general, data should be collected as continuous data whenever possible because learning can occur with many fewer measurements compared to attribute classifications or counts. The control charts for continuous data require fewer measurements in each subgroup than the attribute control charts. Typical subgroup sizes for charts for continuous data range from 1 to 10, while subgroup sizes for attribute data range from 30 to 1000.

Figure 9 contains a summary of the frequently used control charts and the type of data to which they apply.

4.4. Subgrouping and Stratification

The concept of subgrouping is one of the most important components of the control chart method. Shewhart said the following about subgrouping (Shewhart 1931, p. 299):

> Obviously, the ultimate object is not only to detect trouble but also to find it, and such discovery naturally involves classification. The engineer who is sucessful in dividing his data into rational subgroups based upon rational hypotheses is therefore inherently better off in the long run than the one who is not thus successful.

Shewhart's concept was to organize data from the process in a way that is likely to give the greatest chance for the data in each subgroup to be alike and the greatest chance for data in other subgroups to be different. The aim of rational subgrouping is to include only common causes of variation within a subgroup, with all special causes of variation occurring between subgroups.

The most common method to obtain rational subgroups is to hold time constant within a subgroup. Only data taken at the same time (or for some selected time period) are included in a subgroup. Data from different time periods will be other subgroups. This use of time as the basis of subgrouping allows the detection of causes of variation that come and go with time.

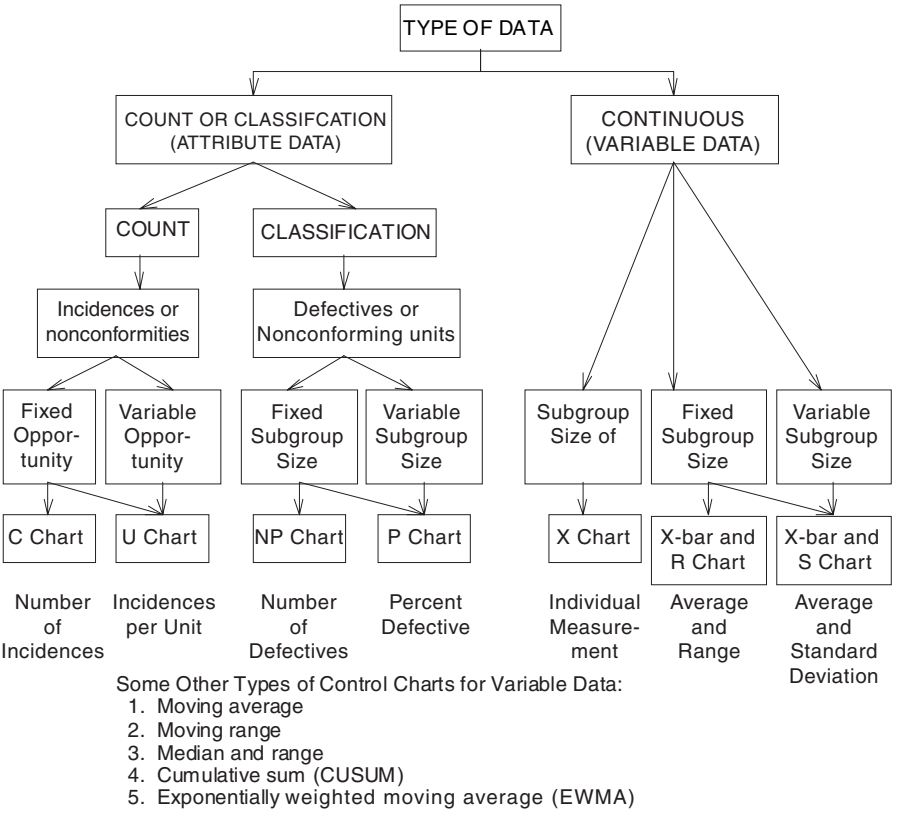

Figure 9 Selection of Particular Type of Control Chart. (Copyright 1980–1998 Associates in Process Improvement)

As an example of subgrouping, consider a study planned to reduce late payments. Historical data from the accounting files will be used to study the variation in late payments. What is a good way to subgroup the historical data on late payments? The data could be grouped by billing month, receiving month, major account, product line, or account manager. Knowledge or theories about the process should be used to develop rational subgroups. Some combination of time (either receiving or billing month) and one or more of the other variables in the process would be a reasonable way to develop the first chart.

After selecting a method of subgrouping, the user of the control chart should be able to state which sources of variation in the process will be present within subgroups and which sources will occur between subgroups. The specific objective of the control chart will often help determine the strategy for subgrouping the data. For example, if the objective is to evaluate differences between raw material suppliers, then only material from a single supplier should be included in data within a subgroup.

Since there is no grouping of the measurements for X charts, the power of rational subgrouping is not available. The use of stratification and rational ordering of the measurements with X charts provides an alternative to rational subgrouping for individual charts. Stratification is the separation and classification of data according to selected variables or factors. Stratification on a control chart is done in two different ways.

1. Plotting a symbol (instead of the usual • or x) to indicate a classification for the measurement or statistic being plotted. For example, plot the symbol A, B, or C to indicate which of the three offices the measurements came from.
2. Ordering the measurements, or subgroups of measurements, by stratification variables such as laboratory, classroom, material type, supplier, shift, programmer, part position, etc., to investigate the importance of these factors.

4.5. Planning a Control Chart

Constructing a control chart is a relatively simple process. Anyone can get started by selecting a measure of quality and plotting it in order of time. When enough data become available, a centerline and control limits can be calculated (e.g., using the individual control limit formulas). Many useful control charts have been developed with this minimal amount of planning.

In other cases, lack of planning and preparation has made attempts to use control charts unsuccessful. In these more complex situations, the effective use of control charts requires careful planning to develop and maintain the chart. Figure 10 contains a planning form that can be used to guide the planning of a control chart.

Every control chart should be associated with one or more specific objectives. The objective might be to improve the yield of the process, identify and remove special causes from a process, or establish statistical control so that the capability of the process can be determined. The objectives should be summarized on the control chart form. After a period of time, the objective may be met. The control chart should be discontinued at that time, or a new objective developed.

A number of issues related to measurement and sampling must be resolved prior to beginning a control chart. The type of data for each variable to be charted will determine the type of chart to

1. OBJECTIVE OF THE CHART:

use. Information about the variability of the measurement system to be used should be documented. If the variability is not known, or if the stability of the measurement process is not documented, an effort to develop that information should be planned.

Important issues of sampling for control charts include the location in the process for measuring or sampling, the frequency of sampling, the number of samples, and the strategy for subgrouping mesurements (see section 4.4).

The documentation of information about the process is a most important part of many control charts. This documentation includes changes in the process, identification of special causes, investigations of special causes, and other relevant process data. Flow charts and cause-and-effect diagrams can be used to identify particular notes that should be recorded. Responsibility for recording this critical information should be clearly stated.

A plan for reaction to special causes on the chart should be established. Often a checklist of items to evaluate or a flow chart of the steps to follow is useful. The reaction plan should state the transfer of responsibility for identification of the special cause if it cannot be done at the local level. A plan for reaction to special causes on the chart should be established. Often a checklist of items to evaluate or a flow chart of the steps to follow is useful. The reaction plan should state the transfer of responsibility for identification of the special cause if it cannot be done at the local level. As an example, a reaction plan for a control chart in a laboratory to monitor a measurement system might have the following reaction plan:

1. Run the quality control standard.
2. Notify operations of a potential problem.
3. Review the log book for any recent changes in instrumentation.
4. Prepare a new QC standard and test it.
5. Replace the column in the instrument.
6. Notify the supervisor and call instrument repair.
7. Document the results of these investigations on the control chart.

There are a number of administrative duties required to maintain an effective control chart. Responsibility for measurement, recording data, calculating statistics, and plotting the statistics on the chart must be delineated. Proper revision and extension of control limits is an important consideration.

Control limits for the chart should be established using 20–30 subgroups from a period when the process is stable. If it is desirable to extend the control limits, any points affected by special causes should be removed and the control limits recalculated. The limits should only be extended when they are calculated using data without special causes.

Revision of the control limits should only be done when the existing limits are no longer appropriate. There are four circumstances when the original control limits should be recalculated:

1. When the initial control chart has special causes and there is a desire to use the calculated limits for analysis of data to be collected in the future. In this case, control limits should be recalculated after removing the data associated with the special causes.
2. When ''trial'' control limits have been calculated with fewer than 20–30 subgroups (note: trial limits should be calculated with fewer than 12 subgroups). In this case, the limits should be recalculated when 20–30 subgroups become available.
3. When improvements have been made to the process and the improvements result in special causes on the control chart. Control limits should than be calculated for the new process.
4. When the control chart remains out of control for an extended period of time (20 or more subgroups) and approaches to identify and remove the special cause(s) have been exhausted. Control limits should be recalculated to determine if the process has stabilized at a different operating level.

The date the control limits were last calculated should be a part of the ongoing record for the control chart. Some notation (such as vertical lines on the chart) should be used to indicate subgroups used to calculate control limits.

The form to record the data and to plot the control chart is another important consideration. The form should allow for a continuing record and not have to be restarted every day or week. The control chart form should include space to document the important decisions and information about the process from the planning form. The recorded data should include the time and place and the person making the measurements as well as the results of the measurements. The scale on the charts should be established to give a clear visual interpretation of the variation in the process. With the control limits centered on the chart, about one-half of the scale should be included inside the control limits.

A schedule for analysis should be established for every active control chart. The frequency of analysis will vary depending on the objective of the chart. For example, the quality improvement team might meet to analyze the chart weekly to assist in their improvement effort, while the department manager might be interested in a monthly review of the chart for planning purposes. The production vice president might review the charts with the department manager at the end of each quarter for planning and evaluation purposes.

Figure 11 shows an example of a completed planning form for a control chart maintained by an accounting group. Taking the time to plan a control chart before data collection is begun will help ensure that the chart leads to learning about the process or system.

4.6. Control Chart for Individual Measurements

One of the most useful control charts is the control for individual measurements, or the X chart. This control chart is a simple extension of the run chart. The control chart for individuals is useful when:

1. OBJECTIVE OF THE CHART: *To learn about the causes of returned invoices in order to reduce the number of returned invoices that have to be billed again.*

2. SAMPLING, MEASUREMENT, AND SUBGROUPING:
Measure of quality to be charted: *Percent of invoices returned that are not paid*
Type of data: *Classification*
Method of measurement: *Accounting supervisor records number of invoices sent each week and number returned unpaid.*
Quality of measurement process: *Complete, accurate counts can be made. The totals can be validated.*
Location of sampling: *Master list and returns that cross the supervisor's desk.*
Strategy for subgrouping: *Subgroup will be all invoices mailed in a given week (historically 35-90 invoices)*
Frequency of subgroups: *One per week—100% of invoices for that week.*
Type of control chart: *P chart*

3. MOST LIKELY SPECIAL CAUSES:
New customers, price changes, computer program updates, new employees in the Accounting Department.

4. NOTES REQUIRED:

Note	Responsibility
Number of new customers each week	*Supervisor*
New employees	*Supervisor*
Changes in computer program	*Systems*

5. REACTION PLAN FOR OUT OF CONTROL POINTS:
Supervisor will call meeting of Department to discuss all special causes.

6. ADMINISTRATION:

Task	Responsibility
Making measurements:	*Supervisor*
Recording data on charts:	*Supervisor*
Computing statistics:	*Supervisor*
Plotting statistics:	*Supervisor*
Extending/changing control limits:	*Dept. QI Team*
Filing:	*Supervisor*

7.SCHEDULE FOR ANALYSIS: QI team review each month

Figure 11 Example of a Completed Control Chart Planning Form. (Copyright 1980–1998 Associates in Process Improvement)

- There is no rational way to organize the data into subgroups (see later section on X-bar and R charts for a detailed discussion of control charts).
- Measures of performance of the process can only be obtained infrequently.
- The variation at any one time (within a subgroup) is insignificant relative to the between subgroup variation.

Examples of situations and data where a control chart for individuals can be useful include batch processes, accounting data, maintenance records, shipment data, yields, efficiencies, sales, costs, and forecast or budget variances. Often the frequency of data collection cannot be controlled for these situations and types of data.

Instrument readings such as temperatures, flows, and pressures often have minimal variation at any one time but will change over time. The study of tool wear is another example of insignificant short-term variation relative to variation over time. Control charts of the individual measurements can often be useful in these cases.

Some advantages of the control chart for individuals (compared to other types of control charts) are:

- The chart is an extension of the familiar run chart.
- No calculations are required when plotting on the chart.
- Plotting is done each time a measurement is made, providing fast feedback. Study of the process does not have to wait for additional measurements.
- Because only one chart is required for each measure of quality, charts for multiple measures of performance can be grouped on one form for presentation purposes to facilitate evaluation of a process.
- The capability of a process can be evaluated directly from the control limits on the chart.

Because of these advantages, the control chart for individuals is sometimes used when another type of control chart is more appropriate. The X chart is somewhat less sensitive than other variable control charts with larger subgroup sizes in its ability to detect the presence of a special cause. Sometimes data analyzed with an X chart will indicate a stable process, but the same data analyzed with a more appropriate chart (P chart, C chart, or X-bar and R chart, discussed in later sections) will clearly indicate the presence of special causes.

Besides this lesser sensitivity, there are some other disadvantages to using an X chart to study variation in data:

- Because each individual measure is plotted on the chart, there is no opportunity to focus on different sources of variation through subgrouping.
- All sources of variation are combined on one chart, sometimes making identification of the important sources of variation difficult.
- The X chart is sensitive to a nonsymmetric distribution of data and may require data transformation to be used effectively.

To develop a control chart for individuals, 20–30 measurements are required. The symbol for the number of measures used to calculate control limits is "k." The individual measurements are plotted on the X chart and the average of the individual measurements is used for the centerline of the chart. The moving ranges of consecutive measurements are used to estimate the variation of the process and develop control limits for the X chart.

The moving range is calculated by pairing consecutive measurements. The range is calculated for each set of two measurements by subtracting the low value from the high value. Each individual measurement is considered twice in the calculation of the moving ranges. Because a previous measurement is not available for the first measurement in the set, only $k - 1$ moving ranges can be calculated. The average of the moving ranges ($\overline{\text{MR}}$) is used for control limit calculations. Because the X chart of individual measurements contains all the information available in the data, it is not necesssary to plot the moving ranges.

A example of an X chart concerns a chemical product that is shipped in hopper cars with a sample taken from each car during loading. Laboratory tests are made on each sample for product certification, and this test becomes one dot on the chart. The cars are loaded from storage bins that are filled on an intermittent basis from a process unit. Laboratory results for the concentration of an additive for the last 25 cars loaded are used to develop control charts for the product shipped.

The control chart for the additive is shown in Figure 12, and the calculations of control limits are shown in Figure 13. As can be seen in the two figures, the moving ranges for car numbers 14 and 15 are greater than the moving range upper control limit of 12.8. These two values are removed

and the average moving range recalculated. The revised $\overline{MR} = 2.95$ was used to calculate the control limits for the X chart. The control chart indicates there is a special cause present for car number 14. Note that the 236 ppm concentration for car 14 is associated with the two moving ranges that were above the upper control limit.

4.7. Control Charts for Attribute Data

The two basic types of attribute data were discussed in Section 4.3:

1. *Classifications of units:* conforming units/nonconforming units, blue/not blue, go/no-go, etc.
2. *Count of incidence:* number of nonconformities, defects, accidents, trips, calls, etc.

Often data can be collected as either type. For example, in evaluating spelling errors in a manuscript (see Figure 14), each page could be classified as (1) having one or more spelling mistakes or (2) having none. This would be classification of units, with each page as a unit. Alternatively, the number of spelling mistakes on each page could be counted.

To develop an attribute control chart, a subgrouping strategy must first be determined. The subgroup size (n) is the number of units tested for classification data, or the area of opportunity for the incidence to occur for count data. There are four commonly used control charts for attribute data, depending on the type of attribute data and the constancy of the subgroup size. Table 1 summarizes these charts.

4.7.1. The P Chart for Classification Data

The P chart is appropriate whenever classifications are made in two categories, such as good parts and scrap parts. The P chart is usually preferred over the NP chart because percentages are more easily interpreted than counts in most applications and the P chart can be used with either a constant or variable subgroup size. The percentage of units in one of the categories (either the positive or the negative one, i.e., percent good product or percent scrap) is then calculated and graphed to develop the chart. Twenty to 30 subgroups are desirable for calculating the control limits, with at least 30 units in each subgroup.

Many times it is desirable to construct and use a P chart when the subgroup size is variable. This is usually the case when a set time period, such as a day or week, rather than a specific number of units, is used to define the subgroup. However, it is not necessary for each subgroup to contain exactly the same number of units to be considered constant. If the maximum and minimum subgroup sizes are within 20% of the average subgroup size, there will be an insignificant effect on the control limits if the average subgroup size is used for all calculations. If this is not the case, the subgroup

TABLE 1 Types of Attribute Control Charts

Chart Name	Type of Attribute Data	Statistic Charted	Subgroup Size
NP Chart	classification	number of nonconforming units (D)	constant
P Chart	classification	percent nonconforming units (P)	may vary
C Chart	count	number of incidents (C)	constant
U Chart	count	incidents per unit (U)	may vary

size must be considered variable and different sets of control limits must then be calculated for each subgroup size (or for sets of subgroup sizes with the individual subgroups within 20% of the average for the set). Methods for accommodating variable subgroup sizes are given under Additional Reading.

Once a subgrouping strategy has been determined, the following steps should be followed when constructing a P chart (see Figure 15 for calculation form):

1. Calculate p {p = (number in a certain category/number in subgroup) $*$ 100} for each subgroup.
2. Calculate $\overline{P}$, the average of the p's and the centerline for the chart
3. Determine the control limits for the P chart.
4. Figure and draw a scale on appropriate graph paper so the upper control limit is placed approximately one quarter of the way from the top. If there is a lower control limit, it should be placed 10–25% above the bottom of the chart. (Note: the scale should begin with zero for most situations.)
5. Plot the p's on the chart and draw in the control limits and centerline.

d = Nonconforming sample units per subgroup
n = Number of sample units per subgroup
k = Number of subgroups
p = Percent nonconforming units = 100*d/n

Control limits when subgroup size (n) is constant:

17	9	10.0	0	0.0
18	5	5.6	2	2.2
19	14	15.6	1	1.1
20	10	11.1	0	0.0
	$\Sigma d = 198$	$\Sigma p = 220.0$	$\Sigma d = 36$	$\Sigma p = 40.0$

A P chart example deals with a situation where a constant subgroup size is appropriate. The manager of the accounting department of a company decided to gather information on the absenteeism of her 90 employees. Each day for one month, the number of employees who were absent and whether their absence was unexcused was noted. Table 2 contains the data collected during that month.

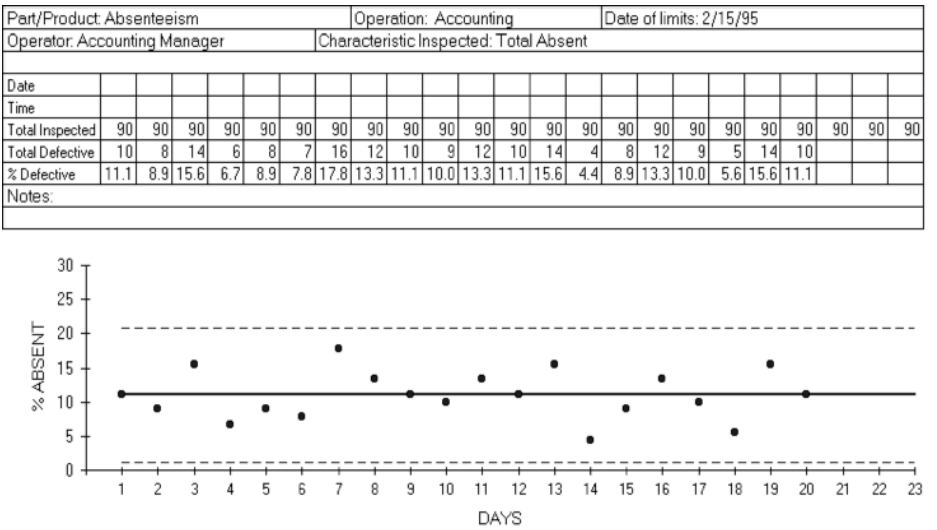

Figure 16 P Chart for Total Absences. (Copyright 1980–1998 Associates in Process Improvement)

d = nonconforming sample units per subgroup
n = number of sample units per subgroup
k = number of subgroups
p = percent nonconforming units = 100*d/n

Control limits when subgroup size (n) is constant:

Total Absent $\bar{p} = \frac{\Sigma p}{k} = \frac{220.0}{20} = \underline{11.0}$ (centerline)

$\hat{\sigma}p = \sqrt{\frac{\bar{p} * (100 - \bar{p})}{n}} = \sqrt{\frac{11.0 * (100 - 11.0)}{90}} = \underline{3.3}$

$UCL = \bar{p} + (3 * \hat{\sigma}p)$ $LCL = \bar{p} - (3 * \hat{\sigma}p)$

$UCL = \underline{11.0} + (3 * \underline{3.3})$ $LCL = \underline{11.0} - (3 * \underline{3.3})$

$UCL = \underline{11.0} + \underline{9.9}$ $LCL = \underline{11.0} - \underline{9.9}$

$UCL = \underline{20.9}$ $LCL = \underline{1.1}$

Figure 17 Calculations for Total Absence. (Copyright 1980–1998 Associates in Process Improvement)

Figure 16 shows the control chart for total absences. Figure 17 shows the calculations for total absences. Since there were 90 employees, calculations for a constant subgroup size were utilized. Figure 18 shows the chart and calculations for unexcused absences. The calculations resulted in no lower control limit for the chart on unexcused absences. The P chart for total absences is stable. A fundamental change to the system is required in order to reduce the average daily absenteeism of 11%. The P chart for unexcused absences indicates a special cause on day 10. Reasons for this special cause should be investigated and used to help develop a strategy to reduce unexcused absenteeism.

4.7.2. Control Charts for Count Data

When actual counts of incidence (often nonconformities) rather than classification of units are made, either a C chart or a U chart is usually the appropriate control chart. Figure 14 illustrated the difference between counts and classifications. Since the subgrouping method for counts is not always based on the selection of a certain number of units, a subgroup is defined as an *area of opportunity,* when working with count data.

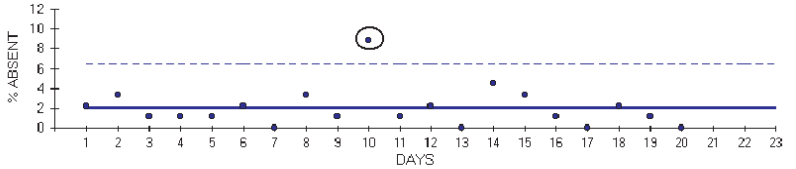
An area of opportunity is simply the region selected for the count and could be of the following forms:

- Number of units (e.g., five television sets, requisitions per day)
- Space (e.g., 200 feet of yarn, 15 square yards of coated paper, one-quart sample of a product)
- Time (e.g., three months, one shift)

The decision whether to use a C chart or a U chart is made by determining whether the area of opportunity will be constant or will vary for each group of counts. For example, an area of opportunity could be the number of bills received in an office each week. If the number of errors on these bills is counted, the count will be distorted if the number of bills received from week to week is different. How to deal with this situation will be included in the discussion of when and how to use the C chart or U chart in the remaining part of this section. Table 3 lists examples of applications of C and U charts.

A C chart is used when the area of opportunity is constant for each subgroup. This would be the case in the example given above if 50 bills were received in the office each week. The statistic plotted for a C chart is simply the number of incidents (errors) in each area of opportunity (a week or 50 bills). It is not necessary for the area of opportunity to be exactly the same for each subgroup in order to use a C chart. The area of opportunity in any analysis can be considered constant if each region (number of units, time, or space) on which the counts are taken is within 20% of the overall average.

Part/Product: Absenteeism						Operation: Accounting						Date of limits: 2/15/95											
Operator: Accounting Manager						Characteristic Inspected: Unexcused Absence																	
Date																							
Time																							
Total Inspected	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90	90
Total Defective	2	3	1	1	1	2	0	3	1	8	1	2	0	4	3	1	0	2	1	0			
% Defective	2.2	3.3	1.1	1.1	1.1	2.2	0.0	3.3	1.1	8.9	1.1	2.2	0.0	4.4	3.3	1.1	0.0	2.2	1.1	0.0			
Notes:																							



Notes:

d = nonconforming sample units per subgroup
n = number of sample units per subgroup
k = number of subgroups
p = percent nonconforming units = 100*d/n

Control limits when subgroup size (*n*) is constant:

Total Absent $\bar{p} = \frac{\Sigma p}{k} = \frac{220.0}{20} = 11.0$ (centerline)

$\hat{\sigma}p = \sqrt{\frac{\bar{p} * (100 - \bar{p})}{n}} = \sqrt{\frac{11.0 * (100 - 11.0)}{90}} = 3.3$

UCL = $\bar{p}$ + (3 * $\hat{\sigma}p$) LCL = $\bar{p}$ − (3 * $\hat{\sigma}p$)

UCL = 11.0 + (3 * 3.3) LCL = 11.0 − (3 * 3.3)

UCL = 11.0 + 9.9 LCL = 11.0 − 9.9

UCL = 20.9 LCL = 1.1

Figure 18 C and U Chart Calculation Form. (Copyright 1980–1998 Associates in Process Improvement)

Once it has been determined that the area of opportunity will be constant for each subgroup, the following steps should be followed to construct a C chart:

1. Record the count c for 20 to 30 subgroups.
2. Compute $\bar{c}$, the centerline for the C chart.
3. Compute the control limits for the C chart.
4. Calculate and draw a scale on the charting form such that the upper control limit is 25% below the top of the chart. Plot the individual c's, the centerline, and the control limits.

The example that follows illustrates some of the important points concerning construction of a C chart. In an effort to improve safety in their factory, a company decided to chart the number of injuries that required first aid each month. Since approximately the same number of hours were worked each month, the area of opportunity (total man-hours worked in one month) was constant and a C chart was utilized. Table 4 contains the data collected over a two-year period.

Figure 19 shows the control chart and Figure 20 shows the calculations of the control limits. In July 1998, the reporting of 23 injuries resulted in a point above the upper control limit. This special cause was the result of a large amount of vacation leave taken during July. Untrained people and excessive overtime were needed to achieve the normal number of hours worked for a month. There

was also a run of nine points in a row below the centerline, starting in April 1999. This indicated that the average number of reported first aid cases per month had been reduced. This reduction was attributed to a switch from wire to plastic baskets for the carrying and storing of parts and tools, which greatly reduced the number of injuries due to cuts. If this trend continues, the control limits should be recalculated when sufficient data is available.

It should be noted that there is no lower control limit in the control chart of the previous example. Therefore, a run of eight or more points is required to demonstrate improvement. Combining data by quarter (three months) is one way to increase c and thus obtain a LCL.

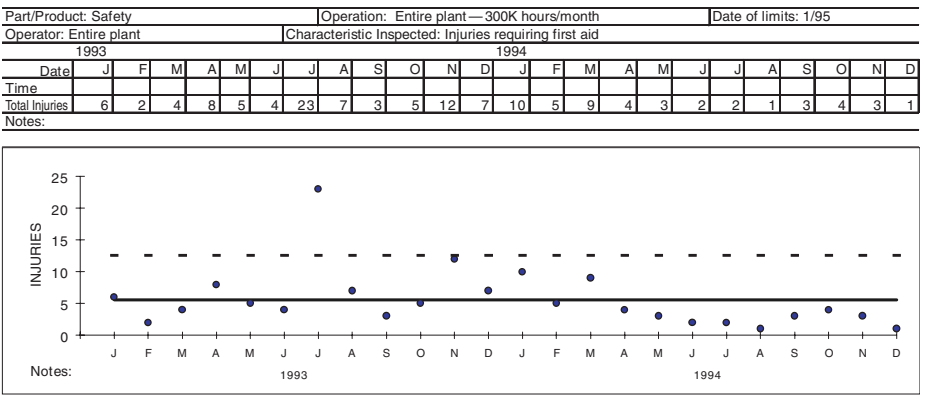

Figure 19 C Chart—Injury Data. (Copyright 1980–1998 Associates in Process Improvement)

C CHART CONTROL LIMITS (area of opportunity constant)

c = number of incidences per subgroup
k = number of subgroups
note: The subgroup size is defined by the "area of opportunity" for incidences and must be constant.

$\bar{c} = \frac{\Sigma c}{k} = \frac{133}{24} = 5.5$ (centerline)

UCL = $\bar{c}$ + (3 * $\sqrt{\bar{c}}$) LCL = $\bar{c}$ − (3 * $\sqrt{\bar{c}}$)

UCL = 5.5 + (3 * 2.3) LCL = 5.5 − (3 * 2.3)

UCL = 5.5 + 6.9 LCL = 5.5 − 6.9

UCL = 12.4 LCL = ____

U-CHART CONTROL LIMITS (area of opportunity may vary)

c - number of incidences per subgroup
n - number of "standard areas of opportunity" in a subgroup (n may vary)
u - incidences per standard area of opportunity = c/n
k - number of subgroups
note: The standard area of opportunity will be defined by the people planning the control chart in units such as man-hours, miles driven, per ten invoices, etc.

$\bar{u} = \frac{\Sigma c}{k} =$ _____ = _____ (Center Line)

UCL = $\bar{u}$ + (3 * $\sqrt{\bar{u}}$) / $\sqrt{n}$ LCL = $\bar{u}$ - (3 * $\sqrt{\bar{u}}$)

UCL = ___ + (3 * ___) / $\sqrt{n}$ LCL = ___ - (3 * ____) / $\sqrt{n}$

UCL = ___ + _____ / $\sqrt{n}$ LCL = ___ - _____ / $\sqrt{n}$

UCL = _____ LCL = _____

n:	_____	_____	_____	_____	_____
$\sqrt{n}$	_____	_____	_____	_____	_____

4.8. X-Bar and R Control Charts

When continuous data are obtained from a process, it is sometimes of interest to learn about both the average level of the process and the variation about the average level. In these cases, two control charts are often used to study the process: the X-bar chart and the R chart.

An important aspect of the collection of data for the construction of X-bar and R control charts is that the collection is done in subgroups. A subgroup for continuous data is a set (usually three to six) of measurements of some characteristic in a process, which were obtained under similar conditions or at about the same time. The X-bar chart contains the averages and the R chart the ranges

calculated from the measurements in each subgroup. These averages and ranges are usually plotted over time.

Figure 21 contains a form used to calculate the appropriate control limits. There are a number of symbols associated with X-bar and R charts:

X = individual measurement of quality characteristic
n = subgroup size (number of measurements per subgroup)
k = number of subgroups used to develop control limits

PROCESS CAPABILITY

If the process is in statistical control, the standard deviation is:

$\hat{\sigma}$ = $\bar{R}$ / d_2
$\hat{\sigma}$ = /
$\hat{\sigma}$ = _____

the process capability is:

$\bar{\bar{X}}$ - 3 * $\hat{\sigma}$ to $\bar{\bar{X}}$ + 3 * $\hat{\sigma}$
- to +
_____ to _____

Figure 21 X-bar and R Control Chart Calculation Form. (Copyright 1980–1998 Associates in Process Improvement)

Σ = summation symbol
$\overline{X}$ = (X-bar) subgroup average
$\overline{\overline{X}}$ = (X-double bar) average of the averages of all the subgroups
R = subgroup range (largest–smallest)
$\overline{R}$ = (R-bar) average of the ranges of all the subgroups
$A2$, $D3$, $D4$, d_2 = factors for computing control limits and process capability
$*$ = multiplication symbol

The steps for developing X-bar and R control charts follow. All averages that are calculated should be rounded to one more decimal place (significant figure) than the values being averaged.

1. Calculate $\overline{X}$ ($\overline{X} = \Sigma\, \overline{X}/n$) for each subgroup.
2. Calculate R (largest $-$ smallest value) for each subgroup.
3. Calculate $\overline{\overline{X}}$ ($\overline{\overline{X}} = \Sigma\overline{X}/k$), the centerline of the X-bar chart.
4. Calculate $\overline{R}$ ($\overline{R} = \Sigma R/k$), the centerline of the R chart.
5. Calculate the control limits for the X-bar chart using:

$$\text{UCL} = \overline{\overline{X}} + (A2 * \overline{R})$$

$$\text{LCL} = \overline{\overline{X}} - (A2 * \overline{R})$$

Note: $A2$ is a constant based on n obtained from Figure 21.

$LCL = 164.06$	

Figure 23 Calculations for X-bar and R chart for Chemical Process. (Copyright 1980–1998 Associates in Process Improvement)

6. Calculate the control limits for the R chart using:

$$UCL = D4 * \bar{R}$$
$$LCL = D3 * \bar{R}$$

   Note: $D3$ and $D4$ are factors that depend on the size of the subgroup and can be obtained from Figure 21. Note that there is no lower control limit for R when n is less than 7.
7. Calculate a scale for the X-bar chart such that the control limits enclose the inner 50% of the charting area. Calculate the scale for the R chart such that the upper control limit is placed 25–35% below the top of the chart.
8. Plot the $\bar{X}$'s on the X-bar chart and the R's on the R chart.
9. Draw the control limits and centerline on the X-bar chart.
10. Draw the control limits and centerline on the R chart.

The following example illustrates some of the important aspects concerning X-bar and R control charts. In a chemical process, a control chart was to be constructed to monitor the concentration of an impurity in finished pellets. Customers wanted the impurity to be stable below 200 ppm. Five grab samples were selected from the continuous process each day (approximately one every five hours). Data were collected for 24 days before control limits were calculated. Therefore, 24 subgroups were used in the calculations. Figure 22 contains the control chart and Figure 23 shows the calculations of the control limits. Since each subgroup contains five measurements, there is no lower control limit for the R chart.

After review of the control chart, the process was determined to be unstable. On June 8 and 17, points were above the upper control limit on the X-bar chart. Beginning on June 21, four points were below the lower control limit on the X-bar chart and there was a run of eight points in a row below the average. Since the process was unstable, action was taken to eliminate the special causes of variation. The special cause detected on June 8 was associated with poor color of the feedstock supplied by the Quality Chemical Company. Discussions with this supplier were initiated immediately and the problem was corrected. Material with better color was introduced into the process on June

21. The lower values of impurity that resulted were detected as a special cause on the X-bar chart. The special cause detected on June 17 was the result of a temporary 10% drop in the production rate. The production planning department was notified to make them aware of the effect of rates on impurity levels.

CHAPTER 69
Statistical Process Control

JOHN R. ENGLISH
TERRY R. COLLINS
University of Arkansas

1. INTRODUCTION

Product-to-product and service-to-service variation is potentially observable in all organizations. For example, a group of size 13 running shoes vary from shoe to shoe in form, fit, and finish. Even though the variation may not be observable by the human eye, it is observable if a more accurate measurement system is employed. Consumers of the product declare the product or service to be of inferior quality. Product variation may become increasingly observable to the consumer in complex systems. For example, consumers readily agree that there exists variation of cars of the exact same model and installed accessories. Otherwise, consumers would not insist upon driving the vehicle before purchase and the producer would not have to provide a warranty period to satisfy the concern of purchasing a failure-prone vehicle (commonly called a ''lemon'').

Examples such as these provide motivation for professionals to consider the implications of product-to-product and service-to-service variation. Clearly, product variation is key to customer satisfaction and loyalty; therefore, successful producers realize this and take appropriate actions to control the variation or quality of the products or services provided.

To monitor the variation of a process or service, data are collected and analyzed for product critical performance metrics. Two types of data are common. Data may be measured on a continuous scale, for example, length, weight, and so on. Such measurements are called variable data. Alternatively, if process observations are of the classification type, they are called attribute data. Examples

of such data include the number of defects in an inspection unit, number of defective units in a sample, and so on.

Well-known and documented techniques exist to monitor product variation while it is within the producer's environment. Most of the techniques require the observations or data to be statistically independent. That is, the data for a specific performance measurement are assumed to have no relationship to prior or successive observations. It is assumed that no correlation exists between data collected prior to or following a specific observation. The techniques used to monitor such data are collectively called statistical process control (SPC). These techniques are utilized in consumer-oriented industries. Some of the more prominent or useful techniques are presented in this chapter. Specifically, seven tools for SPC are reviewed, and their applicability is examined. Furthermore, common and improved approaches for process capability analysis are presented.

2. TOOLSET FOR STATISTICAL PROCESS CONTROL

Ishikawa (1985) presents seven common tools for SPC. He claims that 95% of quality-related problems can be resolved with these tools. The tools have been called the ''Magnificent Seven'' and are as follows:

1. Histogram
2. Check sheet
3. Pareto chart
4. Cause-and-effect diagram
5. Defect concentration diagram
6. Scatter diagram
7. Control chart

In the following subsections, brief overviews and practical examples are presented with the exception of the control charts, which are the topics of detailed discussions in Sections 3, 4, and 5.

2.1. Histogram

The histogram is a graphical tool that presents the relative frequency (in number or percentage) of observations within predefined cells. In other words, the histogram provides a graphical representation of a population or process under examination. The natural spread or distribution, the central tendency, and the variation of the process are readily observable in the histogram. Since the data supporting the histogram are defined by individual observations, the comparison of the process variation to the allowable spread, as defined by specifications, is easily demonstrated by plotting the specifications on the histogram. The histogram is a simple tool that provides a wealth of information regarding the natural tendencies of a product or process under study. Furthermore, from a probability perspective, the histogram provides an empirical estimate of the probability density function defining the product or process.

Example 1 presents an example of the use of the histogram.

Example 1. The following data have been collected from your process. In particular, you produce a child's toy. You have collected 90 values of a critical performance measurement that reflects surface quality for the manufactured product. The upper specification limit (USL) and the lower specification limit (LSL) are known to be 54 and 47, respectively. It is desired to demonstrate the natural tendency, variability, and relationship to the specification limits of the process by constructing a histogram of the data. With the collected data, the histogram is calculated by accumulating the number of observations within prescribed bands. The number of observations can be used to determine the relative frequency of each cell as demonstrated below.

Data for Example 1

The resulting histogram may be plotted with most spreadsheet software systems.

For this example, the resulting histogram is as follows:

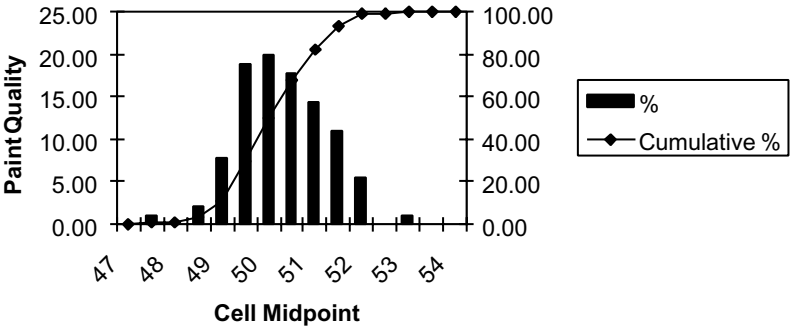

Figure 1 Histogram.

Cell Mid Point	# Observations	%	Cumulative %
47	0	0.00	0.00
47.5	1	1.11	1.11
48	0	0.00	1.11

50	18	20.00	50.00
50.5	16	17.78	67.78
51	13	14.44	82.22
51.5	10	11.11	93.33
52	5	5.56	98.89
52.5	0	0.00	98.89
53	1	1.11	100.00
53.5	0	0.00	100.00
54	0	0.00	100.00
Total =	90		

As observed, the paint quality measurements are contained within the specifications and are relatively symmetric.

2.2. Check Sheet

The check sheet is a simple and useful tool that is often used in the early stages of a quality control program. It provides a uniform and consistent means for data collection and analysis. Like many of the traditional tools, the check sheet is defect oriented and is used to classify the types of defects frequently found for a product or service. It is used to spot problems areas by identifying defect types that frequently occur. As a result, a check sheet is often used as the input to the next tool, called the Pareto chart. The check sheet is most often tabular in format as presented in Example 2.

Example 2. For the same toy of Example 1, defect data have been collected on a weekly basis to attempt to classify the underlying sources of product defects. In particular, several defect types have been established, and the operators are given a matrix simply to track the number of defects of each category for a multiday study period. The resulting check sheet is presented as follows:

Toy 1 Check Sheet: Defect Count—Finished Surface

Type	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Total	%	Cumulative %
Paint drips	11	9	10	11	10	12	17	80	42.3	42.3
Scratches	8	7	7	6	6	9	8	51	27.0	69.3
Handling marks	3	5	4	7	4	5	5	33	17.5	86.8
Chips	2	1	0	0	3	2	2	10	5.3	92.1
Poor color match	1	2	3	0	2	0	0	8	4.2	96.3
Poor assembly	2	1	0	0	1	0	0	4	2.1	98.4
Failure of functional test	0	1	0	0	1	0	0	2	1.1	99.5
Other	0	0	0	0	1	0	0	1	0.5	100.0
							Total	189		

As demonstrated above, the percent breakdown and accumulation of percentages are readily determined for each defect type. If the percent values are ranked from largest to smallest, a Pareto chart (discussed in the next section) is effectively computed, which makes the Pareto chart an obvious companion to the check sheet.

2.3. Pareto Chart

The Pareto chart was named after the Italian economist Vilfredo Pareto (1848–1923). Pareto observed that in certain cultures or economies a majority of the wealth was held by a small segment of the population.

In the context of quality or the observance of defects, time has proved over and over that there are usually a disproportionately small number of defect types that cause a majority of the problems. As a general rule of thumb, it is commonly observed that around 20% of the defect types can cause around 80% of the problems. Pareto analysis and the resulting Pareto chart are used to identify what is commonly known as the ''vital few and the trivial many.'' Most quality professionals agree that the Pareto chart is one of the best tools, if not the best tool, within the Magnificent Seven. Montgomery (1996) states that ''In general, the Pareto chart is one of the most useful of the 'magnificent seven'. Its applications to quality improvement are limited only by the ingenuity of the analyst.''

In the context of the check sheet, the resulting Pareto chart is simply the relative frequency of the defect types as observed during a study period. Pareto charts are effectively the plot of the relative frequency or cumulative frequency, of defect types.

Example 3 provides an enlightening example in the use of the Pareto chart.

Example 3. From the toy data of Example 2, plot the associated Pareto chart. From Example 2, you see that the relative frequencies and cumulative frequencies have been calculated. This is, in fact, the Pareto analysis. The resulting Pareto chart is as follows:

Over 70% of the defect types are caused by two of the eight defect types. The resulting Pareto chart can be used to identify priorities for defect-reduction programs. Assuming that paint drops and scratches are of critical concern to the customer and are yielding excessive costs, paint drops and scratches should be the focus of the defect-reduction program.

2.4. Cause-and-Effect Diagram

Once a defect-reduction program has been defined and the focus of the study has been identified, it is necessary to determine the cause of each of the defect types. The cause-and-effect diagram has proven to be an invaluable team-oriented approach to brainstorm the cause of a specific product defect, or more generally a consumer concern. The cause-and-effect diagram is a graphical tool that is most often constructed in a team setting to identify the contributing factors and their relationship to a defect type. The cause-and-effect diagram is used to identify areas of future data collection and analysis to identify process-improvement strategies. The chart has also been called the fishbone diagram or the Ishikawa diagram (Ishikawa 1985).

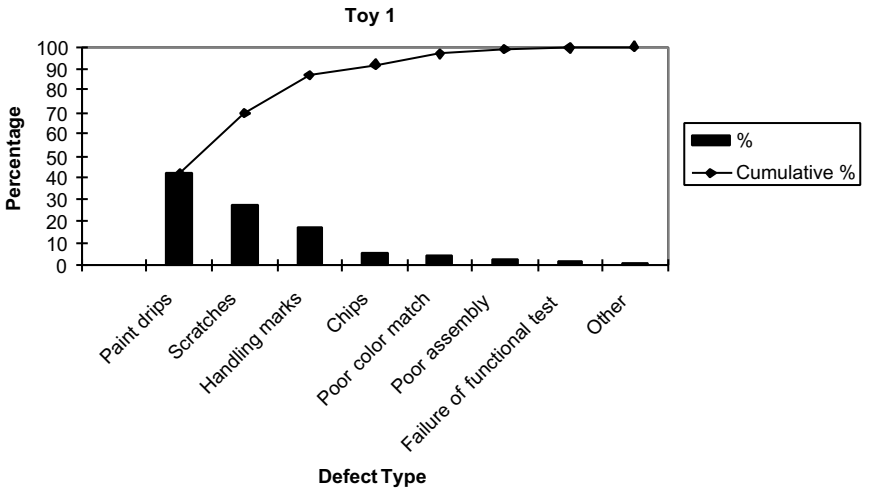

Figure 2 Pareto Chart.

The cause-and-effect diagram basically dissects a defect type into the associated causes. The causes can be further subdivided into additional groupings if the team believes such structure is necessary. Japanese-based tools such as the cause-and-effect diagram are useful for creative problem solving, and teams using such tools should be allowed flexibility in customizing tools for their specific needs. Example 4 presents the use of a cause-and-effect diagram.

Example 4. Within your facility, part accuracy is a consistent problem. You have established a cross-functional team to investigate the causes of this problem in an effort to identify opportunities of process improvement. The resulting cause-and-effect diagram is as follows:

2.5. Defect Concentration Diagram

Of the seven tools of the Magnificent Seven, the defect concentration diagram is most likely the simplest, and one of the most effective, for process-improvement activities. The defect concentration diagram is a schematic diagram of the part being produced. It provides all relevant views, and all defect types are recorded in accordance with a preset key. The operator simply records each observed defect on the defect concentration diagram. This diagram is often used in conjunction with the cause and effect diagram in an effort to identify process opportunities for improvement. The diagram is used to determine the specific location of defect types, and as a result, provides insightful information on process problems and the source of product defects.

Example 5 presents an example of a defect diagram.

Example 5. You produce a metal painted part that serves as the shell of the toy of Example 1. It is effectively a triangular column. The resulting defect concentration diagram for the operators is presented in Figure 4:

The defect concentration diagram is placed at a strategic point in the process, and the operator is instructed to document all observed defects according to location and type. For example, if five paint drips are observed on the top right corner of side 1, five A's would be placed on the top right corner of side 1 of the defect concentration diagram. The collective view of the completed defect concentration diagram provides conclusive evidence supporting the investigation of process-improvement activities.

2.6. Scatter Diagram

The sixth tool of the Magnificent Seven is the scatter diagram. For readers familiar with simple linear regression, the scatter diagram is considered the first step in determining the functional relationship between two variables. The scatter diagram is effectively the plotting of a process or product performance metric against some controllable variable. Most spreadsheet software systems provide the graphical tools to minimize the technical details of constructing such diagrams. Example 6 provides an illustration of the use of the scatter diagram.

Example 6. At the Department of Industrial Engineering at the University of Arkansas, miniature catapults are used to demonstrate the usefulness of statistical modeling. The teaching tool is effec-

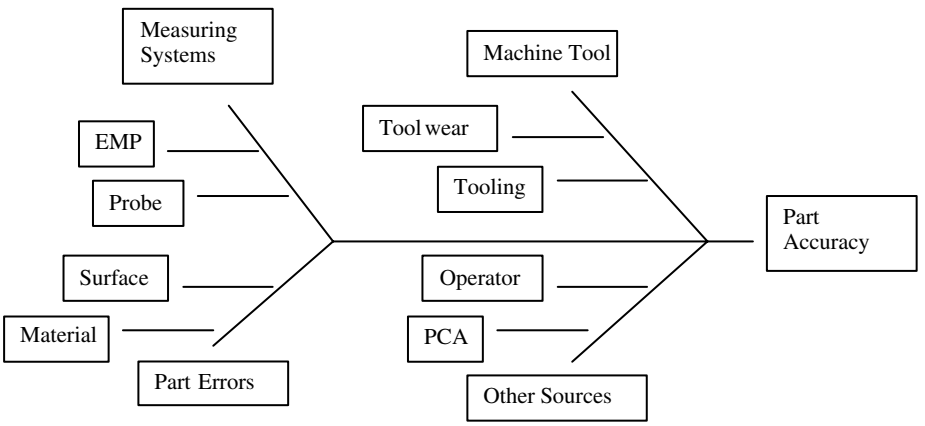

Figure 3 Cause-and-Effect Diagram.

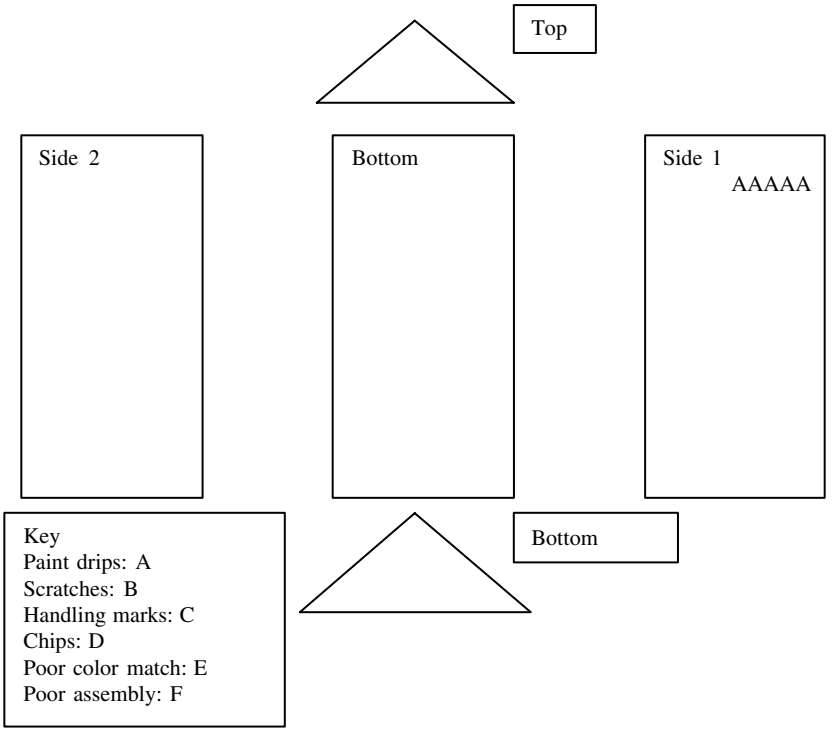

Figure 4 Defect Concentration Diagram.

tively a miniaturization of the classic weapon of ages past. As the arm of the catapult is pulled back further—the angle is called the throwing angle—a given projectile is launched to realize increasing distances. The first step in modeling this process is to demonstrate graphically the relationship between the throwing angle and the resulting throwing distances. In particular, the projectile is launched five times from six different throwing angles. The resulting scatter diagram is given in Figure 5.

There appears to be a fairly linear relationship between the throwing angle and the distance thrown.

3. OVERVIEW OF CONTROL CHARTS

As previously described, almost every product, process, or service varies. The control chart is used to monitor natural process variation in an effort to expose times that the process has shifted such that nonnatural variation is realized. Within the SPC domain, terms have been coined to define various types of variation. The natural variation in the process that cannot be avoided is commonly called common cause variation. It is assumed that such variation is not controllable. Alternatively, undesirable changes occur, causing a process to change in its natural behavior. The variation of the process may become excessively large in view of its common causes, or the central tendency of the data may shift in a positive or negative direction. Such unnatural variations in the data are known as special causes.

In view of these types of variation, it is desired to design SPC approaches such that the user maximizes opportunities for detecting special causes in the midst of the uncontrollable chance causes. In the application of SPC, samples or subgroups are collected and analyzed and are used for this judgment. The logical collection of the subgroups or samples such that opportunities for detecting special causes are maximized is commonly known as rational subgrouping. Most introductory texts in quality control have detailed discussion of this topic (i.e., Grant and Leavenworth 1980).

The tool that is used to monitor process variation over time is known as the control chart. Control charts originate from the work of Walter Shewhart (1927) and are often referred to as Shewhart control charts. Effectively, process observations based upon collected samples or subgroups, at fixed points in time, are plotted in accordance to time. As long as the current observation is within fixed

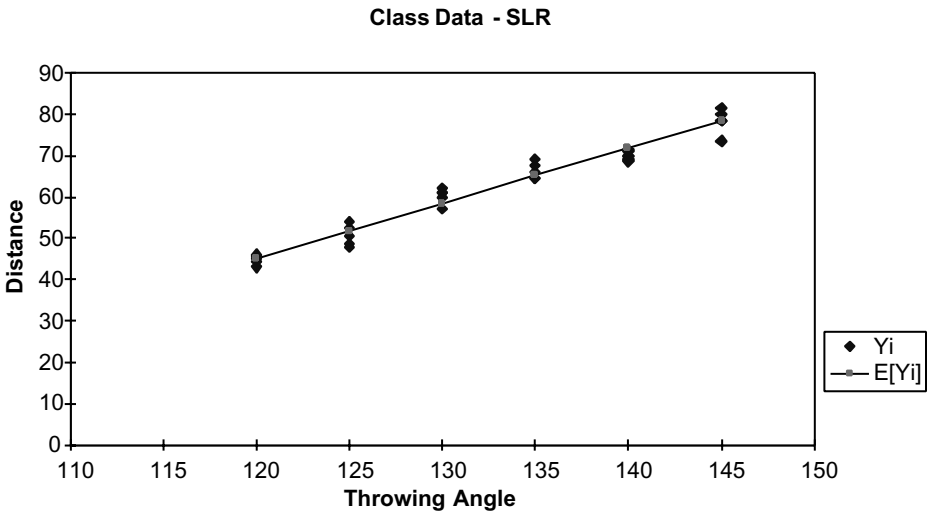

Figure 5 Scatter Diagram.

intervals, called control limits, or no unnatural trends in the data are observed (defined in Section 3.2), it is concluded that the process is operating in the presence of common causes only. Such a process is declared to be operating in a state of statistical control. Alternatively, if the process yields observations that exceed the control limits, or unnatural variation exists, it is concluded that special causes exist in addition to the common causes. Commonly, this process state is known as being out of control.

Figure 6 presents this graphical tool—the control chart. As discussed, there exists a line defining the central tendency as well as the control limits. This process is obviously operating under the presence of both special causes and common causes and should be judged out of control.

The basis of the centerline and the control limits are essentially the same for all charts with the exception of the type of data. Assume that the quality characteristic being monitored is Y_t, for which the mean is known to be $E[Y_t]$, and the variance is known to be $V[Y_t]$. The general centerline (CL) and resulting control limits are:

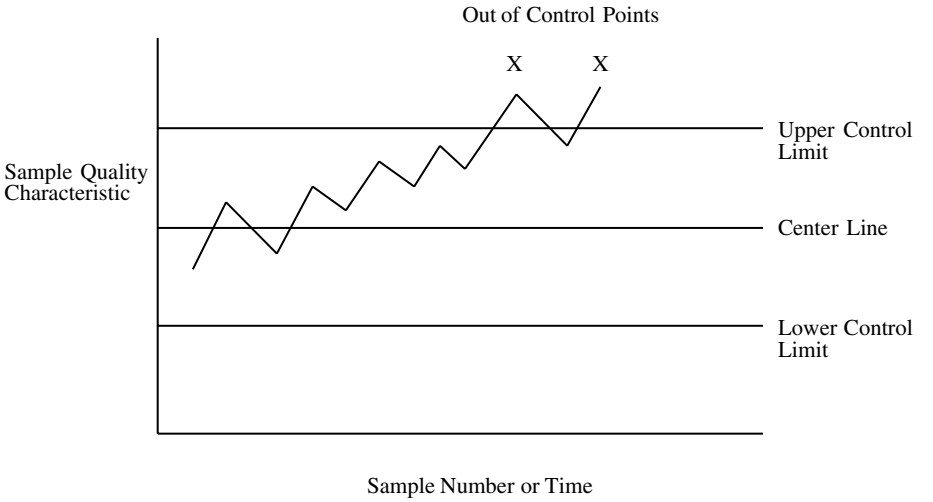

Figure 6 Example Control Chart.

$$\text{Upper control limit (LCL)} = E[Y_t] + k\sqrt{V[Y_t]}$$

$$\text{Centerline (CL)} = E[Y_t]$$

$$\text{Lower control limit (UCL)} = E[Y_t] - k\sqrt{V[Y_t]}$$

where k is defined by the user. In most applications within the United States, k is assumed to be 3 regardless of the type of data.

In Section 4, two control charts for variable data are presented. Both the $\overline{X}$ control chart for monitoring the process mean and the R control chart for monitoring the process variation are presented. In Section 5, two control charts for attribute data are discussed: the p control chart for monitoring percent nonconforming and the c chart for monitoring the number of defects in a sample. Furthermore, brief discussions of data patterns on control charts and recommended supplemental rules for judging nonrandom trends on a control chart are presented.

3.1. Data Patterns on Control Charts

Control charts are powerful tools for monitoring the variation of a process. Furthermore, the nonnatural trends on a control chart can provide significant diagnostic information regarding the cause of a process disturbance. In this section, prevalent trends from out-of-control processes are presented and the suspect causes are briefly discussed. References such as AT&T (1985) and Montgomery (1996) provide more in-depth presentations of this discussion.

First, it is the assumption of most control chart applications that the process from which observations are collected is stable. That is, the statistical behavior of the process is time invariant in that the underlying distribution is fixed, yielding a fixed mean and variance. In some applications, process observations are collected such that multiple processes may feed the data-collection station. As a result, the observations may have a tendency to cluster around the control limits and be sparsely observed around the CL or the mean. This observation is commonly referred to as a mixture.

Secondly, processes may be overly sensitive to factors within the day; for example, temperature cycles. Such trends in the data are known as cycles and are not well suited for traditional applications of control charts, even though the cycling behavior is a natural part of the process variation. When faced with cycling or autocorrelation in the data, it is suggested the advanced techniques, such as the moving centerline exponentially weighted moving average chart, be considered, as presented in Montgomery and Mastrangelo (1991).

Third, a trend (see Figure 6) in the process is typically realized on the control chart as a generally increasing or decreasing trend in the data. Such trends in the data can be caused by process degradation, such as tool or machine wear. In some cases, such trends cannot be tolerated and can be adequately detected with standard control charts. In situations where such trends are a natural part of the process (i.e., tool wear), alternative approaches should be considered. The simplest approach is to fit a reasonable regression model to the process and monitor the process accordingly. Alternatively, Quesenberry (1988) develops an alternative SPC approach for a tool-wear process.

If a shift has occurred in the central tendency of the process, the process data will cluster around the new mean. Such shifts are often caused by changes in raw materials or process settings. In most all cases, such process behavior is not desirable and can be detected quickly with traditional control charts.

3.2. AT&T Runs Rules

Clearly, the term *nonrandom* trend must be consistently defined for the shop floor operators. Such definitions are made by the consistent adoption of rules for judging the current status of a process. Probably the most common set of rules for examining the state of the process is known as the AT&T runs rules (AT&T 1985). In AT&T (1985), these rules are called ''Tests for Instability.'' In applying these tests, each half of the control chart (the area between the CL and UCL and the CL and LCL) is divided into three equally spaced zones, as shown in Figure 7.

In accordance with the AT&T handbook, a process is judged out of control or unstable if any one of the following rules apply:

Test 1: A single point falls outside of the control limits (beyond zone A).

Test 2: Two out of three successive points fall in zone A or beyond for a given side.

Test 3: Four out of five successive points fall in zone B or beyond for a given side.

Test 4: Eight successive points fall in zone C or beyond for a given side.

If these rules are consistently employed throughout a plant, type I errors should be adequately controlled while ensuring reasonable detection of undesirable process shifts. A type I error, in the context of control charts, is the event that the operator falsely concludes that the process is out of control.

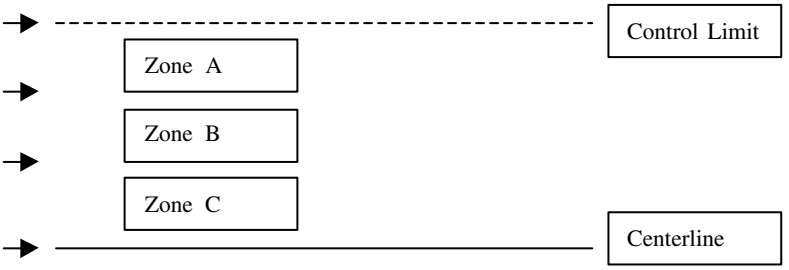

Figure 7 AT&T Runs Rules Zones.

4. CONTROL CHARTS FOR VARIABLES

4.1. $\overline{X}$ and R Control Charts

The most common means of monitoring variable data is with $\overline{X}$ the R and control chart combination. It is assumed that the observations collected from the process are independent and normally distributed. The $\overline{X}$ chart is utilized to monitor the process mean, and the R chart is used to monitor the process variation. Without exception, the $\overline{X}$ and R charts should always be used together. The normality assumption embeds the fact that two parameters, the mean and variance, completely characterize the process; therefore, both control charts are necessary to monitor the process completely.

From an applications perspective, n observations, $X_{i1}, X_{i2}, \ldots X_{in}$ are collected from the process at fixed points in time, i. These n observations from sampling interval i are commonly referred to as subgroup i. As a rule of thumb, the number of observations in each subgroup, n, should be between 4 and 6. Furthermore, for slight departures from normality, such sample averages, $\overline{X}$, can be assumed to be approximately normal, due to the central limit theorem (in as much as the underlying distribution is not excessively skewed). Estimates for the process mean and variance at a point in time i are based upon the sample average and range. That is,

$$\text{Sample average}_i = \overline{X}_i = \sum_{i=1}^{n} x_{ij}/n$$

$$\text{Range}_i = R_i = \text{maximum}(X_{i1}, X_{i2}, \ldots, X_{in}) - \text{minimum}(X_{i1}, X_{i2}, \ldots X_{in})$$

4.1.1. Control Limits: Standards Known

If the mean, μ, and the variance, σ^2, are known for the underlying process, the upper and lower control limits for these charts ($\overline{X}$ and R) can be determined as follows:

For the $\overline{X}$ chart:

$$\text{UCL}_{\overline{X}} = \frac{\mu + 3\sigma}{\sqrt{n}}$$

$$\text{CL}_{\overline{X}} = \mu$$

$$\text{LCL}_{\overline{X}} = \frac{\mu - 3\sigma}{\sqrt{n}}$$

For the R chart:

$$\text{UCL}_R = D_2\sigma$$

$$\text{CL}_R = d_2\sigma$$

$$\text{LCL}_R = D_1\sigma$$

where μ = the process mean
σ = the process standard deviation
d_2, D_2, and D_1 = tabled values for a given n (subgroup size) and are included in the Appendix.

The AT&T runs rules should always be employed for the $\overline{X}$ chart and should be used for the R chart when the sample size is five or more (AT&T 1985). The first rule of the AT&T runs rules should always be used for both charts.

To illustrate the use of the $\overline{X}$ and R charts, the Example 7 is presented:

Example 7. Five observations have been collected from a process where the mean, μ, and the standard deviation, σ, are known to be 50 and 1, respectively. Construct and plot the necessary control limits and calculated observations for both the $\overline{X}$ and R charts. The data are collected and the resulting $\overline{X}_i$'s and R_i's are computed as follows:

i	X_{i1}	X_{i2}	X_{i3}	X_{i4}	X_{i5}	$\overline{X}_i$	R_i
1	51.69	49.59	52.51	51.07	50.01	50.97	2.92
2	49.37	49.13	49.77	49.61	49.89	49.55	0.77
3	50.59	50.08	50.4	47.82	48.67	49.51	2.77
4	51.24	49.79	50	49.89	51.98	50.58	2.19
5	50.78	48.82	50.59	51.48	49.12	50.16	2.66
6	49.86	48.43	49.1	48.76	49.45	49.12	1.43
7	50.86	50.78	50.43	52.12	49.7	50.78	2.42
8	50.94	51.61	50.2	49.08	51.63	50.70	2.55
9	49.25	49.46	51.71	49.08	51.55	50.21	2.63
10	50.52	50.92	49.06	50.43	51.46	50.48	2.40
11	49.45	49.02	51.23	49.96	49.9	49.91	2.20
12	50.12	51.06	50.99	50.98	50.09	50.65	0.97
13	49.32	49.93	51	50.68	48.14	49.81	2.86
14	50.04	50.1	49.08	49.14	50.3	49.73	1.22
15	50.25	49.78	50.51	49.37	48.21	49.62	2.30
16	50.07	49.69	48.81	50.72	50.25	49.91	1.91
17	49	50.25	49.93	48.87	49.32	49.47	1.38
18	49.64	51.22	49.84	50.51	50.68	50.38	1.58
19	51.5	49.49	48.24	48.02	50.86	49.62	3.48
20	51	49.58	49.57	50.08	51.75	50.39	2.19
21	49.66	49.41	47.43	49.68	49.39	49.11	2.25
22	48.64	48.53	50.03	49.85	48.77	49.16	1.50
23	50.35	49.34	51.2	50.82	49.72	50.29	1.87
24	51.49	51.44	50.78	48.91	49.86	50.50	2.57
25	49.81	49.45	49.43	51.46	49.76	49.98	2.03
26	49.82	49.99	51.3	49.4	50.28	50.15	1.90
27	48.59	49.31	49.95	50.63	48.78	49.45	2.04
28	51.67	51.13	49.33	50.93	48.61	50.33	3.05
29	50	50.85	49.53	50.7	49.3	50.08	1.55
30	50.2	48.74	50.42	51.27	48.57	49.84	2.71

The resulting control limits are as follows:

For the $\overline{X}$ chart:

$$\text{UCL} = 50 + \frac{3(1)}{\sqrt{5}} = 51.342$$

$$\text{CL} = 50$$

$$\text{LCL} = 50 - \frac{3(1)}{\sqrt{5}} = 48.658$$

For the R chart:

$$\text{UCL}_R = 4.918(1) = 4.918$$

$$\text{CL}_R = 2.326(1) = 2.326$$

$$\text{LCL}_R = 0(1) = 0$$

The resulting control charts are given in Figures 8 and 9.

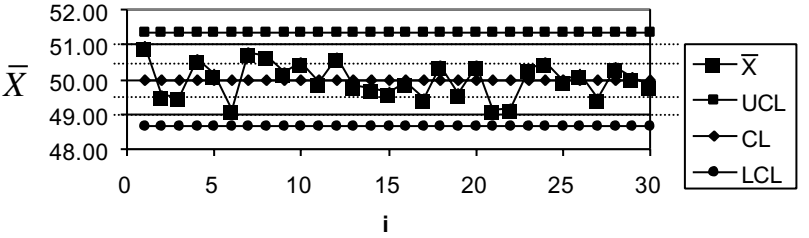

Figure 8 $\overline{X}$ Chart: Standards Known.

From the control charts above, the process exhibits stability using the AT&T runs rules on the $\overline{X}$ chart (see zones marked on Figure 8) and for rule number 1 for the R chart; therefore, the process is judged to be in a state of statistical control.

In most all cases, the process mean, μ, and the process standard deviation, σ, must be estimated from process data and the associated calculation of control limits must be adjusted. In the next section, the calculation of the control limits when the standards are not known is presented.

4.1.2. Control Limits: Standards Not Known

As stated previously, the true values of μ and σ are typically estimated with sampled data from a process. For the quality of estimation, it is typically assumed that at a minimum, 25 to 30 subgroups should be available before estimates of μ and σ are made ($\hat{\mu}$ and $\hat{\sigma}$). The following relationships are used to determine the necessary estimates:

$$\hat{\mu} = \overline{\overline{X}} = \sum_{i=1}^{m} \overline{X}_i / m$$

$$\hat{\sigma} = \overline{R} = \left[\sum_{i=1}^{m} R_i / m \right] \Big/ d_2$$

where m is the number of subgroups
d_2 is a table look-up value from the Appendix

The control limits when standards are unknown are calculated as follows:
For the $\overline{X}$ chart:

$$\mathrm{UCL}_{\overline{X}} = \frac{\hat{\mu} + 3\hat{\sigma}}{\sqrt{n}}$$

$$\mathrm{CL}_{\overline{X}} = \hat{\mu}$$

$$\mathrm{LCL}_{\overline{X}} = \frac{\hat{\mu} - 3\hat{\sigma}}{\sqrt{n}}$$

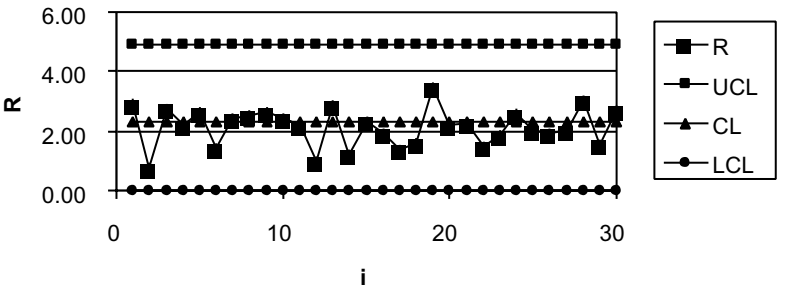

Figure 9 R Chart: Standards Known.

If A_2 is set equal to $3/d_2\sqrt{n}$ and $\overline{\overline{X}}$ and $\overline{R}/d_2$ are substituted for $\hat{\mu}$ and $\hat{\sigma}$, respectively, the resulting control limits can be determined as follows:

$$\text{UCL}_{\overline{X}} = \overline{\overline{X}} + A_2\overline{R}$$
$$\text{CL}_{\overline{X}} = \overline{\overline{X}}$$
$$\text{LCL}_{\overline{X}} = \overline{\overline{X}} - A_2\overline{R}$$

For the R chart:

$$\text{UCL}_{\overline{R}} = D_3\overline{R}$$
$$\text{CL}_{\overline{R}} = \overline{R}$$
$$\text{LCL}_{\overline{R}} = D_4\overline{R}$$

where A_2, D_3, and D_4 are tabled values for subgroup size n (see Appendix).

The AT&T runs rules should always be employed for the $\overline{X}$ chart and should be used for the R chart when the sample size is five or more (AT&T 1985). The first rule of the AT&T runs rules should always be used for both charts.

In practice, the initial estimation of the control limits may require an iterative process in securing control limits that are statistically valid. In particular, it may be necessary to estimate the limits initially. If a given $\overline{X}$ or R plots beyond the initial control limits, it is recommended that the cause of the extraordinary point be resolved and then removed from the calculation. That is, the control limits should be recalculated with the out-of-control point(s) removed. In some extreme cases, this iterative process may be repeated several times. Once the observed data are contained within the trial limits, continued production should be used to collect more data to further validate the limits. Once process stability is obtained, that is control is maintained for an extended period, the new control limits should become the operational standard. Furthermore, once the trial limits are established, the AT&T Runs Rules should be deployed in totality to insure protection against process disturbances.

Example 8 demonstrates the construction of $\overline{X}$ and R charts when standards are not known.

Example 8. Consider the process data of Example 7, except do not assume that the standards are known. Determine the appropriate trial control limits for this process.

i	X_{i1}	X_{i2}	X_{i3}	X_{i4}	X_{i5}	$\overline{X}_i$	R_i
1	51.69	49.59	52.51	51.07	50.01	50.97	2.92
2	49.37	49.13	49.77	49.61	49.89	49.55	0.77
3	50.59	50.08	50.4	47.82	48.67	49.51	2.77
4	51.24	49.79	50	49.89	51.98	50.58	2.19
5	50.78	48.82	50.59	51.48	49.12	50.16	2.66
6	49.86	48.43	49.1	48.76	49.45	49.12	1.43
7	50.86	50.78	50.43	52.12	49.7	50.78	2.42
8	50.94	51.61	50.2	49.08	51.63	50.70	2.55
9	49.25	49.46	51.71	49.08	51.55	50.21	2.63
10	50.52	50.92	49.06	50.43	51.46	50.48	2.40
11	49.45	49.02	51.23	49.96	49.9	49.91	2.20
12	50.12	51.06	50.99	50.98	50.09	50.65	0.97
13	49.32	49.93	51	50.68	48.14	49.81	2.86
14	50.04	50.1	49.08	49.14	50.3	49.73	1.22
15	50.25	49.78	50.51	49.37	48.21	49.62	2.30
16	50.07	49.69	48.81	50.72	50.25	49.91	1.91
17	49	50.25	49.93	48.87	49.32	49.47	1.38
18	49.64	51.22	49.84	50.51	50.68	50.38	1.58

						50.02	2.14
						$\overline{\overline{X}}$	$\overline{R}$

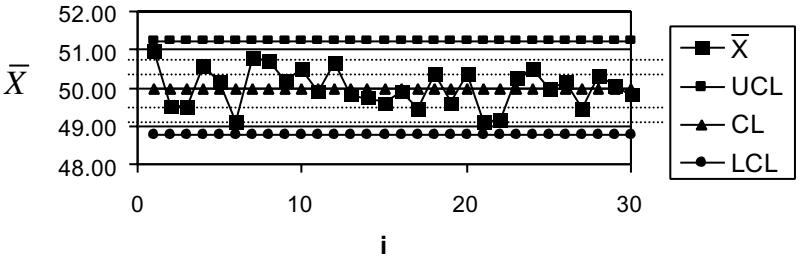

Figure 10 $\overline{X}$ Chart.

The resulting control limits:
For the $\overline{X}$ chart:

$$\mathrm{UCL}_{\overline{X}} = 50.02 + 0.577(2.14) = 51.255$$
$$\mathrm{CL}_{\overline{X}} = 50.02$$
$$\mathrm{LCL}_{\overline{X}} = 50.02 - 0.577(2.14) = 48.785$$

For the R chart:

$$\mathrm{UCL}_{\overline{R}} = 2.115(2.14) = 4.526$$
$$\mathrm{CL}_{\overline{R}} = 2.14$$
$$\mathrm{LCL}_{\overline{R}} = 0(2.14) = 0$$

The resulting control charts are given in Figures 10 and 11.

As demonstrated, all points plot within the control limits; therefore, these trial limits should be employed for production. Furthermore, it is highly recommended that the production also utilize the AT&T runs rules on the $\overline{X}$ chart (see zones on Figure 10) for subsequent production to monitor the state of the process.

4.2. Other Charts

There are many other control charts to monitor variable data. In each case, there should be a control chart for monitoring the mean and a control chart for monitoring the variance. These additional charts include the cumulative sum charts, exponentially weighted moving average charts, modified control charts, trend charts, control charts for short production times, individuals charts, moving average charts, moving range charts, control charts for variable sample sizes, S chart, variance charts, and acceptance control charts. The reader is referred to comprehensive textbooks such as Montgomery (1996) for a complete treatise on these more advanced techniques.

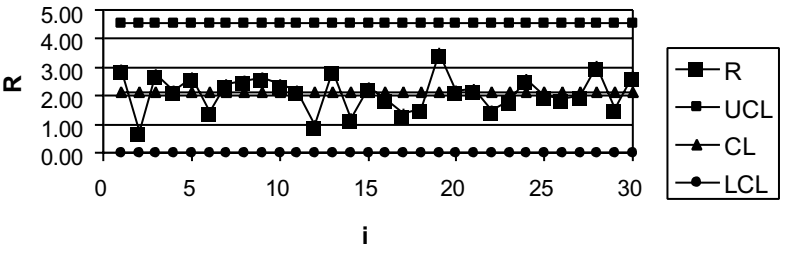

Figure 11 R Chart.

4.3. Process Capability Analysis

Once the process has generated sufficient data to support the conclusion that it is stable or in a state of statistical process control, it is desirable to judge the process's ability to meet customer specifications, that is, the upper specification limit (USL) and lower specification limit (LSL). Within most industries, process capability ratios are used to measure a given process's ability to meet specifications. The effort employed to make this judgment is known as process capability analysis (PCA).

The PCA ratios common to industry are C_p and C_{pk}. The ratios provide different perspectives to PCA. Generally, it is desirable that the ratios exceed 1 to ensure that the process is capable of meeting specifications.

4.3.1. Capability Ratios

The first ratio considered is C_p. This capability ratio estimates the potential that a process has to meet specifications. As demonstrated in the formulation below, the mean of the process is not accounted for.

$$C_p = \frac{\text{USL} - \text{LSL}}{6\hat{\sigma}}$$

4.3.2. C_{pk}

With the C_p calculation above, it is clear that a very good C_p could be determined while the process is generating practically all-bad product. As a result, C_{pk} has been formulated to embed the concern of process centering. C_{pk} is calculated as follows:

$$C_{pk} = \text{minimum}\left(\frac{\text{USL} - \hat{\mu}}{3\hat{\sigma}}, \frac{\hat{\mu} - \text{LSL}}{3\hat{\sigma}}\right)$$

In the formulas above for C_p and C_{pk}, $\hat{\sigma}$ may be determined with almost any known technique. Since the process must be assumed to be in a state of statistical control, it is usually found that $\overline{R}/d_2$ is the most convenient estimate of σ.

It is important to note that the now-famous Motorola 6σ program is based upon PCA. This highly effective program simply requires that C_p and C_{pk} be greater than 2.

Example 9 presents the use of the PCA ratios.

Example 9. For the data presented in Example 8, compute both C_p and C_{pk} and make the appropriate PCA conclusions. The USL is 54 and the LSL is 47.

For the data collected,

$$\hat{\mu} = 50.02$$

$$\hat{\sigma} = \frac{\overline{R}}{d_2} = \frac{2.14}{2.326} = 0.920$$

$$C_p = \frac{54 - 47}{6(0.920)} = 1.268$$

$$C_{pk} = \text{minimum}\left(\frac{54 - 50.02}{3(0.920)}, \frac{50.02 - 47}{3(0.920)}\right) = \text{minimum}(1.442, 1.094) = 1.094$$

As a result, it appears that the process is capable of meeting specifications, but the performance is not at the 6σ level, since C_p and C_{pk} are both less than 2.

4.3.3. Inferential Approaches

In the previous section, the statistical inference of PCA using the capability ratios, C_p and C_{pk}, is questionable. This stems from the fact that only a single point estimate is made and compared to a standard of 1. Clearly, due to the random nature of any process, sample estimates or observed values of C_p and C_{pk} can be greater than 1 when, in fact, the true process values are less than 1.

Chou et al. (1990) provide an inferential approach to PCA using C_p and C_{pk}. Their work necessarily assumes the observations collected from the process in question to be independent and to follow the normal distribution. They establish minimum critical values for both of the parameters that provide a statistical basis to concluding the capability of the process. Essentially, they establish

a critical value for both C_p and C_{pk} for the appropriate test of hypothesis. The test of hypotheses for the ratios is as follows:

For C_p,

$$H_o : C_p < C_0$$
$$H_A : C_p \geq C_0$$

where C_0 is the desired minimum value of C_p such that the process is deemed capable.

For C_{pk},

$$H_o : C_{pk} < C_k$$
$$H_A : C_{pk} \geq C_k$$

where C_k is the desired minimum value of C_{pk} such that the process is deemed capable.

For the estimates of C_p and C_{pk}, the unbiased estimate of σ^2, S^2, should be utilized for the estimates of the capability ratios. Furthermore, the estimate of the mean, μ, should be the sample average, commonly known as $\overline{X}$. In Chou et al. (1990), as long as the calculated or estimated value of the specific capability ratio is greater than the critical value, as defined in Table 1 for various sample sizes (n = 10, 20, 30, and 50), it is concluded that the "process is considered capable 95% of the time." Table 1 presents a small yet practical set of the values presented in Chou et al. (1990).

It is interesting to note that if it is desired that C_p and C_{pk} be both greater than 1, the calculated values of C_p and C_{pk} should be considerably larger than 1 for both cases for the practical sample sizes shown in Table 1. The Motorola 6σ performance criteria ($C_p = C_{pk} = 2.0$) are even greater. Example 10 presents applications of the inferential approach to PCA.

Example 10. Thirty observations have been collected from the in-control process of Examples 8 and 9.

1. If minimum values of one are required for C_p and C_{pk}, is the process capable.

2. Is the process of 6σ quality?

Data:

TABLE 1 Critical Values for Estimated C_p and C_{pk}

C_p:				
C_o	n = 10	20	30	50
1.0	1.65	1.37	1.28	1.20
1.2	1.97	1.64	1.54	1.44
1.4	2.30	1.92	1.79	1.68
1.6	2.63	2.19	2.05	1.92
1.8	2.96	2.47	2.30	2.16
2.0	3.29	2.74	2.56	2.40
C_{pk}:				
C_k	n = 10	20	30	50
1.0	1.80	1.46	1.35	1.25
1.2	2.12	1.73	1.61	1.49
1.4	2.45	2.01	1.86	1.73
1.6	2.78	2.28	2.12	1.97
1.8	3.11	2.55	2.37	2.21
2.0	3.44	2.83	2.63	2.45

i	Observation (X_i)
1	50.13
2	49.65
3	52.41
4	49.19
5	51.16
6	50.01
7	49.99
8	48.76
9	49.59
10	49.73
11	50.36
12	49.19
13	50.02
14	49.46
15	49.47
16	49.75
17	50.42
18	51.84
19	51.14
20	51.74
21	48.07
22	48.9
23	49.95
24	48.85
25	50.24
26	48.87
27	50.5
28	53.13
29	48.82
30	48.39

$S^2 = 1.401$
$\overline{X} = 49.99$

1. The resulting calculated values of C_p and C_{pk} are as follows (assuming the USL of 54 and LSL of 47 from Example 9):

$$C_p = \frac{54 - 47}{6\sqrt{1.401}} = 0.986$$

$$C_{pk} = \text{minimum}\left(\frac{54 - 49.99}{3\sqrt{1.401}}, \frac{49.99 - 47}{3\sqrt{1.401}}\right) = \text{minimum}(1{,}129, 0.842) = 0.842$$

   In both cases, the calculated values are less than the critical values. That is, the critical value for C_p when C_0 is 1 is 1.28, and the critical value for C_{pk} when C_k is 1 is 1.35. As a result, a strong, statistically based conclusion can be made that the process is not capable.
2. Obviously, if the process is not capable at values of 1 for the PCA ratios, it is not capable to meet the 6σ performance criteria. For this sample of 30, minimum critical values for C_p and C_{pk} would have been 2.56 and 2.63, respectively, if C_0 and C_k values of 2 were required (which is implied by the 6σ program).

5. CONTROL CHARTS FOR ATTRIBUTE DATA

5.1. Attribute Data

At this point, we have reviewed $\overline{X}$ and R control charts. Both of these charts are used for variable data. Many more control charts exist for varying conditions for variable data, as described above. In this section, two control charts are presented that are most useful in monitoring attribute data. In particular, a control chart known as the p chart is presented to provide a tool for monitoring the

percent nonconforming from a process. Secondly, the c chart is used to monitor the number of defects being produced in a process.

5.2. Control Chart for Percent Nonconforming: p Chart

The percentage of nonconforming units being produced is of utmost concern to all organizations. A nonconforming unit represents the reality of a process's failure to produce product that meets customers' expectations or specifications. As such, the percent nonconforming control chart can also be thought of as an ongoing estimate of the process's ability to meet customer expectations.

For the p chart, the percent nonconforming is estimated with sampled data observations. Typically, 25–100 observations are collected for a given subgroup. The current percent nonconforming, p, is estimated as follows:

$$\hat{p} = \frac{D_i}{n}$$

where D_i = the number of nonconforming observations in the current subgroup i
n = the number of observations or samples in each subgroup

It is assumed that the number of observations that are defective in a subgroup of n samples follows the binomial distribution with parameters p (the true population percent nonconforming) and n. For the formulation presented here, n is assumed to be fixed. This assumption can be relaxed, but a modified approach for the varying sample size must be employed as demonstrated in most standard quality control textbooks (i.e., Montgomery 1996). The p chart is essentially the plotting of the observed values of $\hat{p}$. These values are individually compared to the control limits (shown below) to determine the current status of the process (i.e., state of statistical control or out of control). Furthermore, the AT&T runs rules should be deployed when possible.

Obviously, p, the true population percent nonconforming, is typically estimated by averaging the observed values of p. As a rule of thumb, it is suggested that 25–30 subgroups be collected before the estimate of p is made. This parameter, known as $\overline{p}$, is estimated as follows:

$$\overline{p} = \frac{\sum_{i=1}^{m} \hat{p}_i}{m}$$

where m is the number of subgroups collected (recommended: 25–30).

Both $\hat{p}$ and $\overline{p}$ are known to be unbiased estimators of p. Once $\overline{p}$ is determined, the control limits can be determined as follows:

$$\mathrm{UCL}_p = \overline{p} + 3\sqrt{\frac{\overline{p}(1-\overline{p})}{n}}$$

$$\mathrm{CL}_p = \overline{p}$$

$$\mathrm{LCL}_p = \text{maximum}\left(0, \overline{p} - 3\sqrt{\frac{\overline{p}(1-\overline{p})}{n}}\right)$$

The LCL is truncated to 0 when the calculated value falls below 0. The AT&T runs rules can be employed in situations where the control limits are reasonably symmetric (AT&T 1985).

The establishment of the trial control limits for the p chart follows the same practice as described for the $\overline{X}$ and R charts. That is, if a given point plots beyond the initial control limits, it is recommended that the cause of the extraordinary point be resolved and then removed from the calculation. That is, the control limits should be recalculated with the out-of-control point(s) removed. In some extreme cases, this process may have to be repeated. Once the observed data are contained within the trial limits, continued production should be used to collect more data in an effort to validate the limits. Once process stability is obtained, that is, control is maintained for an extended period, the new control limits should become the operational standard. Furthermore, once the trial limits are established, the AT&T runs rules should be deployed in totality to ensure protection against process disturbances.

Example 11 demonstrates the use of the p chart.

Example 11. Thirty subgroups of 100 observations each have been collected from your process of producing the toy presented earlier in this chapter. The data collected and calculated $\hat{p}_i s$ are as follows:

i	D_i	p_i
1	1	0.01
2	0	0
3	2	0.02
4	1	0.01
5	2	0.02
6	1	0.01
7	0	0
8	0	0
9	1	0.01
10	1	0.01
11	1	0.01
12	1	0.01
13	2	0.02
14	2	0.02
15	1	0.01
16	1	0.01
17	1	0.01
18	1	0.01
19	0	0
20	4	0.04
21	0	0
22	0	0
23	1	0.01
24	3	0.03
25	2	0.02
26	0	0
27	0	0
28	1	0.01
29	1	0.01
30	3	0.03
	$\overline{p}$	0.011333

Computing the trial limits:

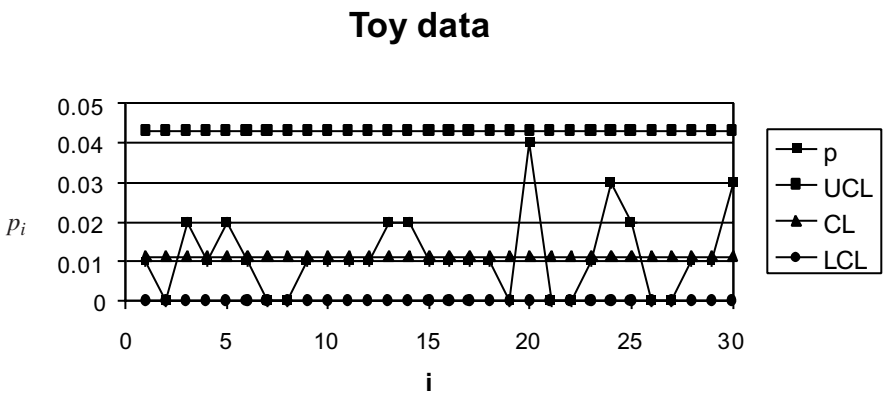

Figure 12 p Chart.

$$\mathrm{UCL}_p = 0.011333 + 3\sqrt{\frac{0.011333(1 - 0.011333)}{100}} = 0.0431$$

$$\mathrm{CL}_p = \bar{p} = 0.011333$$

$$\mathrm{LCL}_p = \text{maximum}\left(0,\ 0.011333 + 3\sqrt{\frac{0.011333(1 - 0.11333)}{100}}\right) = 0$$

As demonstrated, all points plot within the control limits; therefore, these trial limits should be employed for production. Since the control limits are not symmetric, only rule number one of the AT&T runs rules should be used. AT&T (1985) describes an approach that may be used for customizing runs rules to improve the detection strength of a p chart.

5.3. Control Chart for Number of Defective Units: c Chart

An equally important concern in production is the number of defects that are produced. Examples of defects include the type of data included on the check sheet described in Example 2 (i.e., paint drips, scratches). This type of data collected and monitored on a consistent basis in an organization gives rise to the organizational understanding of the defect types and clearly document sustained performance. For this type of data, the sample should be a fixed amount of product, that is, linear feet, number of units, pounds of product. Once the sample is collected, the number of defects, c_i, is determined through the careful analysis of the sampled product. Typically, although not necessarily, all defects are grouped together to construct one control chart.

It is assumed that the number of defects in a sample follows the Poisson distribution with parameter λ (the average defect rate for this application). The c chart is essentially the plotting of the observed values of c_i. These values are individually compared to the control limits (shown below) to determine the current status of the process (i.e., state of statistical control or out of control). Furthermore, the AT&T runs rules should be deployed when the resulting control limits are symmetric (AT&T 1985).

Obviously, c (or λ for the classic Poisson distribution), the true population average defect rate, is never known with certainty. As a result, it is estimated by averaging m c_i's. As a rule of thumb, it is suggested that 25–30 subgroups be collected before the estimate of c, called $\bar{c}$, is made. This parameter is estimated as follows:

$$\bar{c} = \frac{\sum_{i=1}^{m} c_i}{m}$$

where m is the number of samples collected

With an accurate estimate of the average defect rate in hand, the control limits for the c chart are computed as follows:

$$\mathrm{UCL}_c = \bar{c} + 3\sqrt{\bar{c}}$$

$$\mathrm{CL}_c = \bar{c}$$

$$\mathrm{LCL}_c = \text{maximum}(0,\ \bar{c} - 3\sqrt{\bar{c}})$$

The LCL is truncated to 0 when the calculated value falls below 0. The AT&T runs rules should be employed when the control limits are reasonably symmetric (AT&T 1985). Rule number one should always be used. AT&T (1985) describes an approach that may be used for customizing runs rules to improve the detection strength of a p chart.

The establishment of the trial control limits for the c chart follows the same practice as described for the $\bar{X}$ and R and the p charts. Once the observed data are contained within the trial limits, continued production should be used to collect more data in an effort to validate the limits. Once process stability is obtained, that is, control is maintained for an extended period, the new control limits should become the operational standard. Furthermore, once the trial limits are established, the AT&T runs rules should be deployed in totality to ensure protection against process disturbances when appropriate.

The following example demonstrates the use of the c chart.

Example 12. c Chart: 30 samples of five toys have been collected from your process of producing the toy presented earlier in this chapter. The data collected and calculated $c_i s$ are as follows:

i	c_i
1	2
2	4
3	9
4	2
5	1
6	4
7	5
8	1
9	3
10	6
11	1
12	8
13	7
14	2
15	4
16	3
17	5
18	4
19	3
20	5
21	7
22	6
23	2
24	2
25	6
26	7
27	3
28	4
29	5
30	7
$\bar{c}$	4.266667

The resulting trial control limits are as follows:

$$\mathrm{UCL}_c = 4.266667 + 3\sqrt{4.266667} = 10.463$$

$$\mathrm{CL}_c = 4.266667$$

$$\mathrm{LCL}_c = \text{maximum}(0,\ 4.266667 - 3\sqrt{4.266667}) = 0$$

The resulting control chart is as follows:
The process clearly exhibits stability.

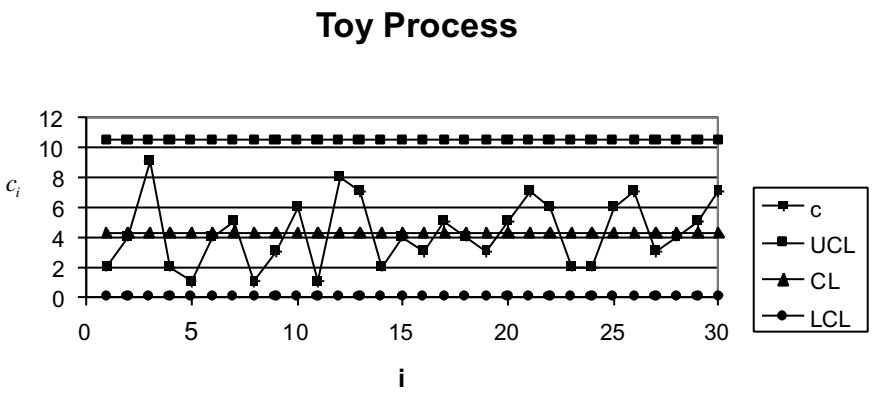

Figure 13 c Chart.

CHAPTER 70
Measurement Assurance

S. CHANDRASEKAR
Purdue University

Measurements play a major role in modern technology. Their purpose is typically threefold: to validate or invalidate a theory or model by comparing the measured value of a variable with a prediction; to determine whether a process or product meets specifications or quality requirements; and to enable closed-loop control of systems and processes. More generally, the purpose of measurement is to present an observer with a numerical value for the variable being measured. The input to a measurement system is the true value of the variable being measured, while the output is the measured value of this variable. In general, this measured value does not equal the true value of the variable. For example, a force sensor may read a value of 10.2 N when the true value of the force is 10.25 N; the speed of an engine as measured by a tachometer may be 3000 rpm when the true value is 3010 rpm; and so on. The problems involved in establishing the true value of the variable, an assessment of measurement error, a determination of the static and dynamic characteristics of measurement systems, and some remarks about noise in measurement systems constitute this chapter.

1. ELEMENTS OF A MEASUREMENT SYSTEM

A modern measurement system typically consists of the four distinct elements, as shown in Figure 1.

1. The *sensing element* probes the process, either in a contact or noncontact mode, and gives an output that depends on the variable being measured. Examples are:

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

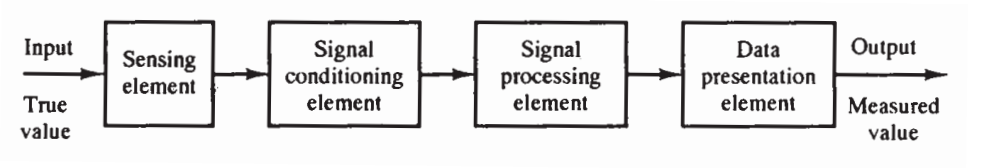

Figure 1 General Structure of Measurement System.

- Thermocouple, where an output voltage depends on temperature
- Piezoelectric force sensor, where an output charge depends on force
- Capacitive displacement transducer, where the capacitance output is a function of position or displacement

2. The *signal conditioning* element converts the output of the sensing element into a form more suitable for processing, usually a current, voltage, or frequency signal. Examples are:
   - Charge amplifier for a piezo force sensor, which converts a charge to a voltage.
   - Amplifier, which magnifies, say, a millivolt signal to a signal of several volts.
3. The *signal processing* element, which converts the output of the conditioning element into a form suitable for presentation. Typically, this element is an analog-to-digital (A/D) converter, which digitizes the analog signal output of the conditioning element.
4. The *data-presentation* element, which presents the measured value in an easily recognizable form. Examples are a chart recorder, graphical or numerical output on a computer terminal, and an oscilloscope.

Figure 2 shows a force-measurement system that incorporates each of these elements. Some measurement systems may have several of these elements.

2. CHARACTERIZATION OF MEASUREMENT SYSTEM ELEMENTS

In the previous section, we described the various elements that constitute a typical measurement system. The characteristics of the elements, as far as their input–output relationship impact the overall performance of the system, and as such it is important to describe these characteristics. In this section, we describe the static and dynamic characteristics of the system or system elements. We begin with a discussion of static or steady-state characteristics; these are the relationships that exist between the output (O) and input (I) of an element when I is either constant or changing slowly.

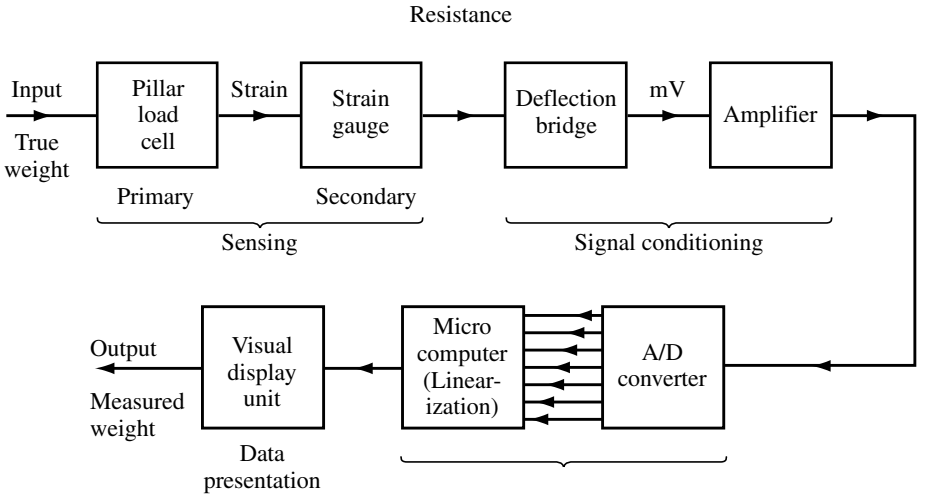

Figure 2 Weight-Measurement System.

2.1 Systematic Characteristics

Systematic characteristics are those that can be accurately quantified by analytical or empirical methods. These are to be distinguished from statistical characteristics, which will be considered later.

2.1.1. Range

This gives the range of values allowable for the input and output. For example, a piezo force sensor may have an input range of 0–10,000 N and a corresponding output range of 0–10 V.

2.1.2. Linearity

The operating ranges of most measurement systems are characterized by a linear relation between input (I) and output (O). In such instances:

$$O(I) = KI + a \tag{1}$$

where

$$K = \text{slope} = \frac{O_{\max} - O_{\min}}{I_{\max} - I_{\min}}$$

In practice, measurement systems show small deviations from linearity even within their operating range. These nonlinearities, which can be obtained from calibration experiments, may be ignored except in specific instances of measurement. In the presence of nonlinearity, equation (1) becomes:

$$O(I) = KI + a + N(I) \tag{2}$$

where $N(I)$ is the nonlinear term.

This nonlinearity is typically expressed as a percentage of the full-scale output range; for most measurement systems this value is less than 1% of the full-scale range.

If we look at the voltage output (E) of a chromel-alumel thermocouple in temperature (T) range of 0–200°C, where $E(T)$ is given by $E(T) = 40.1\ T + 2.09 \times 10^{-2}\ T^2 + 4.31 \times 10^{-4}\ T^4 +$ higher-order terms

Then, with reference to Eq. (2):

$$K = 40.1,\ a = 0, \text{ and}$$
$$N(I) = 2.09 \times 10^{-2}\ T^2 + \ldots$$

2.1.3. Sensitivity(s)

Sensitivity(s) is the rate of change of output with input, that is:

$$S = \frac{dO}{dI}$$

A high value of S is often a common requirement for measurement systems in their operating range.

2.1.4. Environmental Effects, Wear, and Hysteresis

The output O is often influenced by fluctuations in the environment, such as changes in humidity, ambient temperature, and supply voltage. These fluctuations add additional terms to Eq. (2) or cause changes in the sensitivity-related parameter K. Aging of system elements is also a common source of changes in system sensitivity.

Hysteresis refers to the differing dependence of O on I, depending on whether the measurement is being made while I is increasing or decreasing. An example of hysteresis is backlash in gears and rack–pinion arrangements. The input–output relationship for a measurement system with hysteresis and non-linearities is shown in Figure 3.

Interfering and modifying inputs are environmental inputs that cause the linear sensitivity and intercept of the system, respectively, to change. An example of an interfering input is fluctuations in the reference junction temperature of a thermocouple.

We can now collect together the various characteristics of a measurement system, except for hysteresis, and express the general model for the system in the form of a block diagram. Such a block diagram representation is shown in Figure 4. The dynamic and static characteristics are shown decoupled in the diagram. The dynamic characteristics will be discussed shortly.

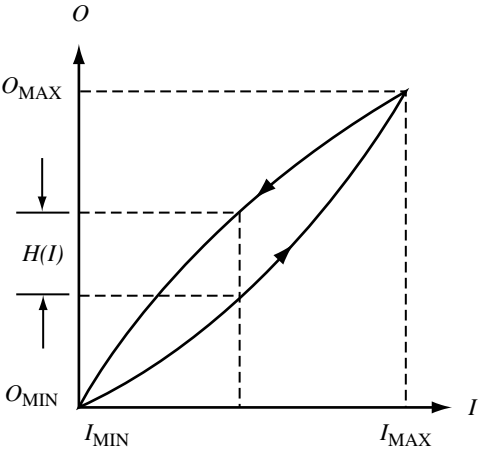

Figure 3 Hysteresis and Nonlinearity.

2.2. Statistical Characteristics

2.2.1. Repeatability

Suppose we apply a constant dead-weight load to a force-measurement system and keep the load applied for several hours. If the output O is monitored over this period of time, it is often likely that the output value will fluctuate about an expected value for the output. For example, if the load is 100 N, for which the expected output value of the sensing element should be 1 V, it is likely that over time the output will assume values such as 1.01, 0.98, 0.99, 0.98, 1.02, etc. This effect is termed as a lack of repeatability. Repeatability is the ability of a system to give the same output for the same input, when this input is repeatedly applied to it. The most common causes for lack of repeatability are random variations in the measurement system elements and their environment. By making reasonable assumptions about the fluctuations of the various inputs, including environment-related ones, it is possible to analytically characterize the fluctuations expected in the output.

Consider an output O that is a function of two types of inputs I and I_E. Further, let us assume, as is typically done, that the fluctuations in I and I_E can be described by normal distributions with standard deviations σ_1 and σ_2, respectively.

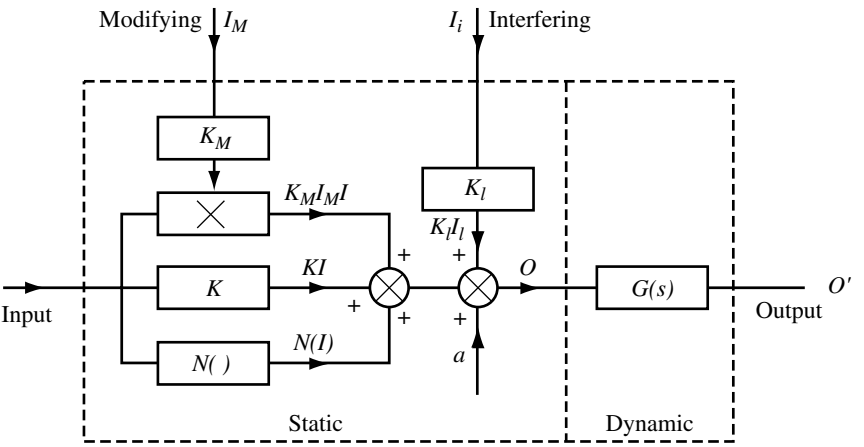

Figure 4 General Model of Measurement Element.

Then for

$$O = f(I, I_E)$$

$$\Delta O = \frac{\partial f}{\partial I}\Delta I + \frac{\partial f}{\partial I_E}\Delta I_E \tag{3}$$

and the standard deviation of O about its mean is given by

$$\sigma_o = \left(\frac{\partial f}{\partial I}\right)^2 \sigma_1^2 + \left(\frac{\partial f}{\partial I_E}\right)^2 \sigma_2^2 \tag{4}$$

Thus, σ_o can be calculated from a knowledge of σ_1 and σ_2. Alternatively, a calibration experiment can be done on the system, which allows for σ_o to be estimated directly from the experimental results. The mean value $\overline{O}$ for the output can be estimated from the experimental data. The corresponding probability density function for O can then be estimated as

$$P(O) = \frac{1}{\sigma_o\sqrt{2\pi}} \exp\left(\frac{-(O - \overline{O})^2}{2\sigma_o^2}\right) \tag{5}$$

3. IDENTIFICATION OF STATIC CHARACTERISTICS—CALIBRATION

The static characteristics of an element can be found experimentally by measuring corresponding values of the input I, the output O and the environmental inputs I_M, I_I, when I is either at a constant value or changing slowly. This type of experiment is referred to as calibration. The measurement of the variables I, O, I_M, I_I must be accurate if meaningful results are to be obtained. The instruments and techniques used to quantify these variables are referred to as standards.

The accuracy of measurement of a variable is the closeness of the measurement to the true value of the variable. It is quantified in terms of measurement error, that is, the difference between the measured value and the true value. Thus, the accuracy of a laboratory standard pressure gauge is the closeness of the reading to the true value of pressure. This brings us to the problem of how to establish the true value of a variable. We define the true value of a variable as the measured value obtained with a standard of ultimate accuracy. Thus, the accuracy of the above pressure gauge is quantified by the difference between the gauge reading for a given pressure and the reading given by the ultimate pressure standard. However, the manufacturer of the pressure gauge may not have access to the ultimate standard to measure the accuracy of his products. They can, however, measure the accuracy of the gauges relative to a portable intermediate or transfer standard, such as a dead-weight pressure tester. The accuracy of the transfer standard must be established by calibration against the ultimate pressure standard. This introduces the concept of a traceability ladder, which is shown in simplified form in Figure 5.

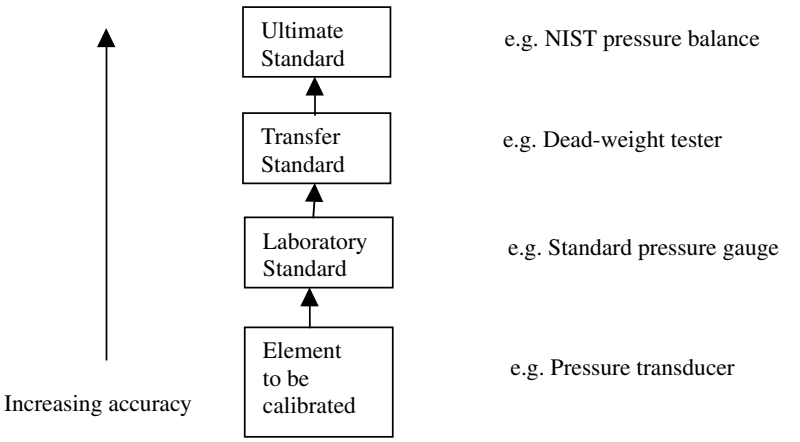

Figure 5 Schematic of Traceability Ladder.

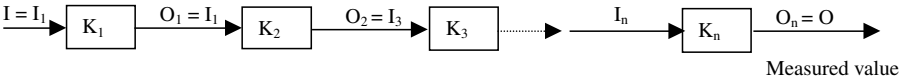

Figure 6 Measurement System Consisting of n Measuring Elements in Series. Input to the System is the True Value of the Variable to be Measured, and Output is the Measured Value of this Variable. The K_i's are the Gains of Each Measuring Element.

The measuring element is calibrated using the laboratory standard, which should itself be calibrated using the transfer standard, and this in turn should be calibrated using the ultimate standard. Each element in a traceability ladder should be significantly more accurate than the one below it.

4. ACCURACY OF MEASUREMENT SYSTEMS IN STEADY STATE

The input to a measurement system is the true value of the variable being measured, while the output corresponds to the measured value of the variable. Also, assuming the measurement system is complete, the system output is the measured value of the variable. Accuracy is defined in terms of measurement error, that is, the difference between the measured and true values of the variable. It follows, therefore, that accuracy is a property of a complete measurement system rather than a single element. Accuracy is quantified using measurement error E where:

$$E = \text{measured value} - \text{true value}$$
$$= \text{system output} - \text{system input}$$

We can use the static model of a single element, developed previously, to calculate the output and thus the measurement error for a complete measurement system that is made up of several measuring elements. Consider the system shown in Figure 6 consisting of n elements in series. Suppose each element is ideal, that is, perfectly linear and not subject to environmental inputs. If it is also assumed that the intercept or bias is zero, that is, $a = 0$, then:

$$O_I = K_I I_I$$

for $i = 1, \ldots, n$, where K_i is the linear sensitivity or slope. It follows that $O_2 = K_2 I_2 = K_2 K_1 I$, $O_3 = K_3 I_3 = K_3 K_2 K_1 I$, and for the whole system:

$$O = O_n = K_1 K_2 K_3 \ldots K_i \ldots K_n I$$

If the measurement system is complete, then $E = O - I$, giving:

$$E = (K_1 K_2 K_3 \ldots K_n - 1) I$$

Thus, if

$$K_1 K_2 K_3 \ldots K_n = 1$$

we have $E = O$ and the system is perfectly accurate. The temperature measurement system shown in Figure 7 appears to satisfy the above condition. The indicator is simply a moving coil voltmeter with a scale marked in degrees Celsius so that an input change of 1 V to the indicator causes a change in deflection of 25°C. This system has $K_1 K_2 K_3 = 40 \times 10^{-6} \times 10^3 \times 25 = 1$ and thus appears to be perfectly accurate. The system is not accurate, however, because none of the three elements present is ideal. For instance, the thermocouple is nonlinear, so that as the input temperature

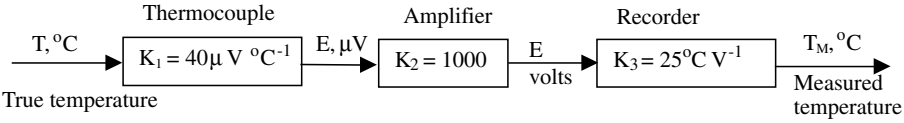

Figure 7 Schematic of a Temperature-Measurement System.

changes the sensitivity is no longer 40 μV°C^{-1}. Also, changes in reference junction temperature cause the thermocouple emf. to change. The output voltage of the amplifier may also be affected by changes in ambient temperature. The sensitivity K_3 of the indicator usually depends on the stiffness of the restoring spring in the moving coil assembly. This is affected by changes in environmental temperature and wear, causing K_3 to deviate from 25°C V^{-1}. Thus, the condition $K_1K_2K_3 = 1$ cannot be always satisfied and the system is in error.

In general, the error of any measurement system depends on the nonideal characteristics—for example. nonlinearity, environmental, and statistical effects—of every element in the system. Thus, in order to quantify this error as precisely as possible, it is necessary to use the general model for a single element.

The error probability density function for a measurement system comprising of n elements in series as in Figure 6 can be estimated from a knowledge of the corresponding density functions for each of the elements. This can be done analytically for a variety of density functions (see, for e.g., Bentley 1995). Alternatively, the density function for the entire system can be estimated from a calibration experiment.

4.1. Error-Reduction Methods

The error of a measurement system depends on the nonideal characteristics of each of the elements in the system. It is possible to identify which of the elements show significant nonideal behavior using calibration experiments. Compensation strategies may then be devised for each of these elements so that significant reductions can be accomplished for the overall system error. Some of these compensation methods are briefly highlighted, especially for nonlinear and environmental effects.

A common method for correcting a nonlinear element is to introduce a *compensating non-linear element* into the system such that the overall characteristic of the system is as linear as possible within the operating range of the system. This is illustrated in Figure 8 for a resistance thermometer. Depending on the degree of linearity desired, the bridge in Figure 8 can be suitably designed.

The most common method for reducing the effects of environmental inputs is *isolation*. Here, each of the measuring elements is effectively isolated from environmental changes. Examples are the placement of reference junction of a thermocouple in a temperature-controlled enclosure and the use of active vibration-isolation tables to isolate a measuring system (e.g., atomic force microscope) from external mechanical vibrations. Of course, it is possible to reduce environmental influences by selecting a transducer material that is completely insensitive to a specific environmental parameter. An example is the use of a metal alloy in strain gauges that has a zero coefficient of thermal expansion. But such an ideal material is often difficult to find and quite expensive.

A successful method for neutralizing environmental inputs is by providing an *opposing environmental input*. This is done by incorporating a second element(s) into the measuring system that is exposed to the same environmental input as the element of interest, such that the two effects tend to cancel out. An example is the use of two identically matched strain gauges in adjacent arms of a Wheatstone bridge to compensate for changes in the ambient temperature. In such an arrangement,

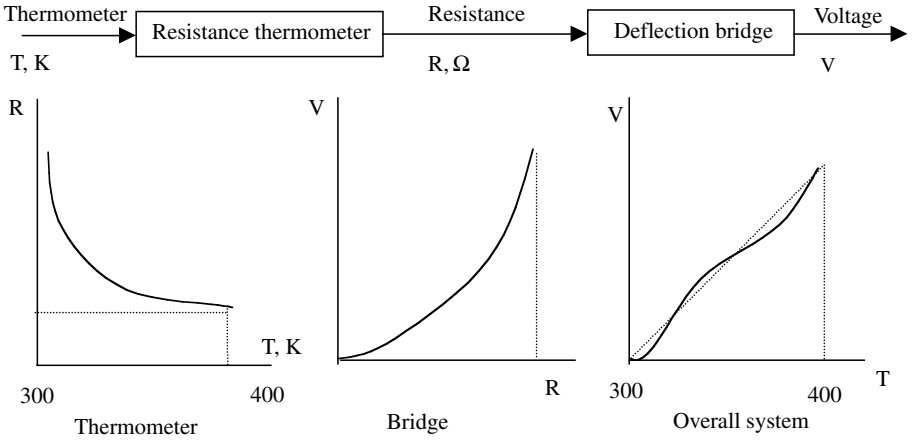

Figure 8 Nonlinearity Compensation in a Temperature-Measuring Element Using a Nonlinear Compensation Element.

one gauge is measuring a mechanical tensile strain and the other an equal compressive strain. However, because temperature-induced strains will have the same sign and magnitude in both the gauges, the bridge design effectively subtracts the resistances corresponding to the strains in the two gauges, thereby canceling out the thermal strain while doubling the mechanical strain being measured.

Other methods of compensation include the use of high-gain negative feedback and computer estimation of measured values. A discussion of these methods can be found in Doebbelin (1990).

5. DYNAMIC CHARACTERISTICS

The discussion thus far has centered on measurement system characteristics that are relevant to measurements of parameters that are either constant or changing very slowly with time. That is, the input (I) to the measurement system or a measuring element is varying rather slowly. By slow, we mean here that the variation in I with time is small over a duration equal to the response time of the measurement system or measuring element. However, in practice there are many instances where the input to a measurement system may change quite rapidly or even, in some cases, almost instantaneously. An example in this regard is the sudden change in the temperature input to a thermocouple from an ambient temperature of 30°C to 90°C when it is brought into contact with, say, an object at 90°C. In this case, the output of the thermocouple will change with time and reach a steady state output value that is equal or close to 90°C only after a finite amount of time. This finite amount may be a few microseconds or a few seconds depending on the type of thermocouple. The characteristics of the measurement system that describe its response to rapid changes in input are known as *dynamic characteristics*, and these are most conveniently described using the concept of a transfer function from linear systems theory.

5.1. Transfer Function of a Measurement System

Consider the measurement system comprising of n measuring elements in series (Figure 6) The input–output relationship for each element in this figure has been specified by an amplifier gain K_I, which means that the output can change instantaneously with time in the same manner as the input. In practice, this is not the case. The variation of $O(t)$ with $I(t)$ for a measuring element is often best described for most elements by a first-order or second-order linear differential equation. This description can be translated into an equivalent description in the form of a block diagram using the concept of a transfer function.

Consider a thermocouple that is brought into contact with a temperature source T. Then the output of the thermocouple, T_o, translated into a temperature reading, can often be described by the first-order differential equation

$$\tau \frac{dT_o(t)}{dt} + T_o(t) = T_i(t)$$

assuming that $T_o(0) = 0$ and $T_I(0) = 0$. The measured value of the variable T_i is T_o. The transfer function of this thermocouple element is given by

$$G(s) = \frac{T_o(s)}{T_i(s)} = \frac{1}{\tau s + 1}$$

The parameter τ is called the time constant of the element, and its value completely describes the response of the element. The smaller the value of τ, the faster the response of the element, which is an extremely desirable characteristic in measurement elements and systems.

Another common type of measurement system is a second-order, linear system described by a linear differential equation of the form

$$\frac{1}{\omega_n^2}\frac{d^2O}{dt^2} + \frac{2\xi}{\omega_n}\frac{dO}{dt} + O(t) = I(t)$$

where $O(t)$ and $I(t)$ are the output and input, respectively. The transfer function of this system is

$$G(s) = \frac{O(s)}{I(s)} = \frac{\omega_n^2}{s^2 + 2\xi\omega_n s + \omega_n^2}$$

and the system behavior is completely determined by the two system parameters, ξ and ω_n, which are the damping ratio and natural frequency, respectively. Together, the two parameters determine the system response. A small value of ξ results in a fast response, but the overshoot in the response is also high. A high value of ω_n also results in a fast response. Furthermore, a high value for ω_n in a measurement element increases the range of signal frequencies over which measurements of the signal

can be made accurately. Roughly speaking, signal frequencies up to a third of ω_n can be measured accurately without much attenuation. For further discussion of first- and second-order systems and their responses, see Franklin and Powell (1994).

We shall illustrate the computation of output and measurement error in a piezoelectric force sensor that is subjected to a time varying force. Figure 9 shows the block diagram of a piezoelectric force sensor or measurement system consisting of three elements. The charge amplifier is a first-order system with time constant of 0.1 sec, while the recording element is a second-order system with ξ and ω_n given in the figure. The measurement system is complete in the sense that the product of the elemental gains, $20 \times 10^{-3} \times 50$, is 1.

Let the system be subjected to a time varying input force,

$$F_i(t) = 100 \left[\sin 10t + \frac{1}{3} \sin 30t + \frac{1}{5} \sin 50t \right]$$

This is the true value of the force to be measured. The output ($F_o(t)$), which is the measured force, can be estimated in the usual way either analytically, or more easily using MATLAB. The error $E(t)$ is then obtained as $F_i(t) - F_o(t)$. An increase in the value of τ or ω_n can be used to reduce the magnitude of the error, as is easily verified by a calculation.

We will not discuss the calibration of dynamic characteristics of measurement systems here. Any one of the books under Additional Reading dealing with measurement systems can be referred to for this purpose.

6. NOISE IN MEASUREMENT SYSTEMS

Unwanted signals that interfere with the measurement process are often present in measurement systems. These signals can be deterministic or random; collectively, they are referred to as noise.

Random signals can be quantified using the following statistical functions: mean, standard deviation, probability density, power spectral density, and autocorrelation. Deterministic noise, such as in rotating machinery, can be quantified by their power spectrum. A variety of methods are available to reduce the effects of different types of noise signals. These include electromagnetic shielding, electrostatic screening, filtering, modulation, averaging, and modulation. See Additional Reading for detailed discussions of these issues.

7. SUMMARY

A brief tutorial on measurement systems has been presented. Description of measurement system elements and their characteristics, assessment of measurement error, and a short discussion of noise in measurement systems have constituted this tutorial. Additional Reading lists books related to these aspects where more detailed discussions of the topics reside. Included are references in which elements of measurement systems for sensing of specific parameters, such as force, temperature, and displacement, are discussed at length.

Acknowledgment

The author would like to thank Linda Weybright and Sridhar Kompella for their help in the preparation of the manuscript.

CHAPTER 71

Human Factors and Automation in Test and Inspection

COLIN G. DRURY
State University of New York at Buffalo

1. DECISION FUNCTIONS IN A GLOBAL BUSINESS ENVIRONMENT

Throughout the world, the business environment is changing, primarily because of globalization. This chapter examines the human factors aspects of one function in industry, test, and inspection to summarize the state of knowledge and practice. Test and inspection are the sense organs of industry; many decisions are based upon their data. They may even be the decision functions themselves when inspection is closely coupled to the control of a business process. Changes in the business environment

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

directly impact the functioning of industry, including in the areas of test and inspection, so these impacts must be considered throughout the chapter. While much of this chapter concentrates on test and inspection in a manufacturing context, there are many other applications, such as in medicine, maintenance, security, and design review, some of which will be considered in Section 7.

Globalization is the combination of market and political forces that has reshaped business and politics since the end of the Cold War in the late 1980s. Some of these forces, such as technological change, are obvious to those who study work, but other forces are changing the nature of jobs, perhaps even more profoundly. Globalization of customers, finance, and production of goods and services has been driven by forces of deregulation, inexpensive transportation, and rapid diffusion of distributed computing (Friedman 1999). Industry is becoming spread across more regions of the world and is shifting away from manufacturing and agriculture towards communications and service. Global capital markets force ''creative destruction,'' the often brutal flow of capital away from enterprises with low shareholder value to enterprises where the capital will generate the greatest return. Investment moves rapidly, forcing industries to respond equally quickly to changing customer demands. We have moved from the managerial capitalism of the first part of this century to investor capitalism with more demanding shareholders (e.g., large pension funds) and more information available instantly (Whitman 1999).

While these changes may seem remote from the lives of human factors professionals, they in fact have very direct effects as they drive industry into new modes of operation beyond technological changes. Perhaps the most important change from the viewpoint of test and inspection is that most workers will be more closely involved with customers because consumers are increasingly demanding a combination of high quality, customization, and low price (Whitman 1999). Exposing the workforce to customers will change the skill requirements of jobs to include communications skills, as has always been the case in service industries such as travel and banking. It also means that the effective batch size is driven towards unity, the individual customer. Quality control in such environments poses a number of challenges because the concepts of continuous control or large-batch sampling no longer apply. Customer involvement can increase job satisfaction but can also increase performance pressure.

Secondly, many operations will be outsourced, leading to reduced levels of job security and more temporary jobs (Whitman 1999). In fact, layoffs in U.S. industry peaked in 1992–1995 at a time of maximum job growth. The fastest-growing category was in temporary jobs, which rose six-fold between 1972 and 1995 (Whitman 1999). The total number of temporary jobs is still small but is a major concern of workers (Kanter 1995, chap. 6). Global competition has forced many companies to downsize their workforces to remain competitive and increase shareholder value. Budros (1999) examines the reasons for downsizing as separate from reorganization. He sees the downsizing trend as being caused by technological innovation and by the existence of highly paid long-term employees, concluding that downsizing is not always effective. From a work perspective, downsizing can be expected to increase workloads for those remaining and to remove some of the company expertise. Work hours overall may be increasing for Americans, according to Schor (1991). She analyzes national data on long-term employment hours of work, vacation time, and work in the home, concluding that total hours of work have increased by about one month per year over the past 40 years or so. While her data and analyses have been questioned, we seem to find very few people who are not working harder than they used to.

Global changes are also driving job demands in ways beyond employment security. Increasingly, work at the world-class levels demanded by global competition generates greater worker skill requirements and a greater rate of worker knowledge obsolescence. Kanter (1999) shows that even in manufacturing, physical assets represented 63% of company capitalization in 1982 but only 38% in 1991. The remainder of the assets are largely composed of company knowledge and competence. Indeed, Siemieniuch and Sinclair (1999) show that even if useful industrial knowledge has a half-life as long as 10 years, only 6% of the knowledge at the start of a working life will be useful at the end 40 years later. Before we retire, we will be producing unknowable offerings (goods and services) with unborn people and uninvented techniques. In turn, this creates a demand for life-long training. Whitman (1999) notes that companies with a heavy emphasis on training show a 19% greater productivity gain over a three-year interval than other companies.

There are other industrial changes taking place at the same time that are not specifically part of the globalization of work. Information technology is becoming a part of ALL jobs as computing power becomes less expensive and more distributed. We not only use information technology to replace workers, but to change the nature of their jobs. While only a few years ago the National Research Council was investigating the gap between IT investment and productivity improvement (NRC 1997), it now appears that the gap has closed and that computing power is having a significant effect on both productivity growth and the nature of work.

As far as the sensing and decision functions of test and inspection are concerned, the factors considered above have large impacts. The pressures for competitiveness have increased the demands on the test and inspection systems for simultaneous improvement of both effectiveness (quality) and efficiency (low cost). In turn, some of these demands have been met by new forms of production. In

the past decades, production changes have been driven by influential, although not always effective, movements in industry such as the quality movement and business process re-engineering. Some of the major impacts are described below.

1.1. Increasing Decision Options through IT

Information technology increases the options open to designers while creating a climate in which automation at any price is seen as a virtue per se. Major breakthroughs in vision systems, visual-scene analysis, and decision systems have allowed systems designers to consider replacing human labor in test and inspection with automation. In addition, the increased speeds of production now being experienced and the legal pressure for a return to 100% inspection have meant that in some industries automated systems are the only feasible answer. Throughout this chapter, we will consider the roles of humans and automation within test and inspection as parallel options for allocation of function so that the full impact of information technology can be brought to bear in the most effective manner rather than be a design goal in itself.

1.2. Quality Control/Assurance/Management

A major influence on industry since the 1980s has been the quality movement. The quality revolution has grown over two decades, beginning in quality technology and proceeding through the quality circles movement. It has stabilized over the past 10 years or so under the general titles of total quality control (Hancock et al. 1992) or total quality management (Evans and Lindsay 1993). Quality itself is defined as *meeting or exceeding customer expectations* (fitness for use) or *conformance to specifications* (manufacturing quality). TQM is seen as having both technical and managerial components, in that quality requires both technical knowledge and organizational knowledge.

The most basic quality requirement is freedom from design error, or ''off-line quality,'' as Taguchi and Wu (1979) characterize it. Agricultural products, manufactured goods, and delivered services must meet the needs of their customer over a wide range of customer environments. Products must be functional and must be free from user/product mismatches because any mismatch is by definition a design error. The implications are that designers know their customers' needs and have the techniques to turn these needs into product design. For test and inspection the implications are largely in the design stage, where human factors test and evaluation is an important component of customer service (O'Brien and Charlton 1997).

Secondly, globalized production cannot work unless all elements of the company's global operations fit together without error. Thus, new production systems based on pervasive computer-mediated design and manufacturing can assemble parts from up and down the supply chain without first-time errors of fit. Modern civil and military aircraft production give prime examples of this freedom from physical error. In a customer-oriented system, any over-cost or delayed delivery is an error with the same effects on company performance as a defective product. The implication for test and inspection is that we must be able to measure these customer needs and convert them into measurable precursors of error states.

1.3. Decisions on Quality Made at Source

From TQM and sociotechnical systems design (Taylor and Felten 1993) comes the concept of controlling key variances at their source. One major effect of the quality movement has been to renounce post-production inspection to a large extent and replace it by in-process inspection. With the introduction of more tightly coupled production systems, error cannot be tolerated without widespread consequences, so that control of quality at source is a key component of advanced manufacturing systems such as flexible manufacturing systems (FMS) cells. The corresponding push towards just-in-time (JIT) manufacturing has also made early control of errors a priority.

Control at source means not producing defective products in the first place rather than trying to sort defective products from good products later in the process. With the ultralow defect rates now being demanded and achieved, even highly effective sorting leaves the error rate too high. If we require defective rates in parts per million ($\sim 10^{-6}$) or at a six-sigma standard, then even a hit rate on inspection of 99% will not give the necessary result unless the production defective rate is $\sim 10^{-4}$. Even this level may be difficult with human inspectors because they tend to move their criterion for reporting a defect to more and more stringent values as the overall quality improves. Thus, we look instead for necessary precursors to error rather than error. If we know the mean of a process has shifted by a given amount, then we can deduce that defects will be more common*, even if we find no defects*. This is the principle of in-process quality control, often using control charts (e.g., Vardeman and Jobe 1998).

1.4. Distribution of Test and Inspection Effort

Given the effects of globalization on all enterprises, it should not be surprising that quality is demanded with minimum expenditure of resources. Test and inspection resources are inherently difficult to justify because they can be easily dismissed as not contributing value added to the goods or

services produced. They do contribute by providing process control, but not necessarily directly. A product is physically unchanged after test or inspection, except perhaps for the addition of a sticker with the inspector's name on it.

In a broader perspective, production systems design had considered for many years the optimal distribution of inspection effort in control of complex processes. For example, Nurani and Akella (1996) studied the best strategies for sampling semiconductor wafers. A later paper (Shindo et al. 1999) showed that the classification of defects by family allowed the accurate in-line yield prediction required in modern production systems. Such work implies that in designing inspection and test systems, we need to look beyond the individual inspection work point and examine the whole range of defects possible, where they are generated, and how they can best be detected using the technology and models available. This theme will be returned to in Section 7.

2. TEST AND INSPECTION REQUIREMENTS

Test and inspection are decision functions in manufacturing and service industry. They provide decisions concerning the fitness for use of either an item of product or a production process. As such, their prime responsibility is in decision quality, and these functions of test and inspection are often placed in a department with ''quality'' in its title. Decisions made by the test and inspection subsystem should be:

- **Precise:** Enough depth of information should be incorporated into the decision process so that its conclusions are unbiased by underspecification or rounding errors.
- **Valid:** Decisions should be the same as would be reached after the product or process has been allowed to proceed to actual use.
- **Reliable:** Valid decisions must be possible repeatedly, with different items of product or different states of the process having consistently correct decisions. An inspection or test system should not need frequent recalibration for reliable operation.
- **Robust:** The inspection system must be capable of detecting and classifying a range of defect types large enough to cover customer concerns. This aspect has also been termed ''flexibility'' (Drury 1992a)
- **Rapid:** Information on a decision is needed rapidly enough for the system to react before many, or even any, defective items have been produced.

Both ''test'' and ''inspection'' are from Latin roots, with the former defined by Websters as ''to view closely in critical appraisal: look over,'' and the latter implying ''a critical examination, observation, or evaluation'' or ''a procedure, reaction, or reagent used to identify or characterize a substance or constituent.'' Precision, depth, and validity are key elements in these definitions, while reliability appears of necessity in a manufacturing context where a sequence of decisions is required. To differentiate between test and inspection, test typically requires a determination of functional suitability for use, while inspection is more usually confined to indications of fitness for purpose short of actual use testing. For example, each new aircraft produced will be flight tested before delivery to determine whether it fulfils its functional requirements. Prior to this flight test, considerable inspection of components and subassemblies will have taken place to ensure that they are free from manufacturing or assembly defects.

2.1. Inspection Measures and Scales

Note that the rather loose term *accuracy* of inspection and test is related to precision, validity, and reliability. To measure the performance of an inspection system, we need to consider how well its decisions match the decisions that should have been made given complete knowledge of the system and the items inspected. First, note that decisions can be of three types, following quality control terminology:

1. Decisions about the fitness of the design of a product. This is off-line quality control, as discussed in Section 1.2. above.
2. Decisions about the fitness of a single item (or group of items) of product. This is the traditional customer protection aspect of any test and inspection system. It is the area traditionally classified as (statistical) quality control, although it can include physical sorting of product items.
3. Decisions about the fitness of a process to continue manufacturing. This is the *jidoka* concept (Monden 1992), aimed at preventing a production system from ever producing a single defective product. A decision not to continue the process does not always imply that individual items produced are unfit (see Section 1.3). Decisions about process fitness are traditionally termed (statistical) process control.

TABLE 1 Definition of Outcome Probabilities

Decision of Test and Inspection System	True State of Conforming	Item (or Process) Nonconforming	Total
Conforming	$p_1\ (1 - p')$	$(1 - p_2)\ p'$	$p_1 + p'\ (1 - p_1 - p_2)$
Nonconforming	$(1 - p_1)\ (1 - p')$	$p_2\ p'$	$(1 - p_1) - p'(1 - p_1 - p_2)$
Total	$1 - p'$	p'	1.0

Each of these types of decision can only have two final outcomes: fitness and unfitness (of item or process). There are many names for these outcomes:

Conforming/nonconforming
In control/out of control
Good/faulty
Effective/defective

A Note on Measurement Scales. Each decision is a binary one, although subdivisions are possible. For example, an individual item may be conforming or nonconforming (scrap) or nonconforming (rework). Similarly, a process may be fit to continue, or fit to continue with increasing monitoring, or unfit to continue. This brings up the question of level of measurement. Final outcome (above) is always measured on a nominal scale with a discrete number of categories, although some implied ordering may exist. Nominal scales are used directly in test and inspection for the recording of discrete defects on an item—for example, scratches on roller bearings (Drury and Sinclair 1983). Ordered, or ordinal, scales are rarely used as such in test and inspection, although they have occasionally been proposed (e.g., Kelly, 1955). Interval scales, where a continuous measurement is taken, or even ratio scales (which are interval scales with a true zero), are often a part of the measurement process leading to a decision. Thus, the outside diameter of a roller bearing may be measured with high precision and plotted upon a statistical process control chart, although the application of standard rules to this measurement will give a decision outcome about whether the process should continue.

The outcomes of test and inspection can thus be classified by the level of measurement upon which they are based and the type of decision required. These outcomes in turn define the typical statistical methods used, such as prototype testing for decision 1 above. For in-process quality control (decision 3 above), nominal scale decisions lead to attributes control charts, while interval or ratio scales lead to variables control charts (Vardeman and Jobe 1998). The second type of decision above would lead to either attributes of variables sampling plans, although the whole concept of sampling a batch to determine its quality has largely been abandoned in favor of in-process quality control.

Because the final decisions are binary ones, we can define performance in terms of the outcomes for product items (or processes) that were in fact either fit or not fit (conforming or non-conforming). If these probabilities are defined as:

p_1 = probability of deciding that a conforming item or process is conforming
p_2 = probability of deciding that a nonconforming item or process is nonconforming

then the probabilities of the various outcomes are as shown in Table 1, where p' is the true fraction of items (or processes) nonconforming.

In the special case of inspection of items for attributes, these cells have common names, as shown in Table 2.

TABLE 2 Outcomes of Inspection of Items by Attributes

Decision of Test and Inspection System	True State of Conforming	Item (or Process) Nonconforming
Accept	Correct Accept	Miss
Reject	False Alarm	Hit

However, as noted above, in cellular and JIT manufacturing, final outcome should be predicted rather than measured. Thus, statistical process control becomes the technique most used for deciding upon process fitness, with attributes inspection of individual product items playing a progressively smaller role. To move from output control to process control, however, requires detailed, predictive models of all processes. Until these are achieved, the dream of eliminating all final functional test and inspection will perhaps remain a rarely attained goal. In particular, large process changes arising through continuous improvement will mean that predictive models still lag behind the need to deliver product. Thus, the practical strategy to achieve fitness with high reliability would appear to be cyclic changes from item to process control as each process cycles through maturity and periodic replacement. The rapidity with which predictive control is achieved can be expected to increase on successive cycles as parts of predictive models can be expected to be usable across innovation cycles.

3. LOGICAL STRUCTURE OF TEST AND INSPECTION

If we are to proceed towards predictive control of any process, detailed models of the process are needed. This applies equally to the test and inspection system itself. In this section, we develop a classification system for test and inspection systems and generic structure for test and inspection activities. These structures will help guide our more detailed examination of human and automated systems in later sections while showing explicitly the similarities between human and automation. Such similarities are not emphasized, and indeed rarely addressed, in the test and inspection literature.

3.1. Human and Automated Test and Inspection

Logically, no inspection or test system can be either fully automated or fully manual. These extremes are approached, for example with the automated functional tests for integrated circuit chips or the visual examination in proofreading. But there is always some human operator involved in the system, even if only for setting up the system and maintaining it. Equally, an apparently unaided human inspector still uses technology in the workplace, from desks and chairs to flashlights and hand tools.

We can thus define the degree of automation of inspection from one extreme of fully manual, through various levels of hybrid inspection, to the other extreme of fully automated. In this chapter, we will use *manual inspection* as a shorthand for inspection primarily using the human operator's minimally aided senses and minimally aided decision mechanisms. At the other extreme, *automated inspection* will be used to denote an inspection system where the human operator is not involved in on-line sensing or decision functions. Most real systems will involve hybrid inspection, as some functions involve humans and some automation.

The design of systems, such as test and inspection, that can logically incorporate alternative designs (manual or automated) of different system functions has a long history in human factors under the label of allocation of function. This is a primary concern to system designers who must choose which parts of the inspection and test system to automate, although in practice few papers on automated inspection mention function allocation explicitly. The typical automation paper (e.g., Komatsu et al. 1999) list the shortcomings of humans as inspectors and uses this as the justification for developing an automated system to replace the humans in the system. Often the automated system is characterized as being able to detect smaller defects, or automated-system performance is assessed by comparing how well the system classifies a test set of items previously classified by human inspectors. Allocation of function has never had much influence as a formal discipline outside human factors circles (e.g., McCarthy et al. 2000), but it still provides a logical framework for considering a range of automation alternatives. In fact, the allocation of function at the design stage is becoming recognized as perhaps too rigid a design tool, with flexible allocation during operations seen as a more natural and useful approach. For inspection systems this means designing alternate means of fulfilling each objective and having these parallel means available during operations. This requires that we still consider automation alternatives function by function.

3.2. Mission and Function in Test and Inspection

In the classical systems design process (e.g., Singleton 1972), a top-down design starts by defining the system mission, then splits the mission into logical functions. Each function is a unit of system behavior that can be assigned to either human or machine without consideration (at least at first) of other function allocations. Functions can be specified by their goals (or outcomes) in a way analogous to the mission specification of the overall system. In a test or inspection system, we have implicitly defined the mission in Section 2 by defining characteristics of the final system (precision, validity, etc.). Now we must be more explicit about such a definition, both to guide our later evaluation of test and inspection systems (Section 7.1) and to help define the system's logical functions.

The implicit mission in Section 2 concerns determination of functional suitability, so this can become the basis for a more formal definition:

> *The test and inspection system determines the suitability of a product or process to fulfil its intended function, within given parameters of accuracy, cost, and timeliness.*

This definition incorporates both the idea of evaluation of suitability and the notions of predefined system performance. It also forces us to concentrate on the ultimate suitability of the product from the point of view of the customer, so that we do not perform test and inspection activities unrelated to customer needs. Finally, the definition covers both products and processes, so that it can apply equally to output control and process control.

Before we can define the mission for any particular test or inspection system we must be able to specify customer needs. While a detailed framework for designing inspection systems is given in Section 7, we must consider now how to define such needs. One way is to apply a failure modes and effects analysis (FMEA) to the product and design a test and evaluation system to cover each of the potential failure modes. But this technique does not make the customer an explicit part of the design process, whereas we have seen earlier (Section 1) that direct customer input is increasingly needed in more customized products. A preferable technique is to begin with customer function and quality requirements as the basis for a list of product attributes that form the basis of test and inspection. In attributes inspection (Section 2.1), this list is often a ''defect list'' or ''fault list'' defining the discrete defects that the inspection system must ensure the customer never experiences.

An explicit approach has been used in a series of studies of paint-inspection systems for automotive painted body panels culminating in Lloyd et al. (2000). Instead of starting with the list of defects traditionally used by process engineers, they sampled many body panels with and without defects and had customers directly rate their dissatisfaction with each defect. This technique produced a list of the most important defects from the customer's point of view and associated criteria for defects to be below the customer's threshold of dissatisfaction. They could then design improved inspection systems, for example, using better lighting for human inspection, that reduced warranty data significantly and had a payback time of only six months.

Function lists for inspection have been defined generically by Drury (1978), Sinclair (1984), and Wang and Drury (1989), and for the specific case of inspecting aircraft structures by Drury et al. (1990). Table 3 defines five functions of inspection, with the goal (or outcome) and representative errors for each. Note that the functions are allocation independent in the systems-design sense, in that the functions can be assigned to either human or machine (mechanical, optical, electrical, computer) components. The outcomes and errors remain the same, although the detailed error-causation mechanisms will obviously differ. Thus, error 3.1, ''Indication missed,'' in the Search function could be caused by the human searcher not detecting a visual indication through inattention or by an automated visual inspection system (AVIS) failing to reach the threshold required for a response to a pixel configuration. The result is identical, although the error mechanism is different.

Because each function can (in principle) be allocated to human or machine, parallel models need to be presented for both types of component. This is done in the next two sections, which provide detail and models for the human and automated components available for building integrated, usually hybrid, systems.

TABLE 3 Generic Function, Outcome, and Error Analysis of Test and Inspection

Function	Outcome	Errors
Setup	Inspection system functional, correctly calibrated, and capable	1.1. Incorrect equipment 1.2. Nonworking equipment 1.3. Incorrect calibration 1.4. Incorrect or inadequate system knowledge
Present	Item (or process) presented to inspection system	2.1. Wrong item presented 2.2. Item mispresented 2.3. Item damaged by presentation
Search	Indications of all possible nonconformities detected, located	3.1. Indication missed 3.2. False indication detected 3.3. Indication mislocated 3.4. Indication forgotten before decision
Decision	All indications located by Search correctly measured and classified and correct outcome decision reached	4.1. Indication incorrectly measured 4.2. Indication incorrectly classified 4.3. Wrong outcome decision 4.4. Indication not processed
Respond	Action specified by outcome taken correctly	5.1. Nonconforming action taken on conforming item 5.2. Conforming action taken on nonconforming item

4. THE HUMAN ROLE IN TEST AND INSPECTION

The framework presented in Table 3 suggests a linear sequence of functions, but in practice there are some branches and reentries in the sequence. For example, an indication of one type may be located, a decision made, and action taken without consideration of any other indications. This occurs when a discrete fault with major consequences is located, such as a missing chip on a circuit board. For simplicity, this treatment will consider only sequential steps.

However, the concept of a one-dimensional sequence is inappropriate for human inspection functions for another reason. Humans can operate at several different levels in each function, depending upon the requirements. Thus, in search, the operator functions as a low-level detector of indications but also as a high-level cognitive component when choosing and modifying a search pattern. It is this ability which makes humans uniquely useful as self-reprogramming devices, but, equally, it leads to more error possibilities. As a framework for examining inspection functions at different levels the skills/rules/knowledge classification of Rasmussen (1983) will be used. Within this system, decisions are made at the lowest possible level, with progression to higher levels being invoked only when no decision is possible at the lower level.

In inspection, two of the functions (2. Present and 5. Respond) have no logical higher-level functions. Note, however, that if test and inspection is regarded as part of a total process-control system, function 5 (Respond) involves considerable higher-level cognitive functioning for diagnosis and prediction of the optimum changes to be made (e.g., Moray et al. 1986; Bainbridge 1990; Umbers 1981). Each function will be considered in turn, but first the terms used in classifying human errors need to be reviewed. System-specific errors have been classified by Hollnagel (1989) as error phenotypes. They are instances of errors generated by an error-generating model or mechanism, which provides the prototypical errors, or error genotypes. Thus, the errors in Table 3 are all phenotypes, but for humans each is an instance of a genotype. Each level of the Rasmussen S/R/K classification has its associated genotypes. Reason (1990) identifies these as skill-based slips, rule-based mistakes, and knowledge-based mistakes. Following Reason (1990), mistakes are choosing the wrong action (or decision), whereas slips are failures to implement the chosen action correctly. Thus, mistakes represent wrong intentions, while slips represent the failure of correct intentions.

With these classifications in mind, the functions will be considered.

4.1. Human Inspection Function by Function

4.1.1. Setup

In setting up a test and inspection system, the measurement devices, decision aids, and recording mechanisms must be procured, checked for functionality, and calibrated. For optical inspection, for example, the correct lighting and magnification levels must be implemented. Calibration consists of checking that the measurement devices respond in the correct manner to known inputs. At the lowest level, these are a sequence of psychomotor activities, equivalent to the items on a pilot's preflight checklist. Job aids consist of checklists, while the tasks themselves are typically closing switches and observing outputs or, more usually now, interacting with computer-based equipment. All of the factors important in good control panel design (Chapter 39) or in human–computer interaction (Chapter 44) become important if these steps are to have a high reliability. Possible slips are those common to any sequential activity, listed by Hollnagel (1989) as:

Wrong place	repetition reversal omission
Wrong time	omission delay premature action
Wrong type	replacement
Not in current plan	insertion intrusion

Note that the errors possible can be mapped onto the set in Table 3 in many different ways, that is, the outcome phenotypes do not necessarily specify the error genotypes.

At the rule-based level, there are typically changes in the setup to accommodate different customers, different products, or different process conditions. Thus, in Drury and Kleiner (1990), a job aid was produced to help inspectors of roller bearings reason more effectively from customer specifications to choice of inspection standards. In aircraft-structure inspection, the calibration of an eddy-current meter must be changed by known rules to accommodate different thicknesses of fuselage skin or detect cracks of different depths. Errors at this level consist of misapplication of rules,

particularly reasoning within multiple conditions. Again, principles for designing job aids to assist in rule application are well documented (Johnson 1990).

Knowledge-based reasoning should rarely be required of a setup inspector under normal conditions. It will be invoked when new products are introduced; after process changes due to continuous improvement; occasionally to substitute an alternate inspection device for one that has failed; to troubleshoot and diagnose errors in the inspection device; or even as an innovation on the inspector's part to improve the inspection function. Examples are specifying an increased magnification for detection of smaller severities of visual defects in circuit chip inspection, or increasing the threshold of an eddy current meter to avoid frequent false alarms in lap joint inspection of an aircraft fuselage. Errors can arise from incomplete models of process, product, and/or inspection device or from faulty application of these models. Examples of such knowledge-based reasoning, and of its error genotypes, are more commonly found in the process-control literature (e.g., Moray et al. 1986). System improvement consists of knowledge-based training of the set-up inspector as well as job aids such as schematics and computer programs (e.g., Johnson 1990) to aid understanding of the various components.

4.1.2. Present

Each selected item of product, or test point in the process, must be presented to, and interfaced with, the inspector. Although typically a machine function, it can be given to the human, for example, picking items from a mass-production process and placing each in turn into a gaging device. In more extended inspection tasks such as inspecting aircraft for structural defects (Wenner et al. 1997), the inspector must move to the inspected area rather than the area being moved to the inspector. In such cases, inspectors must move their whole bodies or their limbs to ensure that each area of the item is available to the (visual) sense. The tasks are again psychomotor, typically picking up, orienting, placing, attaching sensors, and disposing. The reliability of such processes is high, with errors due to either misperception of orientation, or to slips in musculoskeletal execution. Models of such activities are widely available (e.g., Knight and Salvendy 1992; Holden 1981). Standard design techniques for preventing misassembly (e.g., the *poka-yoke* concept of Japanese JIT manufacture, Monden 1992) can be used to reduce error rates. Training in manual skills (e.g., Salvendy and Seymour 1973) should not be ignored to improve reliability.

4.1.3. Search

Search is an active process in any inspection context. The item or process inspected must be searched in stages. At times these stages can involve moving an area of limited extent across the item, as in using a flashlight to inspect the inside of an aircraft fuel tank or a microscope's limited field of view to cover the whole area of a microchip. Within a field of view, a target is visible to the inspector only within a limited area, called the visual lobe. This visual lobe must be actively moved in successive fixations across the field of view with saccadic eye movements. Within a single visual lobe, information can only be extracted at a limited rate (Eriksen 1990), so that an attention area can be said to move successively within the visual lobe.

Note that search is a serial sequential process, terminating upon successful detection of a discrete indication (such as a surface scratch) called a target in visual search. Because of its sequential nature, it is a resource-limited rather than data-limited process (Wickens 1991). As such, the probability of detection increases with time spent searching in a manner dependent upon the search plan.

Visual search is so well practiced as to be automatic at the visual lobe and field of view levels, and experienced inspectors' movements of the field of view across the item can also require little cognitive effort. Thus, to a large extent, the search process occurs at the skill level. Aspects of this skill, such as the attention conditions (Eriksen 1990; Engel 1971) and the optical factors affecting the visual lobe (e.g., Overington 1973) have received considerable study so that reasonable models of the probability of detection are possible (e.g., Greening 1975). Errors at the skill level are failure to detect/locate a target and detection/location of a nontarget. However, there are still strategic issues in visual search as evidenced by error phenotypes. Targets that are fixated do go unreported: parts of the item are not fixated at all, while others receive multiple fixations: search terminates too quickly, or continues unproductively.

At the rule-based level, it is the search plan that is altered. Thus, the choice of the next fixation point for the visual lobe is made. This is a decision partly based upon a fixed top-down search plan, but also partly based upon bottom-up information gained during the search. For example, Kundel and LaFollette (1972) show that searchers of medical X rays return a number of times to fixate places where a possible indication was seen. Search is usually modeled as either a fixed systematic process or as a purely random process (e.g., Morawski et al. 1980), although these are simplifications for mathematical convenience. As noted earlier, the probability of detection increases with search time. Typical cumulative search time distributions are shown in Figure 1 for the extreme cases of random search, where each fixation is placed randomly on the field of view, and repeated systematic search,

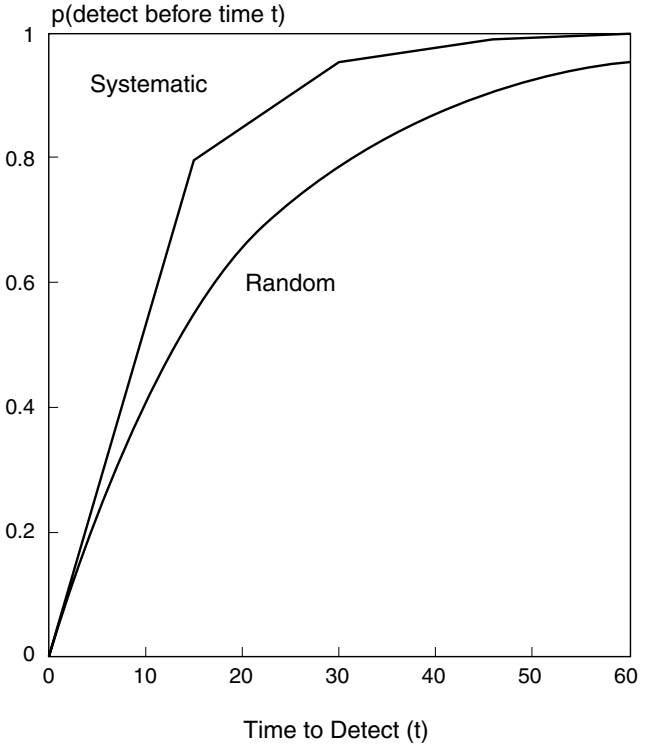

Figure 1 Speed–Accuracy Trade-off Curves for Random and Systematic Visual Search.

where fixations are only placed in unsearched parts of the field of view within each complete scan. Errors at the rule-based level are failing to choose a plan that will lead to the target being fixated.

Knowledge-based functioning in search consists of optimizing choice of parameters for the search. For example, prior information concerning the likelihood of a target being in a particular location will lead to that location being searched first. Choice of how long to spend searching before deciding that no target exists is another optimization aspect of search. There is evidence (Baveja et al. 1996; Chi and Drury 1995) that humans do choose a close-to-optimal stopping policy for search. Errors at this level are stopping too soon, neglecting an area entirely, or the lesser error of failing to detect the target in an optimally short time.

To improve search, the conspicuity of the target in the background must be increased (e.g., by overlays, Chaney and Teel 1967), or the search time increased (e.g., Schoonhard et al. 1973), or the search plan improved by training (e.g., Kundel and LaFollette 1972; Gramopadhye et al. 1997a). If the task requires simultaneous search for more than one type of indication, performance degrades rapidly (e.g., Gallwey and Drury 1986). Recent research (Wenner 1999) on large-scale search tasks, such as inspection of aircraft or searching offices for files, has shown that people need good information support if they are to devise effective and efficient search strategies.

4.1.4. Decision

The output from the search function is either zero, one, or many indications that must be evaluated by the decision process. Logically, if no indications have been found, the item or process must be classified as fit for use. Note that a false alarm is not possible unless at least one indication reaches the decision stage; thus, false alarms are directly diagnostic of decision error rather than search error. Given that decisions will be nontrivial only with an indication, the nature of the decision or indication must be examined.

Decision conditions must always be provided in terms of rules to the inspector, although whether these rules are well formulated depends upon the organization. At times they can be passed on by on-the-job experience from more senior inspectors, while in other instances complex, written, decision procedures exist. Typically, the rules are of one of three types:

Rule 1: IF the magnitude M_i of an indication of type (i) exceeds a severity S_i, THEN item is not fit.

Rule 2: IF the magnitude M_i of an indication of type (i) under circumstances (j) exceeds a severity $S_{i,j}$, THEN item is not fit.

Rule 3: IF the number of indications of type (i) with magnitude M_i exceeding severity S_i exceeds N_i, THEN item is not fit.

The existence of such defining rules would naturally suggest rule-based behavior, but other factors enter into the decision. For extreme indications, such as total absence of an indication or very high severity of indication, the decision will be trivial and essentially skill based. Thus, a missing component in an assembly will ''automatically'' trigger a rejection response, as will a major crack in a magnesium casting. In the former case, the implication is that

$$S_i = 0$$
for i = missing component

while the latter case has

$$M_i >> S_i$$
for i = crack

Most decisions, however, are nontrivial. In inspection, the decision component has been identified with the theory of signal detection (TSD) (e.g., Drury and Addision 1973), although not without necessary warnings about validity (e.g., Megaw 1992). Here, the perceived magnitude of an evidence variable is compared with a perceived criterion, and a decision to reject as unfit made if the evidence variable exceeds the criterion (McNichol 1972). If we modify the notation above with primes indicating perceived variables, we have:

Perceived magnitude for type (i) = M'_i
Perceived criterion (standard) for type (i) = S'_i

TSD states that the decision is based upon $(M'_i - S'_i)$ so that

IF $(M'_i - S'_i) < 0$ THEN accept item
IF $(M'_i - S'_i) > 0$ THEN reject item

The distribution of $(M'_i - S'_i)$ depends upon both the true signal, and the noise in the decision, thus:

$$\begin{aligned} \text{Signal} &= \text{mean}\,(M'_i - S'_i) \\ &= \text{mean}\,(M'_i) - \text{mean}\,(S'_i) \end{aligned}$$

$$\begin{aligned} \text{Noise} &= \text{var}\,(M'_i - S'_i) \\ &= \text{var}\,(M'_i) + \text{var}\,(S'_i) \end{aligned}$$

To maximize decision reliability, that is, the fraction of total decisions made correctly, then the signal must be as large as possible and the noise as small as possible. This gives a maximum signal-to-noise ratio. In inspection terms, this means magnifying the difference between indication magnitude and standard, for example, using optical devices or computer-enhanced images (e.g., Komorowski et al. 1991) to increase the signal. To reduce the noise, the variability in both the indication and the standard should be minimized. Standard variability can be reduced by having comparison standards available at the workplace (Harris and Chaney 1969). Perceived magnitude variability can be reduced by training (e.g., Gramopadhe et al. 1997b; Drury and Kleiner 1990).

For simple rules, such as rule 1, used in the above exposition, performance is skill based and the only possible errors are:

1. Failing to invoke the decision process
2. Deciding that a conforming item is nonconforming (false alarm)
3. Decision that a nonconforming item is conforming (miss)

All are slip errors, but the first is an example of Hollnagel's sequence errors. Misses and false alarms are classic examples of correct intentions failing.

Rule-based decision making is well supported by training and job aids for complex rules (rules 2 and 3) or for lengthy lists of rules of type 1. Errors can be due to invoking the wrong rule,

misapplying the correct rule, or failing to invoke the decision stage. Examples of the first of these errors were given by Drury and Sinclair (1983) in aircraft roller bearing inspection, where there was confusion about defect names among the inspectors, leading to choice of rule appropriate to the wrong type of indication.

In a manufacturing setting, it is rare that the false alarm and miss errors will have equal weights. Thus, in inspection of fuel flow valves for a space shuttle, the consequences of a miss are potentially catastrophic, whereas a false alarm leads only to the delay of component replacement. The weighting of these consequences is an essential component of TSD and represents a form of knowledge-based behavior when consciously applied. An inspector can define an optimum strategy as one that maximizes the expected value of outcomes rather than maximizing the fraction of correct decisions. Expected value depends upon:

1. The costs and values associated with the four decision outcomes, correct accepts, false alarms, misses, hits (V1, V2, V3, V4)
2. The prior probabilities of an item being conforming $(1 - p')$ or non-conforming (p').
3. The criterion (S_i') chosen by the inspector for reaching an accept or reject decision

It is the third of these factors that is under the inspector's control, based upon the perceived values of the other two factors. It is possible to calculate an optimum placement of criteria so as to maximize the expected value across the decision outcomes (McNichol 1972). Experimental evidence from both laboratory studies (Chi and Drury 1995) and field studies (Drury and Addison 1973) shows that inspectors do indeed modify their decision criterion in the direction indicated by the optimum criterion. Changes in chosen criterion are usually less than optimal predictions, an effect dubbed the sluggish beta phenomenon (Wickens 1991).

Clearly, knowledge-based functioning in decision depends upon accurate knowledge of costs, probabilities, and the process of optimization. Misperception of costs and values and misperception of prior defect probabilities can lead to incorrect decisions on criterion placement. Decision support for cost and value perceptions is simple in principle, although it is almost never formalized in an inspection task. Support for estimation of the true defective rate for each type of defect is much more difficult because it is based upon the output of the inspector, or of another inspector who is likely to be equally error prone. It is possible to provide such data to the inspector using another inspector who is allowed more time and/or resources for the decision. When these data are provided as feedforward of likely defect types and probabilities (Sheehan and Drury 1971) or as performance feedback (Drury and Addison 1973), dramatic reductions in error are found.

An alternative way of approaching the decision function in inspection is through the notion of fuzzy sets. Indications of defects such as wear, corrosion, scratches, stains, and quality of cloth have imprecisely defined criteria, and judgments cannot often be represented by a single precise number (Karwowski et al. 1990; Watson et al. 1979). The framework of fuzzy sets (Zadeh 1965) provides us a way of dealing with the category of problems where an absence of sharply defined criteria of class membership is the source of imprecision. Thus, inexact knowledge can be represented, and so can situations where membership in sets cannot be defined purely on an yes/no basis.

Wang et al. (1986) postulate that if the relative contribution of the different cognitive skills towards the performance of a human–machine system can be either known or inferred, then the corresponding subjective assessment of these skills can help in the designing cognitive aids for the human. They developed a fuzzy set approach to formulate a multicriteria decision-making problem to determine whether individuals can prioritize cognitive skills considered important for inspection performance.

A fuzzy set approach was more appropriate than a probabilistic approach because the question was not whether a cognitive factor belongs to a set representing cognitive skills important for inspection, but how strongly it belongs to this set. Thus, the decision alternatives (cognitive factors) for the individuals were imprecise.

The problem was formulated as follows: $X = (X_1, X_2, X_3, X_4)$ constitutes the set of decision-making alternatives corresponding to four cognitive factors. These factors are X_1 = memory, X_2 = attention, X_3 = perception, and X_4 = judgment. The objective was prioritizing the weights associated with these factors and determining the correspondence between these weights and their representation in a multiple-regression model as predictors of inspection performance. The weights are given by

$$FD\ (X_i) = \text{MIN}\ [F_{s,1}\ (X_i), \ldots, F_{s,12}\ (X_i)] \text{ for each } X_i \text{ in } X|S_j$$

where S_j = the fuzzy set of cognitive skills important for inspection performance corresponding to subject j.

$F_{sj}\ (X_i)$ = the membership function associating with each of the four cognitive factors, a number in interval (0, 1) that indites the grade of membership of factor i in S_j

D = the fuzzy subset that results from selecting, for each X_i, the smallest membership value from any of the fuzzy subsets S_1 through S_{12}, under the assumption that the judgments of all subjects are equally reliable.

The membership function was derived using the method proposed by Saaty (1974, 1977), which determined the grade of membership through the process of magnitude estimation derived from pairwise comparisons. The normalized membership for each factor in D was found to be:

$$D = [\underset{\text{memory}}{0.130}, \quad \underset{\text{attention}}{0.354}, \quad \underset{\text{perception}}{0.183}, \quad \underset{\text{judgment}}{0.333}]$$

The priority of importance is seen to be attention, judgment, perception, and memory.

The above study demonstrates an application of fuzzy sets in modeling inspection performance, namely the human's perception of relative importance of various cognitive processes; this could serve as a selection device for inspection tasks. It has to be noted, however, that fuzzy set approaches are applicable in situations where humans must cope with the inexact or imprecise knowledge of the process or system being observed or controlled. It is a descriptive theory that attempts to model the way humans actually cope with a complex problem. Thus, if the space of actions is precise (e.g., inspection of variables such as length, diameter, etc.), then conventional approaches should be followed. Some of the issues that need to be addressed are methodologies for determining membership functions, clarifying the relationship between probability theory and fuzzy set theory, and interpreting of fuzzy utilities (guidelines to interpret the fuzzy advice).

4.1.5. Respond

Actions taken in response to a decision involve both the item itself and a data-capture system. Thus, at the simplest level, defective items can be removed from a production system, or a process can be stopped because it is no longer in control. At the same time, the inspector may need to capture the data in a form usable by the manufacturing system. Again, in a simple form, counters for different defect types are often observed at inspection workstations, with the counter readings recorded at specific times. Another example of a manual system is for aircraft structural inspection (Drury et al. 1990), where an inspector provides details of each defect on a nonroutine repair card.

With modern manufacturing system, evidence of a process or item not being fit to function is expected to be an increasingly rare event, so that action needs to be immediate and data dissemination widespread. Errors in response are, like errors of presentation, likely to be slips rather than mistakes. Actions taken on the basis of the test and inspection response may be complex and require cognitive processing, but the response itself is confined to the skill level. This is not to diminish its importance, as it is the final function of a sequence of processes that can have involved considerable thought and effort. Even if an inspector uses information intelligently to optimize search and decision, the outcome error is just as bad if an item is wrongly tagged or if part of the defect report is omitted. To improve the reliability of the response on the item, principles of workplace design should be followed. Space should be left for rejected items to be stored, and care should be taken to ensure that the response required when an item is rejected does not become so onerous as to discourage a rejection response. Data capture should be efficient and can be simply automated as an alternative to relying on error-prone handwritten forms. One airline company, for example, uses bar codes of all possible faults so that nonroutine repairs (NRRs) can be documented with little written or even keyboard input from the inspector. Portable computer-based systems for aircraft inspection (e.g. Patel et al. 2000) include functionality to allow the inspector to complete NRR forms directly in the computer, ensuring correct identification of the airframe number and the inspector.

4.2. Overarching Considerations: Job Design

Because we are unlikely to reach total automation of the whole manufacturing organization, there will be humans involved somewhere in test and inspection for the foreseeable future, even if only in a supervisory role (Sheridan 1987). Hence, organizational design will continue to impact upon the test and inspection function, requiring at least some familiarity with organizational variables even in highly automated systems.

Many prescriptive models of organizational design exist (e.g., Hackman 1990), but relatively few studies applied specifically to test and inspection. Early work by Jamieson (1966), Thomas and Seaborne (1961), and McKenzie (1958) established that humans change their inspection behavior, and hence performance, in predictable ways when social and organizational variables are changed. Inspection, McKenzie notes, is always of people. The inspector is always judging the work of others, or even his or her own work. Thus, pressures on the inspector are to be expected. More recent work (e.g., Taylor 1991) has examined the sociotechnical systems context of inspection in aviation main-

tenance and shows that similar pressures still exist. As industry moves from an inspection-based philosophy towards control at the point of manufacture, inspection activities are increasingly a part of all manufacturing jobs. Many years ago (Stok 1965), the visual presentation of information using X-bar and R charts was shown to be highly effective in reducing the production of defects by operators who measured their own production quality.

While the change from item to process control has been taking place, management in manufacturing has also been interested in organizational design for quality, also known as total quality management (TQM) (Evans and Lindsay 1993), as noted in Section 1.2 above. The interaction between such quality initiatives and human factors has been considered elsewhere in some detail (Drury 1996).

Job demands for the operator as inspector and controller logically include an enriched range of tasks. Job enrichment has been shown to be highly effective in improving inspection performance. Thornton and Matthews (1982) found missed defects reduced from 35% to 11%, while false alarms also fell slightly when an enriched inspection job was implemented, with the improvement in performance continuing well beyond the initial change. In a more broad-reaching job-enrichment program, Maher et al. (1970) found a halving of both human errors and time for inspection. To reach the level of knowledge and skill required in those new tasks, operators will need expanded training in process control and inspection procedures (Drury and Kleiner 1990).

The group-oriented aspects of organizational changes have been aimed at empowering a small, self-contained group of operators in the same way that job design empowers the individual (Hackman 1990). Good results have been reported in group inspection work within a maintenance environment (Rogers 1991; Diehl 1990). However, when groups such as manufacturing cells are implemented, the training needs again increase. Drury (1991) notes that operators in such environments require communication and interaction skills as well as group decision-making training to function effectively.

5. AUTOMATION IN TEST AND INSPECTION

Automated inspection and test systems are now finding a regular place in many industrial applications, alongside or replacing human inspection. Their main advantage is that they can perform a relatively limited number of inspection services rapidly and reliably, suiting them to high-volume repetitive test and inspection tasks. In this section, we provide a classification of automated systems based on their functions and give some detailed examples of automated systems in the literature. A typical system (Steinmetz and Delwiche 1993) is first introduced to illustrate many of the points raised.

The Steinmetz and Delwiche (1993) example is a Franco-American design of a system for automatic grading of cut roses. It was chosen because it uses a product of considerable geometric and chromatic complexity and variability but that is instantly recognizible and is likely to be well known to readers from different industries. In fact, a human grading was used to develop the test batches required for performance evaluation of the system. A second consideration was that the paper contains some numerical evaluation of system performance.

The paper begins, as is typical, with making the economic case for automation, that is, that the industry has high throughput and the grading and packaging costs (currently human activities) account for about half of total production costs. Direct cost savings should be possible through automation of the grading process. The cut rose has a set of quality characteristics that form the basis for the current grading system:

1. Stem length
2. Stem diameter
3. Stem straightness
4. Bud maturity (degree of opening)
5. Bud color

First, a holding and lighting system was designed, supporting the rose below the bud on a simple hook and surrounding it with diffuse fluorescent light of appropriate spectral characteristics. Note the similarity to the Setup and Present functions of Section 4. A standard color video camera was used to give a 480×512 pixel image (a low figure by today's standards), giving about 1.4 mm/pixel.

Next, a set of algorithms was devised for the computer to ''understand'' the image captured by the camera. Because the rose was in a constant position and orientation, defined by the support hook, the stem and bud could be unambiguously differentiated if the coordinates of the hook were known. Stem length was derived from the distance from the hook to the first cross-section of the image containing a nonwhite pixel, starting from the side farthest from the hook. At this point, other stem features could be extracted. The leaves were differentiated from the stem itself by searching column by column along the length of the stem for wide groups of nonwhite pixels. At each end of the stem, an authorized region (AR) was defined as a rectangle, while where leaves were encountered, triangular ARs were defined. These regions were large enough to include thorns, which had also to be differ-

entiated from the stem proper. Logical detection of stem and leaf boundaries was performed using an edge-detection algorithm. Feature recognition made use of the geometric fact that a stem must be a set of rectangular segments of approximately equal widths located in the space defined by the two ends of the stem already found and oriented approximately parallel to the line between the stem end points. Note the similarity to the early stages of the human function of Search, where overall salient features of the item are used to guide the detailed search process in a top-down manner. Stem straightness was defined by the maximum angle between any of the rectangular stem segments, or by the maximum distance between any segment and the line joining the stem end points. Bud maturity measurement started by searching above the hook for an area of nonwhite pixels. This area was recognized by its edges, transformed to a convex shape and the centroid calculated. Maturity was defined as the maximum distance of any bud edge to either side of the centroid. Bud color was determined by averaging separately the red, green and blue chromaticity coordinates of the convex region of the bud.

From this measurement phase, a set of nine measures was available as a vector for each rose. In fact, the measurements were repeated for two orthogonal views of each rose to ensure that straightness was not an artifact of the direction of view. To test the system, two sets of roses were first graded by experienced graders, and the grades were refined in the laboratory using the raw camera images to improve grading consistency. The two sets were a training set and a test set, for use with the later classification evaluation. For the two direct measurements (length and diameter of the stem), standard errors were used to show that the automated system was accurate enough for use. For each of the other characteristics, the training set was used to train a multilevel neural net (or alternatively a Bayes classifier) to reach the correct classification of each rose. After training, the neural net then classified the test set to measure performance. Compare this technique with the Decision function for human inspectors, where training was again found to be useful. For straightness, the neural net classified 21 of 27 straight roses correctly and 28 of 33 crooked roses correctly, for an overall error rate of 18%. Bud maturity was classified in the same way, but onto a three-point scale rather than into two classes. The misclassification rate was between 15% and 21%, depending on rose color sample. Finally, comparison to a simple threshold of the average red chromaticity was used to classify red and white roses with 0% errors. The final human function of Respond was not used in this prototype system.

Recommendations were finally developed for improvement of the system, including a low-pass filter to prevent thorns interfering with diameter measures, removal of lower leaves to make length detection more reliable, and extension of the system to the more difficult task of detecting defects on the leaves.

From this description, the logic of automated systems is clear, as are many parallels with human inspection. The functions can be separated and implemented, performance measured, and recommendations made for future improvement. The functions of automated inspection will now be considered in turn because they involve quite different mechanisms than the equivalent human functions.

5.1. Automated Inspection Function by Function

Although automated inspection must logically fulfill the five functions presented in Section 4, these functions do not represent the most natural breakdown for automated inspection. Some functions are combined in a single piece of hardware, while some automated functions (e.g., sensing) have a major classificatory role. One example of combined roles is that the Present and Search functions can overlap in a CCD readout. Another is that Search and Decision can be part of one computer program rather than separated as they were in the rose-inspection example. A more natural breakdown for automated inspection would be as follows:

1. Setup
2. Materials handling
3. Sensing
4. Signal processing

Figure 2 shows how these two classification schemes map onto each other. The Materials-handling function of automation covers both the Access and Respond functions of our more general scheme, while, as noted above, sensing and signal processing may be difficult to differentiate physically. All are, however, separable logically.

5.1.1. Setup

The setup function in automated inspection corresponds to configuring the system for the task. Several environmental factors affect the setup function. In a machine vision system, lighting factors such as illumination levels, type of illumination, reflectivity, and contrast affect performance. Most vision systems are quite sensitive to these variables. In many cases, the automated system has failed because

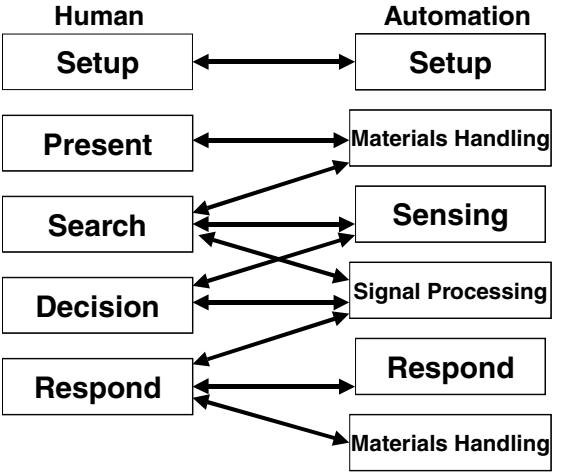

Figure 2 Mapping of Classification Schemes for Manual and Automated Inspection.

the stability of the environment and the effect that environmental factors may have on the measurements have not been correctly understood. In fabric inspection, cloth brightness can change due to environmental conditions that can lead to incorrect detection of dirt on cloth. Thus, we need to have either vision algorithms that can detect defects independent of illumination changes or a tightly constrained environment (e.g., Steinmetz and Delwiche 1993). Lighting intensity is a critical factor and must be sufficient to swamp interference from ambient sources to improve environmental reliability. Similarly, the contrast of the object against its background must be greater than the local lighting variation around the feature that is of interest.

5.1.2. Materials Handling

The materials-handling function for manufacturing test and inspection consists of devices to select items for test, mount them into the test fixture, move them within the fixture (if needed) and transport the item to the next stage. Thus, in the inspection of aircraft engine blades (Rosemau et al. 1999), a robot is used to position the blade in different orientations so as to cover all of the cooling holes with a sequence of video images. Often the fixture for inspection will be that used for transport throughout the system, for example in a flexible manufacturing system. Parts are held in the fixtures by gravity, quick-release clamps, or magnetic couplings, depending upon stability and human compatibility requirements. Pick-and-place robots can be used if an item needs moving from its fixture to the test/inspection device. In nonmanufacturing applications, the sensor must be moved physically around the item inspected, as in the robotic inspection of aircraft skins by Siegel et al. (1998) or the inspection of water pipes by Moraleda et al. (1999).

Very small items produced and tested at very high rates (e.g., fasteners, microcircuit chips) can be handled by vibratory bowl feeders, slides, and small conveyors to ensure that they are correctly presented to the inspection device. These systems often have automated disposal mechanisms built in to gate any defective items along a different track from the good items, an example of a materials-handling component equivalent to the human Response function.

The materials-handling system can be automated or manual. In a system with manual material handling, an operator manually loads the part and then initiates the inspection cycle. In some cases, automated materials handling is suitable and eliminates lifting and lowering of heavy components. The type of materials handling system (and the degree of its automation) depends on the inspection system and its place in the production system (i.e., preprocess, online, or postprocess inspection).

5.1.3. Sensing

In both inspection and process control, we can sense a wide range of properties of the product or item produced, or of the process itself. Thus, in test and inspection, a classification of these sensors aids in choosing the most suitable one from the many available. Here we use a standard listing from a recent computer automation text (Boucher 1996). All use the transducer principle, converting energy of one form (e.g., light, water flow) into a common electrical form with well-defined properties. The electrical signal can then be processed in many ways, independently of the type of transducer used.

A necessary part of sensing is signal generation. Typically some form of energy must be input into the sensor to elicit a response. Thus, a temperature sensor works because the electrical resistance changes, but detecting such a change requires that a voltage be applied across the resistance element and an output voltage measured. Signal generation involves the application of a suitable constant voltage or the illumination of an object to be sensed by appropriate lighting etc. We will consider this explicitly only when we deal with parts of nondestructive inspection in the next section.

5.1.3.1. Discrete-Event Sensors Note that these can be combined into arrays, for example to detect complex logical events, or even items of different sizes when some elements are activated and some not.

- *Mechanical limit switches:* These sense when an object displaces an actuator, either on a lever or by pushing/pulling. Their logic can be normally open or normally closed. Limit switches are used to sense when a machine (e.g., robot) has reached a particular position or when an item arrives on a conveyor.
- *Proximity switches:* Two types are inductive and capacitive, both of which measure when an object enters a defined sensing field. Inductive switches sense only conducting materials such as metals, while capacitive switches indicate the proximity of any object. They are particularly useful because they do not require contact with the item sensed and hence cannot damage it.
- *Photoelectric sensors:* An emitter unit gives out a beam of light or infrared radiation, which is sensed by a receiver unit. The emitter and receiver can be used in an opposed sensing mode, where an electrical event is registered if the beam is blocked. They can also be used in the reflective mode to sense objects of high reflectivity, and even used to sense only objects at a given range of distances using a convergent-beam system.
- *Fluid-flow switches:* An analog of proximity switches for fluid detection, fluid-flow sensors use a sprung or magnetic valve to detect when flow takes place in a pipe.

5.1.3.2. Continuous Sensors Continuous transducers convert energy directly from one form to electrical voltages or currents. A measurement circuit, such as a bridge circuit, is used to make the conversion from the direct sensor signal. The voltage or current is then digitized using an analog-to-digital converter, which provides input to the signal processor. Each type of transducer has a fixed relationship between the input energy and the output digital signal, a form known as the calibration curve.

- *Linear position transducers:* The simplest form is a linear potentiometer, where the position of the slider is proportional to the output voltage. Linear variable differential transformers (LVDIs) move a metal core between primary and secondary coils to produce a voltage proportional to core position.
- *Rotary (angluar) transducers:* Rotary potentiometers sense angle in a way analogous to linear potentiometers. Resolvers use rotary transformers similar to linear variable differential transformers. Optical encoders go directly from angular position to a digital signal by passing light beams through a disc attached to the rotating shaft. The disc has sectors printed in a pattern of black and white so that each angle corresponds to a unique pattern of transmitted and blocked light beams.
- *Float transducers:* As in an automobile gas tank, a float transducer uses a rotary potentiometer to produce a voltage proportional to the angle of an arm with a float attached.
- *Ultrasonic sensor:* The reflection time of a high-frequency sound pulse can be measured to give an accurate estimate of distance from an object or from a liquid level. In the latter case, an ultrasonic sensor is a noncontact alternative to a float transducer.
- *Velocity encoders:* Both velocity (speed) of solid objects and liquid flow rates can be measured. One way is to use an optical encoder and measure time between position changes to give the differential of position, i.e., velocity. Tachometers use an AC or DC generator to give a voltage proportional to angular velocity. Flow rate transducers can use the differential pressure in a pipe to measure a flow rate if pipe diameters are known. Alternatively, a small turbine blade can be inserted into the flow and its rotation velocity used to measure flow rate.
- *Force/pressure transducers:* The simplest force measures use load cells based on an LVDT, which displaces by a small amount as a force is applied. Strain gauges can measure the (small) deformation of thin film attached to a surface by measuring the resistance of an attached conducting element.
- *Temperature transducers:* The most common temperature sensor is a thermocouple made from two different metal wires. As the temperature changes, so does the relative resistance of the wires, giving a signal proportional to the temperature. Thermistors are semiconductors with the property of changing resistance with temperature.

5.1.3.3. Scene Sensors: While the above sensing devices convert discrete or continuous information into electrical signals, they are all essentially one-dimensional. Their output can be characterized by the changing of a single quantity over time, such as position or temperature. However, many automated inspection and test systems need to utilize two-dimensional or even three-dimensional data, for example in inspection of sheet materials or circuit boards. Such systems demand two-dimensional sensing.

The typical sensor for these applications is a charge-coupled device (CCD), which consists of an array of picture elements (pixels) that are light sensitive. Electrons emitted from each pixel are integrated for a field time (typically 1/60 sec) and a voltage proportional to this value is sent out. This voltage is thus proportional to the light intensity at the pixel, although the relationship is not linear. CCD pixels have a number of limitations, such as saturation and bloom, that can degrade image quality.

- **One-dimensional arrays:** Two-dimensional information can be obtained by sweeping a one-dimensional row of sensors across the two-dimensional surface of interest. With a one-dimensional array, such as a row of charge-coupled devices, the necessary condition is that the two-dimensional surface remain constant while the scan is in progress. Thus, any fixed object, such as a circuit board, can be scanned in this way to produce a two-dimensional image for later processing. The essential condition is that the sensor be moved relative to the material to provide an undistorted two-dimensional image. Alternatively, the inspected item itself may be moving at a known velocity, so that data collected from a one-dimensional array will give a complete picture of the material. In such a way, continuous sheet production, such as float glass or sheet steel, can be scanned continuously.
- **Two-dimensional arrays:** If the array is composed of rows and columns of sensors, as in a television picture sensor such as a two-dimensional CCD, then two-dimensional information is available simultaneously for all parts of the inspected material. A lens may be used to form a sharp image on the sensor array. For three-dimensional information, height maps may be constructed with appropriate two-dimensional sensors. The common methods for 3D image acquisition include laser radar, confocal microscopes, and high-speed triangulation-based 3D systems. It is currently believed that triangulation based systems offer the greatest potential, although this is somewhat application dependent (Svetkoff et al. 1989; Gieles et al. 1989).

5.1.4. Signal Processing

While the output from a discrete-event sensor is essentially digital, digitization is first required for all of the sensors of continuous one-dimensional or two-dimensional information,. Digitization is typically performed by an analog-to-digital converter (A to D converter). Such a device quantitizes the continuous information by comparing the signal with known levels or thresholds. If a signal exceeds threshold (i) but not ($i + 1$), then it is digitized at the level corresponding to threshold (i). The reverse process of digital-to-analog (D to A) conversion will not be considered here because it pertains to system effectors rather than receptors. D to A conversion is required when moving from the test and inspection task to a process control task.

For scene sensing, signal processing is more complex and will thus be covered in a separate section.

5.2. Image Processing in Automated Visual Inspection Systems (AVIS)

Because so much of test and inspection is now concerned with vision systems, whether human or automated, this section will use automated vision as an extended example through which to discuss issues of automation in general. A typical example has already been presented, that of rose grading, and will be used to illustrate concepts as they arise.

Lumai (1994) reviews the applications of vision systems and image processing in manufacturing, not all of which are concerned with test and inspection. For example, automated vision systems are applied to control of guided vehicles, control of robot positioning, and determination of orientation of parts for assembly. They may use the same sensors and signal-processing algorithms as an automated visual inspection system (AVIS), but they will not be considered further here.

Figure 3 shows the basic functions of image processing, adapted from Lumai (1994). Note as in Figure 2 that these partially correspond to the generic functions given earlier, with Classification very similar to Decision, Respond the same in both lists, and the other functions partially overlapping with Search. Ventura and Chen (1994) use a similar but more specific breakdown of functions in their system for classifying component shapes based on a two-dimensional image and the original CAD specification.

Signal generation here is the lighting system, as for example in the careful design of even illumination in the rose-grading study. The rest of the image capture system, after the lighting, is composed of a lens and a CCD. The lens is chosen to give the correct ratio between angular coverage

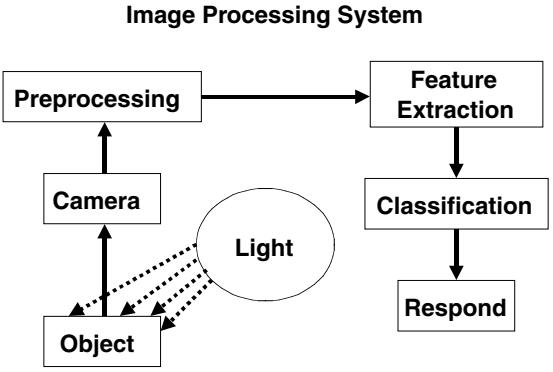

Figure 3 Functions in Image Processing.

and resolution, defined as the solid angle subtended by individual pixels. Note that lenses have their own aberrations, but modern lenses are amazingly free from distortions and also inexpensive. CCD devices are also increasing rapidly in the total number of pixels and the grayscale dynamic range. As of 2000, inexpensive CCDs contain well over 2 million pixels and have at least an 8-bit grayscale range. Note that for color imaging, very important in such inspection applications as food processing, three pixels with red, green and blue filters are used to capture the RGB image, giving $3 \times 8 = 24$ bits per data point. The signal is typically stored in a frame grabber so as to be available as an ensemble to the computer system for further processing. The signal at this stage consists of a grayscale level or RGB value for each pixel for each sampling interval.

Signal preprocessing now has the task of preparing the signal for feature extraction. In the rose-grading example, very little preprocessing was required because the lighting ensured that the object was captured as a dark stem and leaves against a uniform white background. In most industrial applications, however, dirt, visual noise, and stray reflections can degrade both the object inspected and the background. A typical visual noise-reduction technique is smoothing, performed by a low-pass filtering technique. This operation consists of convoluting a small template, say 3×3 pixels, with the original image. The value of the pixel at the center of the template is replaced by the value calculated by summing the product of the 3×3 array of pixel grayscale values and the template values around the center pixel. Thus (Lumia 1994), if the template is composed of nine identical values of $1/9$, then the resulting smoothed value is the average of the 3×3 array of pixels. This means that any deviant (noise) value has its effect reduced by a factor proportional to the square root of the template area. The penalty for this smoothing is that signal information may be reduced along with the noise. If the signal were, to use an extreme example, a single deviant pixel, its discriminability would be reduced as if it were noise. The preprocessing may also consist of changing the overall brightness and contrast of the image, as is done, for example, in image-processing software for photographic purposes. This allows the subsequent feature extraction to utilize the full dynamic range of the image information despite changes in incident illumination.

Feature extraction uses a variety of techniques for converting a pixel value array into a set of discrete features useful for classification. One set of operations involves convolution to detect specific features. For example the template (Sobel operator):

$$\begin{matrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{matrix}$$

when convoluted with a pixel array will yield a high value if the image contains a horizontal edge. If the operator is rotated about its leading diagonal, it will detect vertical edges. If edges are neither horizontal nor vertical, the two Sobel operators can be combined by finding the effective gradient in each direction. Typically, the edge is detected by comparing the value of the convolution at each point to a threshold. This threshold can be a fixed value or chosen algorithmically (e.g., Hou et al. 1993).

In addition to edge detection, there are also operators for thinning edges and for converting a set of pixels forming an edge to a straight line or a circular arc. Additional algorithms can be used to detect circles (e.g., holes drilled in components) or irregular features such as the leaves or thorns of

roses. Some, as in Steinmetz and Delwiche (1993), use the concept of an allowed area or search for the maximum extent of a contiguous area such as a stem or bud. In fact, as with human perception, the more closely a feature can be specified, the easier it is to detect.

Classification: The set of features from feature extraction must be classified to reach conclusions about the overall acceptability or otherwise of the item inspected. Features such as end points, edges, and blobs need to be combined and classified in order to classify the object as a whole. While for a single measured parameter (e.g., force or temperature) a single threshold will provide this classification, for complex two- and three-dimensional objects the process is less obvious. For example, with the rose grading, one algorithm finds the size of the area representing the bud, but eventually a three-level scale is needed to judge bud development. This requires thresholds to be set in the simplest case, or more usually an algorithm must be developed to mimic human judgement of these factors. Fuzzy set theory can provide such an integration (see Section 4), but a preferred solution is to use neural nets as classifying algorithms. One such neural net architecture was used in the rose-grading example.

Neural network models have the ability to explore several competing hypotheses simultaneously. This is done using computational elements connected by links having variable weights that form massive parallel nets. Neural networks can be classified based on the nature of input data, that is, whether they process binary or continuous valued inputs. The pixels of a digitized image can be expressed either in binary (black or white pixels only) or grayscale format. Another classification is based on the type of learning. Learning can be either supervised or unsupervised. In supervised learning, the network is told what the correct answer should be during training. It can then determine whether or not its output was correct and use its learning law to adjust its weights. In unsupervised learning, on the other hand, the network has no knowledge of the correct answer (Caudill 1988a, b). For most inspection applications, neural networks with continuous valued inputs that are trained under supervision seem appropriate.

Current application of neural networks has included speech recognition, handwritten character recognition, target recognition, industrial parts inspection, and signature recognition (Buffa 1985; Cormier 1991). Cormier (1991) developed a three-layer, back-propagation neural network for circuit board component inspection. The system verifies presence of correct surface-mount components on board. Graphical images of various components were used. The scale of the images was chosen to accomplish an effective resolution of 1 mm per pixel, which is the most common resolution for surface-mount inspection systems. Noise was added to the images to simulate variations due to inconsistent lighting, surface irregularities, imaging equipment, and so on. The network was found to have false alarm rate, miss rate, and nonclassification rates nearing zero at a speed equivalent to covering a 100 mm $\times$ 100 mm area per second.

In a study that will be considered in detail in the section on function allocation, a neural net was developed as one of the automated alternatives to human visual inspection of circuit boards (Hou et al. 1993). It used the output from edge detection and thinning algorithms, followed by a Hough transformation as the inputs to a three-layer back-propagation network, with either a fixed threshold (for fully automated inspection) or a multi-level threshold where a human inspector could help the system make the final decision. The network was given a number of boards as the training set and then given another sample as the test set to measure its performance.

Neural network research and its application to the decision-making component in inspection offer interesting possibilities towards more realistic automated inspection systems. However, a number of issues have to be addressed before neural networks can make a significant impact in the area of test and inspection. The training time for neural networks can be extremely long, especially if there is an overlap of categories in the decision space. The speed of the network also has to meet line-speed requirements. With respect to neural networks, the speed is largely a function of the size of the middle layer. Adding middle layer units can significantly increase computation time while only increasing accuracy up to a point. Accuracy of neural networks in terms of both false alarms and misses has to be established and is always application specific. As with human training, the amount of fine tuning that is needed to get the desired performance may be quite large.

The final output from the overall system is a unit of product classified into one of a small number of categories corresponding to different system responses. Thus, a circuit board could be classified as ''Conforming'' or ''Nonconforming'' (Hou et al. 1993) or into three levels of acceptability, such as ''Tight,'' ''Open 1,'' or ''Open 2,'' for rose grades.

5.2.1. Examples

Any recent conference on automated vision from an automation or applied optics viewpoint will provide copious current examples of AVIS applications in a variety of industries. Table 4 lists a number of recent applications of automated vision to show the variety of products and industries covered by the pace of this form of automation. Unfortunately, few technical papers contain the depth of performance evaluation required to assess system reliability or its components. The Steinmetz and

TABLE 4 Examples of Automated Test and Inspection Systems

Industry and Reference	Task	Parameters/ Defects Detected	Technology
Civil Aviation Siegel et al. 1998	In-service structural inspection of aircraft	Cracks, corrosion	3D stereo vision and eddy current
Semiconductor manufacture Komatsu et al. 1999	Detection of defects in lithographic process after development	Contamination, scratches, reduced conductor thickness	Image processing
Aircraft engine manufacture Rosemau et al. 1999	Classification of cooling holes in jet engine fan blades	Cooling hole wrong diameter, blocked cooling holes	Robot movement of fan blade for different views, image processing to classify defects
Food products Legeard et al. 1999	Evaluation of quality of pork hams	Detection and classification of muscle color and fat thickness	Color vision system using hue, saturation, and intensity measures, using thresholding
Ceramics Kälviäinen et al. 1998	Classification of color matches in tile production	Classification of brown tiles by color and feature	Color machine vision system measures RGB pixel values, classify color features using neural nets
Chemical Industry Liu et al., 1998	Detection of welding defects in pipelines	Weld defects of all types	X-radiography followed by image processing and pattern recognition
Automobile Manufacturing Hung and Park 1996	Detection of dents in large automobile steel panels	Dents	3D computer vision measures slope, curvature and depth.

Delwiche (1993) paper was chosen as a worked example partly because such performance data was available and published.

6. NONPRODUCTION TEST AND INSPECTION

Production and manufacturing are not the only realms of inspection and test. Service industries need to inspect goods and services before they are released to the customer. A number of these nonmanufacturing applications are shown below:

- *Regulatory inspection:* To ensure that regulated industries meet meet or exceed regulatory norms. Examples are review of restaurants against local service codes, fire safety inspection of buildings, and safety inspection of workplaces.
- *Maintenance:* To detect failure arising during the service life of a product. This failure detection function can be seen in inspection of road and rail bridges for structural determination or of civil airlines for stress cracks or corrosion (see below).
- *Security:* To detect items deliberately concealed. These may be firearms or bombs carried onto aircraft, drugs smuggled across borders, or camouflaged targets in aerial photographs. They can also be suspicious happenings on a real-time video monitor at a security station. Law enforcement has many examples of searching crime sites for evidence.

- *Design review:* To detect discrepancies or problems with new designs. Examples are the checking of building drawings for building code violations, of chemical plant blueprints for possible safety problems, or new restaurant designs for health code violations.
- *Functionality testing:* To detect lack of functionality in a completed system. This functional inspection can often include problem diagnosis, as with checks of avionics equipment in aircraft. Often functional inspection is particularly dangerous and costly, as in test flying aircraft or checking out procedures for a chemical process.

6.1. Maintenance Inspection

The example chosen here is that of inspection of civil aircraft as part of the system for assuring the public that airworthiness is maintained throughout the service life of airframes, avionics, and aircraft structures. It is part of a maintenance process and is typical of many transportation applications, such as for maritime transport, heavy goods vehicles, or even the space shuttle.

Airworthiness of civil aircraft depends upon a process by which a team composed of aircraft manufacturers, regulators, and one or more airlines predicts possible system failures. This process, Maintenance Steering Group 3 (MSG-3), considers possible failure pathways (e.g., in structures, controls, avionics) and for each pathway determines a recovery strategy. For structural failure, this may be replacement after a fixed service life, regular inspection to ensure detection, or an indication to crew of the malfunction. The concern here is with the reliability of the primary failure recovery system for aircraft structural inspection: regular inspection to ensure detection.

Failure modes of aircraft structures can be cracks, corrosion, fastener/bonding failure, or deformation beyond the plastic limit. Inspection systems are designed to detect all of these in a timely manner, that is, before the failure has a catastrophic effect on structural integrity. For example, crack growth rates can be predicted probabilitistically from material properties and applied stresses, so that the MSG-3 process can schedule inspections before a potential crack becomes dangerous. However, the detection system has certain limits on the size of crack that can be detected, so MSG-3 typically schedules several inspections between the time the crack becomes detectable and the time it becomes dangerous. If too many inspections are scheduled, the costs are driven up in a highly competitive industry and the risk of collateral damage is increased due to the handling activities involved in the inspection process itself. Conversely, if too few inspections are scheduled, the probabilistic rate of the crack growth-prediction process may combine with the probabilistic nature of the detection process to cause dangerous cracks to remain undetected. Spectacular failures of this inspection process have occurred both for aircraft structures (Aloha incident, Hawaii, 1988) and engine components (Pensacola incident, Florida, 1997).

The MSG-3 process thus requires quantitative data on inspection reliability to function correctly. In addition, no rule-based prediction system can foresee all possible malfunctions, so that once an aircraft is in service, regular detailed inspections are made of the whole structure to discover any unexpected cracks. When such ''new'' cracks are found, the information is typically shared among manufacturers, operators, and regulators in the form of supplementary inspections. Similar considerations apply to other failure modes, such as corrosion.

This whole reliability assurance process thus rests upon an inspection system that checks both points where malfunctions are expected and points where they are not expected, for a variety of malfunctions. For good reasons, human inspectors are part of this inspection system, and thus human inspection reliability is an essential element in ensuring structural integrity and hence airworthiness.

The inspection task combines two goals: detection of expected malfunctions and detection of unexpected malfunctions. Neither detection is particularly easy or particularly rapid, so inspection can be a difficult and time-consuming task. In some ways inspection can be classified as an ill-structured task (Wenner 1999) because there is no simple step-by-step procedure that will ensure success and usually no knowledge of task success available during the task. Finding (n) malfunctions in a structure still leaves an unknown number (hopefully zero) potentially undetected.

In addition, inspection is typically scheduled at the beginning of an aircraft's maintenance visit so that malfunctions can be detected early and their repair scheduled to overlap in time with other maintenance activities. As airlines streamline their parts inventory to reduce holding costs, the lead time for replacement components can increase, again pressuring the inspection system to ensure early detection. Aircraft typically arrive following scheduled service, that is, after the last flight of the day. Following opening up and cleaning processes, maximum inspection resources are committed to the initial inspection. In practice, this means inspectors working overtime, even double shifts, starting with a night shift, under some implied pressure for early detection. Human inspection reliability may not be optimal under these conditions.

The inspection task itself is classified in aviation as either visual inspection or nondestructive inspection. Regulatory bodies have issued formal descriptions of both of these tasks (e.g., Bobo 1989, for the FAA), and both have somewhat different characteristics in aviation

Nondestructive inspection (NDI) includes a set of techniques to enhance the ability to detect small and/or hidden malfunctions. One set of NDI techniques is those that enhance what is essentially still a visual inspection task, such as X ray, fluorescent particle, magnetic particle, or D Sight. They show cracks that are very small (fluorescent particle) or hidden within other structures (X ray). Apart from the steps necessary to ensure a good image, they have many of the human interface characteristics of visual inspection. The other set of NDI techniques is focused on specific malfunctions in specific locations, such as eddy current and ultrasound. For this reason, they are useful only for detection of malfunctions already predicted to exist. In practice, such NDI techniques are much more proceduralized than visual inspection or NDI techniques, which contain a human visual inspection component.

Visual inspection is much more common, making up 80% of all inspection (Goranson and Rogers 1983). It consists of using the inspector's eyes, often aided by magnifying lenses and supplementary lighting, as the detection device. Inspectors must visually scan the whole structure of interest, typically using portable mirrors to examine areas not directly visible. Whether the task is categorized as visual inspection or NDI, its aim is to detect flaws (indications) before they become hazardous. Next we consider the bodies of knowledge potentially applicable to aircraft inspection reliability (e.g., Drury and Spencer 1997).

Over the past two decades there have been several studies of human reliability in aircraft structural inspection (Rummel et al. 1989; Spencer and Schurman 1995; Murgatroyd et al. 1994). All of these to date have examined the reliability of nondestructive inspection (NDI) techniques, such as eddy current and ultrasonic technologies.

From NDI reliability studies have come human–machine system detection performance data, typically expressed as a probability of detection (PoD) curve (e.g., Spencer and Schurman 1995). This curve expresses reliability of the detection process (PoD) as a function of a variable of structural interest, such as crack length, providing in effect a psychophysical curve as a function of a single parameter. Sophisticated statistical methods (e.g., Hovey and Berens 1988) have been developed to derive usable PoD curves from relatively sparse data. Because NDI techniques are designed specifically for a single fault type (e.g., cracks) and much of the variance in PoD can be described by just crack length, the PoD is a realistic reliability measure. It also provides the planning process with exactly the data required because remaining structural integrity is largely a function of crack length.

Both the FAA (1993, pp. 26, 35) and the Air Transport Association (ATA) have recognized the need for equivalent studies of the reliability of visual inspection as a research priority.

Aircraft inspection has already benefited from models of human inspection such as those in Section 2. Thus, the ECRIRE program (Spencer and Schurman 1995) examined one NDI technique, eddy current inspection, incorporating human factors variables. They were able to test one-person vs. two-person teams (no consistent effects) and gross body posture (a small decrease in detection performance when the inspector had to work at about knee height). A FAA program on human factors in aviation maintenance and inspection (e.g., Drury et al. 1997) has had some success in improving documentation design, lighting, and communications. This program expanded the search-plus-decision model following industrial inspection findings to include the five generic inspection functions presented earlier.

Such a task description invites task analysis, which would lead naturally to human reliability analysis (HRA). Indeed, perhaps the earliest work in this field applied HRA techniques to construct fault trees for aircraft structural inspection (Lock and Strutt 1985). The HRA tradition lists task steps, such as expanded versions of the generic functions above, lists possible errors for each step, then compiles performance shaping factors for each error. Such an approach was tried early in the FAA's human factors initiative (Drury et al. 1990) but was ultimately seen as difficult to use because of the sheer number of possible errors and PSFs. It is occasionally revised, such as in the current FRANCIE project (Haney 1999), using a much expanded framework that incorporates inspection as one of a number of possible maintenance tasks. Other attempts have been made to apply some of the richer human error models (e.g., Reason 1990; Hollnagel 1997; Rouse 1985) to inspection activities (Latorella and Drury 1992; Prabhu and Drury 1992; Latorella and Prabhu 2000) to inspection tasks. These have given a broader understanding of the possible errors but have not helped better define the PoD curve needed to ensure continuing airworthiness of the civil air fleet.

One outcome of this work has been a detailed analysis of a single process to develop recommendations of human factors good practices for use by industry managers and inspectors (Drury 1999). The project was performed for the regulatory body, the FAA, as part of its response to recommendations arising from investigation of the engine hub failure at Pensacola in 1997. That failure was due in part to failure of the fluorescent penetrant inspection (FPI) system for titanium hubs. Hence a human factors analysis of engine FPI systems was performed.

The human inspection models of visual search and human decision making were shown to be particularly applicable leading to a task analytic framework using hierarchical task analysis (HTA). In this way, human factors knowledge could be applied systematically to observed FPI processes. Visits were made to several engine repair facilities owned by major air carriers and engine manufac-

turers. The site visit team consisted of a human factors engineer specializing in inspection reliability and two senior Federal Aviation Administration (FAA) personnel specializing in NDI.

At each visit the HTA model of FPI was further developed and both good and poor human factors practices were noted. The HTA had seven major tasks, most of which would be classified under Setup in our five-function model. The tasks are shown in a HTA format in Figure 4. Note that Load/transport part in FPI would be equivalent to the Present function, and Read part for defects to Search, Decision, and Respond. For each of these seven tasks, two levels of subtasks were developed and potential errors listed. A fault tree for the primary failure, defect not reported, was developed and used to help generate a set of human factors good practices. Table 5 shows an example of the most detailed level for function 3, Apply penetrant, with the listing of human factors issues and process variances.

Using this process, a set of 90 human factors good practices was generated, with each good practice keyed to one of the seven major tasks listed above. Each was also keyed to the potential errors that that good practice can prevent. In this way, users are given the reasons for the recom-

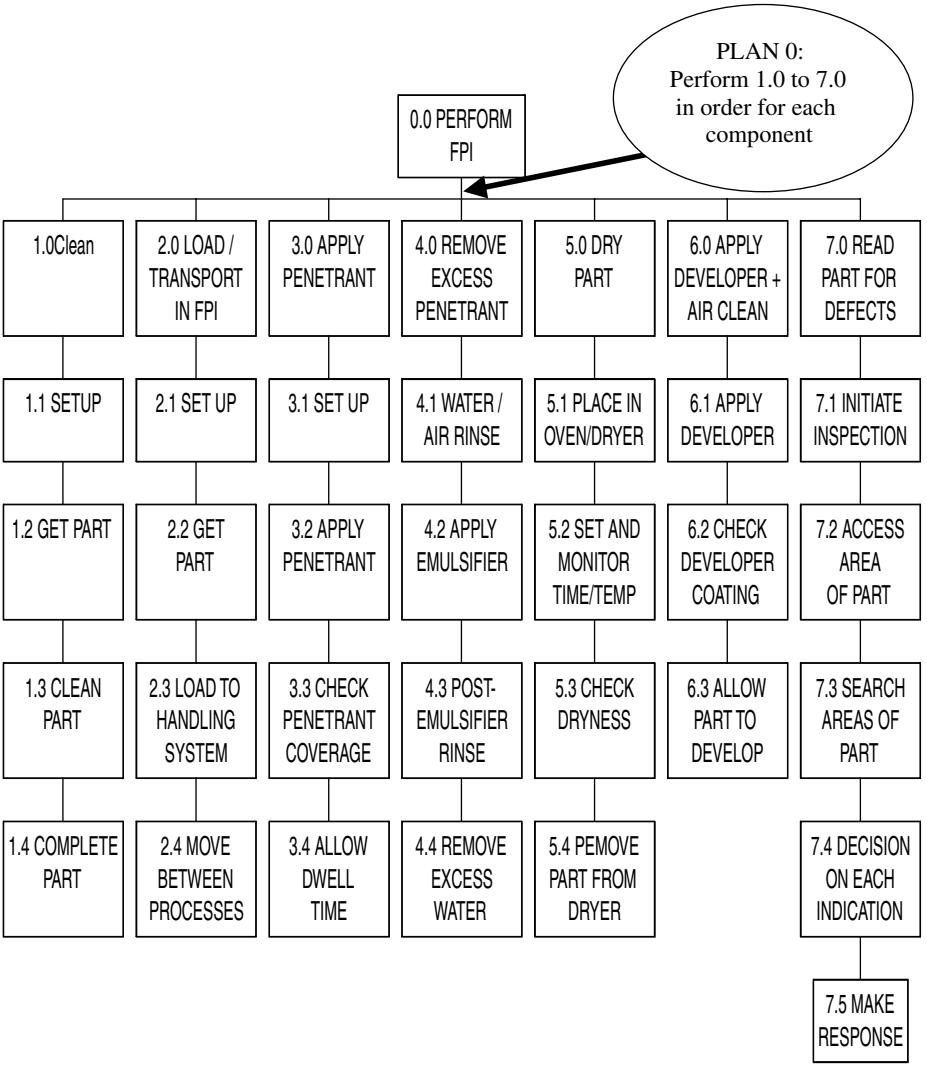

Figure 4 Hierarchical Task Analysis for the Top Level of Fluorescent Penetrant Inspection.

TABLE 5 Detailed Level of HTA for Function 3: Apply Penetrant

Task Step	Task Description	Task Analysis
3.1. Set-up	3.1.1. Monitor penetrant type, consistency (for electrostatic spray) or concentration, chemistry, temperature, level (for tank)	Are measurements conveniently available? Are measurement instruments well human-engineered? Do recording systems require quantitative reading or pass/fail?
3.2. Apply		
3.2.1. Electrostatic spray	3.2.1.1. Choose correct spray gun, water-washable or postemulsifiable penetrants available.	Are spray guns clearly differentiable? Can feeds be cross-connected?
	3.2.1.2. Apply penetrant to all surfaces.	Can sprayer reach all surfaces?
3.2.2. Tank	3.2.2.1. Choose correct tank, water washable or postemulsifiable penetrants available.	Are tanks clearly labeled? Is handling system well-designed to use for part placement?
	3.2.2.2. Place in tank for correct time, agitating/turning as needed.	Does operator know when to agitate/turn? Does carrier interfere with application?
	3.2.2.3. Remove from tank to allow to drain for specified time.	Is drain area available?
3.2.3. Spot	3.2.3.1. Choose correct penetrant, water-washable or postemulsifiable penetrants available.	Are spot containers clearly differentiable? Does operator know which areas to apply penetrant to?
	3.2.3.2. Apply to specified areas with brush or spray can.	Can operator reach all areas with spray can/brush? Is handling systems well human-engineered at all transfer stages?
3.3. Check coverage	3.3.1. Visually check that penetrant covers all surfaces, including holes.	Can operator see penetrant coverage? Is UV light/white light ratio appropriate?
	3.3.2. Return to 3.2 if not complete coverage.	Can operator see all of part? Can handling system back up to reapplication?
3.4. Dwell time	3.4.1. Determine dwell time for part.	Does operator know correct dwell time?
	3.4.2. Allow penetrant to remain on part for specified time.	How is it displayed? Are production pressures interfering with dwell time? Is timer conveniently available, or error-proof computer control?
	Errors/Variances for 3.0 Apply Penetrant	
	Process measurements not taken Process measurements wrong Wrong penetrant applied Wrong time in penetrant Insufficient penetrant coverage Penetrant applied to wrong spots No check on penetrant coverage Dwell time limits not met	

mendations so that they can develop a knowledge base in addition to the rule-based good practices. In addition, there were five general control mechanisms where applications of human factors principles should lead to improved FPI reliability: Operator selection, training and turnover, Hardware design, Software and job aids, Interpersonal systems design, and Environmental control. Each was considered to show how human factors could be applied at a higher level than the 90 specific recommendations. Finally, the analysis established a set of research and development needs to provide better support for improved FPI reliability: Improved solvent and developer, Better magnifying loupe, Better process test panel validity, Job aids for search strategy, and Realistic expectation control.

It was concluded that the FPI system for critical rotating engine components can reach significantly higher reliability through application of specific and general human factors good practices. For the current purposes, the analysis provides a worked example of how human factors knowledge can be applied to find practical changes in an existing inspection system.

7. LOGICAL FUNCTION ALLOCATION IN TEST AND INSPECTION

Given that test and inspection systems must be designed and redesigned on an accelerated cycle, systematic design procedures would be advantageous to modern manufacturing. With the array of devices and human factors interventions available to the designer, a procedure that highlights functional and organizational differences between alternative solutions would assist in the evaluation or convergence phase of design (Jones 1981, p. 68). In Section 3, the functions of inspection were defined and the principles of allocation of function between human and machine proposed (Section 3.1).

Function allocation is a basic technique of human factors engineering, although it has periodically been called into question. Most recently, McCarthy et al. (2000) edited a special issue of a journal devoted to a modern consideration of function allocation in manufacturing. Although test and inspection are not mentioned, the issues raised clearly apply to these manufacturing functions. They argue that function allocation at the design stage is against the principles of localized design and is often rational and atomistic, both currently disfavored concepts in the field. They see function allocation as being at times arrogant instead of growing more naturally out of each particular operating environment. However, in any design there is always allocation of function, even if it is only implicit or a default to automation. Human operators still have too many jobs composed of leftover functions in a system designed for full automation but failing to achieve that in practice.

In test and evaluation, much of the automation literature is frankly antihuman operator. For example, Lumai (1994) states that ''the subjective nature of human inspectors prevents achieving a 'six-sigma' manufacturing capability'' going on to give the argument that if inspectors only achieve a 90% success rate, this will not meet the six-sigma requirement. In fact, if the defective rate is low enough, even a 90% hit rate can achieve arbitrarily low final defect rates. But 100% inspection by humans is rarely the issue in industry. Most research papers, as noted earlier, start by justifying automation based on human error and/or human variability. The implication is that automation will prevent errors and remove unwanted variability. Much of modern manufacturing is based on continual variability reduction (e.g., total quality management), so this aim is reasonable. There is no justification for variability for its own sake. But variability of *response* may well be required in a practical system to allow the system to cope with unexpected variance in inputs or process conditions. Human inspectors provide the required ability to respond to external change, for example by finding defects not initially defined for the process. In fact, one characteristic of automated systems is that they function best when inspecting for a limited set of defect types, often a single type. Humans share this characteristic but can expand their effective set of detect types much more easily than automated devices.

Three examples of direct tests of function allocation have been reported. The first, Drury and Sinclair (1983), compared two alternative designs for inspection of precision roller bearings for discrete surface imperfections (scratches, toolmarks, nicks, and dents). The current manual method using trained inspectors was compared to a computer-based automated visual inspection system (AVIS). In fact, the systems differed on the functions of Setup, Search, and Decision. The latter two functions could not be separated for the AVIS, indicating one difficulty of performing allocation at the function level. Results, in terms of misses and false alarms, were poor for both systems, with the automated system slightly worse than the human inspectors. In fact, the company embarked upon a very effective retraining program for its inspectors (Kleiner 1986), while redesigning the AVIS for better discrimination between conforming and nonconforming indications.

The second example, Drury and Goonetilleke (1992), used an inspection device for populated printed circuit boards (called a CVC) that could be reconfigured to allocate functions progressively between human and device. Direct comparisons of performance (misses, false alarms, performance speed) were possible between six levels of automation from level 1 (fully manual) to level 6 (automated Setup, Present, and Search), with only the final decision left to the inspector. Response via a

control panel was kept constant throughout. Both laboratory and in-plant studies were undertaken, but only the former are presented here. Figure 5 shows performance for a number of measures of defect-detection performance that gave significant effects. Note that performance generally falls with increasing automation until an automated search procedure that detects all indications is reached. Performance differences between the fully manual and fully automated systems were very small.

The final example is from Hou et al. (1993), who examined five function-allocation alternatives for the task of inspecting circuit board height maps for a set of three defects: missing component, misaligned component, and wrong-sized component. The five function allocations were based on the fact that humans are expected to perform worse than computer-based automation on the search function but may be better for decision making. Thus, the extreme allocations of all tasks to the human and all tasks to the machine were complemented by an allocation of machine search/human decision and another of machine search/shared decision. For automated inspection both a template matching system and a neural net system were used. Each of the five systems was optimized, for example by finding the optimum human search time (Morawski et al. 1992) for human search or by choosing parameters for the automated systems that maximized performance. All five systems were tested using four human inspectors for a range of three circuit board sizes and three different image contrast levels to simulate environmental degradation. Results were measured by the set of performance measures [p(miss), p(false alarm), time for inspection], with the two probabilities being combined using signat-detection theory into the single nonparametric measure of discriminability, $p(A)$. There were significant differences between the five systems on $p(A)$, with the two fully automated systems giving the worst discriminability. When inspection time was factored into the evaluation, the graph in Figure 6 could be drawn. This shows the speed–accuracy trade-off (SATO) across the five systems. Optimum performance is in the upper left corner of the figure with maximum discriminability in minimum time. The contours represent potential cost trade-offs for speed and accuracy, shown as straight lines for simplicity. From this figure, it can be seen that the ultimate choice of system depends upon the exact SATO cost weighting, but some systems dominate others no matter what the weightings. For example, template automation dominates neural net automation. Also, the human decision system dominates both the shared decision and the totally human systems. The conclusion from this study was that some form of human/automation hybrid system is preferable to either total allocation to human or total allocation to automation. It was also found that the hybrid systems were more consistent across different levels of environmental degradation.

Note that the set of criteria for deciding on function allocation was different for the three studies. The first used only the error probabilities, the second expanded this set to include performance measures such as misclassification rate, while the third also included performance speed. The issue of flexibility was addressed in the third study by comparing the competing systems across different contrast levels and board sizes. In none of these examples was there any measure of the cost of

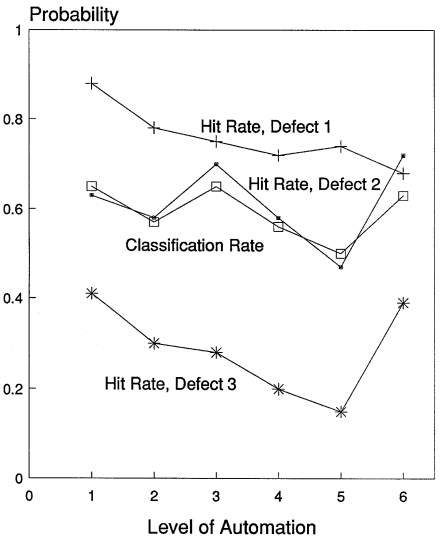

Figure 5 Performance with Increasing Automation.

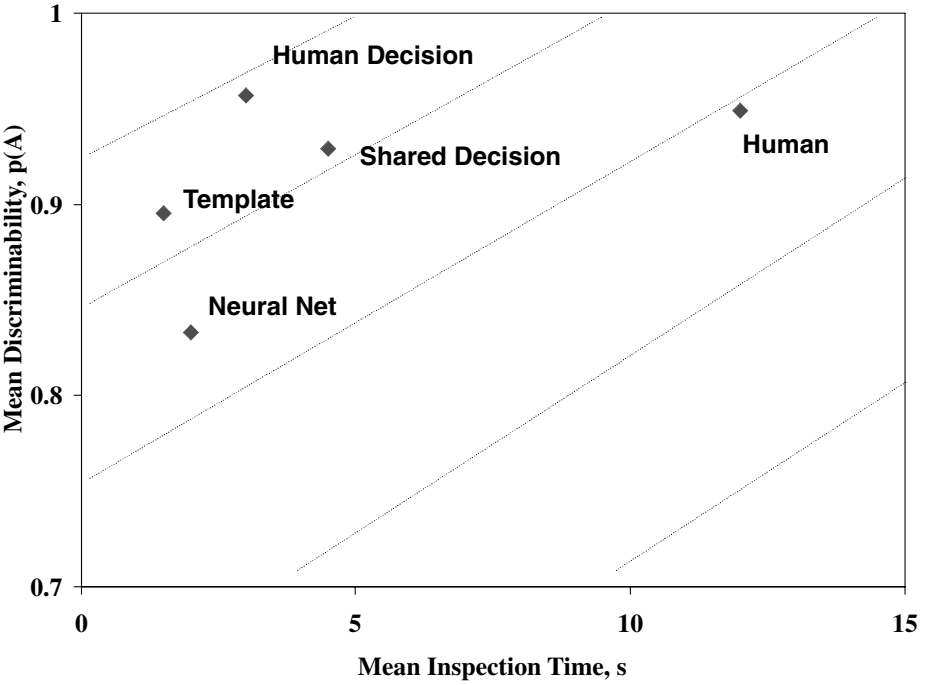

Figure 6 Accuracy and Speed Measures for the Five Alternative Function Allocations of Hou et al. (1993). The Dotted Lines Represent Typical Isocost Contours.

performance to the human inspector, although another part of the second study did use measures of workload and stress. The final choice of allocation is dependent on the set of criteria used to compare the systems.

7.1. A Methodology for Test and Inspection Systems Design

The implication that there are five functions in Table 3 that can each be allocated to either component is perhaps too simplistic. Not only are there practical interactions between functions, but there are multiple potential solutions to the design problem represented by each function. The best function allocation may well change over time, meaning that a dynamic rather than a static allocation procedure is needed. One approach to the design problem is the design for inspectability procedure proposed by Drury (1992b), although this was concerned primarily with the design of a product to enhance its inspectability. Here the procedure is further developed to examine different design alternatives.

Note that the outcome errors for test and inspection were defined as misses, false alarms, and (to a lesser extent) delays. Any system must attempt to minimize some function of these errors, although it has been shown that they can have trade-offs. For example, in the Search function, allowing greater time per item (increased delay) reduces misses. Also, in Decision, variation of the criterion for reporting (S_i) has the effect of causing misses and false alarms to covary inversely. Thus, compromises among all three measures will usually be required. Because the functions are sequential, failure to detect a defect (miss) is usually a much more common error than a false alarm (e.g. Megaw 1992).

If the probability of search success is p_s and the probability of decision success is p_d (here for simplicity both are assumed constant for good and faulty items):

$$p\ (\text{miss}) = p_s\ (1 - p_d) + (1 - p_s)$$

$$p\ (\text{false alarm}) = p_s\ (1 - p_d)$$

Thus,

$$p \text{ (false alarm)} < p \text{ (miss) for}$$
$$0 < p_s < 1$$
$$0 < p_d < 1$$

In addition to being numerically the most important error, misses are usually the most expensive in consequences because they imply failure of the system in use. False alarms, while still costly, can often be reevaluated by slower, off-line testing and usually corrected.

Thus, while the complete set of performance measures [p(miss), p(false alarm), time for inspection] is required to evaluate competing systems and systems components, for design purposes the detection of nonconforming items must be the priority. This is particularly so in modern manufacturing environments, where nonconforming items are increasingly rare and increasingly important to detect early. Thus, rather than optimizing the set of all three measures, in practice it is often imperative to optimize (minimize) p(miss) subject to fixed limits or constraints on p(false alarm) and time for inspection.

The design for inspectability procedure noted above starts from the assumption that a list of defects to be detected can be developed at the product design stage, perhaps from a failure modes and effect analysis (FMEA) of the product's components. These defects (D_1, D_2, . . . , D_i, . . . , D_n) represents the challenges to the test and inspection system because all must be detected, and detected at the appropriate stage of manufacture. Only three components of the inspection system can be changed, or changes can affect:

Product: the item produced and its subcomponents

Process: each test or inspection process used on the item and its subcomponents

Person: the human or humans interfacing with the product or process at each test or inspection

A design procedure must find an optimum mix of product, process, and person design features for each function to ensure that the probability of detection is maximized, subject to false alarm and time constraints. Note that the function-allocation procedure has been transformed into a function design feature, with design suggestions for each function (or even group of functions) being evaluated for how it impacts product, process, and person design and how it affects the probabilities of detection of each defect. Table 6 summarizes this design procedure, with each row representing a design alternative for one function and containing design impacts on both system components (product, process, people) and detection probabilities for the set of all defects. Entries in the System Design Impacts columns are references to notes concerning, for example, impact upon training or product weight. Entries in System Performance Impacts are detection probabilities for each defect or, where these are not available, in indication of the direction of change from a reference test and inspection system, perhaps the current system. Symbols of +, −, or 0 would be suitable in such a procedure, with actual magnitudes included if available.

TABLE 6 Design Procedure for Test and Inspection

Function	Design Alternative	System Design Impacts			System Performance Impacts

	R Alternative 2							
	—							

In many automated inspection systems reported in the literature, there is a concentration on a single performance measure, which makes it difficult to handle allocation decisions. For example, a vision system may be quoted as being able to detect surface defects ''in the 20 μm range'' without saying what the false alarm rate would be in those conditions. As Drury and Sinclair (1983) have shown, it is possible to change the ratio of misses to false alarms over the complete range by varying the sensitivity or threshold of an automated system. Most papers on human inspection quote at least the miss and false alarm rates and often the time per item. For automated systems, this is not typically true, making direct comparisons currently difficult.

8. CONCLUSIONS ON TEST AND INSPECTION

While much ground has necessarily been covered in this review, certain rather general and simple conclusions are possible. First, there is indeed a role for test and inspection in modern business. Global pressures are likely to increase the quality requirements over time while simultaneously requiring efficient performance with minimal resources. Give that test and inspection will still be needed, their role within the organization is moving from checking output for customer protection to collecting process data for point of manufacture control. This contextual change should in fact benefit human operators by including an explicit test and inspection function within most jobs. In the context of automation, we now have a plethora of sensors and signal processors to choose from, with capability increasing while cost decreases over time. Our choice of human and automation roles is likely to require hybrid systems, at least for image data where pattern recognition is required. Having said this, there appears to be a general conclusion that automation is preferable for the search function, at least where defects can be specified in advance. For routine measurement, such as of forces or temperatures, human roles are much reduced. Fortunately, for such measurements the ultimate goal is process control, where humans have a definite role in interpretation of patterns of results and choice of remedial action.

CHAPTER 72
Reliability and Maintainability

KAILASH C. KAPUR
The University of Washington

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

The ultimate objective of any system is the performance of some intended function. This function is frequently called the *mission*. The term often used to describe the overall capability of a system to accomplish its mission is *system effectiveness* For consumer products, system effectiveness is related to customer satisfaction, which is related to the overall concept of quality. Quality of products and services is defined and evaluated by the customers and users. Similarly, system effectiveness is defined and evaluated by the customers and users of the product. System effectiveness is defined as the probability that the system can successfully meet an operational demand within a given time when operating under specified conditions. Effectiveness is influenced by the way the system is designed, manufactured, used, and maintained. Thus, the effectiveness of a system is a function of several attributes, such as design adequacy, performance measures, safety, reliability, quality, manufacturability, and maintainability. The disciplines of assurance sciences help to increase the overall effectiveness of any system. The assurance sciences are engineering disciplines that have the common objective of attaining product integrity (product does what it says it is supposed to do) (Carrubba and Gordon 1978). The term *product assurance* is also popular in many companies. This chapter is concerned with the reliability, maintainability, serviceability, and availability aspects of the product assurance system.

Reliability is one of the major attributes determining system effectiveness. It is generally defined as the probability that a given system will perform its intended function satisfactorily, for its intended life, under specified operating conditions. With this definition the obvious problems are (1) the acceptance of the probabilistic notion of reliability; (2) the problems associated with defining adequate performance, particularly for system parameters that deteriorate slowly with time; and (3) the judgment required to determine the proper statement of operating conditions. Thus, reliability is a relative measure, or in terms of probability, it is conditional probability. It is relative to (1) definition of function from the viewpoint of the customer; (2) definition of failure from the viewpoint of the customer; (3) definition of intended life; and (4) customer's operating and environmental conditions.

Reliability is an inherent attribute of a system resulting from design, just as is the system's capacity, performance, or power rating. The reliability level is established at the design phase, and subsequent testing and production will not raise the reliability without a basic design change. Because reliability is an abstract concept that is difficult to grasp and to measure, many organizations find themselves unable to implement a comprehensive reliability program, primarily because of the lack of understanding on the part of both management and technical system design personnel. This is not to say that the system designers or managers in the organization are not interested in a reliable product; rather, the pressures on the design engineer, and very often on the organizational structure, impede the development of an effective reliability program (Kapur and Lamberson 1996).

With increasing system complexity, reliability becomes an elusive and difficult design parameter. It becomes more difficult not only to define and achieve as a design parameter, but to control and demonstrate in production and thus to ensure as an operational characteristic under the projected environmental conditions of use. However, past history has demonstrated that where reliability was recognized as a necessary program development component, with the practice of various reliability engineering methods throughout the evolutionary life cycle of the system, reliability can be quantified during the specification of design requirements, can be predicted by testing, can be controlled during production, and can be sustained in the field (Kapur 1996a). The purpose of this chapter is to present

some of the reliability and maintainability methodologies and philosophies that are applicable throughout the life cycle of a system.

1.1. Reliability and Maintainability Activities during the System Life Cycle

Reliability and maintainability activities should span the entire life cycle of the system. Figure 1 shows the major points of reliability practice in a typical system life cycle (AMC 1968). The activities given in the exhibit are briefly explained here. There is a continuous feedback, and designs go through several cycles of the reliability program activities.

1.1.1. Step 1: The Need

The need for a reliability and maintainability program must be anticipated right from the beginning. The need for such programs cannot be overemphasized. These programs are justified based on specific system requirements in terms of life-cycle cost and other operational requirements. As already mentioned, the effectiveness of a system is determined by its reliability and maintainability characteristics.

1.1.2. Step 2: Goals and Definitions

All the requirements must be specified in terms of well-defined and quantitative goals. The goals and requirements are defined by some of the following measures:

1. *Reliability measures.* Mission reliability, a reliability function based on specified failure distribution, mean time to failure (MTTF), and failure rate.
2. *Maintainability measures.* Maintainability function based on time to repair distribution, mean time to repair (MTTR), percentile of time to repair, and maintenance ratio.

There are other measures as well, and the relationship among them is given in Figure 2 (Von Alven 1964).

The term *reliability* has already been defined; some of the other terms are defined as follows:

1. *Mission reliability* is the probability that the product and/or system will successfully complete a given mission with specified operating requirements and time duration.
2. *Maintainability* is defined as the probability that a failed system can be made operable in a specified interval of downtime. As shown in Figure 2, the downtime includes the failure detection time, the active repair time, the logistics time connected with the repairs of the product, and all the administrative time. The maintainability function describes probabilistically how long a system remains in the failed state.

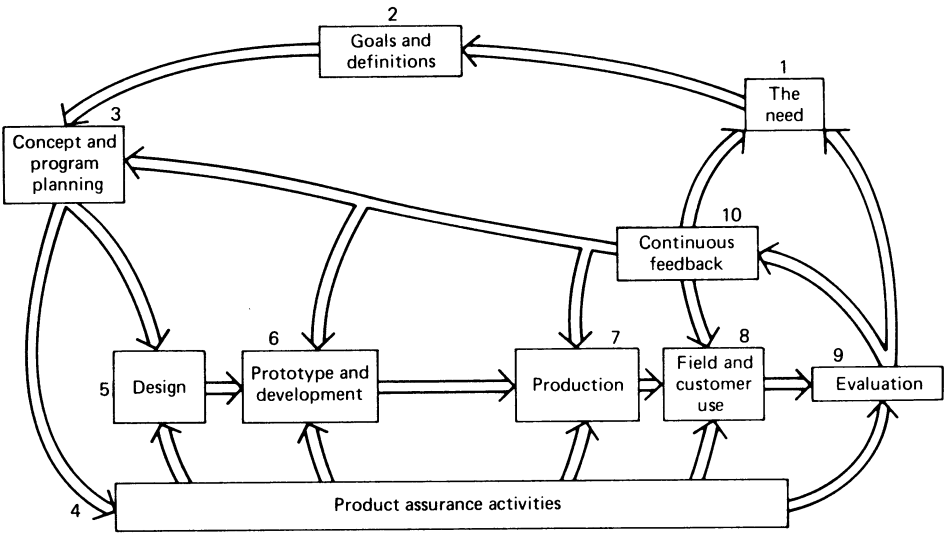

Figure 1 Reliability and Maintainability Activities During System Life Cycle.

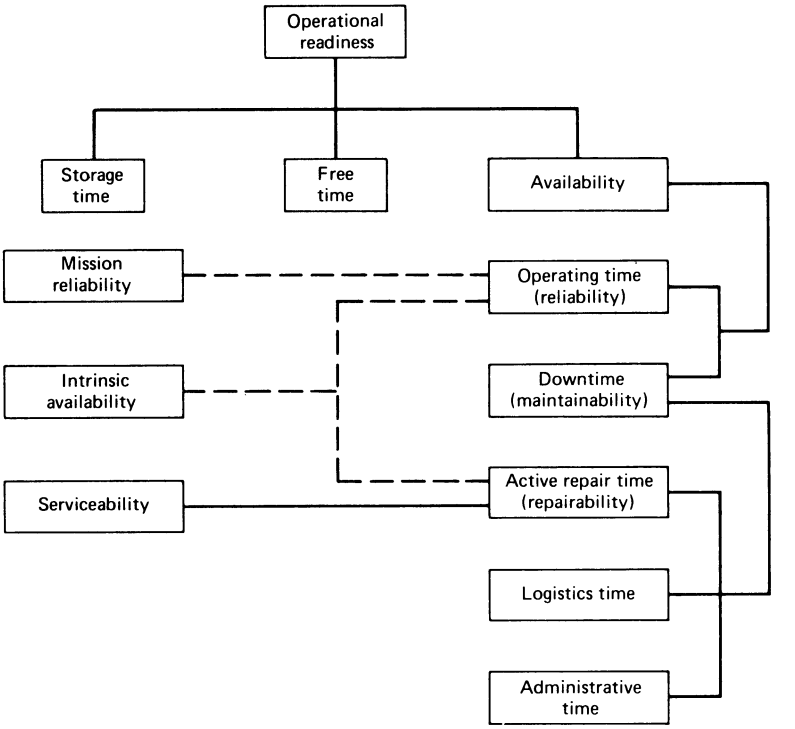

Figure 2 Relationship Among Various Product Assurance Measures.

3. *Repairability* deals only with the active repair time and can be defined by the time to actively repair random variable and the associated distribution. Repairability is defined as the probability that a failed system be restored to a satisfactory operating condition in a specified interval of active repair time. This measure is more valuable to the administration of the repair facility since it helps to quantify the workload for the facility and its workers.
4. *Serviceability* is defined as the ease with which a system can be repaired. Serviceability, like reliability, is a characteristic of the system design and must be planned at the design stage. Serviceability is difficult to measure on a ratio scale; however, it can easily be measured on an ordinal scale by a specifically developed rating and/or ranking procedure, which requires that systems be compared and ranked according to the ease of serviceability.
5. *Operational readiness* is defined as the probability that a system either is operating or can operate satisfactorily when the system is used under stated conditions. Operational readiness deals with all the time elements, including storage time, free time, operating time, and downtime.
6. *Availability* is defined as the probability that a system is operating satisfactorily at any point in time. Availability considers only the operating time and downtime, thus excluding the idle time. Therefore, it is a measure of the ratio of operating time of the system to the operating time plus the downtime. Availability is a function of both the reliability and maintainability of the system.
7. *Intrinsic availability* is more restrictive than availability because it is limited to operating and active repair time only.

These reliability, maintainability, and availability measures should be defined and system requirements specified using these quantitative measures. The effectiveness of the total product assurance program depends on these definitions.

1.1.3. Step 3: Concept and Program Planning

Based on the reliability and other operational requirements, various concepts are developed that can potentially meet these requirements. Also, at this stage, total product assurance program plans must

be formulated and responsibilities assigned to different groups. The conceptual stage is an important part of the system life cycle because it has a major impact on the future system. Studies done by the U.S. Department of Defense indicate that 70% of the system life-cycle cost is determined by the decisions made at the concept stage. The detailed nature of the reliability programs will also determine the effectiveness of the total program.

1.1.4. Step 4: Product Assurance Activities

The plans developed in step 3 are implemented and the total program is continuously monitored, as indicated in Figure 1. An organization for the implementation of these plans must exist, with well-defined responsibilities

1.1.5. Step 5: Design

The conceptual system selected in step 3 is designed. Reliability and maintainability of this design are assessed. Various methodologies, such as design review, failure mode and effect analysis, fault tree analysis, and probabilistic design approach, can be applied at this step. Reliability is a design parameter and must be incorporated in the system at the design step.

1.1.6. Step 6: Prototype and Development

Prototypes are developed based on the design specifications. Reliability of the design is verified by testing. If the design has certain deficiencies, they are corrected by redesign. Reliability growth-management plans must be developed for this step in order to monitor continuously the growth and progress of the program. After the system has achieved the required level of reliability, the design is released for production.

1.1.7. Step 7: Production

The system is manufactured based on design specifications. Quality control methodologies are essential during this step. All the parts, materials, and processes are controlled based on methodologies discussed in previous chapters in the area of quality assurance. One of the objectives of the quality control program is to make sure that the inherent reliability of the design is not degraded.

1.1.8. Step 8: Field and Customer Use

Before the system is actually used in the field by its customers, it is very important to develop all the service and maintenance instructions, which are well documented. Just like reliability, maintainability is considered throughout the life cycle, and its purpose is to sustain required levels of reliability and availability in the field. Maintainability program plans are developed at the planning step.

1.1.9. Step 9: System Evaluation

The system in the field is continuously evaluated to determine whether the original reliability and maintainability goals are met by the system. For this purpose a reliability monitoring program and field data-collection program must be established.

1.1.10. Step 10: Continuous Feedback

There must be continuous feedback among all the steps in the system's life cycle. A proper communication system should be developed among all the groups responsible for the various steps. All the field deficiencies must be reported to the appropriate groups. This will help guide the system improvements.

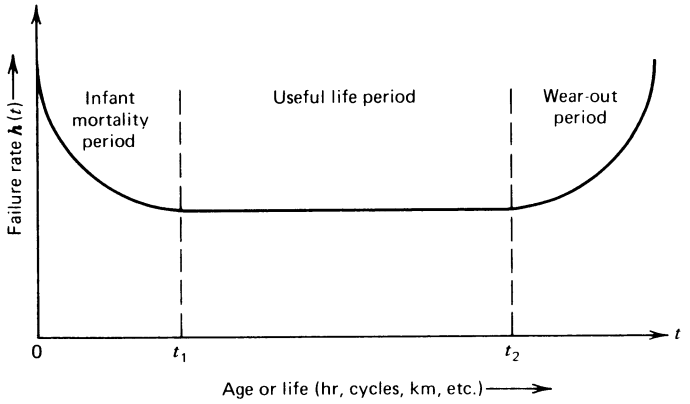
The methodology related to some of the activities during the system life cycle is given in this chapter.

1.2. Reliability and Life Characteristic Curve

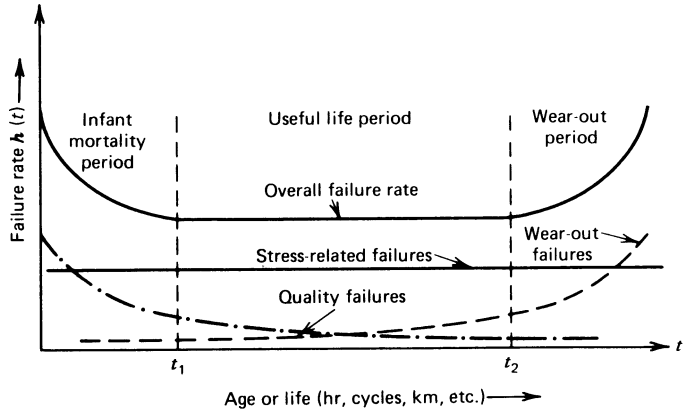
Reliability has sometimes been described as ''quality in the time dimension'' (RDG-376 1964) and a ''time oriented quality characteristic'' (Kapur 1986). The reliability characteristics of a product change with time. One of the characteristics is the concept of failure rate, which is defined mathematically later in this chapter. The failure rate, or the hazard rate, changes with the age or life of a product and has three distinct periods, as shown in Figures 3(*a*) and 3(*b*). These three periods are described here (Kececioglu 1991).

1.2.1. Infant Mortality Period

The total item population or a system generally exhibits a relatively high failure rate in the beginning, which decreases rapidly and stabilizes at some approximate time t_1. This initial period is generally called the 'burn-in,'' ''infant mortality,'' or ''debugging'' period. The item population has ''weak'' items, and these fail in the beginning. To understand the nature of these early failures, some of their causes are listed:



(a)



(b)

Figure 3 (*a*) Failure Rate-life Characteristic Curve. (*b*) Failure Rate Based on Components of Failure.

Substandard workmanship
Poor quality control
Substandard materials
Insufficient debugging
Poor manufacturing techniques
Poor processes and handling techniques
Problems due to assembly
Contamination
Improper installation
Improper start-up
Human error
Parts failure in storage and transit
Improper packaging and transportation practices

Fundamentally, these failures reflect the "manufacturability" of the product, and many are due to the lack of an effective quality control system in manufacturing. Thus, these early failures would show up during process audits, in-process or final tests, life tests, environmental tests, and so on.

Most manufacturers provide a burn-in period for their products so that the early or infant mortality failures occur in the plant and are not experienced by the customer in the field, where it is much more costly to fix these failures. The duration of the burn-in period determines what portion of the early failures is eliminated. Burn-in is a very expensive way to improve quality. A better way is to improve the process capability in terms of reducing variance. This will decrease the weak items in the population.

1.2.2. Useful Life Period

After having burned in, the item population reaches its lowest failure rate level, remaining relatively constant during this period. This failure rate is related to the inherent design reliability of the product and hence is given the most weight during the design reliability. This is also the most significant period for reliability prediction and assessment activities. Some of the causes of these failures are:

Low safety factors
Stress-related failures—higher-than-expected random loads
Lower random strength than expected
Defects that cannot be detected by the ''best'' available inspection techniques
Abuse
Human errors
Failures that cannot be observed during debugging
Failures that cannot be prevented by the ''best'' preventive maintenance practices
Unexplainable causes
''Act of God'' failures

1.2.3. Wear-Out Period

Most of the products are designed to last for a specified period of useful life. The time t_2 in Figures 3(*a*) and 3(*b*) indicates the end of useful life or the start of the wear-out period. After this point, the failure rate increases rapidly. The wear-out, or deterioration, results from a number of familiar chemical, physical, or other causes, some of which are as follows:

Corrosion or oxidation
Frictional wear or fatigue
Aging and degradation
Creep
Poor maintenance or service practices
Improper overhaul practices
Short designed-in life
Shrinkage or cracking in plastics

A reliability program must consider all three of these distinct periods. It must also be pointed out that not all products have these three periods. The importance of the periods depends on the magnitudes of time t_1 and t_2, where $0 \leq t_1 \leq t_2 < \infty$. Thus, we can develop various types of life characteristic curves, depending on the values t_1 and t_2. The best way to reduce infant mortality failures is to reduce the variance of the manufacturing process and reduce variation from the target. Early failures can also be eliminated by systematic procedures of controlled screening, quality control, and burn-in tests. Stress-related failures during the useful life can be minimized by providing adequate design or safety margins. Wear-out failures can be minimized by preventive maintenance and replacement policies.

2. RELIABILITY MEASURES

Reliability has been defined as the probability that a given system will perform satisfactorily its intended function for its intended life under specified operating conditions. Thus, reliability is related to the probability of the successful performance of any system. It is clear that we must define what the successful performance of any system is or what we mean by the failure of the system; otherwise it is not possible to predict when any system will fail to perform its intended function. The time to failure or ''life'' of a system cannot be deterministically defined, and hence it is a random variable. Thus, we must quantify reliability by assigning a probability function to the time to failure random variable.

2.1. Mathematics of Reliability Measures

Let T denote the time to failure random variable. Then reliability at any time t, denoted by $R(t)$, is the probability that the system will not fail by time t, or mathematically:

$$R(t) = P[\mathrm{T} > t] \tag{1}$$

Let $f(t)$ be the probability density function for the failure random variable T. Then the cumulative distribution function $F(t)$ is given by

$$P[T \leq t] = F(t) = \int_0^t f(\tau)d\tau \tag{2}$$

Hence from Eqs. (1) and (2) we have the following fundamental relationships (Eq. 3) between

$$R(t) = 1 - P[T \leq t] = 1 - F(t) = 1 - \int_0^t f(\tau)d\tau \tag{3}$$

the reliability function, cumulative distribution function, and probability density function.

Figures 4(a), 4(b), and 4(c) show, respectively, the failure probability density function, the cumulative distribution function, and the reliability function for the well-known case when the time to failure is exponentially distributed. Here we have

$$f(t) = \lambda e^{-\lambda t} \qquad t \geq 0,\ \lambda > 0 \tag{4}$$

and

$$F(t) = \int_0^t \lambda e^{-\lambda \tau}\, d\tau = 1 \geqslant \mathrm{q}\ e^{-\lambda t} \qquad t \geq 0 \tag{5}$$

$$R(t) = e^{-\lambda t} \qquad t \geq 0 \tag{6}$$

These functions are all related, and selection of any one determines the others. This is obvious from Eqs. 1, 2, and 3 or 4, 5, and 6.

Obviously, the reliability function inherent in a system, by virtue of its design, dictates the probability of successful system operation during the system's fife. A natural question is then, ''How does one know the shape of a reliability function for a particular systems?'' There are basically three ways in which it can be determined:

1. Test many systems to failure using a mission profile that is identical to use conditions. This would allow one to develop empirically a curve such as that shown in Figure 4(c).
2. Test many subsystems and components to failure where use conditions are recreated in the test environment This allows one to develop empirically the component reliability functions and then to derive analytically the system reliability function.
3. Based on past experience with similar systems, the underlying failure distribution may be hypothesized. Then one can test fewer systems to determine the parameters needed to adapt the failure distribution to a particular situation. For example, the lifetime of many different kinds of electronic components follows the exponential distribution as previously given in Eq. 4. To apply this distribution, one must know the value of the parameter λ for a particular situation. Elaborate studies have been done, so that for a given environment and mission, parameter λ can be determined for most electronic components.
4. In some cases, the failure physics involved in a particular situation may lead one to hypothesize a particular distribution. For example, fatigue of certain metals tends to follow either the lognormal or Weibull distributions. Here again, once a distribution is selected, the parameters for a particular application must be ascertained (MIL-HDBK 1974, 1979; Klion 1992).

Another measure that is frequently used as an indirect indicator of system reliability is the MTTF, which is the expected or mean value of the time to failure random variable. Thus, the MTTF is theoretically defined as

$$\mathrm{MTTF} = E[T] = \int_0^\infty t f(t)dt = \int_0^\infty R(t)dt \tag{7}$$

Sometimes the term *mean time between failures* (MTBF) when the product can be repaired or renewed is also used to denote $E[T]$. The problem with using only the MTTF as an indicator of

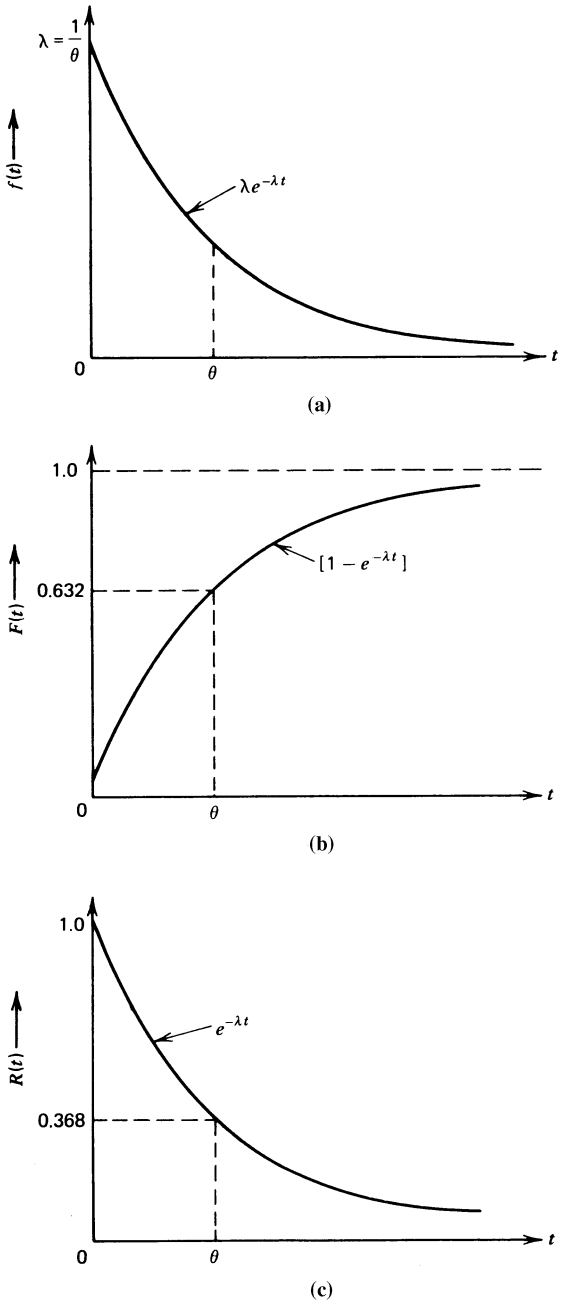


Figure 4 (*a*) Exponential Density Function. (*b*) Exponential Distribution Function. (*c*) Reliability Function for Exponential Distribution.

system reliability is that it uniquely determines reliability only if the underlying time to failure distribution is exponential. If the failure distribution is other than exponential, the MTTF can produce erroneous comparisons and we must develop other moments of the life distribution.

If we have a large population of the items whose reliability we are interested in studying, then for replacement and maintenance purposes we are interested in the rate at which the items in the population that have survived at any specific time will fail. This is the failure rate, or hazard rate, and is given by the following relationship:

$$h(t) = \frac{f(t)}{R(t)} \tag{8}$$

The failure rate for most components follows the curve shown in Figure 3(*a*), which is also called the life characteristic curve.

To help understand the notion of failure rate or hazard rate, basic mathematical relations are given here.

The hazard rate is defined as the limit of the instantaneous failure rate given no failure up to time t and is given by

$$\begin{aligned} h(t) &= \lim_{\Delta t \to 0} \frac{P[t < T \leq t + \Delta t | T > t]}{\Delta t} \\ &= \lim_{\Delta t \to 0} \frac{R(t) - R(t + \Delta t)}{\Delta t R(t)} \\ &= \frac{1}{R(t)} \left[-\frac{d}{dt} R(t) \right] \\ &= \frac{f(t)}{R(t)} \end{aligned} \tag{9}$$

Also

$$f(t) = h(t) \exp \left[-\int_0^t h(\tau) d\tau \right] \tag{10}$$

and thus

$$R(t) = \exp \left[-\int_0^t h(\tau) d\tau \right] \tag{11}$$

2.2. Various Life Distributions

The properties of some life distributions that are used in reliability and maintainability discipline are given below.

2.2.1. Exponential Distribution

$$f(t) = \lambda e^{-\lambda t} \qquad t \geq 0 \tag{12}$$

$$F(t) = 1 - e^{-\lambda t} \qquad t \geq 0 \tag{13}$$

$$R(t) = e^{-\lambda t} \qquad t \geq 0 \tag{14}$$

$$h(t) = \lambda \tag{15}$$

$$\text{MTBF} = \theta = \frac{1}{\lambda} \tag{16}$$

Thus, the failure rate for the exponential distribution is always constant.

2.2.2. Normal Distribution

$$f(t) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{t-\mu}{\sigma}\right)^2\right] \quad -\infty < t < \infty \tag{17}$$

$$F(t) = \Phi\left(\frac{t-\mu}{\sigma}\right) \tag{18}$$

$$R(t) = 1 - \Phi\left(\frac{t-\mu}{\sigma}\right) \tag{19}$$

$$h(t) = \frac{\phi[(t-\mu)/\sigma]}{\sigma R(t)} \tag{20}$$

$$MTBF = \mu \tag{21}$$

Thus, $\Phi(z)$ is the cumulative distribution function and $\phi(z)$ is the probability density function, respectively, for the standard normal variable Z. The failure rate for the normal distribution is a monotonically increasing function. Normal distribution should be used as a life distribution when $\mu > 6\sigma$ because then the probability that T will be negative is exceedingly small. Otherwise, truncated normal distribution should be used.

2.2.3. Lognormal Distribution

$$f(t) = \frac{1}{\sigma t\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{\ln t - \mu}{\sigma}\right)\right]^2 \quad t \geq 0 \tag{22}$$

$$F(t) = \Phi\left(\frac{\ln t - \mu}{\sigma}\right) \tag{23}$$

$$R(t) = 1 - \Phi\left(\frac{\ln t - \mu}{\sigma}\right) \tag{24}$$

$$h(t) = \phi\left(\frac{\ln t - \mu}{\sigma}\right) \Big/ t\sigma R(t) \tag{25}$$

$$\text{MTBF} = \exp\left(\mu + \frac{\sigma^2}{2}\right) \tag{26}$$

The failure rate for the lognormal distribution is neither always increasing nor always decreasing. It takes different shapes, depending on the parameters μ and σ.

2.2.4. Weibull Distribution (Three Parameters $\theta > \delta$)

$$f(t) = \frac{\beta(t-\delta)^{\beta-1}}{(\theta-\delta)^\beta} \exp\left[-\left(\frac{t-\delta}{\theta-\delta}\right)^\beta\right] \quad t \geq \delta \geq 0 \tag{27}$$

$$F(t) = 1 - \exp\left[-\left(\frac{t-\delta}{\theta-\delta}\right)^\beta\right] \tag{28}$$

$$R(t) = \exp\left[-\left(\frac{t-\delta}{\theta-\delta}\right)^\beta\right] \tag{29}$$

$$h(t) = \frac{\beta(t-\delta)^{\beta-1}}{(\theta-\delta)^\beta} \tag{30}$$

$$\text{MTBF} = \delta + (\theta-\delta)\Gamma\left(1 + \frac{1}{\beta}\right) \tag{31}$$

The failure rate for the Weibull distribution is decreasing when $\beta < 1$, constant when $\beta = 1$ (same as the exponential distribution), and increasing when $\beta > 1$.

2.2.5. Gamma Distribution

$$f(t) = \frac{\lambda^{\eta}}{\Gamma(\eta)} t^{\eta-1} e - \lambda t \qquad t \geq 0 \tag{32}$$

$$F(t) = \sum_{k=\eta}^{\infty} \frac{(\lambda t)^k \exp[-\lambda t]}{k!} \qquad \text{when } \eta \text{ is integer} \tag{33}$$

$$R(t) = \sum_{k=0}^{\eta-1} \frac{(\lambda t)^k \exp[-\lambda t]}{k!} \qquad \text{when } \eta \text{ is integer} \tag{34}$$

$$h(t) = \frac{f(t)}{R(t)} \qquad \text{[Using Eqs. (32) and (34)]} \tag{35}$$

$$MTBF = \frac{\eta}{\lambda} \tag{36}$$

The failure rate for the gamma distribution is decreasing when $\eta < 1$, constant when $\eta = 1$, and is increasing when $\eta > 1$.

2.3. Summary

Properties of extreme value distributions are given by Gumbel (Gumbel 1958). Other mathematical properties of the preceding distributions and their use in the reliability field have been discussed extensively by several authors, and results are available in the literature (Barlow and Proschan 1975; Kapur and Lamberson; 1977; Kececioglu 1991, 1993). To use these distributions in the product assurance field, one must understand their nature and properties and the conditions under which they are applicable to describe various physical phenomena (Bane and Engelhardt 1991; Elsayed 1996). The following discussion on the application of life distributions is given in Kapur (1996b).

Exponential distribution is a good model for the life of a complex system that has a large number of components. Because the exponential distribution has a constant failure rate, it is a good model for the useful life of many products after the end of the infant mortality period. Some applications for the exponential distribution are electrical and electronic systems, computer systems, and automobile transmissions. The *normal distribution* is used to model various physical, mechanical, electrical, or chemical properties of systems. Some examples are gas molecule velocity, wear, noise, chamber pressure from firing ammunition, tensile strength of aluminum alloy steel, capacity variation of electrical condensers, electrical power consumption in a given area, generator output voltage, and electrical resistance. The *lognormal distribution* is a positively skewed distribution and can be used to model situations where large occurrences are concentrated at the tail (left) end of the range. Some examples are amount of electricity used by different customers, downtime of systems, time to repair, light intensities of bulbs, concentration of chemical process residues, and automotive mileage accumulation by different customers. The *two-parameter Weibull distribution* can also be used to model skewed data. When $\beta < 1$, the failure rate for the Weibull distribution is decreasing and hence can be used to model infant mortality or debugging period or for situations when the reliability in terms of failure rate is improving or for reliability growth. When $\beta = 1$, the Weibull distribution is the same as the exponential distribution, and all of the previous comments for the exponential distribution are applicable. When $\beta > 1$, the failure rate is increasing, and hence it is a good model for determining wear out and end-of-useful life period. Some of the examples are corrosion life, fatigue life, life of antifriction bearings, transmission gears, and electronic tubes. The *three-parameter Weibull distribution* is a good model when we have a minimum life and the odds of the component failing before the minimum life are close to zero. Many strength characteristics of systems do have a minimum value significantly greater than zero. Some examples are electrical resistance, capacitance, and fatigue strength.

3. SYSTEM RELIABILITY MODELS

To analyze and measure the reliability and maintainability characteristics of a system, there must be a mathematical model of the system that shows the functional relationships among all the components, the subsystems, and the overall system. The reliability of the system is a function of the reliabilities of its components. A system reliability model consists of some combination of a reliability block diagram or cause–consequence chart, a definition of all equipment failure and repair distributions, and a statement of spare and repair strategies (Kapur 1996a). All reliability analyses and optimizations are made on these conceptual mathematical models of the system.

3.1. Reliability Block Diagram

A reliability block diagram is obtained from a careful analysis of the manner in which the system operates. An analysis has to be done of the effects on overall system performance of failures of the various components; the support environment and constraints, including such factors as the number and assignment of spare parts and repairpersons; and the mission for the system.

Engineering analysis on the system has to be done in order to develop a reliability model. The engineering analysis consists of the following steps:

1. Develop a functional block diagram of the system based on physical principles governing the operations of the system.
2. Develop the logical and topological relationships between functional elements of the system.
3. Performance-evaluation studies are used to determine the extent to which the system can operate in a degraded state.
4. Define the spares and repairs strategies (for maintenance systems).

Based on the preceding analysis, a reliability block diagram is developed, which is used for calculating various measures of reliability and maintainability. The reliability block diagram is a pictorial way of showing all the success or failure combinations for the system. Some of the guidelines for drawing these diagrams are as follows:

1. A group of components that are essential for the performance of the system and/or its mission are drawn in series [Figure 5(*a*)].
2. Components that can substitute for other components are drawn in parallel [Figure 5(*b*)].
3. Each block in the diagram is like a switch: it is closed when the component it represents is working and is opened when the component has failed. Any closed path through the diagram is a success path.

The failure behavior of all the redundant components must be specified. Some of the common types of redundancies are:

1. *Active redundancy* or *hot standby:* The component has the same failure rate as if it was operating in the system.
2. *Passive redundancy, spare,* or *cold standby:* The standby component cannot fail. This is generally assumed of spare or shelf items.
3. *Warm standby:* The standby component has a lower failure rate than the operating component. This is usually a realistic assumption.

Some mathematical relationships between the system reliability and the reliabilities of its components are given in the next subsections. In the following, R_s denotes the reliability of the system, and R_i denotes the reliability of the ith component, where $i = 1, 2, \ldots, n$ and the system has n components. In addition, in the following relationships, it is also assumed that all the components work or fail independently of each other.

3.1.1. Series Configuration [See Figure 5(*a*)]

For the static situation we have

$$R_s = \prod_{i=1}^{n} R_i \tag{37}$$

and for the dynamic situation

$$R_s(t) = \prod_{i=1}^{n} R_i(t) \tag{38}$$

The failure rate $h_s(t)$ for the system is given by

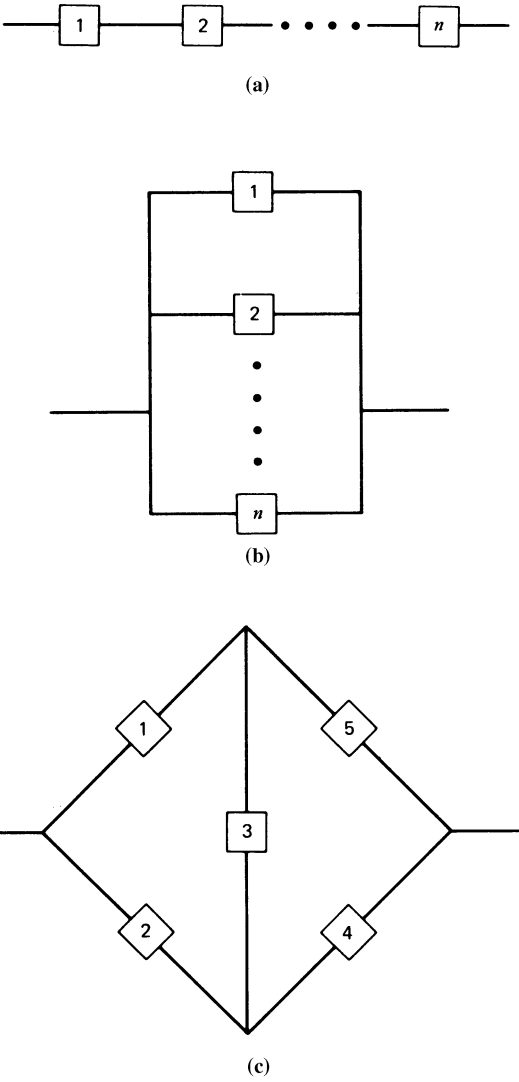

Figure 5 (*a*) Series Configuration. (*b*) Parallel configuration. (*c*) Bridge Structure.

$$h_s(t) = \sum_{i=1}^{n} h_i(t) \tag{39}$$

where $h_i(t)$ is the failure rate of ith component.

If all the components have an exponentially distributed time to failure, we have

$$h_s(t) = \sum_{i=1}^{n} \lambda_i \tag{40}$$

and MTBF for the system is given by

$$\frac{1}{\sum_{i=1}^{n} \lambda_i} \tag{41}$$

3.1.2. *Parallel Configuration* [See Figure 5(*b*)]

For the static case, we have

$$R_s = 1 - \prod_{i=1}^{n} (1 - R_i) \tag{42}$$

and for the dynamic case

$$R_s(t) = 1 - \prod_{i=1}^{n} [1 - R_i(t)] \tag{43}$$

If the time to failures for all the components is exponentially distributed with MTBF θ, then the MTBF for the system is given by

$$\sum_{i=1}^{n} \frac{\theta}{i} \tag{44}$$

where θ = MTBF for every component.

3.1.3. *The* k-*out-of*-n *Configuration*

In this configuration the system works if and only if at least k components out of the n components work, $1 \leq k \leq n$. For this case, when $R_i = R(t)$ for all i, we have

$$R_s(t) = \sum_{i=k}^{n} \binom{n}{i} [R(t)]^i [1 - R(t)]^{n-i} \tag{45}$$

If $R(t) = e^{-t/\theta}$, for exponential case, MTBF for the system is given by

$$\sum_{i=k}^{n} \frac{\theta}{i} \tag{46}$$

3.1.4. *Coherent Systems*

The reliability block diagrams for many systems cannot be represented by the preceding three configurations. In general, the concept of coherent systems can be used to determine the reliability of any system (Barlow and Proschan 1975). The performance of each of the n components in the system is represented by a binary indicator variable, x_i, which takes the value 1 if the ith component functions and 0 if the ith component fails. Similarly, the binary variable ϕ indicates the state of the system, and ϕ is a function of $x = (x_1, \ldots, x_n)$.

The function $\phi(x)$ is called the "structure function" of the system. The structure function is represented by using the concept of minimal path and minimal cut. A minimal path is a minimal set of components whose functioning ensures the functioning of the system. A minimal cut is a minimal set of components whose failures cause the system to fail. Let $\alpha_j(x)$ be the jth minimal path series structure for path A_j, $j = 1, \ldots, p$ and $\beta_k(x)$ be the kth minimal parallel cut structure for cut B_k, $k = 1, \ldots s$. Then we have

$$\alpha_j(x) = \prod_{i \in A_j} x_i \tag{47}$$

$$\beta_k(x) = 1 - \prod_{i \in B_k} (1 - x_i) \tag{48}$$

and

$$\phi(x) = 1 - \prod_{j=1}^{p} [1 - \alpha_j(x)] \tag{49}$$

$$= \coprod_{k=1}^{s} \beta_k(x) \tag{50}$$

For the bridge structure [Figure 5(c)] we have four minimal paths and four minimal cuts, and their structure functions are given as

$$\alpha_1 = x_1x_5 \qquad \beta_1 = 1 - (1 - x_1)(1 - x_2)$$
$$\alpha_2 = x_2x_4 \qquad \beta_2 = 1 - (1 - x_4)(1 - x_5)$$
$$\alpha_3 = x_1x_3x_4 \qquad \beta_3 = 1 - (1 - x_1)(1 - x_3)(1 - x_4)$$
$$\alpha_4 = x_2x_3x_5 \qquad \beta_4 = 1 - (1 - x_2)(1 - x_3)(1 - x_5)$$

Then the reliability of the system is given by

$$R_s = P[\phi(x) = 1] = E[\phi(x)]$$

If R_i is the reliability of the ith component, we have for the bridge structure

$$\begin{aligned} R_s = {} & R_1R_5 + R_1R_3R_4 + R_2R_3R_5 + R_2R_4 \\ & - R_1R_3R_4R_5 - R_1R_2R_3R_5 - R_1R_2R_4R_5 \\ & - R_1R_2R_3R_4 - R_2R_3R_4R_5 + 2R_1R_2R_3R_4R_5 \end{aligned}$$

If all $R_i = R = 0.9$, we have

$$\begin{aligned} R_s &= 2R^2 + 2R^3 - 5R^4 + 2R^5 \\ &= 0.9785 \end{aligned}$$

The exact calculations for R_s are generally very tedious because the paths and the cuts are dependent, since they may contain the same component. Bounds on system reliability are given by

$$\coprod_{k=1}^{s} P[\beta_k(x) = 1] \le P[\phi(x) = 1] \le - \prod_{j=1}^{p} \{1 - P[\alpha_j(x) = 1]\}$$

Using these bounds for the bridge structure, we have, when $R_i = R = 0.9$,

$$\begin{aligned} \text{Upper bound on} \quad R_s &= 1 - (1 - R^2)^2(1 - R^3)^2 \\ &= 0.9973 \\ \text{Lower bound on} \quad R_s &= [1 - (1 - R)^2]^2[1 - (1 - R)^3]^2 \\ &= 0.9781 \end{aligned}$$

The bounds on system reliability using the concepts of minimum paths and cuts can be improved. Further details and derivations for coherent systems can also be found in Barlow and Proschan 1975.

4. FAULT TREE ANALYSIS

Fault tree analysis is one of the methods for system safety and reliability analysis (Henley et al. 1992). The concept was originated by Bell Telephone Laboratories as a technique for safety evaluation of the Minuteman Launch Control System. Many reliability techniques are inductive and are concerned primarily with ensuring that hardware will accomplish its intended functions. Fault tree analysis is a detailed deductive analysis that usually requires considerable information about the system. It is concerned with ensuring that all critical aspects of a system are identified and controlled. It is a graphical representation of Boolean logic associated with the development of a particular system failure (consequence), called the top event, to basic failures (causes), called primary events. These top events can be broad, all-encompassing events, such as release of radioactivity from a nuclear power plant or inadvertent launch of an ICBM missile, or they can be specific events, such as failure to insert control rods or energizing power available to ordnance ignition line.

Fault tree analysis is of value in:

1. Providing options for qualitative and quantitative reliability analysis
2. Helping the analyst to understand system failures deductively
3. Pointing out the aspects of a system that are important with respect to the failure of interest
4. Providing the analyst an insight into system behavior

A fault tree is a model that graphically and logically represents the various combinations of possible events, both fault and normal, occurring in a system that lead to the top event. A fault event is an abnormal system state. A normal event is an event that is expected to occur. The term *event* denotes a dynamic change of state that occurs in a system element. System elements include hardware, software, human, and environmental factors. Details about the construction of fault trees can be found in Henley et al. (1992).

5. ALLOCATION OF RELIABILITY REQUIREMENTS

Reliability and design engineers must translate overall system performance, including reliability, into component performance, including reliability. The process of assigning reliability requirements to individual components in order to attain the specified system reliability is called reliability allocation. There are many different ways in which reliability can be allocated in order to achieve this end.

The allocation problem is complex for several reasons, including: (1) the role a component plays for the functioning of the system; (2) the methods available for accomplishing this function; (3) the complexity of the component; and (4) the reliability of the component, which may change with the type of function to be performed. The problem is further complicated by the lack of detailed information on many of these factors early in the system design phase. However, a tentative reliability allocation must be accomplished in order to guide the design engineer. The typical decision process from a reliability allocation standpoint is illustrated in Figure 6. A process such as this attempts to force all concerned to make decisions in an orderly and knowledgeable fashion rather than on an ad hoc basis.

Some of the advantages of the reliability allocation process are:

1. The process forces system design and development personnel to understand and develop the relationships among component, subsystem, and system reliabilities. This leads to an understanding of the basic reliability problems inherent in the design.
2. The design engineer is obliged to consider reliability equally with other system parameters, such as weight, cost, and performance characteristics.
3. Reliability allocation ensures adequate design, manufacturing methods, and testing procedures.

The allocation process is approximate, and the system effectiveness parameters, such as reliability and maintainability apportioned to the subsystems, are used as guidelines to determine design feasibility. If the allocated parameters for a system cannot be achieved using the current technology, then the system must be modified and the allocations reassigned. This procedure is repeated until an allocation is achieved that satisfies the system requirements.

Various allocation algorithms for reliability and availability requirements are available (Von Alven 1964; Kapur and Lamberson 1977).

6. DESIGN FOR RELIABILITY

Reliability is a time-oriented quality characteristic (Kapur 1986) and is defined and evaluated by the customer just like any other quality characteristic. Inherent reliability is a function of system concept and its design. After a design has been completed and released for manufacturing, the maximum reliability level of the system has been determined by virtue of its design. Essentially, the reliability effort is over once the design is released, and all that quality control during manufacturing phase can do is to ensure that this reliability level does not degrade during manufacturing. From a reliability standpoint, quality control during manufacturing is after the fact and thus is too late to consider reliability. Thus, the reliability effort must be an integral part of system design and development because this is where the reliability level is established. Reliability activities that can be performed during system design and development are described briefly in the remainder of this section.

To ensure most economically and effectively the production of a reliable product, the reliability activities must start early in the product-development cycle. However, at this stage, the identification of reliability improvements depends heavily on the experience of the personnel studying the product from blueprints and preliminary system mock-ups because no hard data are available for a quantitative assessment of reliability. To consider reliability early in the design cycle, one must rely on a formalized design review procedure, which is now briefly explained.

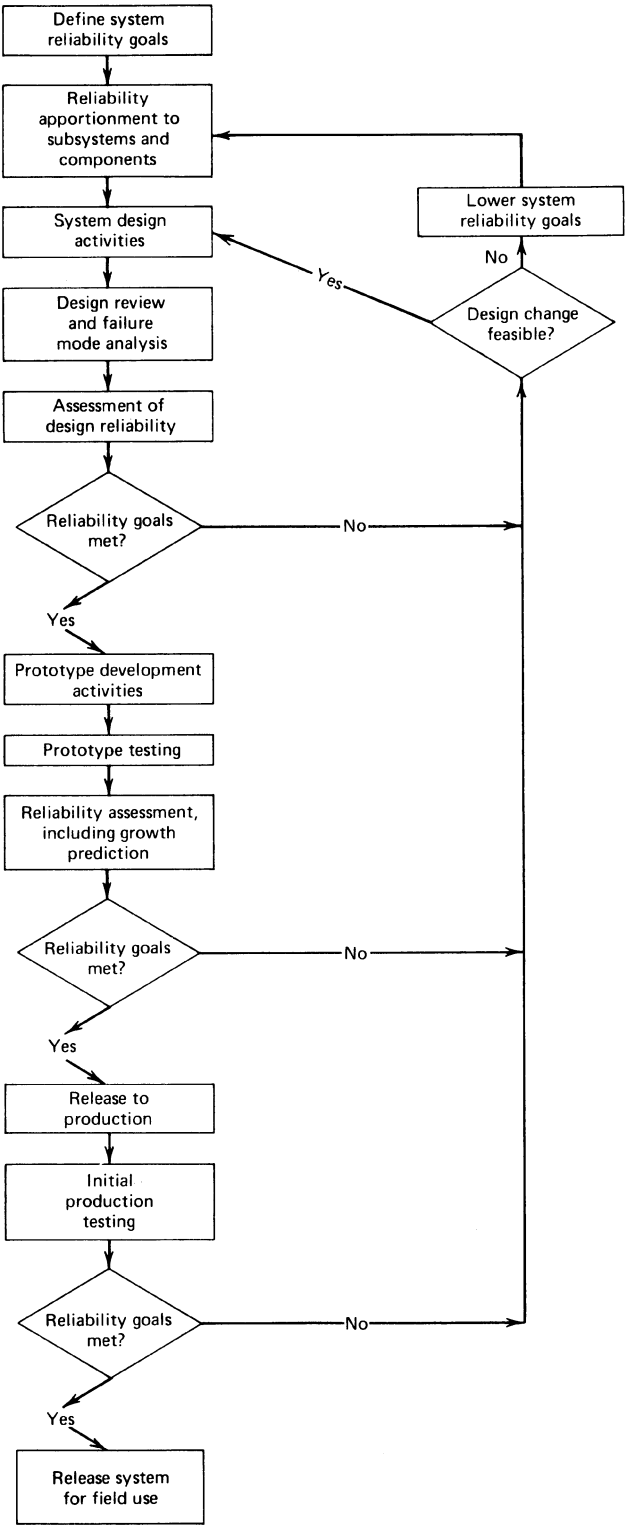

Figure 6 Reliability Allocation Process.

6.1. Design Review

The design review, a formal and documented review of a system design, is conducted by a committee of senior company personnel who are experienced in various pertinent aspects of product design, reliability, manufacturing, materials, stress analysis, human factors, safety, logistics, maintenance, and so on. The design review extends over all phases of product development, from conception to production. In each phase, previous work is updated, and the review is based on current information.

A mature design requires trade-offs between many conflicting factors, such as performance, manufacturability, reliability, and maintainability. These trade-offs depend heavily on experienced judgment and require continuous communication among experienced reviewers. The design review committee approach has been found to be extremely beneficial to this process. The committee adopts the system's point of view and considers all conceivable phases of design and system use to ensure that the best trade-offs have been made for the particular situation.

A complete design review procedure must be multiphased in order to follow the design cycle until the system is released for production. A typical example of a review committee, including personnel and their responsibilities, is shown in Table 1. Here the review process has been subdivided into three phases, and each phase is an update of more detailed analysis based on the latest knowledge.

Ultimately the design engineer has the responsibility for investigating and incorporating the ideas and suggestions posed by the design review committee. The committee's chairperson is responsible for adequately reporting all suggestions by way of a formal and documented summary. The design engineer then can accept or reject various points in the summary; however, he or she must formally report back to the committee, stating reasons for his or her actions.

It should be recognized that considerably more thought and detail than the basic philosophy presented here must go into developing the management structure and procedures for conduct in order to have a successful review procedure. It should be noted that this review procedure considers not only reliability, but all important factors in order to ensure that a mature design will result from the design effort.

In the next subsection, attention is focused on a technique that has been proven effective in identifying failure situations early in the design cycle and before product testing.

TABLE 1 Design Review Committee

	Review Phase			
Member	1	2	3	Responsibility
Chairperson	x	x	x	Ensure that review is conducted in an efficient fashion. Issue major reports and monitor follow-up.
Customer and/or marketing representative	x	x	x	Ensure that the customer's viewpoint is adequately presented (especially at the design trade-off stage)
Design engineer (of this product)	x	x	x	Prepare and present initial design with calculations and supporting data.
Design engineer (not of this product)	x	x	x	Review and verify adequacy of design.
Reliability engineer	x	x	x	Evaluate design for maximum reliability consistent with system goals.
Manufacturing engineer		x	x	Ensure manufacturability at reasonable cost. Check for tooling adequacy and assembly problems.
Materials engineer		x		Ensure optimum material usage considering application and environment.
Stress analyst		x		Review and verify stress calculations.
Quality control engineer		x	x	Review tolerancing problems, manufacturing capability, inspection strategies, and testing problems.
Human factors engineer		x		Ensure adequate consideration to human operator, identification of potential human-induced problems.
Safety engineer		x		Ensure safety to operating and auxiliary personnel.
Maintainability engineer		x	x	Analyze for ease of maintenance repair and field servicing problems.
Logistics engineer		x	x	Evaluate and specify logistic support. Identify logistics problems.

6.2. Failure Mode and Effects Analysis

Failure mode and effects analysis is a design-evaluation procedure used to identify all conceivable and potential failure modes and determine the effect of each failure mode on system performance. This procedure is accomplished by formal documentation, which serves (1) to standardize the procedure, (2) as a means of historical documentation, and (3) as a basis for future improvement.

The procedure consists of a sequence of logical steps, starting with the analysis of lower-level subsystems or components. The analysis assumes a failure point of view and identifies all potential modes of failure along with the causative agent, termed the ''failure mechanism.'' The effect of each failure mode is then traced up to the systems level (MIL-STD-1969 1974).

A criticality rating is developed for each failure mode and resulting effect. The rating is based on the probability of occurrence, severity, and detectability. For failures scoring high on this rating, design changes to reduce criticality are recommended. This procedure is aimed at providing a better design from a reliability standpoint.

6.3. Probabilistic Approach to Design

Reliability is basically a design parameter and has to be incorporated in the system at the design stage. One way to quantify reliability during design and design for reliability is the probabilistic approach to design (Kececioglu and Cormier 1968; Kececioglu 1991, 1995; Haugen 1968). The design variables and parameters are random variables, and hence the design methodology must consider them as random variables. The reliability of any system is a function of the reliabilities of its components. To analyze the reliability of the system, we first have to understand how to compute the reliabilities of the components. The basic idea in reliability analysis from the probabilistic design methodology viewpoint is that a given component has certain strength that, if exceeded, will result in the failure of the component. The factors that determine the strength of the component are random variables, as are the factors that determine the stresses or loading acting on the component. ''Stress'' is used to indicate any agency that tends to induce failure, whereas ''strength'' indicates any agency resisting failure. ''Failure'' is taken to mean failure to function as intended; it occurs when the actual stress exceeds the actual strength for the first time.

Let $f(x)$ and $g(y)$ be the probability density functions for the stress random variable X and the strength random variable Y, respectively, for a certain mode of failure. Also, let $F(x)$ and $G(y)$ be the cumulative distribution functions for the random variables X and Y, respectively. Then the reliability R of the component for the failure mode under consideration, with the assumption that the stress and the strength are independent random variables, is given by

$$R = P\{Y > X\} \tag{51}$$

$$= \int_{-\infty}^{\infty} g(y) \left\{ \int_{-\infty}^{y} f(x)dx \right\} dy \tag{52}$$

$$= \int_{-\infty}^{\infty} g(y)F(y)dy \tag{53}$$

$$= \int_{-\infty}^{\infty} f(x) \left\{ \int_{x}^{\infty} g(y)dy \right\} dx \tag{54}$$

$$= \int_{-\infty}^{\infty} f(x)\{1 - G(x)\{dx \tag{55}$$

For example, suppose that the stress random variable X is normally distributed with mean value of μ_x, and standard deviation (SD) of σ_x, and that the strength random variable Y is also normally distributed with parameters μ_y and σ_y. The reliability R is then given by

$$R = \Phi\left(\frac{\mu_y - \mu_x}{\sqrt{\sigma_y^2 + \sigma_x^2}} \right) \tag{56}$$

where $\Phi(z)$ is the cumulative distribution function for the standard normal variate Z.

The reliability computations for other distributions, such as exponential, lognormal, gamma, Weibull, and extreme value distributions, have also been developed (Kapur and Lamberson 1977). In addition, the reliability analysis has been generalized when the stress and strength variables follow a known stochastic process. The references cited in this subsection also contain simple design examples illustrating the use of the probabilistic approach to design.

7. HUMAN FACTORS IN RELIABILITY

All systems are of, by, and for humans. Human factors therefore become actively important in the system design process and consequently must be weighed against safety, reliability, maintainability, and other system parameters in order to obtain trade-offs to increase system effectiveness. Human interaction with the system of interest consists of:

1. Design and production of systems
2. Operators and repairers of systems
3. Operators and repairers as decision elements

Man–machine interface consists of such aspects as allocation of functions (man vs. machine), automation, accessibility, human tasks, stress characteristics, information presented to the human, and the reliability of interfaces coupled with the decisions on the basis of such information. Both human and machine elements of a system can fail, and their failures have varying effects on the system's performance. Some human errors cause total system failure or increase the risk of such failure. Human factors exert a strong influence on the design and ultimate reliability of a system (Kirwan 1994).

Both reliability and human factors are concerned with predicting, measuring, and improving system effectiveness. When the man–machine interface is complex, the possibility of human error increases, which results in an increase in the probability of system failure. An interesting facet of the human factors–reliability–maintainability relationship is that the system's reliability–maintainability depends on the detection and correction of system malfunctions. This task is generally performed by humans. Thus, the system performance can be enhanced or degraded depending on the human response. The quantification of human reliability characteristics and the development of a methodology for quantifying human performance, error prediction, control, and measurement are given in many sources (Gertman and Blackman 1994; Meister 1996).

Reliability of a system is affected by the allocation of system functions to man, machine, or both. Characteristics tending to favor humans are:

1. Ability to detect certain forms of energy
2. Sensitivity to a wide variety of stimuli within a restricted range
3. Ability to detect signals and patterns in high-noise environments
4. Ability to store large amounts of information for long periods and remember relevant facts
5. Ability to profit from experience
6. Ability to use judgment
7. Ability to improvise and adopt flexible procedures
8. Ability to arrive at new and completely different solutions to problems
9. Ability to handle low-probability or unexpected events
10. Ability to perform fine manipulations
11. Ability to reason instinctively

Characteristics tending to favor machines are:

1. Computing ability
2. Performance of routine, repetitive, and precise tasks
3. Quick response to control signals
4. Ability to exert large amounts of force smoothly and precisely
5. Ability to store and recall large amounts of data for short periods
6. Ability to reason deductively
7. Insensitivity to extraneous factors
8. Ability to handle highly complex operations that involve doing several things at once

8. RELIABILITY MEASUREMENT

Reliability measurement techniques provide a common discipline that can be used to measure, predict, and evaluate system reliability throughout the system life cycles. The two major components of the reliability measurement system are the test program and the data system. Test programs have to be developed throughout the life cycle, and the test effort has to ensure that the reliability goals are met at different stages in the cycle. Procedures for gathering the data generated throughout all the phases

must be documented in sufficient detail for complete identification and integration into the data-processing system.

8.1. Test Programs

Figure 7 shows a sequence of different types of tests that may be used throughout the life cycle, consisting of design, development, production, and service/field use phases. Brief descriptions of these tests follow.

8.1.1. Design Support Tests

These tests are used to determine the need for parts, materials, and component evaluation or qualification to meet system performance and other reliability design criteria. Some of the objectives are:

Parts application data
Parts evaluation
Parts qualification
Parts comparative evaluation
Vendor control

8.1.2. Design-Verification Tests

These tests are used to verify the functional adequacy of design and to corroborate preliminary predictions and failure mode and effects analysis that disclose high-risk areas and reliability problems in the proposed design. Design-verification tests fulfill the following essential design phase functions:

Analytical verification
Functional evaluation
Parts and materials definition
Preliminary reliability verification

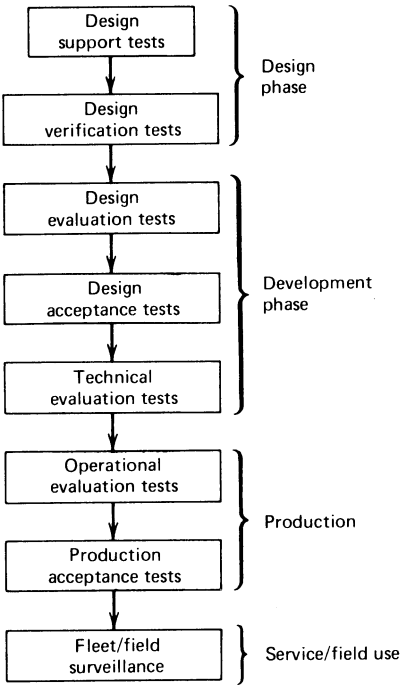

Figure 7 Integrated Test Flow Diagram.

8.1.3. Design-Evaluation Tests

These tests are used to evaluate the design under environmental conditions, verify the compatibility of subsystem interfaces, and review the design from the maintainability point of view. Some of the tests under this category are:

Environmental (evaluation tests)
Longevity (failure rates) tests
Operability tests
Engineering change-evaluation tests

8.1.4. Design-Acceptance Tests

These tests are used to demonstrate that design meets required levels of reliability. Thus, a reliability demonstration test is considered mandatory for design acceptance. Definitions of test requirements are:

1. Define acceptable levels of reliability and decision risks (type 1 and type 2 errors, confidence limits).
2. Define test conditions.
3. Define the specific test plan:
   (a) MTBF tests
   (b) Mission reliability test
   (c) Availability tests
4. Define ''failure'' and scoring criteria:
   (a) System failures
   (b) Mission failures
   (c) Maintenance actions (chargeable, nonchargeable)
   (d) Criticality factors
5. Determine sample size.

8.1.5. Technical Evaluation Tests

These tests are used to evaluate the technical suitability of a prototype or a preproduction model. It is sometimes practical to integrate technical evaluation with operational evaluation when the earlier design-acceptance test demonstrates complete conformance.

8.1.6. Operational Evaluation Tests

These tests are used to evaluate operational suitability of the production model.

8.1.7. Production Acceptance Tests

These tests are used to determine the acceptability of individual production items in order to ensure production control and critical interfaces, parts, and material quality. Manufacturing operations that result in significant reliability degradation should be carefully studied.

8.1.8. Fleet/Field Surveillance Tests

These tests and evaluation programs during the field use of the product are for the continuing assessment of reliability and quality.

8.1.9. Test Procedures

Any test procedure must consider the following factors:

1. Purpose of test
2. Test items—description and sample selection
3. Test monitoring and review procedures
4. Test equipment requirements
5. Test equipment-calibration procedures
6. Test equipment proofing
7. Environmental conditions to be applied

8. Operating conditions
9. Test-point identification
10. Definition of failures and scoring criteria
11. Procedure for conducting tests
12. Test report procedures and documents

8.2. Reliability Estimation

Reliability measurement tests are used to make estimates of the reliability of a system or a population of items. Parametric and nonparametric estimates are used. Parametric estimates are based on a known or assumed distribution of the system characteristic of interest. The parameters are the constants that describe the shape of the distribution. Nonparametric estimates are used without assuming the nature of the underlying probability distribution. Generally, nonparametric estimates are not as efficient as parametric estimates. Nonparametric reliability estimates apply only to a specific test interval and cannot be extrapolated. Parametric estimates are described in this section when the underlying distribution is exponential and Weibull. The three types of parametric estimates that are frequently used are:

1. Point estimate: a single-valued estimate of a reliability measure
2. Interval estimate: an estimate of an interval that is believed to contain the true value of the parameter
3. Distribution estimate: an estimate of the parameters of a reliability distribution

8.2.1. Reliability Estimation: Exponential Distribution

The two types of test procedures considered here are:

1. Type 1 censored test: The items are tested for a specified time T, and then the testing is stopped.
2. Type 2 censored test: The test time is not specified, but the testing is stopped when a desired number of items fail.

Let us consider the situation when n items are placed on test and the test is stopped as soon as r failures are observed ($r \leq n$). This is type 2 censoring with nonreplacement of items. Let the observed failure times be, in order of magnitude,

$$0 = t_0 < t_1 < t_2 < \ldots < t_{r-1} < t_r \tag{57}$$

Then, making the transformation,

$$u_i = \begin{cases} nt_i & i = 0 \\ (n - i)(t_{i-1} - t_i) & i = 1, 2, \ldots, r - 1 \end{cases} \tag{58}$$

it is well known that the (u_i, $i = 0, \ldots, r - 1$) are independently and identically distributed with common density function

$$\left(\frac{1}{\theta}\right) e^{-u/\theta}$$

It is clear that the total time on test is given by

$$\begin{aligned} V(t_r) &= \text{total time on test} \\ &= \sum_{i=0}^{r-1} u_i \\ &= \sum_{i=1}^{r} t_i + (n - r)t_r \end{aligned} \tag{59}$$

Then

$$\hat{\theta} = \frac{V(t_r)}{r} = \frac{1}{r}\left[\sum_{i=1}^{r} t_i + (n - r)t_r\right] \tag{60}$$

is the minimum variance unbiased estimator of θ. Since $V(t_r) = \Sigma_{i=0}^{r-1} u_i$ and the $\{u_i\}$ are independently distributed with a common exponential density function, it follows that $V(t_r)$ has a gamma distribution with parameters (θ, r). Hence $2V(t_r)/\theta = 2\hat{\theta}r/\theta$ is distributed as χ^2_{2r}.

The $100(1 - \alpha)\%$ confidence limits on θ are given by (Bane and Engelhardt 1991; Kececioglu 1993; Kapur and Lamberson 1977):

$$P\left[\chi^2_{1-(\alpha/2),2r} \leq \frac{2\hat{\theta}r}{\theta} < \chi^2_{\alpha/2,2r}\right] = 1 - \alpha$$

or

$$\frac{2\hat{\theta}r}{\chi^2_{\alpha/2,2r}} \leq \theta \leq \frac{2\hat{\theta}r}{\chi^2_{1-(\alpha/2),2r}} \tag{61}$$

The life-testing procedures are often used in a quality control context in which we wish to detect the deviations of θ below some desired levels, say, θ_0. Then for a significance level of α, the probability of accepting H_0 is

$$P_a = P\left(\frac{2r\hat{\theta}}{\theta_0} \leq \chi^2_{\alpha,2r} | \theta = \theta_0\right) = 1 - \alpha \tag{62}$$

The expected time to complete the test is given by

$$E(t_r) = \theta \sum_{i=1}^{r} \frac{1}{n - i + 1} \tag{63}$$

Let

θ_0 = desired reliability goal for MTBF

$1 - \alpha$ = probability of accepting items with true MTBF of θ_o

θ_1 = alternative MTBF ($\theta_1 < \theta_0$)

β = probability of accepting items with true MTBF of θ_1

With this information, reliability testing consists of putting n items on test and stopping the test when the number of failures is given by the smallest integer satisfying

$$\frac{\theta_1}{\theta_0} \leq \frac{\chi^2_{\alpha,2r}}{\chi^2_{1-\beta,2r}} \tag{64}$$

Thus, when we know θ_0, θ_1, α, and β, we can compute the necessary value for r.

For the type 1 censored test, where r failures are observed on an interval of total test time T, the $100(1 - \alpha)\%$ confidence limits on θ are given by [a modification of Eq. (61)]

$$\frac{2T}{\chi^2_{\alpha/2,2(r+1)}} \leq \theta \leq \frac{2T}{\chi^2_{1-(\alpha/2),2r}} \tag{65}$$

8.2.2. Reliability Estimation: Weibull Distribution

Weibull distribution (Weibull 1961) is probably one of the most widely used distributions in life-testing applications. One of the reasons is the ease with which graphic procedures can be used to estimate the parameters of the Weibull distribution and thus the reliability of the product. Confidence limits can also be easily developed. In addition, various statistical estimation procedures have recently been developed, and these can also be easily used by reliability engineers (Nelson 1990; Abernethy 1996; Kapur and Lamberson 1977).

The density function for the Weibull time to failure random variable is given by [see Eq. (27)]

$$f(t) = \frac{\beta(t - \delta)^{\beta-1}}{(\theta - \delta)^{\beta}} \exp\left[-\left(\frac{t - \delta}{\theta - \delta}\right)^{\beta}\right] t \geq \delta > 0 \tag{66}$$

where

β = shape parameter or the Weibull slope, $\beta > 0$
θ = scale parameter or the characteristic life
δ = location parameter or the minimum life

If the minimum life $\delta = 0$, the cumulative distribution is given by

$$F(t) = 1 - \exp\left[-\left(\frac{t}{\theta}\right)^{\beta}\right] \tag{67}$$

After rearranging and talking twice the natural logarithm, we have

$$\ln\left[\ln\frac{1}{1 - F(t)}\right] = \beta \ln t - \beta \ln \theta$$

or

$$\ln t = \frac{1}{\beta} \ln\left[\ln\frac{1}{1 - F(t)}\right] + \ln \theta \tag{68}$$

Weibull graph paper is constructed by plotting $\ln t$ as the horizontal axis vs. $\ln\{\ln(1/[1 - F(t)]\}$ as the vertical axis, and then β is the slope of the straight-line plot. Figure 8 shows such Weibull paper. Various plotting procedures as well as statistical estimation methods with tables are available (Mann et al. 1974). Mann et al. offer point and interval estimation procedures for various other distributions and also tables that can be used for statistical estimation of the parameters of the Weibull distribution. This source is also a good reference for testing reliability hypothesis. The statistical methods discussed in this section can also be applied for accelerated life testing, which consists of a variety of test methods for shortening the life of products or hastening degradation of their performance (Nelson 1990). The aim of such testing is to obtain data quickly that, properly modeled and analyzed, give the proper information on product life under normal operating conditions by the customer.

9. MAINTAINABILITY

Maintainability is one of the system design parameters that has a great impact on the effectiveness of the system (Kececioglu 1995). Failures will occur no matter how reliable a system is made to be. A system's ability to be maintained, that is, retained in or restored to effective usable condition, is often as important to system effectiveness as is its reliability. Maintainability is a characteristic of the system and its design just like reliability. It is concerned with such system attributes as accessibility to failed parts, diagnosis of failures, repairs, test points, test equipment and tools, maintenance manuals, displays, and safety. Maintainability may be defined as a characteristic of design and installation that imparts to a system a great inherent ability to be maintained, so as to lower the required maintenance person-hours, skill levels, tools, test equipment, facilities, and logistics costs and thus achieve greater availability.

9.1. Maintainability Measures

Maintainability is the probability that a system in need of maintenance will be retained in or restored to a specified operational condition within a given period. Thus, the underlying random variable is the maintenance time. Let T be the repair time random variable. Then the maintainability function $M(t)$ is given by

$$M(t) = P[T \leq t] \tag{69}$$

If the repair time T follows the exponential distribution with mean time to repair, MTTR, of $1/\mu$, where μ is the repair rate, then

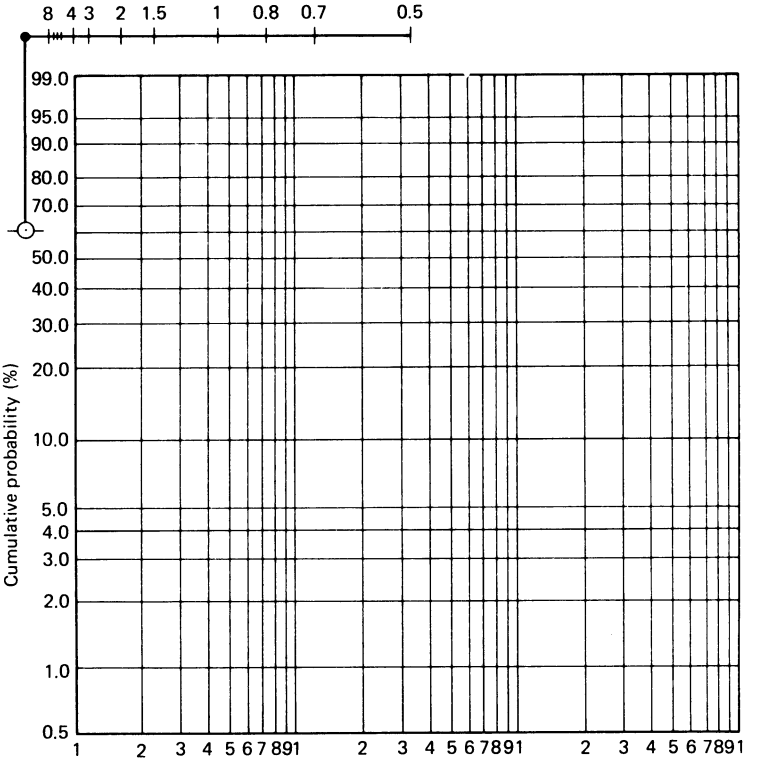

Figure 8 Weibull Probability Paper.

$$M(t) = 1 - \exp\left(-\frac{t}{\text{MTTR}}\right) \tag{70}$$

Various other distributions, such as lognormal, Weibull, and normal, are used to model the repair time. In addition, other time-related indices, such as median (50th percentile) and M_{MAX} (90th or 95th percentile), are used as maintainability measures. The lognormal probability density functions with an MTTR of 15 min, but with different values for SD, are given in Figure 9(*a*), whereas the associated maintainability functions are shown in Figure 9(*b*). From the maintainability function plot, different percentiles, such as the 90th, can be easily read. In other instances, the maintenance person-hours per system operating hours or maintenance ratio MR may be specified and maintainability design goals then derived from such specifications.

The MTTR, which is the mean of the distribution of system repair time, may be evaluated by

$$\text{MTTR} = \frac{\sum_{i=1}^{n} \lambda_i t_i}{\sum_{i=1}^{n} \lambda_i} \tag{71}$$

where n = number of components in the system
λ_i = failure rate of ith repairable component
t_i = time required to repair the system when the ith component fails

In addition, other measures, such as mean active corrective maintenance time and mean active preventive maintenance time, are used to measure maintainability. Some of the components of the corrective maintenance tasks are:

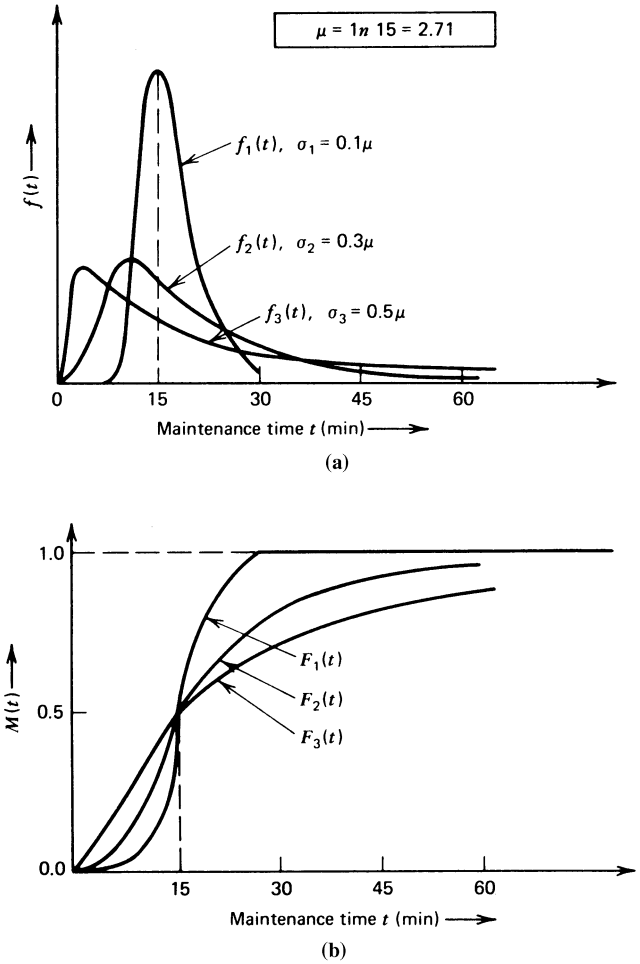

Figure 9 (*a*) Lognormal Probability Density Functions. (*b*) Maintainability Function $M(t)$ Based on Lognormal Distribution with median equal to 15 min.

Localization: determining the location of a failure to the extent possible, without using accessory equipment

Isolation: determining the location of a failure by the use of accessory test equipment

Disassembly: disassembling the equipment to gain access to the item being replaced

Interchange: removing the failed item and installing the replacement

Alignment: performing any alignment, testing, and adjustment made necessary by the repair action

Checkout: performing checks or tests or verify that the equipment has been restored to a satisfactory operating condition

As an example of MTTR computation, assume that a communication system consists of five assemblies, with the data given in Table 2. Column 2 gives the number of units n_i for assembly i. Column 3 indicates the failure rate per thousand hours for each unit. Thus, column 4 gives us the total failure rate for an assembly i. Column 5 gives the average time to perform all the maintenance actions discussed previously. Then, MTTR is given by

$$\text{MTTR} = \frac{\sum n_i \lambda_i t_i}{\sum n_i \lambda_i} = \frac{63.5}{161} = 0.394 \text{ hr} \tag{72}$$

TABLE 2 Worksheet for MTTR Prediction

Assemblies	n_I	λ_i ($\times 10^3$)	$n_i\lambda_i$ ($\times 10^3$)	t_i (hr)	Repair Time per 10^3 hr ($n_i\lambda_i\ t_i$)
1	4	10	40	0.10	4.0
2	6	5	30	0.20	6.0
3	2	8	16	1.00	16.0
4	1	15	15	0.50	7.5
5	5	12	60	0.50	30.0
			$\Sigma = 161$		$\Sigma = 63.5$

10. AVAILABILITY

Availability is the vehicle that translates measures of reliability and maintainability into a combined index of effectiveness for a system. It is based on the question ''Is the equipment available in a working condition when it is needed?'' Availability analysis can be used for trading between and establish requirements for reliability and maintainability.

10.1. Availability Measures

By its very nature, availability measures are time related. The breakdown of total time upon which the availability analyses are based was briefly described earlier in this chapter. The time elements are:

1. Storage, free, and off time
2. Operating time
3. Standby time—availability for operations
4. Downtime, which consists of corrective and preventive maintenance and is also due to administrative and logistics delays

Measures for operational readiness are based on all the time elements. However, the availability measures do not consider the off time, including storage and free time. Achieved availability (A_a) is used for development and initial production testing where the system is not operating in its intended operational environment and is equal to operating test time divided by operating test time plus total preventive and corrective maintenance time (clock time). Excluded are operator before-and-after operating checks and supply, administration, and waiting time. Standby time is excluded both by definition and by environment. Thus,

$$A_a = \frac{\text{OT}}{\text{OT} + \text{TPM} + \text{TCM}} \tag{73}$$

where OT = operating time
TPM = total preventive maintenance time
TCM = total corrective maintenance time

Operational availability (A_o) covers all segments of the time that the system should be operative. Thus, we must consider standby time (ST) as well as administrative and logistics delay time (ALDT). Hence,

$$A_o = \frac{\text{OT} + \text{ST}}{\text{OT} + \text{ST} + \text{TPM} + \text{TCM} + \text{ALDT}} \tag{74}$$

Sometimes there is a need to define the availability with respect to operating time and corrective maintenance when the system is operating in an ideal support environment. This form of availability, called inherent availability (A_I), is useful for determining certain figures of merit for the system per se, such as frequency and type of failure occurrence, repairability (active repair time), and analysis of maintenance actions. Thus, A_I is given by

$$A_I = \frac{\text{MTBF}}{\text{MTBF} + \text{MTTR}} \tag{75}$$

Standby time, delay times associated with scheduled or preventive maintenance, and administrative and logistics downtime are excluded.

10.2. Reliability–Maintainability–Availability Trade-Off

The system availability A_I, is a function of variables of reliability (MTBF) and maintainability (MTTR) as given by Eq. (75). Since MTBF = $1/\lambda$ where λ is the failure rate and MTTR = $1/\mu$ where μ is the repair rate (both valid when the underlying distribution is exponential), Eq. (75) may be rewritten as

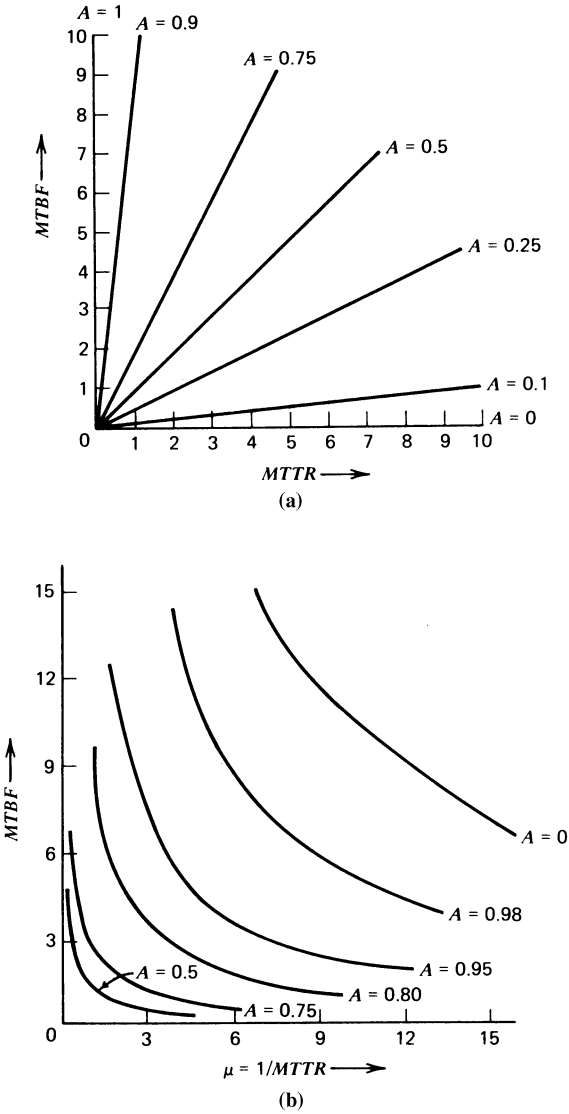

Figure 10 (*a*) Availability (*A*) as a Function of MTBF and MTTR. (*b*) Availability as a function of MTBF and Repair Rate.

$$A_I = A = \frac{\mu}{\mu + \lambda} \tag{76}$$

A generalized plot of Eq. (75) is given in Figure 10(*a*). This shows that to optimize availability, it is desirable to make the ratio of MTBF to MTTR as high as possible. Since increasing MTBF and decreasing MTTR is desirable, the equation for availability is plotted in terms of MTBF and $\mu = 1/\text{MTTR}$, as shown in Figure 10(*b*). Each of the curves representing the same availability is called an isoavailability contour; corresponding values of MTBF and MTTR give the same value of A, all other things being equal. Based on various physical, technological, and economic constraints, trade-off optimization models can be developed. There are practical limits as to how high a value for MTBF can be achieved or how low MTTR can be made. Increasing MTBF may require the redundancy level to be so high that the desired reliability could not be realistically achieved within the state of the art or else the cost would be high. Low values for MTTR would require excellent maintainability design features, such as complete built-in test features, automatic fault isolation, and automatic switchover from a failed to a standby item.

11. RELIABILITY GROWTH

As the product goes through the various steps in the life cycle, its reliability should be estimated and predicted. These values, when plotted at selected points in the life cycle, result in a growth curve, as shown in Figure 11, that reflects the comparative levels of reliability.

Reliability growth represents the effort spent to achieve the reliability potential either during design and development or during production or subsequently during field and operational use. During early development the achieved reliability of a prototype is much lower than its predicted reliability because of initial design and engineering deficiencies as well as manufacturing flaws. Also, the reliability of a fielded system is much lower than its inherent or potential reliability predicted during design and development for the following reasons:

1. Reliability degradation due to manufacturing, assembly, and quality control errors as well as to ineffectiveness of some of the screening tests.
2. Reliability degradation due to interaction of man, machine, and environment. Degradation may be due to rough handling, extended duty cycles, or neglected maintenance.
3. There is degradation due to maintenance activities because excessive handling brought about by frequent preventive maintenance or poor maintenance practices reduces reliability.

However, during all phases there is also reliability growth due to the underlying learning process. There is reliability growth during design and development as a result of an iterative design process. The essential elements involved in achieving reliability growth are:

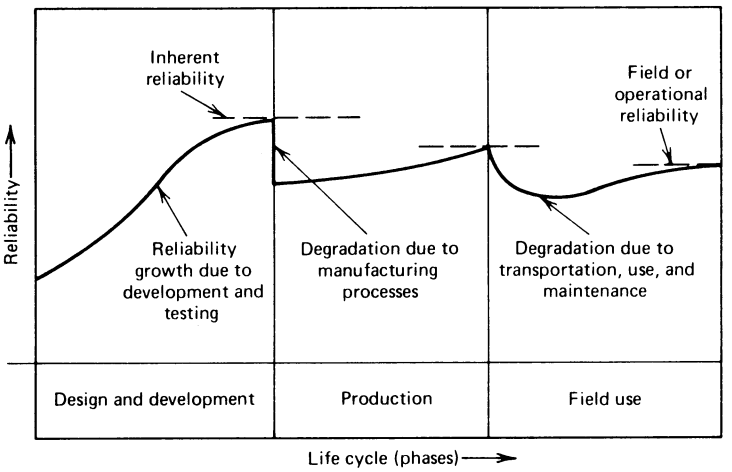

Figure 11 Reliability Growth and Degradation During System Life.

1. Detection of failure sources
2. Feedback of problems identified
3. Redesign effort based on problems identified that will potentially be corrected

If the failure sources are detected by testing, then we have the following:

4. Manufacturing or fabrication of prototype hardware.
5. Redesign, detection, and analysis of failure sources serve as verification of redesign effort.

Some of the benefits of reliability growth methodology are:

1. It enables us to take advantage of experience gained in similar programs in the past.
2. It enables us to evaluate better the progress being made by an ongoing program.
3. It enables us to evaluate possible courses of corrective actions if an ongoing program experiences problems.

11.1 Reliability Growth Models

In 1964, Duane of GE (Duane 1964) published a report describing his observations on failure data for five different types of systems during their development programs at GE. His analysis revealed that for these systems the observed cumulative failure rate followed a consistent pattern, approximately a straight line, when plotted on a log–log paper as a function of cumulative test hours. This can be expressed mathematically as

$$\Lambda(t) = kt^{-\beta} \tag{77}$$

where $\Lambda(t)$ = cumulative failure rate at time t
t = cumulative test time
k = a constant ($k > 0$)
β = growth factor ($\beta > 0$)

Let $N(t)$ be the total number of failures accumulated over the cumulative test time t. Then

$$\Lambda(t) = \frac{N(t)}{t} \tag{78}$$

Thus, the cumulative failure rate $\Lambda(t)$ will decrease as reliability grows as a result of the development of corrective effort because fewer failures will be observed. If we take logarithms of both sides of Eq. (77), we have

$$\log \Lambda(t) = \log k - \beta \log t \tag{79}$$

The value of constant k depends on system complexity, design margins, and design objectives for reliability, whereas the value of growth factor β depends on the development effort

Substituting Eq. (78) in Eq (77), we have

$$N(t) = kt^{1-\beta} \tag{80}$$

$$= kt^{\beta'} \qquad (\beta' = 1 - \beta) \tag{81}$$

Talking the logarithm of both sides of Eq. (81), we have

$$\log N(t) = \log k + \beta' \log t \tag{82}$$

Thus, if we plot the cumulative number of failures with respect to cumulative test time t on a log–log paper, we get a straight line with slope β'. It is clear from Eq. (77) that the higher the value of β, the more growth the system has.

The actual failure rate of the system if the design is released after test time t is given by

$$\lambda(t) = \frac{dN(t)}{dt} = k(1 - \beta)t^{-\beta} \tag{83}$$

Thus, if we are given some goal for failure rate $\lambda(t)$, we can compute the total test time required during the development effort using Eq. (83).

12. DESIGN AND MANAGEMENT OF RELIABILITY PROGRAMS

The establishment of an effective product assurance program throughout the system life cycle requires a management with exceptional perception of the assurance sciences. This is because of the many conflicting factors involved when making decisions on the delegation or redistribution of responsibility and authority and also because reliability is at best a poorly understood discipline without a universal approach that applies to every product and every organization. A reliability program extends far beyond the estimation of reliability numbers: it must create an attitude of anticipation of reliability problems and initiate the preplanning necessary to eliminate or reduce the effects of unreliability to an acceptable and planned-for level. Because of the breadth of the subject, a product assurance program must span the total system life cycle; therefore, the program will infringe on several well-established technical management groups, such as design, testing, purchasing, quality control, manufacturing, sales, and service groups.

Unreliability is actually not the result of any one group but is due to the complexity of today's systems and of the organization required to create these systems. During system design, development, and production, anything that can contribute to unreliability should be identified and reviewed. A reliability-management structure must be created to accomplish this task. The question then is, "Who should do this?" In a "perfect" organization with complete flow of information, the unreliability problems might be taken care of by existing groups. However, such an organization rarely exists in practice; thus, over the years many organizations have found it necessary and advantageous to spend the extra effort to create a reliability group and integrate this group into the existing organization. The reliability group performs essentially an assurance function, facilitating and supporting the design and development process from a reliability point of view.

The establishment and maintenance of a viable reliability program must be done based on management foresight and intuition since the payback is not readily measured in dollars. Unreliability problems uncovered by a reliability group tend to be taken care of outside of the formal organizational communication channels and in general will be attributed to design engineering. Forcing a reliability group to point up all unreliability problems will mean that management is forcing it into a position of accusation, and this will create an intractable climate that may well hinder the product development cycle and the reliability improvement effort. Thus, it is very important to understand the role and the function of the reliability group in the total organization.

12.1. Elements of a Reliability Program

Management and control of system reliability must be based on a recognition of the system's life cycle, beginning at concept and extending through design, production, use, and discarding of the system. One of the objectives is to achieve acceptable levels of operational reliability and maintainability. Achievement of this objective requires numerous tasks. The activities of a reliability program have applications throughout the system life cycle. Some of these applications are: as follows:

Applications during design

Develop safety margins from reliability viewpoint.

Predict component reliability from the data bank of the failure rates.

Compute system reliability from component reliability.

Determine amount of redundancy needed to achieve a reliability goal.

Provide input to human engineering.

Interact with value engineering.

Evaluate design changes.

Perform trade-off analysis.

Compare two or more designs.

Provide guidelines for design review.

Work with cost-reduction programs.

Applications during development of testing

Establish reliability growth curves for the development and testing phase.

Develop guidelines for the amount of testing.

Develop bathtub curve based on the failure rate data and the test data.

Participate in the development of failure definition and scoring criteria document.

Participate in the scoring of the test failures.

Applications during manufacturing

Provide guidelines for manufacturing processes.

Provide input to quality control.

Provide input for guidelines to evaluate the suppliers and vendors.

Develop product burn-in or debugging time.

Applications during Field Use

Establish warranty cost and help reduce it.

Optimize the length of warranty.

Reduce inventory costs.

Develop maintenance procedures, both corrective and preventive.

Provide input to the spare parts-allocation models.

Participate in the collection and analysis of the field data.

Participate in the feedback process to report and correct the field failures.

The reliability group coordinates and directs the overall reliability effort to provide assurance that the optimum reliability has been achieved and that the consequences of unreliability have been considered in the overall plans. Obviously, the reliability group can be effective only if given proper authority, demanding formal sign-off during all critical stages of system development

An acceptable reliability level for a system is really a many-faceted problem that requires many complex trade-offs. Considerations in design, cost, and manufacturability, material availability, maintenance, and serviceability all enter into this problem. For example, a highly reliable design that cannot be manufactured effectively or cannot be maintained may represent an unacceptable situation from the total system point of view. The important thing is to plan for adequate overall system effectiveness, utilizing good knowledge on the actual reliability level of the system.

CHAPTER 73
Service Quality

LAURA RAIMAN DUPONT
Quality Engineering Consultant

1. DEFINING SERVICE QUALITY

Service quality is hard to define, hard to achieve, but easy to identify when missing. Service encounters happen every day when customers come into contact with an organization, its people, its communications, and the services it provides. These service encounters have been termed the "moment of truth" by Jan Carlzon, CEO of Scandinavian Airlines System (SAS)—the moment at which the representatives of the service provider must prove to their customers that their organization is the best alternative (Carlzon 1987). In order to become a leader in service quality, an organization must adopt a multidimensional perspective to managing service encounters. It must be effective at both designing and delivering services. In other words, an organization must do what the customer wants, and do it the right way. Accomplishing this requires an organization to implement effective approaches in five key areas: service strategy; service-driven leadership; service-driven workforce; systems for service delivery; and measurement and evaluation of service quality. When approaches in these areas are integrated together into an overall template for managing service quality, the result is an organization with a new, customer-oriented culture.

Although specific approaches and methods used in these five areas may differ widely between organizations, there is a vehicle that provides the framework for defining service quality and for guiding an organization in selecting and implementing approaches for managing service quality. That framework is the Baldrige National Quality Program *Criteria for Performance Excellence* (2000). The Baldrige Award was designed to publicize and promote successful quality strategies as a result of the Malcolm Baldrige National Quality Improvement Act of 1987. The Baldrige criteria are designed to help organizations enhance their performance through a focus on two results-oriented goals: delivery of ever-improving value to customers, resulting in marketplace success; and improvement of overall organizational effectiveness and capabilities. For over 12 years, the Baldrige Criteria have been used successfully by all types of organizations to assess and evaluate their operations. Explicit and well-articulated core values and concepts form the foundation of the criteria. The focus on values recognizes the different paths organizations may take to attain performance excellence. The Baldrige criteria provide an organization with a systems perspective for managing operations and for achieving performance excellence.

The Baldrige criteria are presented in seven categories, which are each subdivided into several items (Table 1). The remainder of this chapter describes key approaches in five global areas of service

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.

   7.5. Organizational effectiveness results

quality. Where there are very clear linkages to the Baldrige criteria, such as in the area of systems for service delivery, the criteria are presented to clarify best practice. In other cases, the criteria will just be referenced. The intent of drawing the Baldrige criteria into the discussion of service quality is not only to provide key ideas and approaches, but also to demonstrate the value of the Baldrige criteria in setting up an integrated approach for addressing service quality, and ultimately performance excellence.

2. CREATING A SERVICE STRATEGY

Service quality happens when an organization has employees who are committed to quality in their own work and are willing to go out of their way to deliver that high level of quality to customers. This will only happen when there is a well-developed service strategy that defines an organization's shared values and organizes all of the other elements of service.

The key step in developing a service strategy involves segmenting customers according to their service expectations. Within each market an organization tries to reach, there are different segments. All of these segments most likely have common core needs and expectations, but once customer segments are defined, an organization can find out exactly what the expectations are for each segment. This allows the organization to develop a service concept that provides it with a competitive advantage in the eyes of its customers. In other words, while an organization is providing a good core service, it may cater to each particular segment in order to differentiate itself from competitors in the eyes of those customers.

The identification of service differentiators can help an organization position itself as a leader. This requires all customer contact points to be carefully analyzed, particularly relative to each key customer segment. For each customer contact point, the organization must analyze what it does right or wrong and compare this to what customers want, need, and expect. It must also analyze what competitors provide and do not provide. Identifying service differentiators for customer segments also allows an organization to identify what employees play a role in each portion of the service-delivery process. This allows salespeople, administrators, production staff, and other employees to adapt their style, behavior, or environment to each key segment.

The right service strategy for a given organization is defined to an even greater extent by considering the strengths of key competitors, the guiding principles and values of the organization, and the organization's market. An effective service strategy provides a concept of service for an organization

to rally around and allows leaders to identify conflicts between corporate strategy and customer service. It also allows the organization to design effective ways to measure service performance and service quality, as discussed later. The service strategy also provides an effective means for leadership to choose the optimum mix and level of service for different customer segments.

3. CREATING SERVICE-DRIVEN LEADERSHIP

Strong, effective leadership turns a service strategy into an everyday reality. While a service strategy provides the overall strategy for dealing with customers, customer-contact employees typically must exercise broad discretion when serving customers. Although the strategy is typically supported by service standards, employees must also rely on a strong service culture to guide them in making decisions. That culture takes it tone and its values from an organization's leaders. As W. Edwards Deming clearly pointed out, quality can be no better than the intent of top management. Leaders shape culture, and culture is key to customer service.

Employees at every level in an organization must understand leadership's commitment to customers and service. This requires an organization's senior leaders to set directions and create a customer focus, clear and visible values, and high expectations. A clear, compelling, memorable vision should convey the result to be achieved for the customer and the way in which the results are to be achieved. The leadership category in the Baldrige criteria examines how an organization's senior leaders address values and performance expectations as well as how they focus on customers and other stakeholders, empowerment, innovation, learning, and organizational directions.

An organization's vision is communicated to employees through signals sent by management attitudes, policies, and rewards. Leaders in companies that produce outstanding service incessantly pronounce their beliefs and back up their words with actions. When leaders behave in a manner consistent with the organization's mission and values and focuses on empowering people to make decisions and take risks, it supports a wide variety of desired behaviors and builds self-esteem and teamwork among employees. Leaders also must exemplify for their employees what it means to produce great service. This may include answering calls from customers and fielding complaints one day a month, writing thank-you letters, spending time working in front line jobs, and so on. Their goal is to nurture a service culture that will shape employee behavior more effectively than rules and regulations can. They make service everybody's business and empower employees to make on-the-spot decisions in the customer's interest. By doing this, leadership helps make strategy a day-to-day reality.

TABLE 2 Baldrige Criteria Item 1.1—Organizational Leadership

1.1. Organizational Leadership

Describe how senior leaders guide your organization and review organizational performance.

Within your response, include answers to the following questions:

a. Senior Leadership Direction

(1) How do senior leaders set, communicate, and deploy organizational values, performance expectations, and a focus on creating and balancing value for customers and other stakeholders? Include communication and deployment through your leadership structure and to all employees.

(2) How do senior leaders establish and reinforce an environment for empowerment and innovation, and encourage and support organizational and employee learning?

(3) How do senior leaders set directions and seek future opportunities for your organization?

b. Organizational Performance Review

(1) How do senior leaders review organizational performance and capabilities to assess organizational health, competitive performance, and progress relative to performance goals and changing organizational needs? Include the key performance measures regularly reviewed by your senior leaders.

(2) How do you translate organizational performance review findings into priorities for improvement and opportunities for innovation?

(3) What are your key recent performance review findings, priorities for improvement, and opportunities for innovation? How are they deployed throughout your organization and, as appropriate, to your suppliers/partners and key customers to ensure organizational alignment?

(4) How do senior leaders use organizational performance review findings and employee feedback to improve their leadership effectiveness and the effectiveness of management throughout the organization?

This also means treating employees as leaders wish employees would treat customers. Leaders must express the same values in their dealings with front-line employees that they want these employees to show in their dealings with customers. Creating a positive climate for customer service means demonstrating concern for employees, enhancing their dignity, and solving their problems quickly and fairly. One of the most frustrating experiences of service employees is to work in an organization that stresses total customer satisfaction and then imposes controls or provides facilities that make it difficult or impossible to deliver it.

Clearly, an organization's leaders play a key role in setting directions, creating and balancing value for all stakeholders, and driving performance. Success requires a strong future orientation and a commitment to both improvement and change. As the Baldrige criteria note, increasingly this requires creating an environment for learning and innovation as well as the means for rapid and effective application of knowledge.

4. CREATING A SERVICE-DRIVEN WORKFORCE

Customers judge service by the quality of their interactions with the people who provide that service. The more contact employees have with customers, the more critical employee behavior is to perceptions of service quality. Therefore, organizations that lead in service quality must pay extraordinary attention to their workforce. Organizations with a strong customer focus achieve this through efforts in three key areas: (1) work and job design, compensation, career progression, and related workforce practices; (2) education and training efforts at all levels; and (3) maintenance of a work environment and an employee support climate that contribute to the well-being, satisfaction, and motivation of all employees.

The entire human resource focus category in the Baldrige criteria directly addresses all three of these areas that are critical to hiring, training, and growing service-driven employees. The criteria focus on how an organization enables its employees to use their full potential in accomplishing organizational objectives and how the organization maintains an environment that promotes performance excellence, full participation, and personal and organizational growth. Accomplishing this requires a close coupling between the leadership system and human resource system to enable defining and implementing the methods and structures needed to lead the organization in its strategic direction. The integration of these two systems sets the stage for effective performance. As leaders change the focus of the organization, employees need to acquire new skills and knowledge to be able to implement the leaders' new direction.

4.1. Work Systems

The work system starts with hiring people whose personalities predispose them to serve customers well. It continues with developing flexible, high-performance work practices tailored to employees with diverse workplace and home life needs. Major challenges in the area of valuing employees include demonstrating leadership's commitment to employees, providing recognition opportunities that go beyond the normal compensation system, providing opportunities for development and growth within the organization, sharing the organization's knowledge so employees can better serve customers and contribute to achieving strategic objectives, and creating an environment that encourages risk taking.

Companies that provide superior service use a wide variety of motivational programs to keep employees' energy flowing. The higher the degree of customer contact a group of employees has, the greater the number and power of motivational programs it can use. Award programs are one formal expression of the encouragement and praise that effective front-line supervisors continually provide. Compensation and recognition might need to be based, totally or in part, on leaders and employees attaining degrees of expertise in skill areas that align with organization objectives. Incentive approaches could include profit sharing and compensation based on acquiring new skills, building existing skills, or demonstrating self-learning. This might also be linked to customer retention or other performance objectives. Compensation and recognition, both monetary and nonmonetary, reward personnel for significant performance contributions that link to achieving the company objectives.

In addition to enabled employees and proper work system design, high-performance work requires ongoing education and training and information systems that ensure proper information flow. To help employees realize their full potential, many organizations use individual development plans for every employee that address individual career and learning objectives. Compensation and recognition approaches might also include profit sharing, team or unit performance, and linkage to customer satisfaction and loyalty measures or other organizational objectives.

4.2. Education and Training

Employee success depends increasingly on having opportunities for personal learning and practicing new skills. Organizations invest in employee personal learning through education, training, and opportunities for continuing growth. Learning opportunities in good service organizations are constant,

TABLE 3 Baldrige Criteria Item 5.1—Work Systems

5.1. Work systems
Describe how your organization's work and job design, compensation, career progression, and related work force practices enable employees to achieve high performance in your operations.
Within your response, include answers to the following questions:
a. Work Systems
(1) How do you design, organize, and manage work and jobs to promote cooperation and collaboration, individual initiative, innovation, and flexibility, and to keep current with business needs?
(2) How do your managers and supervisors encourage and motivate employees to develop and utilize their full potential? Include formal and/or informal mechanisms you use to encourage and support employees in job- and career-related development/learning objectives.
(3) How does your employee performance management system, including feedback to employees, support high performance?
(4) How do your compensation, recognition, and related reward/incentive practices reinforce high performance?
(5) How do you ensure effective communication, cooperation, and knowledge/skill sharing across work units, functions, and locations, as appropriate?
(6) How do you identify characteristics and skills needed by potential employees; how do you recruit and hire new employees? How do you take into account key performance requirements, diversity of your community, and fair work force practices?

intensive, lavish, and universal. Opportunities might include job rotation and increased pay for demonstrated knowledge and skills. On-the-job training offers a cost-effective way to train and better link training to organizational needs. Informal or not, the training is consistent and tightly linked with the company's strategy, culture, and personnel policies and is supported by the design of the service delivery system. Personal learning can result in more satisfied and versatile employees, greater opportunity for organizational cross-functional learning, and an improved environment for innovation.

Education, training, and development require ascertaining both education and training needs, including long-term development of employees' skills and knowledge that will be essential for an

TABLE 4 Baldrige Criteria Item 5.2—Employee Education, Training, and Development

5.2. Employee Education, Training, and Development
Describe how your organization's education and training support the achievement of your business objectives, build employee knowledge, skills, and capabilities, and contribute to improved employee performance.
Within your response, include answers to the following questions:
a. Employee Education, Training, and Development
(1) How does your education and training approach balance short- and longer-term organizational and employee needs, including development, learning, and career progression?
(2) How do you design education and training to keep current with business and individual needs? Include how job and organizational performance are used in education and training design and evaluation.
(3) How do you seek and use input from employees and their supervisors/managers on education and training needs, expectations, and design?
(4) How do you deliver and evaluate education and training? Include formal and informal education, training, and learning, as appropriate.
(5) How do you address key developmental and training needs, including diversity training, management/leadership development, new employee orientation, and safety, as appropriate?
(6) How do you address performance excellence in your education and training? Include how employees learn to use performance measurements, performance standards, skill standards, performance improvement, quality control methods, and benchmarking, as appropriate.
(7) How do you reinforce knowledge and skills on the job?

TABLE 5 Baldrige Criteria Item 5.3—Employee Well-Being and Satisfaction

5.3. Employee Well-Being and Satisfaction

Describe how your organization maintains a work environment and an employee support climate that contribute to the well-being, satisfaction, and motivation of all employees. Within your response, include answers to the following questions:

a. Work Environment

How do you address and improve workplace health, safety, and ergonomic factors? How do employees take part in identifying these factors and in improving workplace safety? Include performance measures and/or targets for each key environmental factor. Also include significant differences, if any, based on different work environments for employee groups and/or work units.

b. Employee Support Climate

(1) How do you enhance your employees' work climate via services, benefits, and policies? How are these enhancements selected and tailored to the needs of different categories and types of employees, and to individuals, as appropriate?

(2) How does your work climate consider and support the needs of a diverse work force?

c. Employee Satisfaction

(1) How do you determine the key factors that affect employee well-being, satisfaction, and motivation?

(2) What formal and/or informal assessment methods and measures do you use to determine employee well-being, satisfaction, and motivation? How do you tailor these methods and measures to a diverse work force and to different categories and types of employees? How do you use other indicators such as employee turnover, absenteeism, grievances, and productivity to assess and improve employee well-being, satisfaction, and motivation?

(3) How do you relate assessment findings to key business results to identify work environment and employee support climate improvement priorities?

organization's future work systems. It also includes short-term needs of both the organization and its employees. Learning is directed not only toward better products and services but also toward being more responsive, adaptive, and efficient, giving the organization and its employees marketplace sustainability and performance advantages.

4.3. Employee Well-Being and Satisfaction

If work systems are to be effective, employees must have a suitable work environment and climate that fulfill their basic needs. Ensuring a safe and healthful environment must be part of an organization's improvement activities. Establishing measures and targets and recognizing that employee groups, might be in very different environments.

An organization must have approaches for enhancing employee well-being, satisfaction, and motivation based upon a holistic view of its entire workforce. A variety of approaches are usually necessary to satisfy a diverse workforce with differing needs and expectations. There must also be approaches for assessing employee well-being, satisfaction, and motivation and relating these assessment findings to key organizational results to set improvement priorities. Some examples of factors to consider in this assessment are effective employee problem and grievance resolution; employee development and career opportunities; work environment and management support; workload; communication, cooperation, and teamwork, job security; and organizational support for serving customers. Measuring how well employees understand the connection between quality and customers can also show what an organization needs to do to achieve an organizational customer focus.

5. SYSTEMS FOR SERVICE DELIVERY

As noted in the criteria's core value of ''customer driven,'' quality and performance are judged by an organization's customers (Criteria 2000). Thus, an organization must take into account all product and service features and characteristics that contribute value to its customers and lead to customer satisfaction, preference, referral, and loyalty. Being customer driven has both current and future components—understanding today's customer desires and anticipating future customer desires and marketplace offerings. Value and satisfaction may be influenced by many factors throughout a customer's overall purchase, ownership, and service experiences. These factors include an organization's relationship with customers that helps build trust, confidence, and loyalty.

Without a clear understanding of customer expectations and priorities, an organization's leaders risk making bad decisions and resource allocations leading to poor quality as perceived by customers.

Information gathered, interpreted, and communicated properly can reduce the likelihood of pursuing inaccurate customer expectation priorities. Customer-driven organizations address not only the product and service characteristics that meet basic customer requirements, but also those features and characteristics that differentiate products and services from competing offerings.

The customer and market focus category in the criteria examines how an organization determines requirements, expectations, and preferences of customers and markets. It also considers how an organization builds relationships with customers and determines their satisfaction. The category looks at how an organization seeks to understand the voices of customers and the marketplace and stresses relationships as an important part of an overall listening, learning, and performance excellence strategy.

The criteria asks an organization to consider its key processes for gaining knowledge about its current and future customers and markets, with the aim of offering relevant products and services, understanding emerging customer requirements and expectations, and keeping pace with changing markets and marketplaces. Listening and learning strategies depend on an organization's key business factors. Some frequently used strategies include focus groups with key customers; close integration with key customers; interviews with lost customers about their purchase decisions; use of the customer complaint process to understand key product and service attributes; won/lost analysis relative to competitors; and survey/feedback information, including use of the Internet. Involving the workforce in identifying customers and their needs and communicating that information throughout an organization reinforces the connection among employees, customers, and quality.

Service organizations often get process specifications by creating customer commitments. Customer commitments are statements of outcomes expected in nonmanufacturing situations. These commitments are designed to satisfy customers' needs and expectations, written to include a little something extra to distinguish an organization from competitors. Customer commitments are based on everyone's inherent general understanding of customer needs, combined with actual knowledge of what the customer wants. For commitments to be as effective as specifications, all employees must know who their customers are; the specific expectations of these customers must be written down; and employees must be empowered by management to do whatever is necessary to meet these expectations.

Customer commitments are frequently translated into service standards. Setting a standard of service that everyone can understand establishes a target. This is critical to success because when written service standards are published, it establishes a goal toward which all employees can aim. People need tangible goals that communicate expectations and let employees know what is expected of them in specific and measurable terms. The process of setting service standards lets all employees, from the top down, know who is responsible for what jobs and reduces conflicts and misunderstandings on who is going to do what.

The second criteria item in the customer and market focus category deals with customer satisfaction and relationships. Customer satisfaction and dissatisfaction results provide vital information for understanding an organization's customers and the marketplace. In many cases, such results and trends

TABLE 6 Baldrige Criteria Item 3.1—Customer and Market Knowledge

3.1. Customer and Market Knowledge
Describe how your organization determines short- and longer-term requirements, expectations, and preferences of customers and markets to ensure the relevance of current products/services and to develop new opportunities.
Within your response, include answers to the following questions:

a. Customer and Market Knowledge

(1) How do you determine or target customers, customer groups, and/or market segments? How do you consider customers of competitors and other potential customers and/or markets in this determination?

(2) How do you listen and learn to determine key requirements and drivers of purchase decisions for current, former, and potential customers? If determination methods differ for different customers and/or customer groups, include the key differences.

(3) How do you determine and/or project key product/service features and their relative importance/value to customers for purposes of current and future marketing, product planning, and other business developments, as appropriate? How do you use relevant information from current and former customers, including marketing/sales information, customer retention, won/lost analysis, and complaints, in this determination?

(4) How do you keep your listening and learning methods current with business needs and directions?

TABLE 7 Baldrige Criteria Item 3.2—Customer Satisfaction and Relationships

3.2. Customer Satisfaction and Relationships
Describe how your organization determines the satisfaction of customers and builds relationships to retain current business and to develop new opportunities.
Within your response, include answers to the following questions:

a. Customer Relationships
(1) How do you determine key access mechanisms to facilitate the ability of customers to conduct business, seek assistance and information, and make complaints? Include a summary of your key mechanisms.
(2) How do you determine key customer contact requirements and deploy these requirements to all employees involved in the response chain?
(3) What is your complaint management process? Include how you ensure that complaints are resolved effectively and promptly, and that all complaints received are aggregated and analyzed for use in overall organizational improvement.
(4) How do you build relationships with customers for repeat business and/or positive referral?
(5) How do you keep your approaches to customer access and relationships current with business needs and directions?

b. Customer Satisfaction Determination
(1) What processes, measurement methods, and data do you use to determine customer satisfaction and dissatisfaction? Include how your measurements capture actionable information that reflects customers' future business and/or potential for positive referral. Also include any significant differences in processes or methods for different customer groups and/or market segments.
(2) How do you follow up with customers on products/services and recent transactions to receive prompt and actionable feedback?
(3) How do you obtain and use information on customer satisfaction relative to competitors and/or benchmarks, as appropriate?
(4) How do you keep your approaches to satisfaction determination current with business needs and directions?

provide the most meaningful information, not only on customers' views but also on their marketplace behaviors—repeat business and positive referrals.

Obtaining useful information on customer satisfaction requires carefully designed and developed surveys. Responses must be interpretable and translatable into specifications or strategies for improvement. Surveys should identify and prioritize customer needs and expectations and should rate the importance of the product or service attributes and how well the organization is meeting the attributes. Complaint and satisfaction survey results aggregation, analysis, and root cause determination should lead to effective elimination of the causes of problems and to priority setting for process, product, and service improvements. Successful outcomes require effective deployment of information throughout an organization.

The item also deals with how an organization provides easy access for customers and potential customers to seek information or assistance and/or to comment and complain. Excellent service depends on welcoming customer requests and responding flexibly. Organizations keep customers by remedying commitment failures. To be able to fix a commitment failure on the spot, an organization must anticipate possible failures and devise suitable remedies. These plans must be mapped out in advance, written down, and agreed to by management, and the workforce must be empowered to act on them.

Having an effective, customer-driven system for service delivery is a strategic concept. It is directed toward customer retention, market share gain, and growth. It demands constant sensitivity to changing and emerging customer and market requirements and the factors that drive customer satisfaction and retention. It demands anticipating changes in the marketplace. Being customer driven thus demands awareness of developments in technology and competitors' offerings and rapid and flexible response to customer and market requirements.

6. MEASURING AND EVALUATING SERVICE QUALITY

Measuring and evaluating service quality rounds out the five key areas that that began with creating a service strategy. Through measurement and evaluation, leadership can understand how well their strategies are working and can identify weaknesses in the other elements of service. Measuring and tracking also allows employees at all levels of an organization to increase service quality awareness,

understand their performance levels, understand performance relative to competitors and benchmarks, identify strengths and weaknesses, focus efforts, and monitor progress.

Despite the serious difficulties of measuring and controlling the quality of customer service, service leaders have figured out ways of doing it. Measuring service performance or quality is quite different than measuring product quality because service is an experience. Generally, the better measurement systems focus on three different aspects of service: process, product, and customer satisfaction.

Process measures are the more traditional measures, which compare the actual work employees perform in the process of creating service with standards for quality and quantity. These might include measures such as time to answer the phone, time to respond to customer inquiries, and ability to solve a problem without passing a customer on to somebody else. These measures are often associated with the service standards an organization defines. Measuring service standards provides employees with a sense of achievement and accomplishment and motivates them to aim at even higher levels.

Product measures focus on outcomes of a service process and show whether the work has produced the desired results, such as delivering packages when customers want them delivered. Ideally, product measures summarize the effects of the process from the customers' point of view (without actually asking the customer first hand) and are closely linked to customer satisfaction. Examples of such measures include access, courtesy, reliability, and responsiveness.

Satisfaction measures look at the extent to which customers are satisfied with the service they have received. Customer satisfaction must be measured for each area of customer contact that affects the customer's decision to buy. In order to get a full understanding of the benefits and costs of service quality, customer satisfaction surveys should ask how satisfied customers are with a service encounter, what problems were experienced, whether assistance to answer a question or solve a problem was sought and where the customer sought advice, how many people the customer told about the experience, costs incurred by both servers and customers to prevent and correct poor service, and whether the customer intends to purchase the product or service again.

Zeithaml et al. (1990) proposes five attributes of quality service, including reliability, empathy, assurance, responsiveness, and tangibles. By comparing customer perceptions with expectations in these areas, the model provides a two-part measure of perceived quality that links back to market segmentation relative to different service expectations. Whatever measures are used, measurement and evaluation are necessary to establish bases for improvement. The initial fix of a customer commitment failure is really just a temporary fix to keep customers satisfied. Once good data is available, employees can effectively identify and address the real problems behind commitment failures.

The data obtained from service quality measures may be used in a variety of ways: to correct specific performance deficiencies, to identify problems for correction, and to supply data to a variety of economic models on the profit impact of causes of dissatisfaction and the revenue opportunities of sources of satisfaction. Whatever methods are used to obtain the data, service quality results must reach all of the concerned areas of the organization, and they must be evaluated and needed to balance customer satisfaction and company profits. When customer expectations are met or exceeded, they have a tendency to increase, and service-obsessed companies never see the end of programs and actions to improve service.

There is an entire category devoted to information and analysis in the Baldrige criteria, and a core value centered around management by fact, demonstrating the extent to which organizations depend upon the measurement and analysis of performance. The measures and indicators an organization selects should be represent the factors that lead to improved customer, operational, and financial performance. A comprehensive set of measures or indicators tied to customer and/or organizational performance requirements represents a clear basis for aligning all activities with an organization's goals (Criteria 2000).

There are no magic formulas for developing measures, and there is no one recipe for success in monitoring service quality. Lacking good measures, however, an organization cannot assess its progress or adjust to changes in customer expectations. Without effective measures, managers cannot reward employees appropriately, tune strategies and infrastructure to customer needs, or design products and service delivery systems that support outstanding service. Without valid measurement systems, it is impossible to know what actions are required to improve customer service. There must be a continuous, permanent commitment to measuring, evaluating, and acting on actual service delivery.

7. CONCLUSIONS

Organizations that provide outstanding service quality are quite different from their competitors. Leaders act and manage differently, missions are stated differently, employees are treated differently, services are delivered differently, and results are measured and acted upon. Actions are based on totally different assumptions about the way success is achieved. And the results show it, in terms of both conventional measures of performance and the impact these services have on their competitors.

Genuine quality improvements that make a difference to customers and build a stronger, more competitive organization are achievable by any type of organization—manufacturing, service, health care, education, and nonprofit alike. With a framework such as the Baldrige criteria, any organization can systematically identify both strengths and areas for improvement in its own approaches to service quality. Whether being used on an entire corporation, division, or a small service or manufacturing company, the criteria provide a methodical approach for creating a common language and enhancing cooperation and communication with employees and customers alike. Using the criteria can help achieve consensus on what needs to be done and help integrate various quality management and business efforts.

Service quality is definable, achievable, and sustainable when an organization is provided with a systematic approach for self-assessing and improving existing approaches to service delivery. The Baldrige criteria provide a robust, organizational management model, which has been repeatedly used by all types of organizations to gain competitive advantage, enhance their image, improve their overall performance, and ultimately help them achieve excellence.

CHAPTER 74

Standardization, Certification, and Stretch Criteria

HARRISON M. WADSWORTH, JR.
Georgia Institute of Technology

1. INTRODUCTION

This chapter will discuss international and national standards for quality management systems. After defining some terms and concepts, it will consider the need for such standards and how they are used.

The history and evolution of these standards will then be presented, leading up to the current ISO standards, which have revolutionized quality management. The requirements in the latest version (2000) of the QMS standards will be presented. The topic of registration to these standards will be discussed. This includes reasons for registration and means for becoming registered. Similar standards for environmental management, the ISO 14000 family of standards, were discussed in Chapter 39 of this handbook.

1.1. Definitions

The definitions given here are taken from ISO/DIS 9000-2000, which is the latest version of the terminology standard as of the writing of this chapter. This standard will be discussed later. It su-

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

persedes and replaces the previous terminology standard, ISO 8402-1994, and its American counterpart, ANSI/ISO/ASQ A8402-1994.

A quality management system is defined in this standard as a ''system to establish quality policy and quality objectives and to achieve those objectives'' (2.2.3).

Quality policy is defined in the standard as the ''overall intentions and direction of an organization related to quality as formally expressed by top management'' (2.2.4).

Quality objective is defined as ''something sought, or aimed at, related to quality'' (2.2.5).

Other terms that are useful for the presentation given in this chapter are:

- Quality management: ''coordinated activities to direct and control an organization with regard to quality'' (2.2.8)
- Quality control: ''part of quality management focused on fulfilling quality requirements'' (2.2.10)
- Quality assurance: ''part of quality management focused on providing confidence that quality requirements are fulfilled'' (2.2.11)

1.2. Reasons for Quality Management System Standards

There are several reasons for standards for quality management systems. As indicated, quality assurance involves the demonstration of good-quality products and services. The quality management system is the organization that enables this assurance to be accomplished. Quality management system standards provide a guideline for a manufacturing or service company to determine if proper quality assurance requirements can be met.

The first reason for such standards is to provide these guidelines. While each organization is different and thus has different needs for quality assurance, there are many elements that are fundamental to all organizations. These elements can be standardized and are found in such standards. This provides internal quality assurance.

In addition, quality management system standards provide a means to evaluate an organization's quality management system and thus its ability to provide high-quality products. This is the provision of external quality assurance by a supplier of a product or service. In an increasing number of situations, customers require, for contractual purposes, the registration or certification of their suppliers' quality systems. Such registration must use standards for guides.

As we move into a global marketplace, we find the need for standardization increases. Without such internationally recognized standardization we cannot communicate with suppliers or customers in other countries.

These needs for standardization have been recognized by international and national standards writing bodies. The present standards for quality systems and quality assurance are the results of this recognition. More will be said about the development of such standards in the next section.

2. HISTORY OF QUALITY MANAGEMENT SYSTEM STANDARDS

2.1. American Standards

For the marketplace, standardization is a necessity. Product standards, monetary standards, measurement standards, and so forth have been with us for thousands of years. This chapter does not address these standards, however. It addresses generic quality standards that are not product or industry specific. The earliest quality management system standards were developed for contractual purposes. Such standards, for example MIL-Q-9858A (1963) and MIL-I-45208A (1981), were developed by the United States Department of Defense (DoD). These are mandatory standards created for the purpose of assuring the defense procurement agencies of the United States that a supplier has the ability to provide high-quality weapons systems. Other countries developed similar standards for quality management systems.

In the United States, voluntary national standards (as opposed to the mandatory standards) have been published by several organizations. The most prominent publishers of such standards are the American Society for Testing Materials (ASTM), the American Society of Mechanical Engineers (ASME), the Institute of Electrical and Electronic Engineers (IEEE), the American Society for Quality (ASQ), and others. All of these technical societies publish many of their standards under the auspices of the American National Standards Institute (ANSI). ANSI approves such standards, and most of them carry a dual designation of both the writing organization and ANSI. There are currently more than 11,000 ANSI standards, most of which are product-specific standards. ANSI itself consists of individual members, approximately 1,000 companies, 30 government agencies, and 250 professional, technical, trade, labor, and consumer organizations.

ANSI is the sole U.S. representative to international standards writing bodies such as the International Organization for Standardization (ISO), the International Electrotechnical Commission (IEC), and the Pacific Area Standards Congress (PASC). To facilitate the development of standards dealing with quality assurance and quality control, the American Society for Quality was accredited as a standards-writing body in 1974 by ANSI, with its Standards Committee charged with promoting such standards. Later, in 1978, the ANSI Accredited Standards Committee Z1 was established, with the ASQ holding its Secretariat.

One of the early voluntary quality system standards developed in the United States was ANSI Standard Z1.8-1971, *Specification of General Requirements for a Quality Program.* This was written by the ASQ and later revised as ANSI/ASQC C1 in 1985. A later, much more detailed standard was published by the ASQ as ANSI/ASQC Z1.15-1979, *Generic Guidelines for Quality Systems*. This latter standard was written by a subcommittee of the ANSI Accredited Standards Committee Z1. It was the basis for international standard ISO 9004, published in 1987. In the United States it has been superseded by the American version of ISO 9004, which is designated ANSI/ISO/ASQ Q9004. The third revision of this standard has now been completed and published as ISO 9004-2000. Its American counterpart will be ANSI/ISO/ASQ Q9004-2000. This edition of the standard will be reviewed later in this chapter.

2.2. European Standards

Other single-level standards similar to MIL-Q 9858A and ANSI/ASQC Z1.15 were being developed at the same time by other countries. A partial list of such early standards is:

Country	Standard
United Kingdom	BS4891:1972, *A Guide to Quality Assurance*
France	AFNOR NFX50-110, *Recommendations for a System of Quality Management for the Use of Companies*
France	AFNOR NFX50-111, *Quality Assurance Systems for the Use of Companies*
Germany	DIN 55-355, *Basic Elements of Quality Assurance Systems*

Some standards developed during this time were multilevel standards. That is, they have several levels of quality assurance standards that depend on the requirements placed on the supplier. They were chiefly developed for use in contractual situations. The following are some of these standards:

Country	Standard
United Kingdom	BS 5750-1979, *Specification for Design, Manufacture, and Installation*
Canada	CSA Z299-1978, *Quality Assurance Program Requirements*
Norway	NVS-S-1594, *Requirements of the Contractor's Quality Assurance Program*
South Africa	SABS 0157-1979, *Code of Practice for Quality Management Systems*
Australia	AS 1821-1975, *Suppliers Quality Control System*

2.3. International Standards

In 1979, ISO formed Technical Committee 176, with Secretariat given to Canada. The scope of this Technical Committee, as stated in the 1989 Momento of ISO, is ''Standardization in the field of generic quality management, including quality systems, quality assurance, and generic supporting technologies, including standards which provide guidance on the selection and use of these standards.'' The Technical Committee published six standards in 1986-1987. Since then, other standards have been published, bringing the total to 27 as of 1999. The six original standards were the principal accomplishments of the committee. The first of the six standards published in 1986 was ISO 8402, *Vocabulary*. This standard consisted of 22 terms. It was revised in 1994 with 67 terms. The 2000 edition of the standard, now designated as ISO 9000-2000, has 87 terms. As with the 1994 edition, the terms are divided into 10 sections as follows:

- Seven terms related to quality
- Fourteen terms related to management
- Seven terms related to organization
- Eight terms related to process and product
- Five terms related to characteristics
- Thirteen terms related to conformity
- Six terms related to document
- Six terms related to examination

- Thirteen terms related to audit
- Eight terms related to quality assurance for measurement processes

Many of the standards in the ISO 9000 family will be discontinued following publication of the new edition of the basic standards, ISO 9000, ISO 9001, and ISO 9004. The original 9002 and 9003 standards will be merged with ISO 9001. ISO 9000-1 will be merged with 8402 and designated 9000. ISO 9004-1, 9004-2, 9004-3, and 9004-4 will be merged and designated ISO 9004. ISO 10011-1, 10011-2, and 10011-3 on auditing have been merged with auditing standards for environmental management. The new standard is designated 19011. The remaining members of the ISO 9000 family are as follows:

Core standards

ISO 9000:2000, *Quality Management Systems—Fundamentals and Vocabulary*

ISO 9001:2000, *Quality Management Systems—Requirements*

ISO 9004:2000, *Quality Management Systems—Guidelines for Performance Improvements*

ISO 19011, *Guidelines for Auditing Management Systems*

Other international standards

ISO 10012, *Guidelines for Quality Assurance for Measuring Equipment*

ISO 10015, *Quality Management—Guidelines for Training*

Technical reports

ISO 10006, *Guidelines to Quality in Project Management*

ISO 10007, *Guidelines for Configuration Management*

ISO 10013, *Guidelines for Developing Quality Manuals*

ISO 10014, *Guidelines for Managing the Economics of Quality*

ISO 10017, *Guidance on Statistical Techniques for ISO 9001*

The only standard in this family that may be used for registration of a quality management system is ISO 9001. In previous editions there were three such requirements standards, ISO 9001, 9002, and 9003. The 9001 standard was the most complete in that it covered all parts of a quality management system. ISO 9002 was identical to 9001 except that the design function was not included. Several other functions were omitted from the 9003 standard. The 2000 edition of ISO 9001 allows for the tailoring of the standard to delete requirements such as design when they do not apply to an organization.

3. DETAILS OF THE ISO 9001:2000 STANDARD

3.1. Process Model

This edition of the standard is based on a process approach to quality management. Any activity that receives inputs and converts them to outputs is a process. Most processes are linked in that outputs from one process are often the inputs to other processes. The systematic identification and management of the processes employed within an organization is the process approach.

This edition of ISO 9001 is considered as one part of a consistent pair of standards, the other being ISO 9004:2000. The two standards have identical clause structures, an important property that was missing in earlier editions. ISO 9004:2000 gives guidance on a wider application of a quality management system meant to improve the organization's overall performance beyond that required by ISO 9001:2000. It is not a guideline for implementing ISO 9001:2000 and is not intended for certification or other contractual use. The ISO 9001:2000 standard also has an identical clause structure with ISO 14001:1996 in order to improve the compatibility between registration of quality and environmental management systems.

3.2. Scope

ISO 9001:2000 specifies requirements for a quality management system where an organization needs to demonstrate its ability to consistently provide product that meets requirements of customers and regulatory agencies. It also addresses customer satisfaction through the requirements for continual improvement and the prevention of nonconformities.

3.3. Principles of Quality Management

ISO 9000:2000 lists the following steps that might be used to develop a quality management system:

1. Determine the needs of the customer.
2. Establish the quality policy and quality objectives of the organization.
3. Determine the processes needed to implement the quality objectives.
4. Develop measures for the effectiveness of each process towards the attainment of the objectives.
5. Develop means of preventing nonconformities.
6. Look for opportunities to improve the effectiveness and efficiency of processes.
7. Determine and prioritize proposed improvements.
8. Plan strategies, processes, and resources to obtain improvements.
9. Implement the plan.
10. Monitor the improvements.
11. Assess the results against expected outcomes.
12. Determine follow-up actions.

An organization that adopts the 12 steps outlined above creates confidence in the capability of its processes and provides a basis for continual improvement. This, in turn, leads to increased customer satisfaction and the success of the organization.

3.4. QMS Requirements

Clause 4 of ISO 9001:2000 presents some general requirements of the quality management system. These include requirements dealing with the identification and management of the processes in the system. General documentation requirements are also discussed in this clause. These include the requirements for documented procedures, work instructions, and manuals. The actual, detailed requirements of the standard are stated in four clauses:

- Management Responsibility
- Resource Management
- Product Realization
- Measurement, Analysis, and Improvement

Each of these clauses is discussed briefly in the following sections.

3.5. Management Responsibility

Clause 5 of the standard is entitled ″Management Responsibility.″ It designates a requirement for management commitment to high quality. It states that this management commitment must be highly visible. This is done by the establishment of a quality policy, setting of quality objectives, and a description of the quality system that emphasizes problem prevention rather than dependence on detection after a problem occurs.

Management must develop and state its corporate policy as it relates to quality. This quality policy must be consistent with all other corporate policies. It is the responsibility of management to ensure that its quality policy is understood, implemented, and maintained. The policy contains management's definition of good quality and its goals for quality improvement.

Quality objectives must be explicitly stated. These include the key elements of quality, such as fitness for use, performance, safety, and reliability.

Management's responsibilities also include the organization and operation of the quality system. This responsibility includes the provision of all necessary resources. Management is responsible for seeing that the quality system functions in such a manner that the system is well understood and effective, confidence is provided that products or services satisfy requirements and customer expectations and that its emphasis is on prevention of problems rather than problem detection.

The clause also requires the appointment of a management representative charged with the operation and maintenance of the quality system. The management representative must have direct access to top management. A manual must be developed by management that describes the quality system and includes references to appropriate documented procedures. The manual and the procedures must be controlled using a document control procedure.

Top management shall review the quality management system at prescribed intervals to ensure its continuing effectiveness. These reviews shall include results of audits, customer feedback, process performance and product conformance, status of corrective and preventive actions, and changes that could affect the quality management system.

3.6. Resource Management

Clause 6 of the standard requires the provision of resources needed to maintain the quality management system. These include human resources, requiring the identification of competency needs for personnel, the provision of training to satisfy these needs, evaluation of the effectiveness of this training, and the maintenance of appropriate records of education, training, and qualifications of all personnel. There is also a requirement for the maintenance of a proper work environment and all facilities needed to provide high-quality products and services.

3.7. Product Realization

The last two clauses, 7 and 8, are large and include a number of subclauses. The first subclause of clause 7 deals with quality planning. This requires a statement of the quality objectives for the product or project and the processes needed. These plans are to be recorded in the form of quality plans, and they include any inspection or tests needed to verify the product quality. The second clause, 7.2, requires the organization to determine all customer requirements. It also requires a review of product requirements prior to a commitment to produce a product to ensure the organization is able to meet the requirements. The organization is also required to implement arrangements for adequate communication with the customer, including customer feedback or complaints.

Clause 7.3 deals with the design of a product or service. This clause contains all the requirements of earlier editions of the standard regarding design and development. An appropriate planning activity is required that controls the entire design process. Design input states that inputs must be defined and documented, including all functional, regulatory, and legal requirements. The organization must document that knowledge from prior design activities is used when it is available. Design output must be such that verification against input requirements is feasible. The output must give the necessary requirements for production operations, address product acceptance criteria, and explain how the product may be used safely and correctly. The output documents must be approved before publication.

The standard requires design reviews at suitable stages using a review team made up of representatives of all functions associated with the product. There must be a verification stage during which the output is matched to the design input. There must also be a validation stage during which the final product's performance is compared to requirements. Finally, all design changes must be documented and controlled.

Clause 7.4 covers the control of the purchasing function to ensure that purchased product meets the specified requirements. Criteria for the selection and periodic evaluation of suppliers shall be defined and results recorded. The organization shall identify and implement all activities necessary for the verification of purchased product.

Clause 7.5 is entitled Production and Service Operations. The first subclause in this section requires the control of operations relevant to production and service by making available information including all specifications about the product, work instructions, devices needed for measuring and monitoring, and instructions for release and post delivery activities. The second subclause requires product to be identified and traceable throughout production. Clause 7.5.3 requires the organization to protect and control any customer-owned property used in production. This includes customer-owned tooling, shipping containers, and intellectual property that may be provided in confidence.

Clause 7.5.4 requires the organization preserve the property during all internal processing and delivery to the final destination. Subclause 7.5.5 requires the validation of all production and service processes that cannot be verified by subsequent measurement or monitoring. This includes any processes where deficiencies may not be detected until after the product is put in use. The last subclause, 7.5.6, in this section deals with the control of measuring and monitoring devices. The devices must be controlled, serviced at regular intervals, and protected from damage. The results of calibration must be recorded and corrective action taken whenever a device is found to be out of calibration.

3.8. Measurement, Analysis, and Improvement

Clause 8 contains five subclauses, the first of which, 8.1, states that the organization shall define, plan, and implement the measuring and monitoring activities needed to ensure conformity and improvement. Clause 8.2 on measurement and monitoring requires the organization to measure customer satisfaction, conduct internal audits, and measure and monitor all processes and the product. The internal audits must be performed at regular intervals and must assess whether the quality management system is effective and conforms to the standard.

Clause 8.3 is on control of nonconformity. This is a requirement to identify and control product that is in nonconformance and to take appropriate action to see that such product does not reach the customer. The next subclause requires data dealing with the quality system to be collected and analyzed. These data include customer satisfaction and dissatisfaction, conformance to requirements, characteristics of processes and products, and suppliers.

Clause 8.5 requires the organization to plan for continual improvement of the quality system through the ''use of quality policy, objectives, audit results, analysis of data, corrective and preventive action, and management review.'' The last two subclauses in clause 8.5 are entitled Corrective and Preventive Action. These two requirements were a single clause in the 1994 edition of the standard. This led to some confusion among users of the standard as to the difference between them. Corrective action includes the correction of problems that have occurred, whereas preventive action deals with potential problems that may have never occurred.

4. ISO 9004-2000

ISO 9004-2000 is a guidance document that provides more information regarding the quality management system. As stated earlier, the clause structure of this standard is the same as that of 9001-2000. The title of this standard is *Quality Management Systems—Guidelines for Performance Improvements.* It is, however, based on the same quality management principles as ISO 9001-2000. The focus of this standard is the improvement of the processes of an organization in order to enhance its performance.

When ISO 9001-2000 and ISO 9004-2000 are used together, the benefits to an organization are likely to be greater than if only one is used. The two standards have identical structures but different scopes. ISO 9004 is not intended to be used as guidance document for compliance to ISO 9001. The purpose of ISO 9001 is to define the minimum requirements needed to achieve customer satisfaction by meeting specified product requirements. The purpose of ISO 9004 is to provide guidance on the application and use of a quality management system to improve the overall performance of an organization.

The clauses of ISO 9001-2000 are included in a box within the clauses of 9004 for immediate reference for users of ISO 9004. The verb used in ISO 9001 is ''shall,'' whereas that used in 9004 is ''should.'' The clauses of ISO 9004-2000 are based on the following eight quality management principles: customer focus, leadership, involvement of people, process approach, system approach to management, continual improvement, factual approach to decision making, and mutually beneficial supplier relationships.

A clause in the measurement and monitoring section provides a means for self- assessment of an organization's quality system. The actual methodology along with appropriate questions to be answered are included in an annex to the standard.

5. OTHER STANDARDS AND GUIDES IN THE ISO 9000 FAMILY

In addition to the three standards discussed above, ISO 9000-2000, 9001-2000, and 9004-2000, there are three other standards, five technical reports, and three brochures in the 2000 edition of the ISO 9000 family. Some of these documents have not been revised to agree with the 2000 editions of the basic standards at the time of the publication of this chapter. The three additional standards are:

- ISO 19011, *Guidelines for Auditing Management Systems*
- ISO 10012, *Quality Assurance Requirements for Measuring Equipment*
- ISO 10015, *Quality Management–Guidelines for Training*

The five technical reports are:

- ISO 10006, *Quality Management–Guidelines to Quality in Project Management*
- ISO 10007, *Quality Management–Guidelines for Configuration Management*
- ISO 10013, *Guidelines for Developing Quality Manuals*
- ISO/TR 10014, *Guidelines for Managing the Economics of Quality*
- ISO/TR 10017, *Guidance on Statistical Techniques for ISO 9001-1994*

The three brochures are:

- *Quality Management Principles and Quidelines on Their Application*
- *Selection and Use of Standards*
- *Small businesses*

Two other standards were formerly in the 9000 family. The first of these is ISO 9000-3:1997, *Quality Management and Quality Assurance Standards*—Part 3: Guidelines for the Application of ISO 9001:1994 to the Development, Supply, Installation, and Maintenance of Computer Software. This standard was transferred to ISO/IEC JTC/SC7, who will update it to correspond to the 2000 edition of ISO 9001. The second is ISO 9000-4:1993, *Quality Management and Quality Assurance*

Standards– Part 4: Guide to Dependability Program Management. This standard has been transferred to IEC/TC 56, Dependability, who is updating it for the 2000 edition of ISO 9001. The following standards in the 9000 family have been dropped:

- ISO 8402:1994, *Vocabulary*—now part of ISO 9000-2000
- ISO 9000-1:1994, *Selection and Use of ISO 9000 Standards*—now part of ISO 9000-2000
- ISO 9002:1994, *Model for Quality Assurance*—now part of ISO 9001-2000
- ISO 9003:1994, *Model for Quality Assurance*—now part of ISO 9001-2000
- ISO 9004-1:1994, *Quality Management and Quality System Elements*—Part 1: Guidelines, now designated as ISO 9004-2000
- ISO 9004-2:1991, *Quality Management and Quality System Elements*—Part 2: Guidelines for Services—now included in ISO 9004-2000
- ISO 9004-3:1993, *Quality Management and Quality System Elements*—Part 3: Guidelines for Processed Materials—now included in ISO 9004-2000
- ISO 9004-4:1993, *Quality Management and Quality System Elements*—Part 4: Guidelines for Quality Improvement—now included in ISO 9004-2000
- ISO 10005:1995, *Quality Management—Guidelines for Quality Plans*—now included in ISO 10013

6. STANDARDS DEVELOPED BY OTHER ORGANIZATIONS

6.1. ANSI/ASQ/Z1.11, *The Application of ISO 9001 to Educational Institutions*

This standard is an American National Standard, published by the American Society for Quality. The standard, now being updated to the 2000 edition of ISO 9001, was written to assist educational institutions conform to the requirements of ISO 9001. The current edition contains the ISO 9001: 1994 standard in the left column of each page, with the corresponding clauses of ANSI/ASQ/Z1.11 on the right. The Z1.11 standard puts the 9001 standard in terms recognizable to persons dealing with education.

6.2. QS 9000, *Quality System Requirements*, 3d Ed., 1998

This document is not really a standard, in that it was not developed using a consensus procedure. It is a set of requirements, in addition to the ISO 9001 requirements, that have been developed by the Automotive Industry Action Group. The actual set of requirements were developed by representatives of Chrysler, Ford, and General Motors in 1994. The second edition was published in 1995 and the third edition published in 1998. The clause structure corresponds to that of ISO 9001:1994. In fact the ISO standard is printed in italics within each clause, while the additional requirements are in roman letters. Since 1994, the document has been printed in five languages in at least 63 countries. The original equipment manufacturers in the automotive industry have required their suppliers to be registered to this document in order to sell their product to them.

The additional requirements of this document consist of additional statistical requirements, such as requirements for statistical process control, gage repeatability and reproducibility studies, and failure mode and effects analyses. Other requirements imposed by the automotive group are also included. Most of the additional requirements are discussed in a set of supplementary manuals entitled *Statistical Process Control Reference Manual, Production Part Approval Process Reference Manual, Measurement Systems Analysis Reference Manual, Advanced Product Quality Planning and Control Plan Reference Manual,* and the *Failure Mode and Effects Analysis Reference Manual.* Organizations wishing to be registered to QS 9000 must be familiar with all of the supplementary manuals as well as the basic set of requirements. QS 9000 is to be replaced in 2000 by ISO/TS 16949, which is the result of cooperation of both European and American automotive industry groups.

6.3. Other Quality Management Requirement Documents

Taking an approach similar to that taken by the automotive industry, the aerospace industry has developed a set of requirements entitled AS 9100 and the telecommunication industry has developed TL 9000. Both of these documents are based on ISO 9001:1994 and contain additional requirements considered necessary for quality management systems in their industry.

7. REGISTRATION TO QMS STANDARDS

Since the original adoption of the ISO 9000 standards in 1987, the registration of companies to the standards has become an accepted practice throughout the world. As of the end of 1998, there were 271,966 certificates of conformance issued in 143 countries on every continent, according to data

released by the International Organization for Standardization. The number of certified organizations has increased rapidly over the years, indicating that the interest in registration is increasing. As an indication of the growth rate, the September 1999 issue of *Quality Systems Update* reports there were 27,816 certificates in January 1993; 70,364 certificates in June 1994; 127,353 in December 1995; 162,704 in December 1996; and 223,403 certificates in December 1997. The 1998 data also show there were 7,887 registrations to ISO 14001, the environmental management standard.

These registrations represent every possible industry, from service industries to heavy manufacturing organizations. According to the ISO report, there were 573 registrars listed in 1999. This number had grown from 309 in 1995. During the same period the number of countries with registrars grew from 73 to 93. The directory lists 52 registrars operating in the United States. The number of accreditation agencies that accredit the registrars has increased from 33 in 1995 to 40 in 1999. Usually there is no more than one accreditation agency in any country. Some accreditation agencies operate in several countries.

Of the more than 270,000 registered companies, 36,653 are from the electrical and optical equipment industries, 28,885 from the basic metal and fabricated metal products industries, 20,275 from the machinery and equipment industries, 19,768 from the construction industries, and 16,451 from wholesale and retail trade. More than 61% of the registrations have been issued to organizations in Europe. In the United States, the accreditation agency is the Registrar Accreditation Board, a wholly owned subsidiary of the American Society for Quality and the American National Standards Institute. However, several other accreditation agencies operate in the United States, most notably the Raad voor Accreditatie (RVA) of the Netherlands.

There are several reasons for an organization to consider registration to these standards. The most commonly quoted reason is that their customers require it. In many instances, customers require extensive audits and/or surveys from their suppliers. These are often waived if the supplier is registered to ISO 9001. Of course, the principal reason is that the company will be a better company if it conforms to the standard, even if it is not registered. However, registration is an indication that this conformance has been met.

DONALD FUSARO
Lucent Technologies

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

Quality is ultimately defined by customers. There is significant literature available on how to measure quality and value as perceived by customers. In virtually every analysis, a major component of customer satisfaction is the ability of the company to provide a competitively priced product into which quality is designed, built, marketed, and maintained. A company-wide system for achieving that objective must be developed and deployed.

This chapter outlines a complete design and process platform characterization methodology and the system for deployment. The underlying principle of this methodology is to provide a vehicle that starts with identification of customer requirements and ends only when the product has been delivered to a customer who is thoroughly delighted.

This chapter is based on an actual corporate deployment. This provides clear evidence that the methodology works. It also demonstrates that this methodology is a critical part of strategic management that will dependably produce superior profits through satisfied customers.

The elements of design and process platform characterization methodology and system include:

- Product development
- Design characterization
- Process platform development
- Design and process platform characterization methodology

- Linkage of product design and process platform
- Deployment process

Each of these will be discussed in detail in subsequent sections.

2. PRODUCT DEVELOPMENT

Traditionally, product development includes initial research, prototype production, design finalization, and transfer to manufacturing. Today's fast-moving market requires a product-development process that is integrated and efficient. This demands up-front planning and execution of design optimization and manufacturing platform-development activities that ensure conformance to end-product requirements.

2.1. Product Development Process

The product development process consists of six stages; initial stage, specification alignment stage, initial models stage, product released to initial manufacture stage, production ramp stage, and product maintenance stage.

2.1.1. Initial Stage

The purpose of the initial stage is to assemble the relevant information for the product-development team, which includes marketing, design, manufacturing, supply chain, operations, and finance, and to make a fact-based go/no-go decision to develop the product. A go decision requires allocating the resources needed to document detailed specifications and plans for the development of the product. The specific goal of this stage is to evaluate the product concept efficiently and objectively as a function of strategic fit, competition, finance, operations technology, market window, and available resources.

2.1.2. Specification Alignment Stage

The primary function of the specification alignment stage is to generate the information that is required to decide whether to allocate resources to design and develop the proposed product. The product-development team develops detailed initial product specifications in response to market requirements. This permits proper project management by creating accountability for completion of the elements that make up this stage. The specification alignment stage is critical to ensure that sufficient lead time is available to develop, acquire, and prove in any new product and process platform facilities needed to ramp the product according to the business plan.

2.1.3. Initial Models Stage

In the initial models stage, product, test programs, software, and associated hardware are designed and developed. Completion is achieved when prototype hardware/software is fabricated and initial evaluation is started. This stage confirms that the initial model results match the initial product specifications. Finally, a ready-for-production checklist is reviewed by the product development team. One of the critical elements of this stage is the development and implementation of design and process platform characterization objectives and plans.

2.1.4. Product Released to Initial Manufacture Stage

The purpose of this stage is to ensure that product is released to production and validation of manufacturability, procedures, documentation, and customer demand is established. This activity verifies compliance of product and system performance, fixes design issues, and prepares for manufacturing ramps. At the end of this stage, the execution of design and process platform characterization plans are well in progress. This includes identification of critical design and process platform performance parameters, estimation of accuracy and precision for test systems, and planning and validation of experiments. In addition, product performance qualification testing, environmental testing, and final system testing progresses during this stage.

2.1.5. Production Ramp Stage

The launch through production ramps is where all the final product qualification, final manufacturing platform tests, design characterization, and process platform characterization requirements are completed. The purpose of this stage is to ensure that all required documentation is in place to efficiently support the release of the product to the market. The product development team also defines and implements plans for stable ongoing manufacturing, which includes validation of design and process models, control of critical platform processes, and surveillance testing. Appropriate product-

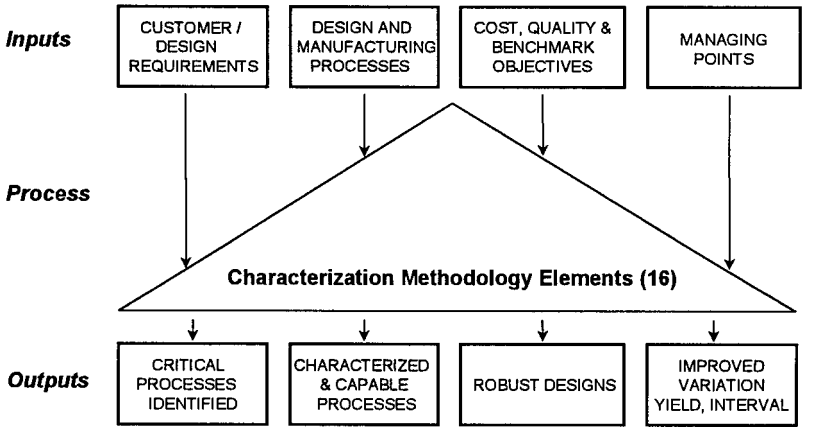

Figure 1 Characterization Overview.

maintenance plans, business strategies, and product-performance enhancements are established. This is the stage where product robustness and meeting all market and customer requirements are demonstrated.

2.1.6. Product Maintenance Stage

The focus of the product-maintenance stage is to ensure continued product success in the market. The manufacturing and operations teams ensure that product meets all requirements and continues to be robust. This activity ensures stable shipment of product to customers. In addition, periodic quality assurance audits are conducted to determine continued compliance relative to quality system requirements. This is the stage where all required design and platform activities are validated using large samples and appropriate corrective actions and continuous improvement activities are implemented.

2.2. Need for Characterization

Customer requirements and intense competition demand high level of product performance, reliability, and lower costs. This message has profoundly affected corporate America in its strategic goals and objectives as well as day-to-day business policies. During the 1990s we experienced an enormous advancement in all facets of technology. We now see products that have higher performance, more features, and in some cases lower costs. To meet these challenges, it is critical to characterize designs and processes/platforms to optimize the cause-and-effect relationships between customer performance requirements and process tolerances. The absence of this characterization can lead to a lack of consistency, resulting in ineffective planning and eventually higher costs.

2.3. Characterization Overview

Characterization is aimed at improving the overall business by enabling a better understanding of designs and processes. Characterization can be viewed as a process in itself defined by a set of inputs and activities to produce desired outcomes. One such view of a characterization process is shown in Figure 1. It includes a summary of inputs and expected outputs and a characterization methodology. The characterization methodology includes the specific steps for achieving robust designs and processes. The specific steps to the characterization methodology are described in Section 5.

3. DESIGN CHARACTERIZATION

3.1. Understanding Customer Requirements

Customer needs for product performance, reliability and quality are a given in today's market. Customers are no longer bound by national interests as they pursue quality products and services worldwide. To be competitive in this environment, businesses must exceed the needs of their customers by providing products that are high quality, cost effective, and reliable. The standard approaches for

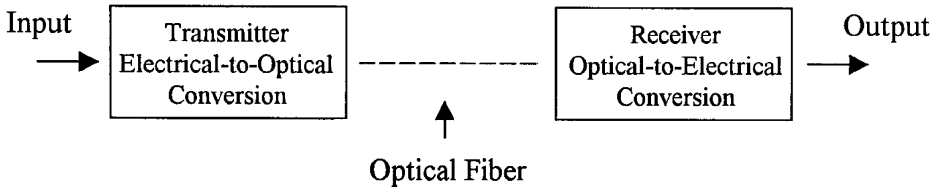

Figure 2 Fiberoptic System.

comprehending customer requirements include review of product specifications and drawings, performance evaluation of similar technology, and simulated testing for customer's application.

Communications with customers is the most important approach for understanding their requirements. This can be initiated by the customer as well as by the supplier. The customer-initiated feedback can be through formal product requests, product returns, field application data, and audits. The supplier-initiated feedback may include product-performance reviews, market trends, technology integration, competitive analysis, and design-characterization models.

3.2. Design Models

Design models are cause-and-effect quantitative models that translate product performance requirements to process requirements and identify key in-process output parameters and associated tolerances. Control of these parameters at in-process steps during manufacturing will generally ensure conformance to end-product requirements. In effect, design models establish the linkage between customer and manufacturing requirements. Design models are typically generated from current knowledge of existing technologies, proven theories, and data from planned experimentation. It is the experimental data that provides the new insight for a specific design. A formal characterization methodology is described in Section 5.

As an example, design models were developed for a fiber-optic system that includes three elements, the *transmitter*, which allows for data input and produces an optical signal, the *optical fiber*, which carries the data, and the *receiver*, which converts optical signal to electrical signal to output the data. Figure 2 depicts the key elements of a fiber-optic system.

3.2.1. Example: Optical Transmitter Design Model

An optical transmitter is the device that generates the signal that is sent through an optical fiber. One of the product parameters that is critical to transmitter performance is optical output power. The optical output power level that is delivered to the fiber is inevitably lower than what the light source generates because of transfer losses. The optical output power of a transmitter is affected by many design parameters, including parameters related to the laser chip, lens, optical fiber, and processing. Figure 3 depicts key elements of a transmitter.

As an example, a design model linking the relationship between key characteristics of these elements and optical output power is:

$$\text{Optical output power} = f\{\text{laser facet power, laser placement, lens placement, fiber alignment ...}\}$$

In this model, optical output power is impacted by the manufacturing processes, which include

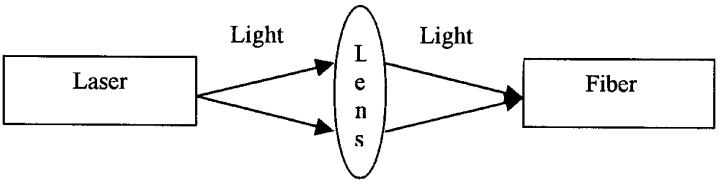

Figure 3 Transmitter Elements.

laser fabrication and the processes associated with laser, lens, and fiber attachment. Hence, control of these processes will ensure conformance to design requirements for optical output power.

4. PROCESS PLATFORM DEVELOPMENT

In addition to characterizing designs, manufacturing processes must also be characterized and controlled to achieve overall business objectives. When a design reuses well-established processes (i.e., platforms), improved time-to-market and reduced development and manufacturing costs can be achieved. This section describes an approach to developing these process platforms.

4.1. Process Platform Concept

All products are built on a series of processes to meet customer requirements and achieve desired performance measures. As products change or new products are introduced, many advantages are gained by the reuse of existing processes. These advantages include minimizing the cost in the development and introduction of new processes. In addition, overall time-to-market can be reduced by the elimination of process-development time in the product-development cycle. Also, requiring new process development as part of new product introduction reduces the probability of overall success of the project due to the additional variable of successful process development to achieve successful product development. However, reusing existing, well-understood processes makes both performance and impact on manufacturing known. The platform concept relies on establishing such processes and taking advantage of their capabilities to achieve new design goals. To introduce the platform concept into a business the following key elements will need to be developed for successful implementation:

- Common definition and understanding of platform concept
- Platform scope based on business plans
- Migration plans
- Characterization plans
- Platform capabilities and requirements

4.1.1. Platform Definition

The definition of platforms to a particular business needs to be jointly developed and communicated throughout all organizations (manufacturing, development, design, and marketing). This definition needs to be tailored to fit the company's infrastructure, systems, and culture for it to be effectively deployed. However, any definition of a platform should include elements of commonality, reusability, characterization, and capability. An example of one such definition is given in Figure 4. The platform definition will provide an organization with the basic framework to determine which processes are to be considered as platforms. In some instance, various levels of platform can be defined to allow for some additional platform flexibility. For example, a level one platform may mean no changes are allowed, a level two platform may allow for changes to process settings, a level three platform may allow for changes to fixturing, and so on.

COMMON:
- Process is used on a variety of product codes and families

REUSABLE:
- Process is used for several generations of product designs

WELL DEFINED:
- Defined Boundary Conditions & Design Guidelines (what it can and can't do)
- Characterized, Stable and Capable Process Inputs and Outputs
- Defined Characteristics, Documented

COMMON CHARACTERISTICS:
- Methods: Common procedures, sequence, recipe (inputs)
- Skills: Defined training requirements (skill needs - operating & engineering)
- Hardware: Machine, Equipment (function & features)
- Materials: Common piece part characteristics, Material composition
- Environment: Controls, Conditions

Figure 4 Process Platform Definition.

4.1.2. Platform Scope

To implement platform processes successfully, an organization needs to develop fundamental business plans in terms of market perspective, technology directions, and existing manufacturing capability. From a market perspective, detailed market plans need to be established that identify direction of future product performance requirements in the markets it serves. From a technology standpoint, technology roadmaps are needed to set design and technology plans that provide design direction to achieve future product performance requirements. From manufacturing, the capability of existing processes and technologies need to be well understood and defined to determine the impact of design changes on process capabilities. All of this information needs to be integrated to develop comprehensive platform plans and objectives.

4.2. Process Platform Implementation

4.2.1. Platform Migration

If the implementation of platforms includes processes already used in manufacturing, then individual platform-specific plans need to be developed to migrate existing products onto the platform. A typical process for the development of these migration plans is shown in Figure 5.

Each product should be evaluated to determine whether it should be migrated to the platform. This evaluation should also consider future products and designs. The evaluation has two key parts associated with it. First, a business case needs to be developed to determine what are the specific expected benefits in terms of cost, interval, capacity improvements vs. the cost of implementation of the platform. Second, there needs to be an assessment to establish the technical feasibility of manufacturing the product using the platform. The technical feasibility must be done from both the design and process viewpoints. This will require that both process and design characterization have been completed. Once both benefits and technical feasibility have been demonstrated, specific experimental and qualification plans can be developed and implemented to migrate products onto the platform.

4.2.2. Platform Characterization

As per the definition, a platform must be well characterized to provide the confidence that the performance achieved from this process is sustainable. This characterization activity will lead to the

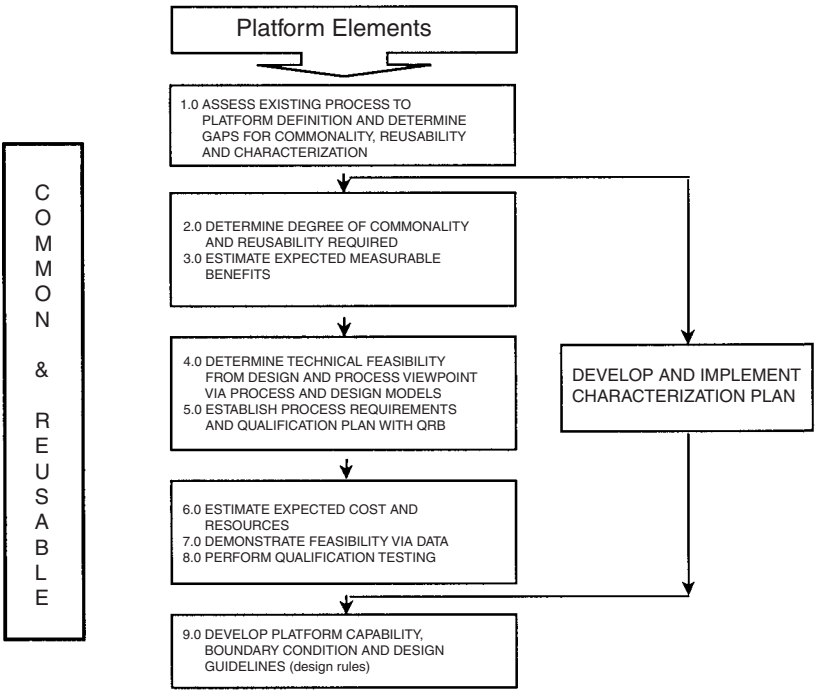

Figure 5 Platform Migration Methodology.

development of a process model, which is a cause-and-effect quantitative model that establishes the relationships between process requirements and process variables. The process model identifies key process inputs and level of control (i.e., tolerances) needed to achieve desired process performance. An example of such a model is given in Section 5. As with any tolerance, if it is unnecessarily tight it may lead to overall higher processing costs and if it is too loose it may result in producing defective product. A formal methodology to characterize platforms and processes is described in Section 5.

4.3. Process Platform Capability

4.3.1. Boundary Conditions

Upon completion of characterization, a platform's true capability can be determined. This capability provides design organizations with tolerances to design within. These capabilities must be defined relative to appropriate constraints on process conditions. These constraints are termed boundary conditions. Process boundary conditions must be defined that clearly specify any restrictions necessary to achieve the capability and benefits of the platforms. These boundary conditions can include restriction to process settings, fixture requirements, environmental conditions, process methods or sequences, and so on. Thus, these conditions provide design groups with what a process can and cannot achieve.

4.3.2. Platform Performance

For each performance characteristic, the associated process capability needs to be defined. Capability is evaluated in terms of the ability of the process to meet its target and in terms of reproducing results consistently (i.e., process variation). Capability is developed through collection and analysis of performance data after process characterization and control has been established. The resulting measures define the expected performance of a platform. This information is critical input into design in terms of expected product performance.

5. DESIGN AND PROCESS PLATFORM CHARACTERIZATION METHODOLOGY

Each business must have a sound approach for understanding and improving its processes and designs. The design and process platform characterization methodology presented here is one such approach that has been proven successful in modeling, controlling, and improving products and processes. This approach, shown in Figure 6, provides the detailed steps and associated tools to achieving process and design goals.

The methodology consists of five major elements:

- Process definition
- Measurement system characterization
- Design and process characterization (i.e., model development)
- Process control
- Process capability

5.1. Process Definition (Steps 1 and 2)

5.1.1. Step 1: Identify Critical Designs and Processes

Products are built on a series of processes, each with its own impact on the overall performance. The purpose of this step is to determine which processes need to be characterized. A process includes the combination of people, equipment, materials, methods, and environment that produces products or services. Any process whose inputs and outputs are measured, monitored, controlled, or observed should be evaluated. Designs and processes for characterization are typically identified based on their overall impact to the business. A critical design and process is one that has major impact on cost, quality, manufacturability, performance, reliability, or customer satisfaction. Some of the methods and tools available for determining this are given below:

- Product performance analysis
- Design and reliability reviews
- Customer field returns analysis
- Quality function deployment
- Quality improvement methodologies
- Cost of quality
- Fishbone analysis

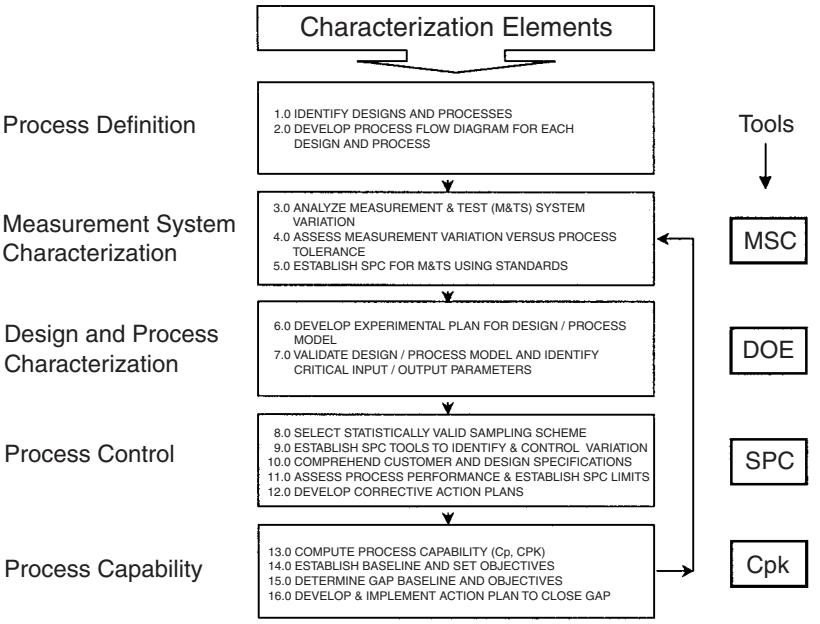

Figure 6 Design and Process Platform Characterization Methodology.

Example: Fiber-Alignment Platform

Platform Description:

This process consists of aligning a fiber to the lens for minimizing optical power loss and then welding the fiber to the lens while maintaining fiber alignment. A measure of this fiber alignment is the change in power loss due to welding (i.e., delta insertion loss).

Process	**Inputs**	**Outputs**	**Impact**
Fiber alignment	Weld energy, weld pattern, lens holder roughness, fiber gap, optical fiber, lens, package	Delta insertion loss	Optical output power
Design	**Inputs**	**Outputs**	**Impact**
Transmitter design	Laser facet power, laser placement, lens placement, fiber alignment (delta insertion loss)	Optical output power	System performance

5.1.2. Step 2: Develop Process Flow Diagram for Each Design and Process

For each design and process selected, a process flow diagram should be developed. A process flow diagram will aid in determining the scope of the characterization effort. The flow chart should be developed with inputs from engineering, design, manufacturing, suppliers, and customers to identify all potential design and process characteristics and includes items such as:

- Sequential process steps and/or material flow
- Relationship between process steps
- Rework loops
- List process step, setups, inputs (i.e., temperature, pressure, force)
- List outputs (i.e., epitaxial thickness, pull strength, wavelength, power)
- Decision points
- Process control and yield points

Example

The process flow diagram for the fiber-alignment platform is shown in Figure 7.

5.2. Measurement System Characterization (Steps 3–5)

5.2.1. Step 3: Analyze Measurement and Test System (M&TS) Variation

Once the process characteristics have been identified, it is then critical that appropriate measures of these characteristics be available. If data does not exist, an appropriate measurement method must be developed and evaluated. If data already exists, a thorough study on the measurement system variation in terms of both accuracy and precision needs to be completed to determine the overall measurement system capability. Excessive variation in the measurement and test system (M&TS) will adversely affect the sensitivity of the decision-making process and may be a source of unnatural variation.

To determine statistically the accuracy and precision of the measurement system, calibration and an error of measurement study must be completed.

Accuracy can be defined as the extent to which the average of a series of repeat measurements of the same item agrees with the "true" value. Accuracy is achieved via calibration, where calibration is the combination of checking and adjusting (if needed) M&TS to a known or traceable standard to bring the M&TS within its tolerances for accuracy.

Precision can be defined as the variation observed in individual repeated measurements of the same item. Precision is also referred to as measurement error, repeatability, or reproducibility. The common method of estimating precision is by performing an error-of-measurement study. This study

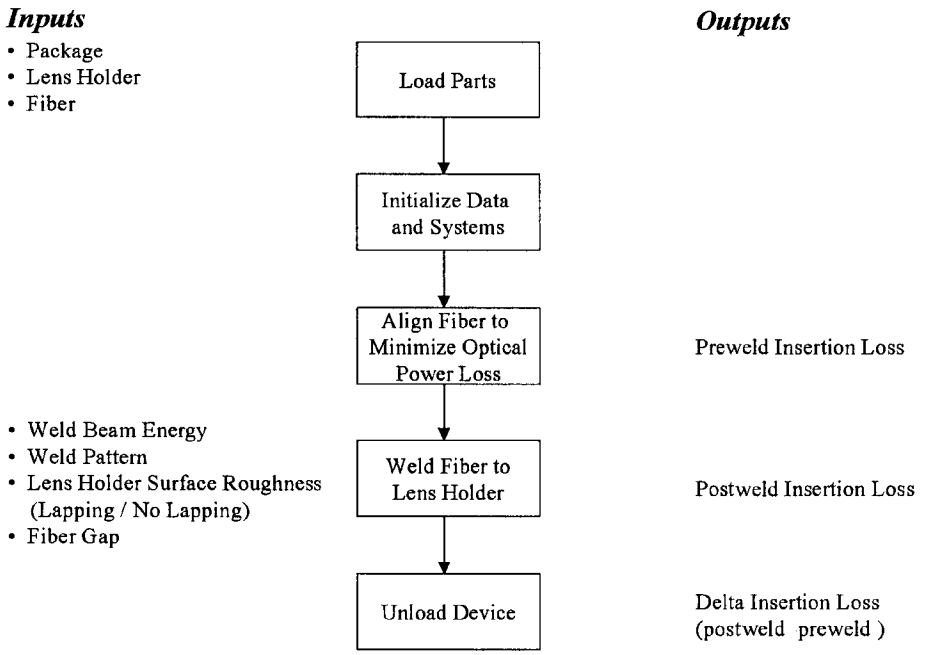

Figure 7 Fiber-Alignment Process Flow.

TABLE 1 Insertion Loss Error-of-Measurement Data.

Device	Reading 1 (dB)	Reading 2 (dB)	Average	Range
1	0.54	0.52	0.53	0.02
2	0.81	0.85	0.83	0.04
3	0.82	0.81	0.82	0.01
4	0.16	0.18	0.17	0.02
5	0.89	0.85	0.87	0.04
6	0.73	0.72	0.73	0.01
7	0.68	0.68	0.68	0.00
8	0.55	0.55	0.55	0.00
9	0.85	0.83	0.84	0.02
10	0.83	0.84	0.84	0.01
11	0.24	0.25	0.25	0.01
12	0.90	0.91	0.91	0.01
13	0.77	0.80	0.79	0.03
14	0.69	0.66	0.68	0.03
15	0.57	0.54	0.56	0.03
16	0.85	0.85	0.85	0.00
17	0.35	0.34	0.35	0.01
18	0.90	0.88	0.89	0.02
19	0.73	0.79	0.76	0.06
20	0.68	0.70	0.69	0.02

is performed by measuring several devices multiple times each and then estimating the error from the repeated measurements.

If more than one piece of equipment or measurement system is used to make measurements, then it is also necessary to perform appropriate correlation studies to demonstrate the compatibility of the multiple systems.

Example: Fiber-Alignment Platform

An error-of-Measurement study was performed to determine the measurement error of the insertion loss-measurement system. This study included measuring 20 devices repeatedly and creating control charts to evaluate measurement performance. The data and analysis are shown in Table 1 and Figures 8 and 9 respectively.

The X-bar chart in Figure 8 shows the discriminating power of the MT&S by plotting the average (i.e., mean) measurements vs. limits derived from the range of repeated measurements from the same device. Since this chart shows the ability of the MT&S to differentiate between different devices, ideally the data points should be out of control for this chart.

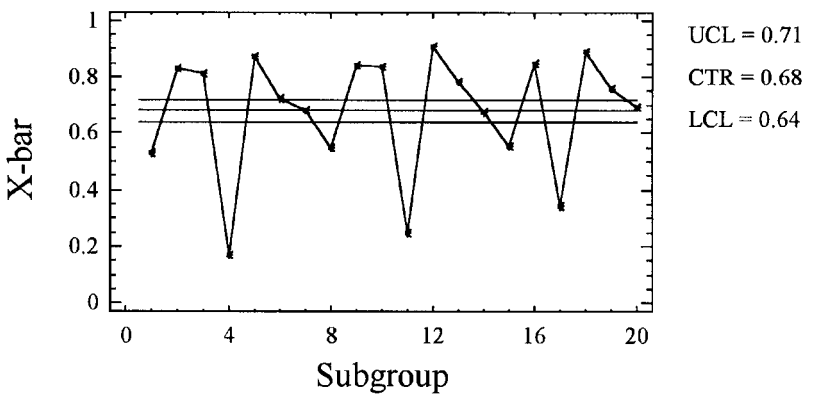

Figure 8 X-bar Chart for Insertion Loss Error of Measurement.

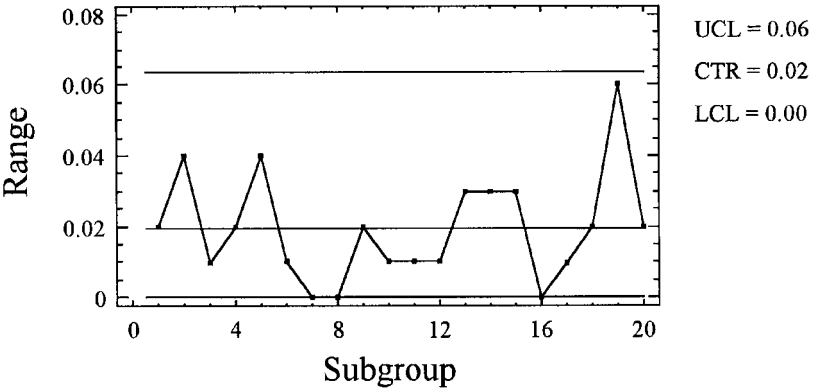

Figure 9 Range Chart for Insertion Loss Error of Measurement.

The range chart in Figure 9 shows directly the magnitude and consistency from device to device of the measurement error associated with this MT&S. The plot shows the difference between measurements made on the same device. Ideally, this chart should have a low centerline and be in control.

Based on the average range (r-bar), the measurement error (σ_m) was then estimated by using the formula as $\sigma_m = r$-bar divided by d_2, where d_2 is the factor that converts the range of a sample of size n from a normal distribution into an unbiased estimate of the standard deviation of that distribution. For a sample size of $n = 2$, $d_2 = 1.128$.

$$\text{Insertion loss-measurement error } (\sigma_m) = 0.02 \text{ dB}$$

5.2.2. Step 4: Assess Measurement Variation vs. Process Tolerances

Once the measurement variation has been estimated, one needs to determine its acceptability for its intended use. This is typically done by comparing the measurement system variation vs. process tolerances or product performance. These two methods are described below:

5.2.2.1. Precision to Tolerance (P/T) Ratio This method is used to compare the measurement error relative to process tolerance (i.e., a parameter with an upper and lower specification limit).

$$P/T \text{ ratio} = \left\{\frac{6 * \sigma_m}{\text{USL} - \text{LSL}}\right\} * 100\%$$

A recommended level is that the M&TS have a $P/T < 30\%$. This would be interpreted as meaning that 30% of tolerance interval could be used up by measurement error and still be acceptable.

5.2.2.2. Percent Measurement Error (Percent Error) This method is used to compare the measurement error relative to the total variation in the process and is typically applied for one-sided specification.

$$\text{Percent measurement error} = \left\{\frac{(\sigma_m)^2}{(\sigma_t)^2}\right\} * 100\%$$

where σ_t is an estimate of the variation from the process under study.

A recommended level is that M&TS have percent error $< 10\%$. This would be interpreted as meaning the measurement component to the overall total process variation could be up to 10%.

Note that P/T ratio and % error objectives are only recommendations. These levels should be selected based on individual requirements and applications.

Example: Fiber-Alignment Platform

The following criterion was used to determine acceptability of the insertion loss-measurement system:

Percent measurement error $< 10\%$ is acceptable

For this example the measurement error was 0.02 dB and an estimate of total error from production data was 0.1 dB:

$$\text{Percent measurement error} = \frac{\{0.02\}^2}{\{0.1\}^2} * 100\% = 4.0\%$$

5.2.3. Step 5: Establish Statistical Process Control for M&TS Using Standards

The purpose of monitoring measurement and test systems is to determine whether the measurement system is stable, where stability is the absence of drift or other changes over time. This will ensure that the estimates of accuracy and precision remain the same over time. In many cases, when the measurement system is consistently stable over a long period of time, a reduced calibration frequency can be implemented.

A method to determine stability is to monitor M&TS using product or traceable standards via statistical process control. Measuring and monitoring standards at a specified frequency allows a measure of stability to be assessed. If traceable standards are not available, then devices that represent the behavior of a product on the M&TS can be used. It is recommended that two active and one reserve standard be specified. The reason for using two active standards is to determine the nature of the problem (i.e., is it due to malfunctioned standard or the M&TS). The active standards should be used to monitor the M&TS performance. The frequency of monitoring active standards depends upon a particular application (i.e., per shift or per day or before use). The reserve standard should be used to replace an active standard that degrades or no longer functions. The reserve standard may be used for confirmation or resolution of a problem. To accomplish these functions, the reserve standard must be measured regularly (typically at less frequency than active standard) to establish a performance history.

Some of the key elements for establishing statistical process control for measurement and test system include:

- Identification of critical parameters
- Determination of measurement error
- Selection of traceable (if available) and/or product standards
- Determination of the sample size and the frequency of measurements for each standard
- Selection of statistical tools (i.e., control charts) to monitor and control variation
- Development and implementation of corrective action procedure for out-of-control conditions

Example: Fiber-Alignment Platform

To assess the stability of the MT&S for insertion loss, two standards were measured and plotted once a day. Individual control charts were implemented to monitor and control this testing process. These control charts are shown in Figure 10.

5.3. Model Development (Steps 6 and 7)

5.3.1. Step 6: Develop Experimental Plan for Design/Process Model

In this step, the designer or process owner develops the hypothesized relationships (i.e., forms the tentative model to be estimated) between design or process inputs and outputs and associated experimental plan.

The two types of models that are developed are the design and process models. Design models are cause-and-effect quantitative models that translate product-performance requirements to process requirements. The design model identifies key in-process output parameters and associated tolerances. For example:

$$\text{Optical output power} = f\{\text{laser facet power, laser placement, lens placement, fiber alignment ...}\}$$

Inputs to include in the design model may be identified through:

- Physical (theoretical) relationship
- Previous design work
- Defect analysis via reliability monitoring

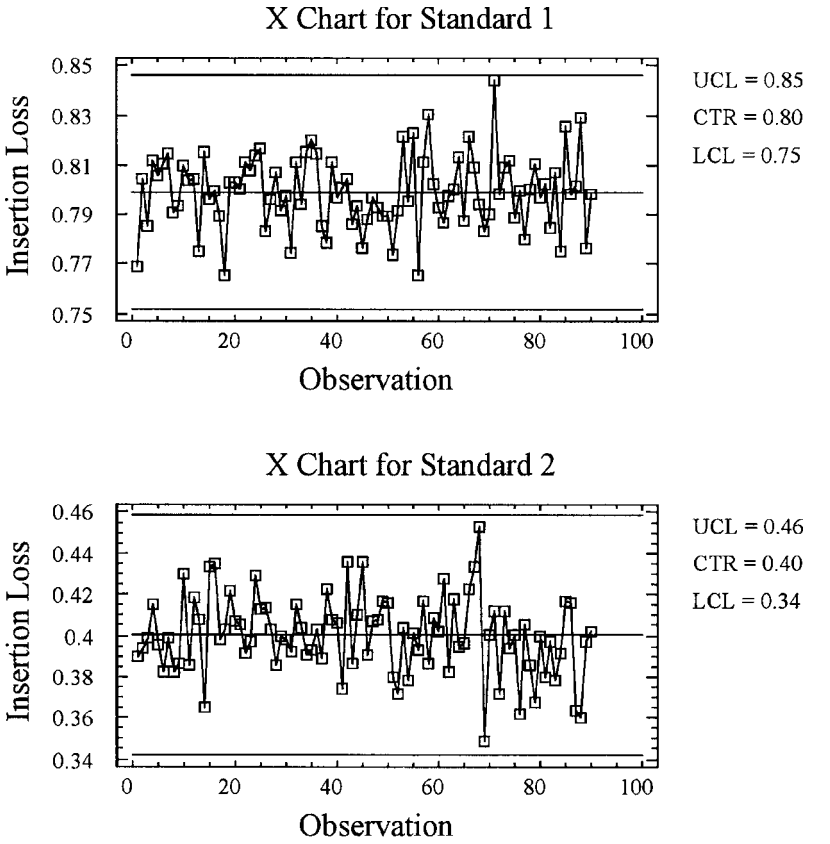

Figure 10 X Charts for Insertion Loss Measurement Standards.

- Device quality issues
- Customer feedback

Process models are cause-and-effect quantitative models that establish the relationships between process requirements and process variables. The process model identifies key process inputs and level of control (i.e., tolerances) needed to achieve desired process performance. For example:

$$\text{Fiber alignment} = f\{\text{weld energy, weld pattern, lens holder roughness, fiber gap ...}\}$$

Inputs to include in the process model may be identified through:

- Physical (theoretical) relationship
- Engineering design
- Defect analysis via manufacturing monitoring
- Customer feedback

Once the process or design variables have been identified, a statistically designed experiment should be employed to collect appropriate data to fit the model. This plan includes developing the experimental objective, design matrix, and sample size (i.e., number of experimental replicates).

Example: Process Model

Fiber-Alignment Platform

Experimental objectives: Determine the relationships and settings for key process variables to meet process objective of delta insertion loss less than 1 dB.
Response variable: Delta insertion loss (fiber alignment)
Process variables: Weld energy
Weld pattern
Lens holder roughness
Fiber gap
Experimental design: 2^4 factorial
Experimental matrix:

Weld Energy (joules)	Weld Pattern (# welds)	Lens Holder Roughness	Fiber Gap (μm)	Delta Insertion Loss (dB)
0.5	2.0	0	2.0	0.466
1.0	2.0	0	2.0	1.141
0.5	6.0	0	2.0	0.134
1.0	6.0	0	2.0	1.783
0.5	2.0	1	2.0	0.346
1.0	2.0	1	2.0	0.945
0.5	6.0	1	2.0	0.269
1.0	6.0	1	2.0	1.803
0.5	2.0	0	8.0	0.519
1.0	2.0	0	8.0	0.907
0.5	6.0	0	8.0	0.440

30	1.5	5.8	1	23.26
20	6.5	5.8	1	11.91
30	6.5	5.8	1	19.03

5.3.2. Step 7: Validate Design/Process Model and Identify Critical Parameters

From the experimental data, a mathematical model is developed to identify significant input factors and quantify their impact on the output. From this, appropriate settings for the inputs can be determined as well as the level of control required during manufacturing. The statistical techniques to accomplish this are analysis of variance and regression analyses.

Example: Process Model

Fiber-Alignment Platform

Data from the experiment were analyzed using ANOVA and multiple regression techniques. The results are shown in Figure 11.

The analysis of this data identifies weld energy and weld pattern as critical process variables and develops the following model:

$$\text{Delta insertion loss} = \{0.354 + 0.320\ (\text{weld energy}) - 0.240\ (\text{weld pattern}) + 0.399\ (\text{weld energy} * \text{weld pattern})\}$$

From this model and other processing considerations, the following process settings were implemented.

Parameter	*Setting*
Weld energy	0.6 J
Weld pattern	3
Lens holder roughness	0 (no lapping)
Fiber gap	5 μm

Example: Design Model

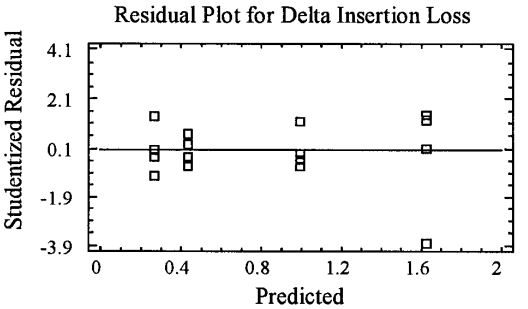
R-squared = 94.3644 percent, R-squared (adjusted for d.f.) = 92.9555 percent
Standard Error of Est. = 0.150152



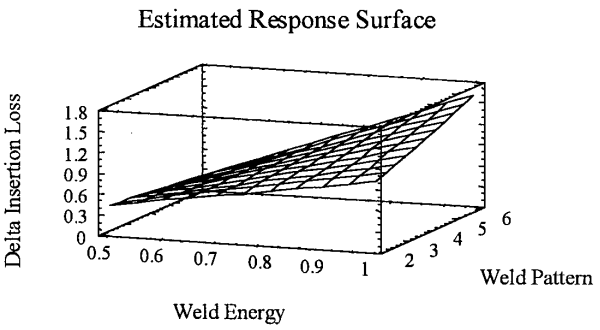


Figure 11 Results of Fiber-Alignment Platform Experiment.

Transmitter Optical Output Power

Data from the experiment were analyzed using ANOVA and multiple regression techniques. The results are shown in Figure 12.

The analysis of this data identifies laser facet power, laser placement, lens placement, and fiber alignment as critical design variables and develops the following model:

$$\begin{aligned}\text{Optical output power} = \{&1.527 + 0.824\ (\text{laser facet power}) - 0.038\ (\text{laser placement})\\ &- 0.025\ (\text{lens placement}) - 1.498\ (\text{fiber alignment})\\ &- 0.021\ (\text{laser facet power} * \text{laser placement})\\ &- 0.034\ (\text{laser placement} * \text{lens placement})\}\end{aligned}$$

Based on the design model, customer requirements, platform requirements, costs, and other design considerations, the following specifications were developed.

Parameter	*Specification*
Laser facet power	22–28 mW
Laser placement	5 μm maximum
Lens placement	5.8 mils maximum
Fiber alignment	1 dB maximum

5.4. Statistical Process Control (Steps 8–12)

Once the critical inputs and outputs have been determined, appropriate statistical process controls can be implemented to control and improve process performance.

In the example, a design model was first developed that indicated that optical output power is a function of laser facet power, laser placement, lens placement, and fiber alignment. To control optical output power, statistical process control must be applied to these critical process output parameters and, where applicable, must be applied to corresponding process input parameters.

Below is the summary of the design model for optical output power and the corresponding process models associated with the critical process output parameters.

- Design model:

$$\begin{aligned}\text{Optical output power} = f\{&\text{laser facet power, laser placement, lens placement,}\\ &\text{fiber alignment ...}\}\end{aligned}$$

- Process models:

$$\begin{aligned}\text{Fiber alignment} &= f\{\text{weld energy, weld pattern ...}\}\\ \text{Laser facet power} &= f\{\text{laser chip slope, epitaxial grating, metal doping composition ...}\}\\ \text{Laser placement} &= f\{\text{laser chip size, bond temperature, piece part quality ...}\}\\ \text{Lens placement} &= f\{\text{bonding temperature, ambient conditions, solder oxidation ...}\}\end{aligned}$$

Hence, the control of process output parameters and associated input parameters will ensure conformance to optical output power requirements.

5.4.1. Step 8: Select Statistically Valid Sampling Scheme

Based on the process models, appropriate sampling plans for process controls can be developed. A sampling scheme using rational subgroupings is one that provides the valid or right data at minimal cost. The main effort is to ensure that the samples in any one subgroup have been produced under essentially the same conditions. Elements of a rational subgroup include:

- Samples are randomly selected within a subgroup.
- Subgroups are collected at proper frequencies.
- Subgroup size is adequate to detect desired level of change or shift in the process.
- Subgrouping minimizes variation within subgroups.

A typical guideline is to collect small samples frequently rather than large samples less frequently.

Example: Fiber-Alignment Platform

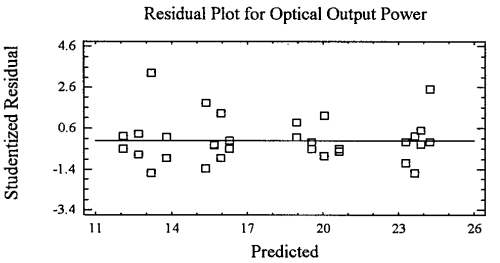

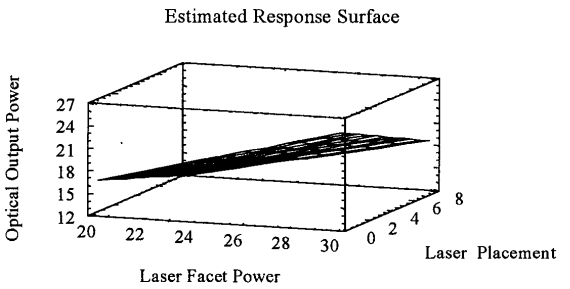

Figure 12 Results of Optical Output Power Experiment.

Based on costs, chosen risk levels associated with detecting assignable cause variation, magnitude of process change to be detected, and rational subgrouping considerations, a sampling scheme to weld and measure the first five parts of each shift was implemented.

5.4.2. Step 9: Establish Statistical Tools to Identify and Control Variation

Many statistical tools have been developed to control critical process parameters. The most commonly used is the control chart, which is an effective way to monitor and control processes and can be defined for both variables and attributes data. The selection of variables data will typically make basic statistical tools more efficient (i.e., lower sample size requirements to achieve necessary confidence levels).

Example: Fiber-Alignment Platform

In order to monitor and control this process, an X-bar and R control chart for fiber alignment (delta insertion loss) was established and data collection and analysis were implemented. These charts were used to identify and address assignable cause variation.

5.4.3. Step 10: Comprehend Customer and Design Specifications

The implementation and validation of design models in manufacturing ensures alignment of specifications. Implementation includes:

- Analyzing design specifications relative to the process capability
- Examining and understanding the reasons for process specifications
- Determining and implementing statistically valid specifications
- Enhancing the specification-alignment process

Example

Based on customer requirements and platform capabilities, the design model was used to align specifications to meet requirements. In this example, based on a customer requirement for optical output power of 15–24 mW, existing fiber-alignment platform requirement of <1 dB, and the design model, the following process tolerances were generated for the remaining processes:

Parameter	*Tolerances*
Laser facet power	22–28 mW
Laser placement	5 μm maximum
Lens placement	5.8 mils maximum

From these process tolerances, the fiber-alignment platform capability was maintained and the ability to meet customer requirement was met at a Cpk of 1.33. Depending on costs and other considerations, additional trade-offs between design and process requirements can be established.

5.4.4. Step 11: Assess Process Performance and Establish Statistical Limits

Assessment of process performance is a systematic procedure that uses statistical tools (usually control charts) to detect and eliminate (via corrective action) the unnatural (assignable) causes of variation until a state of statistical control is reached and hence statistical limits are established. A state of statistical control is a condition describing a process from which all assignable causes of variation have been eliminated via corrective action and only natural causes remain.

Example: Fiber-Alignment Platform

After assignable causes were eliminated, statistical limits were established for the control chart. Figure 13 shows the X-bar and R control charts for the last 90 data points.

5.4.5. Step 12: Develop Corrective Action Plans

Development and timely execution of corrective action procedures for out-of-control conditions is one of the most critical elements of effective implementation of process control. Corrective action procedures must be documented and should include the following information:

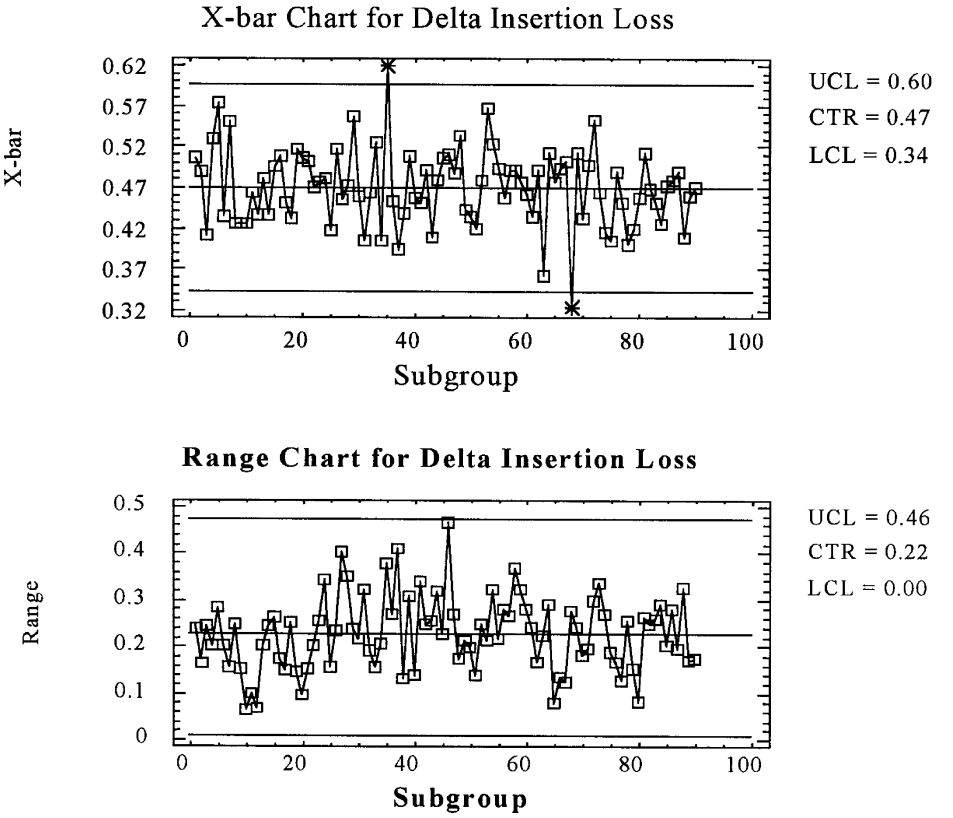

Figure 13 X-Bar and Range Chart for Fiber Alignment Process.

- When to take corrective action (i.e., when control chart signals an out-of-control condition)
- Who should initiate the corrective action procedure (i.e., operator, engineer)
- What corrective action should be performed per each failure mechanism
- What should be the disposition of the suspect devices/lots

It is also important to record properly the corrective action performed for Pareto analysis to further enhance the corrective action procedure.

Example: Fiber-Alignment Platform

Corrective action procedures were documented for this process and included items on verifying process conditions, such as weld beam energy and fiber gap position, establishing failure mode analysis procedures, determining disposition of work in process, and confirming procedures for re-starting the process.

5.5. Capability Analysis (Steps 13–16)

Once a state of statistical process control has been achieved, process capability can be estimated.

5.5.1. Step 13: Compute Process Capability (Cp, Cpk)

In order to understand the true process capability for the critical processes, it is important to compute process capability indices using proper statistical procedures. These indices estimate the process's ability to meet design and customer requirements. Two of the most common capability indices are Cp and Cpk, where:

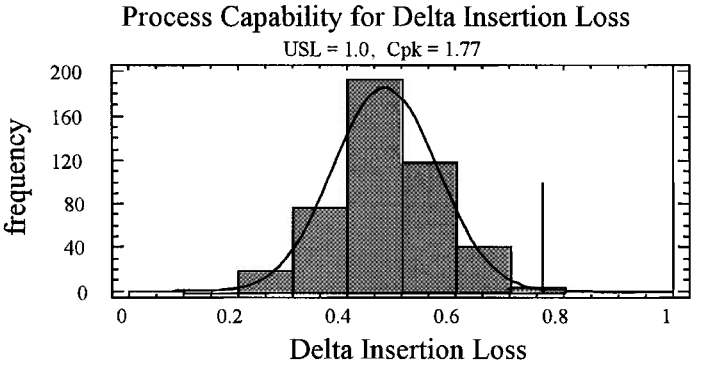

Figure 14 Fiber-Alignment Process Capability Analysis.

$$\text{Cp} = \text{USL} - \text{LSL}/6 \text{ sigma}$$
$$\text{Cpk} = \text{Minimum of } \{\text{Cpl, Cpu}\}$$

where

$$\text{Cpl} = \{\text{mean} - \text{LSL}\}/3 \text{ sigma}$$
$$\text{Cpu} = \{\text{USL} - \text{mean}\}/3 \text{ sigma}$$

A standard method for computing and reporting process capability indices for the critical designs and processes should be developed. Following are some of the key elements that should be considered for a process capability algorithm and report:

- Assessment and identification of statistical outliers from the data set
- Estimation of process capability indices for nonnormal data
- Warning for special conditions (i.e. insufficient data, multimodal distribution and excessive outliers)
- Estimation of Cp and Cpk indices, confidence intervals, summary statistics

Example: Fiber-Alignment Platform

The process capability index (Cpk) was estimated to determine the ability of the process to meet design objectives. Based on last 450 observations, the Cpk was estimated to be 1.77 and is shown in Figure 14.

5.5.2. Step 14: Establish Baseline and Set Objectives

For each process, estimates of process capability and yield for critical processes should be summarized and reported (baseline). Based on overall business objectives, realistic and attainable objectives for process capability and first pass yield should be set.

5.5.3. Step 15: Determine Gap between Baseline and Objectives

A gap analysis should be performed between the current baseline and objectives for each critical process to determine the extent of the improvement plans.

5.5.4. Step 16: Develop and Implement Action Plan to Close Gap

Based on gap analysis, an action plan should be developed and implemented to close the gap and promote continuous improvement.

6. LINKAGE OF PRODUCT DESIGN AND PROCESS PLATFORMS

In order to use the product and platform knowledge gained through characterization effectively, it needs to be documented and available to appropriate functions. This allows an organization to respond to customers more effectively in terms of new product development. One method is the development of platform and design manuals that would contain key aspects of platform elements and design characterization.

6.1. Process Platform Manual

6.1.1. Platform Description

A brief description of the function of the platform process should be included. The description should uniquely identify the scope and purpose of the particular platform.

6.1.2. Platform Characteristics

A list and associated description of the key attributes of the platform needs to be included. Attributes should be defined to document platform components sufficiently. These elements include hardware or equipment sets being used as well as necessary software algorithms. Elements also include what incoming materials are used on the process. Incoming materials may be from internal or external suppliers. When environmental controls are necessary, such as clean-room conditions, that also should be included. Also, items related to carrying out the process, such as methods, skills, and process conditions, should be summarized.

6.1.3. Platform Boundary Conditions

Boundary conditions should be established for each of the key platform characteristics. For each characteristic, the platform developer must determine the limits to which a characteristic can vary and still be manufactured on the platform to meet process and product features. These limits define the boundary conditions. These conditions include tolerance requirements on piece parts and materials, equipment and software specifications, and training requirements. These overall boundary conditions (i.e., what a process can and cannot do) will be the basis of the design guidelines that will be shared with design and marketing organizations.

6.1.4. Platform Characterization Model

For each performance characteristic, a process model must be developed and defined. The process model is a cause-and-effect quantitative model that establishes the relationships between process requirements and process variables. The process model identifies key process inputs and level of control (i.e., tolerances) needed to achieve desired process performance.

6.1.5. Platform Capability

For each performance characteristic, the associated process capability needs to be defined in terms of the ability of the process to meet its target and in terms of reproducing results consistently (i.e., process variation). The following items are typically included in the capability section of the platform manual:

- *Performance parameter*: lists critical platform outputs, as typically defined by design characterization activities, that must be met.
- *Process model*: establishes the relationship between platform inputs and performance parameters (platform outputs).
- *Parameter boundary conditions*: establishes platform requirements in terms of target performance that a platform will achieve. This may be a nominal target, single target, multiple targets, or a range of targets depending on the scope of the platform.
- *Nominal Performance (μ)*: defines actual performance of how well the platform is meeting its target.
- *Capability (1σ)*: defines the process variability associated with respect to each performance parameter.
- *Measurement methods*: describes the measurement method used to obtain performance results.
- *Measurement error*: defines the measurement error (1σ) for each performance parameter.

6.1.6. Platform Manual Example

6.1.6.1. Fiber-Alignment Platform Manual

- *Platform description*: The process consists of aligning a fiber to the lens for minimizing optical power loss and then welding the fiber to the lens while maintaining fiber alignment. A measure of this fiber alignment is the change in power loss due to welding (i.e., delta insertion loss).

Platform/Process Characteristics and Boundary Conditions (Design Rules)

Elements	Platform Characteristics	Boundary Condition
Hardware/equipment	Welder	
Software (algorithms)	Standard	Standard
Incoming materials	Lasers, Package, 3 × 3 Laser Carrier, Lens, Optical Fiber	3 × 3 laser carrier dimensions per drawing C1501 Package foot print dimensions per drawing C1432 Laser chip dimension of 20 by 25 mils Lens diameter (775 to 825 μm) and spherical shape Lens holder size must be 10–12 mm
Elements	Platform Characteristics	Boundary Condition
Environment	Class 10,000 clean room	Class 10,000 clean room
Method	Welding	Welding
Skills	Photonic processor	Photonic processor
Performance level	See below[1]	See below[2]

Platform/Process Capability (Performance Level)

Performance Parameter	Process Model	Parameter Boundary Condition[2]	Nominal Performance (μ)[1]	Capability (1σ)	Measurement Method	Measurement Error (1σ)
Delta insertion loss	Weld energy, weld pattern	1.0 dB maximum	0.47 dB	0.1 dB	Power meter	0.02 dB
Torque	Weld energy, weld pattern, focus, beam balance	10 in./lb minimum	17.8 in./lb	1.2 in./lb	Destructive	$<$ 0.5 in./lb

6.2. Design Manual

As a platform manual defines platform capability and requirements, a design manual defines design capability and requirements. Below is the description of a design manual.

6.2.1. Design Description

The design description covers a brief overview of the design scope and intent, including a description of the design construction, physical dimensions, electrical, optical, mechanical, and environmental objectives.

6.2.2. Design Parameters and Requirements

This includes a brief description of design parameters and their functions for a given product or family of products. The description may also include any special test conditions or requirements. In addition, specific customer requirements that must be met for each performance characteristic, including reliability, performance, maintainability, producibility, testability, safety, and cost objectives.

6.2.3. Design Characterization Model

For each performance characteristic, a design model should be developed and defined. The design models are cause-and-effect quantitative models that translate product performance requirements into process requirements and identify key in-process output parameters and associated tolerances.

6.2.4. Design Capability

For each design parameter, its associated capability needs to be defined and documented in terms of current and potential platform capabilities. Including potential capabilities enables improved market plans and offerings to be developed because design possibilities will be known.

6.2.5. Design Boundary Conditions

Boundary conditions should be established for each design parameter that define requirements to achieve design performance. These conditions define design limitations based on process and tech-

nology capabilities. They also provide marketing with the ability to develop better plans and respond to customer requests in a more timely fashion.

6.2.6. Design Manual Example

6.2.6.1. Transmitter Design Manual

- *Design description*: The transmitter is designed to operate at 2.5 Gb/sec with a NRZ data input format. The elements include housing, electrical interface, optical interface, drive circuitry, temperature control, optical sensors, data buffers, modulator, and attenuator.
- *Design parameters*: The absolute maximum ratings for supply voltage range from –5 to +5 volts with storage temperature range 0–65°C. The electrical and optical requirements include power supply current $<$ 500 mA, optical power output 15–24 mW. The environmental and mechanical requirements include 5 temperature cycles at 0–70°C. The targeted wavelength must be between 1523–1527 nm.

- Design Boundary Conditions
  - Lens must be spherical with a diameter range of 775–825 μ
  - Optical fiber must be single mode and polished at 5° with polishing flatness not to exceed 10 μ
  - Laser far-field angle not to exceed 35°
  - Laser chip facet coating reflectivity should be between 80–88%.

Design Capability

Performance Parameter	Design Model	Design Specifications	Nominal Performance (μ)	Capability (1σ)	Measurement Method	Measurement Error (1σ)
Optical output power	Laser facet power, laser placement, lens placement, fiber alignment	15–24 mW	19.5 mW	1.1 mW	Transmitter test set	0.25 mW
Targeted wavelength	Current, temperature	1523–1527 nm	1525 nm	0.5 nm	Wavelength test set	0.05 nm

7. DEPLOYMENT

Well-defined methodologies with broad objectives do not lead directly to results. They must first be deployed. However, successful deployment is by itself insufficient to guarantee program success. To maximize benefits and ensure longevity, the methodology must become ingrained as part of the culture of the organization. Achieving this is a complex process. It involves, at a minimum, recognition by the user that the methodology is a benefit to them, coupled with incorporation of the methodology into the structure of the business management processes that govern the organization. The following sections describe the deployment of the product design and process platforms methodology and the steps necessary to make it part of the culture of an organization. A case study of one organization is presented as an example.

7.1. Critical Components

In the deployment of the design and process platform characterization program, the critical components of success are, as expected, user education, management commitment, deployment infrastructure, and business process integration. A more subtle and ubiquitous component of success must also be recognized—the celebration of every success, no matter how small.

7.1.1. Education

The foundation upon which any program deployment is built is the knowledge base of the participants. In most organizations, the technical expertise in the use of the principles and the acknowledgment of their utility resides in the quality organization and the population at large has little or no training/recognition of this area. Hence, the initial step in the deployment must be the education of the user community. In addition, for a culture change to occur, the entire populace must speak the

same language. Therefore, customized courses must be designed for all levels in the business, from manufacturing operators to the executive leadership team, including the chief operating officer (COO) of the business.

Example

The entire executive management team of the business was required to attend an overview session on the basics of measurement system characterization, design of experiments, statistical process control and process capability analyses. The objective of this course was to provide an overview of the principles of these methods, including how it works, when to use it, and what results to expect. The overall objective was to provide the manager with just enough information so that he or she could ask the right questions of the engineers and in so doing reinforce the objectives of the program.

All R&D and manufacturing engineers were required to attend 48 hours of training in measurement system characterization (4 hours), design of experiments (32 hours), statistical process control (8 hours), and process capability analysis (4 hours). These courses were presented on site by recognized experts in those fields from universities around the country. In addition, these courses were customized to its industry and each participant was required to bring his or her own problem to the class to be worked as an exercise. This brought relevance to the sessions and achieved timely recognition by the participant that ''this stuff works.'' Over 90% of the engineering staff completed this training within 18 months.

Advanced training was also provided on a voluntary basis. Courses in advanced design of experiments/multivariate analysis (24 hours), regression analysis/ANOVA (16 hours), and DOE, modeling, and SPC using a platform software tool (16 hours) were provided. Seventy percent of the engineering population completed this level of training. These courses were also offered by external technical experts in those fields from the university community.

Finally, the manufacturing associates had required training in statistical process control (8 hours), which was provided by the quality organization. Eighty-five percent of the staff had completed this training in a 12-month period. Advanced training was also made available on a voluntary basis and 60% of the manufacturing staff completed this level of training.

The result of all this education/training was a whole population of believers in these methods and an engineering staff that uses them as a matter of routine.

7.1.2. Management Commitment

A company can undertake such drastic change in quality methodologies only if its executive managers are trained and supportive and are participants in the program. Management commitment can be demonstrated in many ways. However, the effectiveness of any specific approach will depend on the existing culture of the organization.

Example

An approach based on constant recognition of compliance rather than exception-based reporting was used. Teams at various levels of completion presented their results at the quarterly quality leadership council meetings with the executive leadership team and the COO in attendance. Within a 12-month period, all the teams in the business had this opportunity to demonstrate their progress. It was not required that a program be complete, only that it be actively worked in the methodology to get positive reinforcement from upper management.

The reward system for managers and engineers was tied to completion of milestones. This included the annual performance management system and special rewards. Every small success was celebrated, including participation. These were annual celebration banquets held off-site for the entire engineering staff. At this annual event, the teams that had progressed furthest in the program presented their report to their peers and the entire management staff, including the executive team and COO. Constant positive reinforcement with public recognition was a key component of success. The COO was the recognized leader of this activity. He reinforced his leadership role by including references and/or results of this program at every presentation he made to the organization. In addition, he was committed to personal involvement by meeting engineers on a regular basis and asking about their progress and offering any help to eliminate roadblocks.

Finally, to ensure that all levels of management were involved, it was required that first-level managers report the progress of the teams in their area of responsibility at the quality leadership council meetings.

7.1.3. Deployment Infrastructure

The success of every quality initiative is dependent on its acceptance by the receiving organizations. This acceptance is critically dependent on the means of deployment used. Successful deployment of this program cannot result solely from quality consultants assigned to support each functional area. Progress must be driven from within the functional area. Only then can a culture change result.

Example

Champions were designated in each functional area to drive and monitor actively and report progress. These were either the first-level managers or lead engineers in those areas. The methodology was promulgated by the active involvement of these acknowledged and recognized technical leaders. Engineers and managers had been trained and now were expected to apply that training according to the outline of the methodology. They were supported by the quality engineering staff, who provided significant assistance, guidance, and technical leadership initially, which decreased as time passed and competency increased.

The engineering community identified its critical designs and/or processes to which the methodology would be applied. Together with the quality engineering staff, individual customized project plans were developed. Biweekly meetings were held wherein all champions reported their progress and problems. Issues were escalated from these meetings and resolution was swift. In addition, sharing of problems resulted in opportunities for further education of the champions. By the end of the first 12 months, the champions were acknowledged by the engineering and management staff as subject matter experts in the methodology and its application.

7.1.4. Integration

Initially this program must be an adjunct to the quality system that governs the business. It must be viewed as a quality-improvement program and not officially required for design, production, or shipment of product. Since its application initially will be sporadic, management should not wish to raise customer expectations on a program that will not be uniformly applied throughout the business for some time. As customers are apprised of the methodology, they will desire it to be applied to their products.

Example

It took nearly three years of application of this methodology before it was widespread and uniformly applied sufficiently to formally incorporate it into the quality system. The quality system defines two levels of field grade products to customers: model code and full code. The latter has all aspects of the quality system applicable and complete. The former has some aspects of the quality system incomplete but recognized as low risk for customer use. The application of this methodology and its linkage to the quality system via the product level is shown in Figure 15. Review of the qualification review board (QRB) plan before acceptance and progress reporting by quality assurance in the regular monthly executive report are the significant linkages. In addition, the product robustness criteria used for QRB acceptance were also formalized and are shown in Figure 16.

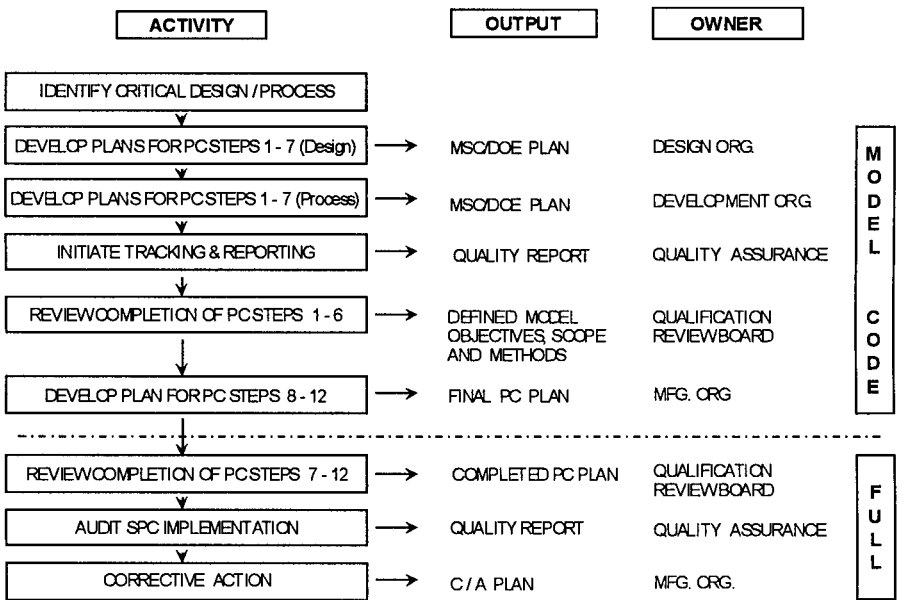

Figure 15 Quality System Linkage.

Modeling:	• Completion of Design Models (PC Steps 1-7) • Completion of Process Models (PC Steps 1-7)
SPC:	• Implementation of SPC for outputs/inputs (PC Steps 8-12)
Capability:	• Design Parameters Capable - Goal @ Cpk $\geq$ 1.33 (PC Step 13-16) • Process Parameters Capable - Goal @ Cpk $\geq$ 1.33 (PC Step 13-16)
Platforms:	• Use of Platform Processes

Figure 16 Product-Robustness Criteria.

Included and implicit in these criteria are achievements of minimum yield and variation targets before a design is transferred to manufacture. As with all the metrics in this program, these are customized for each design and process with regard to the complexity and technological capability of the design and process.

Reviews of the activity, required by the quality system, are the critical components to ensuring compliance and guaranteeing longevity of the program. It must be independent of the individuals administering or driving the program and ingrained in the fabric of the quality culture of the organization. It must be linked via appropriate documentation to the quality system, which are then audited regularly. It must simply become part of the way a company does business.

7.2. Performance Measures

Corporations generally set broad quality goals and leave the path to achievement to the discretion of the individual business units. However, these broad goals do not lead directly to results. They must first be deployed to lower levels of the organization via division and subdivision of the objectives until they identify specific activities to be carried out and allocation of responsibility for performing those activities. Execution of the activities incorporated in this program collectively results in improving operational excellence.

In addition, reviews of progress are an essential part of ensuring that goals are being met. The very fact that an executive team reviews progress sends a message to the rest of the organization as to the priority given to the program goals. The metrics chosen to review are critical to the success of the program. They must show steady progress to maintain program momentum, and at the same time they must measure actual operational performance, a much slower improvement process. This is a difficult but achievable combination.

7.2.1. Metrics

The quality adage ''You improve what you measure'' should be the operational credo. There are two categories of measurements: progress toward compliance with the methodology and operational performance. Progress reviews are also an essential part of ensuring that application of the methodology is resulting in the expected improvements. Reviews should be carried out in two major ways: summarized reports on actual operational performance and reports of program status.

Modeling:	• Percent of Design Output Parameters Modeled • Percent of Process / Platform Output Parameters Modeled
SPC:	• Percent of Process / Platform I/O Controlled
Capability:	• Percent of Design Output Parameters Capable at Cpk $\geq$ 1.33 • Percent of Process / Platform Output Parameters Capable at Cpk $\geq$ 1.33
Education:	• Percent of Engineering & Operating Completed PC Training

Figure 17 Metrics.

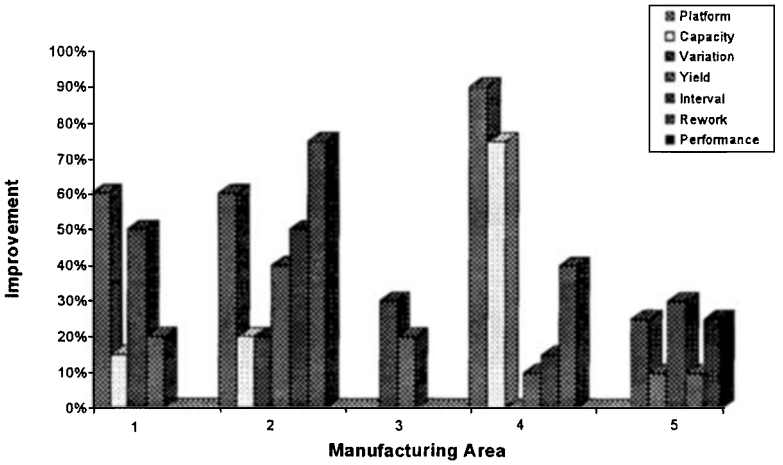

Figure 18 Performance Measures.

Example

The compliance metrics are shown in Figure 17. At the same time, measures were designed for key characterization elements and link to variation, performance, yield, and interval improvements. Results of improvements in operational performance for five manufacturing areas are shown in Figure 18.

Measures of each customized project plan and its specific schedule and reported progress against the steps of the methodology were summarized in a monthly report and also presented at the quality leadership meetings by the first-level manager with the COO and the executive team. In conducting these reviews, it was necessary (albeit difficult) for upper managers to maintain a constructive approach. In general, metrics were used to track progress and define cause for celebration.

7.2.2. Progress of Culture Change

The overall goal is to create a process control-minded culture and exceed customer expectations. On the road to achieving that goal, the foundation and a set of platforms unique to the specific industry should be developed. These goals can be deployed via the design and process platform methodology.

Example

After five years, a fundamental change in the culture of the business was demonstrated. The use of design of experiments is a way of life in this business. Designers and process engineers use it routinely (without quality organization expert assistance) to characterize and control designs and processes. In a three-year period, over 250 DOE were completed resulting in significant yield, variation and cycle time improvements. About 40–50 DOE are in progress at any given time. The designers and process engineers gained sufficient technical expertise to perform the quality engineering function as part of their existing assignments.

The methodology also became an integral part of the product-realization process. Comprehensive implementation of the methodology and achievement of minimum yield and variation targets are required before the design is transferred to manufacturing.

Although there was strong resistance at first, this changed to global acceptance by the technical community as their experience increased. The improvement in operational performance metrics led to a total embracing of the methodology by the management team.

Finally, the keys to success were the active involvement and support of executive management, recognition at executive meetings and peer events, education, and user involvement in the methodology development.

Supply Chain Management and Logistics

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

CHAPTER 76
Logistics Systems Modeling

DAVID SIMCHI-LEVI
Massachusetts Institute of Technology

EDITH SIMCHI-LEVI
LogicTools Inc.

1. OVERVIEW

Information technology is a critical enabler of effective logistics strategies. Indeed, much of the current interest in logistics and supply chain management is motivated by the opportunities that appeared due to the abundance of data and the savings that can be achieved by sophisticated analysis of these data. Thus, in this chapter we focus on models and decision support systems for logistics management that take advantage of the opportunities provided by information technology and allow companies to reduce costs and increase service levels. In particular, we review models and decision support systems for strategic, tactical, and operational decisions and look at the impact of new technology, such as the Internet, on the way decision support systems are used in practice.

2. INTRODUCTION TO LOGISTICS MANAGEMENT

Fierce competition in today's global markets, the introduction of products with short life cycles, and the heightened expectations of customers have forced manufacturing enterprises to invest in and focus attention on their logistics systems. This, together with changes in communications and transportation technologies, such as the Internet, mobile communication, and overnight delivery, has motivated continuous evolution of the management of logistics systems.

In these systems, items are produced at one or more factories, shipped to warehouses for intermediate storage, and then shipped to retailers or customers. Consequently, to reduce cost and improve service levels, logistics strategies must take into account the interactions of the various levels in the logistics network. This network consists of suppliers, manufacturing centers, warehouses, distribution centers, and retail outlets as well as raw materials, work-in-process inventory, and finished products that flow between the facilities.

The goal of this chapter is to present the state of the art in the modeling, analysis, planning, and control of logistics systems, so-called logistics management. But what exactly is logistics management? According to the Council of Logistics Management, a non-for-profit organization of logistics educator and professionals, it is:

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

> the process of planning, implementing and controlling the efficient, cost effective flow and storage of raw materials, in-process inventory, finished goods, and related information from point-of-origin to point-of-consumption for the purpose of conforming to customer requirements.

This definition leads to several observations. First, logistics management takes into consideration every facility that has an impact on cost and plays a role in making the product conform to customer requirements, from supplier and manufacturing facilities through warehouses and distribution centers to retailers and stores. Second, the goal in logistics management is to be efficient and cost effective across the entire system; the objective is to minimize system-wide costs, from transportation and distribution to inventory of raw material, work-in-process, and finished goods. Thus, the emphasis is not on simply minimizing transportation cost or reducing inventories, but rather on a systems approach. Finally, because logistics management evolves around planning, implementing, and controlling the logistics network, it encompasses many of the firm's activities, from the strategic level through the tactical to the operational level.

Indeed, following Hax and Candea's (1984) treatment of production-inventory systems, logistical decisions are typically classified in the following way.

- The *strategic level* deals with decisions that have a long-lasting effect on the firm. This includes decisions regarding the number, location, and capacities of warehouses and manufacturing plants or the flow of material through the logistics network.
- The *tactical level* typically includes decisions that are updated anywhere between once every quarter and once every year. This includes purchasing and production decisions, inventory policies, and transportation strategies, including the frequency with which customers are visited.
- The *operational level* refers to day-to-day decisions such as scheduling, routing, and loading trucks.

In the next section we provide examples of three logistics models that span the three levels of decisions described above. In Section 4 we describe the key components of decision support systems (DSS) for logistics management. Finally, in Section 5 we describe the advantages and impact of using DSS on logistics management.

3. LOGISTICS MODELS

3.1. Logistics Network Design and Configuration

The logistics network consists of suppliers, warehouses, distribution centers, and retail outlets as well as raw materials, work-in-process inventory and finished products that flow between the facilities. In this section we present some of the issues involved in the design and configuration of a logistics network.

Network configuration may involve issues relating to plant, warehouse, and retailer location. As explained earlier, these are strategic decisions since they have a long-lasting effect on the firm. Specifically, in a typical logistics network model, we concentrate on the following key strategic decisions:

1. Determine the appropriate number of warehouses.
2. Determine the location of each warehouse.
3. Determine the size of each warehouse.
4. Allocate space for products in each warehouse.
5. Determine which products customers will receive from each warehouse.

We therefore assume that plant and retailer locations will not be changed. The objective is to design or reconfigure the logistics network so as to minimize annual system-wide costs including production and purchasing costs, inventory holding costs, facility costs (storage, handling and fixed costs), and transportation costs, subject to a variety of service-level requirements.

In this setting, the trade-offs are clear. Increasing the number of warehouses typically yields:

- An improvement in service level due to the reduction in average travel time to the customers
- An increase in inventory costs due to increased safety stocks required to protect each warehouse against uncertainties in customer demand
- An increase in overhead and set-up costs,
- A reduction in outbound transportation costs, i.e., transportation costs from the warehouses to the customers,

- an increase in inbound transportation costs, i.e., transportation costs from the suppliers and/or manufacturers to the warehouses.

In essence, the firm must balance the costs of opening new warehouses with the advantages of being close to the customer. Thus, warehouse location decisions are crucial determinants of whether or not the supply chain is an efficient channel for the distribution of the products. This task requires specialized solvers since it is a complex problem involving large data sets. That is, manual or spreadsheet analysis is not practical to solve most real-life problems. For example, in a simple site-selection problem requiring the identification of 5 optimal warehouse locations from a set of 25 potential sites, 50,000 different combinations must be considered. This is far too many to analyze with a spreadsheet. As Figure 1 demonstrates, the number of combinations grows exponentially as potential sites are added to the analysis.

Figure 2 and Figure 3 present two typical DSS screens that the user would see at different stages of the optimization. The first screen represents the network prior to optimization and the second represents the optimized network.

3.2. Supply Chain Planning

These planning tools determine the appropriate production, transportation, and inventory policies for a set of manufacturing plants, warehouses and retailers. Specifically, given manufacturing, warehouse and retailer locations, production, inventory and transportation costs and capacities, and demand forecasts for each retail outlet, the objective is to determine policies that achieve high levels of customer service with minimal cost.

In this case, we typically refer to three types of models:

1. *Production planning models:* efficient allocation of manufacturing resources over a period of several months to meet demand
2. *Distribution planning models:* efficient allocation of logistics resources over a period of several months to meet demand
3. *Demand planning models:* determine accurate forecasts based on historical data, understanding of customers' buying pattern, economic conditions, etc.

Evidently, these models and decisions are not independent. For instance, the production planning model relies on the quality of the data generated from the demand planning phase. It also depends

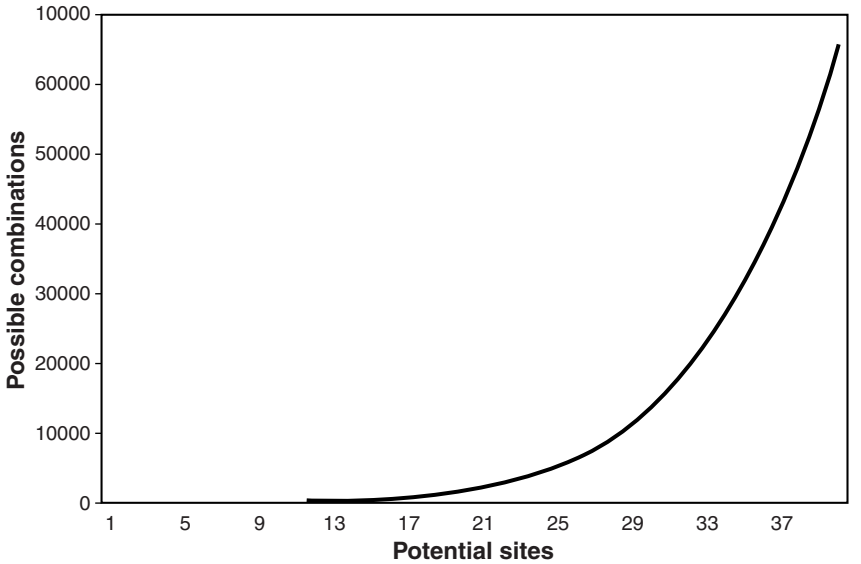

Figure 1 Number of Combinations when Locating Five Facilities in a Given Number of Potential Sites.

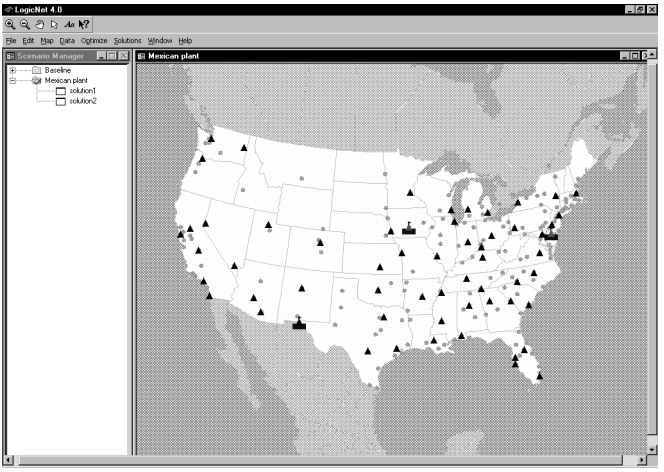

Figure 2 The DSS Screen Representing Data Prior to Optimization.

on the distribution plan since the mode of shipping, inventory plans, and deployment schedule will effect the manufacturing requirements. In addition, in many situations, there is a need to find the optimal trade-off between production timing and inventory levels. Specifically, is it more cost effective to store inventory than to work overtime in the manufacturing plants? A new breed of supply chain coordination DSS is now in the market that optimizes production, inventory, and transportation decisions by taking into account the entire supply chain.

Another key challenge at the tactical level is to take into account the dynamics of the supply chain. Indeed, in recent years many suppliers and retailers have observed that while customer demand for specific products does not vary much, inventory and back-order levels fluctuate considerably across their supply chain. For instance, examining the demand for Pampers disposal diapers, executives at Procter & Gamble noticed an interesting phenomenon. As expected, retail sales of the product were fairly uniform; there is no particular day or month in which the demand is significantly smaller or larger than any other. However, the distributors placed orders to the factory that fluctuated much more than retail sales. In addition, P&G's orders to its suppliers fluctuated even more. This increase in variability as we travel up in the supply chain is referred to as the Bullwhip effect. For more on this effect, see Simchi-Levi et al. (1999).

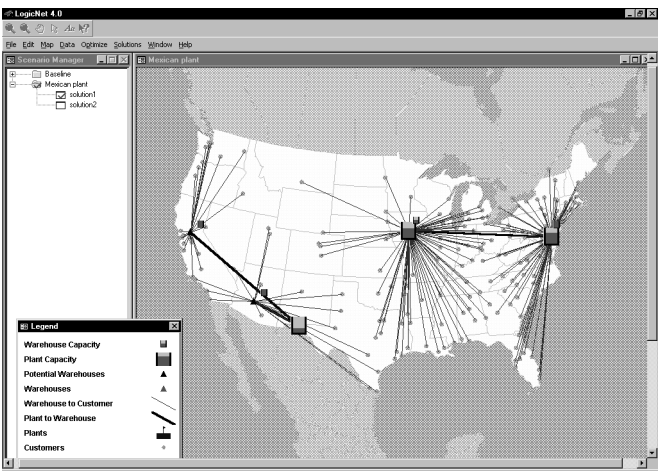

Figure 3 The DSS Screen Representing the Optimized Logistics Network.

3.3. Transportation Planning

The transportation component of logistics management is evolving into a complex process where costs are optimized at every step and sophisticated DSS are utilized to achieve efficiencies.

There are a few typical types of DSS used in the transportation planning. Some examples include:

1. *Routing and scheduling:* Streamline daily delivery operations by developing least-cost routes that meet customer delivery requirements. The DSS sums multiple routing passes to determine the best daily plan that meets the specific needs of user's operation. There are many DSS geared towards routing; however, the requirements can differ based on industry and type of transportation used. For instance, garbage pickup routes are different from a soft drink distributor's direct store delivery (DSD) routes. There are also DSS that concentrate specifically on fuel efficiency, driver swaps, and other complex aspects of routing. Figure 4 shows an example of a typical routing software map display.
2. *Mode selection:* Common transportation modes include overnight package, parcel, less-than-truckload (LTL), truckload (TL), and rail carload (CL). Each mode offers different cost and service advantages and disadvantages relating to shipment size, cost, and delivery time. For instance, TL is generally cheaper and faster than LTL but requires large loads. Shipping by air is expensive but may reduce inventory costs considerably.
3. *Carrier selection:* In situations where companies must analyze and negotiate pricing bids from carriers, there are DSS that assist with this process. Inputs are shipping requirements and carrier bid responses that handle selected lanes of freight. The DSS optimally chooses the least-cost set of carriers to fulfill the shipping volumes. A number of operational constraints such as minimum carrier commitment levels, and maximum number of carriers to select can be imposed.

Transportation DSS are evolving to accommodate for real-time needs that are pushed by on-board computers and wireless communication. In addition, data interfaces with enterprise resource planning (ERP) systems are becoming more streamlined and allow optimization of transportation decisions by considering their impact on the entire logistics network. Finally, transportation DSS also have to take into account the recent proliferation of Internet transportation exchanges.

4. DECISION SUPPORT SYSTEMS

In order to select and use decision support systems effectively, it is helpful to understand the essential pieces of a properly configured decision support system. The three major components of a DSS are the input databases and parameters, the analytical tools, and the presentation mechanism:

- The input database is a form of database with the basic information needed for the decision making. This can be a PC-based database extract designed for the specific problem, a data

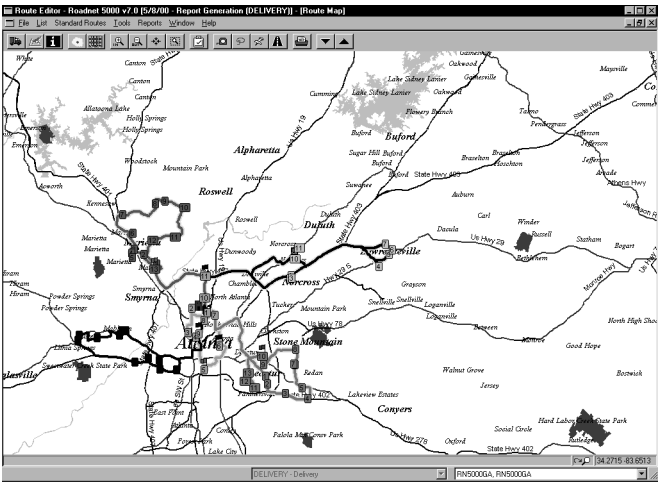

Figure 4 A Typical Routing Software Display.

warehouse with an accumulation of the company's transactions, or distributed databases accessed through a network. This database can also include certain parameters and rules such as the desired service level, hard-coded restrictions, and various other constraints.

- The data analysis usually involves embedded knowledge of the problem while also allowing the user to fine-tune certain parameters. The tools employed are operations research and artificial intelligence-based algorithms, cost calculators, simulation, flow analysis, and other embedded logic procedures. This component is the most complex because there are few off-the-shelf solvers that can deal with the huge variety of problems that companies face.
- Various database and spreadsheet presentation tools can be used to present the results of DSS analysis. Often, however, the output contains too much information, such as lists and tables, that may be too difficult for the decision maker to absorb. Therefore, various data visualization techniques are employed to enable the user to comprehend the vast quantity of output data. For example, location, routing, and sales DSS use geographic information systems (GIS) (see Section 4.3) to display complex geographic data in problems such as site location, routing and supply chain analysis. Similarly, scheduling systems use Gantt charts to display factory schedules, and simulations use animation to illustrate the relationships in the model.

All of these components are markedly affected by the planning horizon of the problem being considered. As we have seen, strategic decisions typically require long-term planning and may involve aggregation of historical data and forecasting considerations, while their analysis and presentation does not need to be particularly fast, since immediate response is not an issue. In contrast, operational decisions typically involve short-term planning, require current data, and demand fast response from the DSS.

4.1. Input Data

As in all kinds of analysis, the data used as input to the DSS is critical to the quality of the analysis. Until fairly recently, acquiring the appropriate information was in itself a complicated feat. By and large, the information-collection battle has now been won in corporate America. Extensive deployment of information systems, bar coding, point of sale, and electronic commerce have provided companies with large databases of business data. These are now often collected into huge data warehouses or smaller data marts that, along with the appropriate tools, facilitate the analysis of the data. In addition, the proliferation of networks and network access tools means that accessing various geographically distributed databases is now feasible.

Depending on the type of analysis, a DSS may require collecting information from various parts of the company. For example, supply chain network design requires both static and dynamic information from different parts of the company. The static data include plant production rates, locations of the plants, warehouses, and customers as well as warehousing costs and transportation costs, and the dynamic data involve forecasts, orders, and current deliveries. This type of information will not usually be found in one database or one department in a company.

In order to evaluate the quality of the data as well as the quality of the models built into the system it may be possible to load the current data and models into the system and see if these correspond to reality. For example, consider a truck-routing decision support system. Ultimately, the goal of such a system is to provide routes that enable the trucks to make deliveries and pickups efficiently at the required times. The model can be tested by loading the current truck routes into the system and observing whether travel times, for example, are the same as the travel times actually experienced by the truck drivers. Similarly, projected costs from the model can be compared with actual financial and accounting records. This process, typically known as model and data validation, is essential to ensure that the model and data are accurate enough. Of course, the meaning of ''accurate enough'' depends on the decisions being made. For more information on this issue, see Simchi-Levi et al. (1999).

In addition, the decision-planning horizon affects the detail of the data required. For strategic planning, it often makes sense to aggregate yearly data, while for short-term planning it may be best to utilize recent raw daily or weekly data. The accuracy of the solution depends on the input data, and therefore the quality of the input data will determine to some extent the tools needed for the analysis.

For instance, consider the logistics network design model discussed previously. A DSS is often used to assist in optimizing the number of warehouses required as well as their size and customer allocation to each warehouse. The DSS uses information about the distribution system to calculate the various costs related to the site selection and customer allocation. The data required for this problem involve the manufacturers, warehouses, and customers and the transportation between them. Since this is a long-term planning tool, yearly demand data and costs are typically used, but sometimes the user may need to determine how to account for seasonality. In addition, in order for this kind of DSS to be utilized successfully, the user needs to break the products into product families

and specify inventory policies. This will allow calculation of the warehouse sizes and frequency of deliveries. Some of the required input data are summarized in Table 1.

It is clear that this type of data may not be readily available in the company database. Even if the data are accessible, they may not be in the required format, particularly if the DSS involves geographic display and analysis. As one might expect collecting, tabulating, and verifying the data can take some time.

4.2. Analytical Tools

Another issue that needs to be established when working with a DSS is the measures by which the various solutions will be evaluated. Reducing total cost may be a goal, but in some cases improving customer service level may be more pertinent. DSS interfaces usually allow setting these parameters and indicating the balance required by the user.

Once data has been collected, it must be analyzed and presented. Of course, depending on the DSS and the particular decision being made, there are many different ways to analyze the data. It is important for the decision makers to understand how the DSS analyzes the data, in order to assess the validity and accuracy of the DSS's recommendations. Of course, depending on the analysis, statistics can tell many different stories (see Shenk 1997 for an interesting discussion of these issues). It is up to the decision-maker to determine what analysis is most appropriate.

In what follows we examine common DSS analysis tools and techniques in general.

- *Queries:* Often, vast quantities of data make manual analysis difficult. Simply allowing decision makers to ask specific questions about the data, such as "How many clients do we service in California?" and "How many clients purchased over $3000 of a certain product by state?" often facilitates decisions.
- *Statistical analysis:* Sometimes asking questions is not sufficient. In this case, statistical techniques can sometimes be used to determine trends and patterns in the data. For example, often statistical data such as the average inventory in a warehouse, the average number of stops and length of a route, and the variability of customer demand can be useful to decision makers.
- *Data mining:* Recently, as corporate databases have become larger and more all-encompassing, new tools have been developed to look for hidden patterns, trends, and relationships in the data. Data mining, for example, produced the marketing gem that men tend to purchase beer AND diapers on Friday afternoons.
- *OLAP tools:* Online analytic processing tools provide an intuitive way to view corporate data, typically stored in data warehouses. These tools aggregate data along common business dimensions and let users navigate through the hierarchies and dimensions by drilling down, up, or across levels. OLAP tools also provide sophisticated statistical tools to analyze the data and include presentation tools as well. Mostly they are generic tools, more sophisticated than spreadsheets and easier to use than database tools, for the analysis of large amounts of data.
- *Calculators:* Simple decision support tools can facilitate specialized calculations, such as accounting costs. In many cases, more than simple calculations may not be warranted, especially if the changes are predictable and easy to evaluate. This may be the case with some product

TABLE 1 Input Data for Logistics Network Design

Component	Data
Manufacturer	location production capacity and cost transportation costs to warehouses
Warehouse	location fixed costs variable costs (labor, utilities) inventory turnover transportation costs to retailers
Retailer	location annual demand by product
Product	volume weight holding cost

types for forecasting or inventory management, while for others more sophisticated tools may be needed.

- *Simulation:* All business processes have random components. Sales may take one value or another. A machine may or may not fail. Often these random, or stochastic, elements of a problem make analyzing it very difficult. In these cases, simulation is often an effective tool to help with decisions. In simulation, a model of the process is created on a computer. Each of the random elements of the model (sales, failures, etc.) is specified with a probability distribution. When the model is run, the computer simulates carrying out the process. Each time a random event occurs, the computer uses the specified probability distribution to randomly decide what happens.

  For example, consider a simulation model of a production line. As the computer runs the model, a series of decisions is made. How long does a job take on machine one? On machine two? Does machine three break while job four is being processed on it? As the model runs, statistical data (utilization rates, completion times, etc.) are collected and analyzed. Since this is a random model, each time the model is run, the results may be different. Statistical techniques are used to determine the average outcome of the model as well as the variability of this outcome. Also, varying different input parameters allows different models and decisions to be compared. For example, different distribution systems can be compared utilizing the same simulated customer demand. Simulation is often a useful tool for understanding very complex systems that are difficult to analyze analytically.
- *Artificial intelligence:* Artificial intelligence tools may be employed in the analysis of DSS input data. These may be databases of rules collected from experts that can be applied to specific problems, or online intelligent agents. The former systems are often used to solve technical problems, such as troubleshooting a computer failure or a complex chemical procedure, while the latter are more appropriate for managing different components in the supply chain. Following Fox et al. (1993), we define an agent as a software process whose goal is to communicate and interact with other agents so that decisions effecting the entire supply chain can be made on a global level. Indeed, a number of DSS for supply chain management can be viewed as using intelligent agents to plan and execute different activities in the supply chain. These systems are characterized (see Fox et al. 1993) by the following interrelated issues:

- The activities allocated to each intelligent agent (i.e., software processor)
- The level and nature of interactions between the different agents
- The level of knowledge embedded within each agent

For instance, a real-time supply chain planning tool involves the following components. Intelligent agents are located at each facility and collect information about this facility as well as enable planning and scheduling for the facility. In this case, facilities include manufacturing plants and distribution centers. Each agent interacts with other agents so that they can balance excess capacity at different plants, find missing parts, or coordinate production and distribution. A central planning agent communicates with the agents at each facility to collect status information and relate central planning decisions. The type and level of decisions made by the agents as opposed to human operators, as well as the frequency and level of communications among the agents, depends on the specific implementation.

- *Mathematical models and algorithms:* Mathematical tools, often from the discipline of operations research, can be applied to the data to determine potential solutions to problems. For example, these tools may generate the best set of locations for new warehouses, or an efficient route for a truck to take, an effective inventory policy for a retail store. These algorithms fall into two categories:
- *Exact algorithms:* Given a particular problem, these algorithms will find a solution that is mathematically the best possible solution. In general, these kinds of algorithms may take a long time to run, especially if a problem is very complex. In many cases, it is impossible to find the optimal, or very best, solution. In other cases, it may be possible but not worth the effort. This is because the input data to these algorithms is often approximated or aggregated, so exact solutions to approximate problems may be worth no more than approximate solutions to approximated problems.
- *Heuristics:* These are algorithms that provide good, but not necessarily optimal, solutions to problems. Heuristics typically run much faster than optimal algorithms. Most DSS that use mathematical algorithms employ heuristics. A good heuristic will rapidly give a solution that is very close to the optimal solution. Often, heuristic design involves a trade-off between quality of solution and speed. If is often useful if in addition to the solution, the heuristic

provides an estimate of how far the heuristic solution is from the optimal solution.
See Simchi-Levi et al. (1999) for additional discussion on exact and heuristic algorithms.

The analytical tools used in practice are typically a hybrid of many of the tools described above. Almost all decision support systems will offer a combination of tools, and many will allow further analysis using generic tools such as spreadsheets. Note that some of the tools listed above may be embedded in generic tools, such as spreadsheets.

Of course, most DSS employ analytical tools that have some specific embedded knowledge of the problem being solved. Since these problems are usually complex, the DSS employs its problem knowledge to find efficient solutions.

There are many factors that dictate the appropriate analytical tools selected for a particular decision support system, including:

- The type of problem being considered.
- The required solution accuracy—there may be no need to find the optimal solution.
- Problem complexity—some tools may not be appropriate for very complex problems.
- The number and type of quantifiable output measures.
- The required speed of the DSS. Particularly for operational systems such as lead-time quotation and vehicle routing, speed may be essential.
- The number of objectives or goals of the decision maker. For example, a DSS for truck routing may need to find a solution with the minimum number of vehicles such that total distance traveled is as short as possible.

Applications for DSS are extremely varied, and each problem will typically use a different mathematical tool. In Table 2 we describe some of these applications and the type of tools that would typically be used. Most of these problems are extremely complex, and seemingly similar problems could require a different approach.

Consider the logistics network design problem described in the previous example. For this problem, heuristic approaches as well as optimization based techniques have been developed in the last few years. The choice between heuristics and optimization depends on the complexity of the specific problem as well as on the various modeling issues, such as service level, that the user wishes to consider. For instance, optimization-based techniques may be limited in the size of problem they can handle as well as in the number of parameters and special cases they can consider. Finally, some solvers also combine heuristics and optimization.

4.3. Presentation Tools

These are the tools used to display the data to the decision maker. There are a varied number of formats including:

- Reports
- Charts
- Spreadsheet tables
- Animation

TABLE 2 Applications and Analytical Tools

Problem	Tools Used
Marketing	Query, statistics, data mining
Routing	Heuristics, exact algorithms
Production scheduling	Simulation, heuristics dispatch rules
Logistics network configuration	Simulation, heuristics, exact algorithms
Mode selection	Heuristics, exact algorithms

- Specialized graphic formats, e.g., a layout of a floor plan
- Geographic information systems

The reader is likely to be familiar with most of these items. Reports, charts, and tables are of course very common. Animation is often used as a tool to present output of the simulation models described above. This helps the user verify the validity of the simulation model and understand the simulation results. Specialized graphic formats are, of course, extremely dependent on the nature of the problem being solved. For example, a facility layout DSS may present a suggested floor plan for a new facility.

Of course, particularly in the area of supply chain management, much of the output of DSS is geographic in nature. For example, logistics network design, sales territory analysis, and truck routing software all include geographic-related output. In the last few years, geographic information systems (GIS) have become more and more common as the presentation vehicle of choice for many supply chain management decision support systems. In the following we describe GIS systems in more detail.

4.3.1. Geographic Information Systems

A geographic information system (GIS) is an integrated computer mapping and spatial database management system that provides a broad array of functions for the storage, retrieval, management, analysis, and display of geographically referenced data.

Typical GIS capabilities include:

- Mapping and thematic mapping
- Database management
- Interactive data query
- Spatial data retrieval
- Geographic data manipulation
- Spatial data analysis
- Geocoding
- Geographic data import/export
- Buffering/polygon overlay

The advantage of using a GIS platform is that it combines database, query, and reporting tools as well as geographic display and analysis. In logistics modeling, GIS has the further advantage of allowing automated distance and travel time calculations. Some limited forms of GIS are now included in spreadsheets (Excel 7.0) but are not as extensive as the full-blown packages. These systems originally came only on high-end UNIX workstations, but there are now many excellent, relatively inexpensive systems that run on PC platforms and networks. A major issue in deploying GIS is the availability and quality of the geographic data. Excellent data, with information about the geography, street networks, and census information, are available for the United States at a very low price. However, in other countries the data itself may not exist or may be tightly held so that they can be a major expense and deterrent to the effective use of GIS. Even in the United States the data may not be perfect for every application or may be outdated and need to be upgraded to be used effectively.

Originally, GIS was extensively used in applications such as:

- Market analysis
- Census and demographic data analysis
- Real estate
- Geology
- Forestry

More recently, however, GIS has found application in areas of potentially more interest to the supply chain manager, such as:

- Network analysis—transportation, telecommunications
- Site selection
- Routing
- Supply chain management

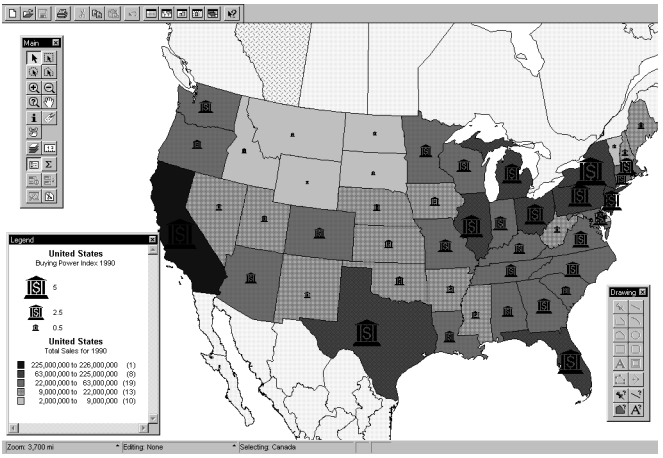

Figure 5 A Typical GIS Interface.

Figure 5 presents a typical GIS interface. The screen includes a thematic display of a typical marketing application with data on 1990 U.S. buying power index given by state.

Not surprisingly, there are special considerations when using GIS in logistics modeling. Often, time must be spent geocoding and estimating travel time. Geocoding is the translation of addresses into geographic coordinates. Geocoding requires databases that can assist in the translation. Although widely available in the United States, these data may be hard to come by in other countries. In order to prepare customer data for use by a DSS, this step is required and may be lengthy, depending on the quality of the address data.

In most logistics applications, it is necessary to use the distance between two locations in order to estimate travel time and transportation costs. This can be done in several ways. One is to calculate the straight-line distance between the two coordinates and multiply it by a factor that estimates the circuity of the roads between the two points. This, of course, is a very simplistic approach, and it does not require more information than the coordinates. In this case, the DSS typically apply different factors for different zones. Another way to calculate travel distance is to use the actual road network, identify the best route, and determine the distance. This requires extensive accurate information about the road network, including one-way streets and other details. It is also an extremely time-consuming process to calculate the network even for a moderate-sized problem.

In both types of calculations, assumptions need to be made about the speed of travel in order to estimate the travel time. It is always possible to let the user enter the travel time between each pair of locations in the model, but this is usually not practical in large problems.

Although users of routing systems may demand a road network since it intuitively seems to be a more accurate solution, experience has shown that this approach may not produce significantly better results than using estimates of the distance. This is true even in shorthaul distances and inner city routing, such as school bus routing. See Table 3 for an analysis of road vs. estimated distances.

DSS may come with an embedded GIS or use a commercial GIS as a platform or server for presentation of geographic data. The U.S. geographic data available are mostly based on TIGER/ line files. TIGER stands for Topologically Integrated Geographic Encoding and Referencing, for the system and digital database developed at the Census Bureau to support its mapping needs for the

TABLE 3 Road and Estituated Distance

Item	Estimated distance	Road Distance
Data	Cheap	Expensive
Complexity	Low	High
Accuracy	Medium	High
Speed	High	Low

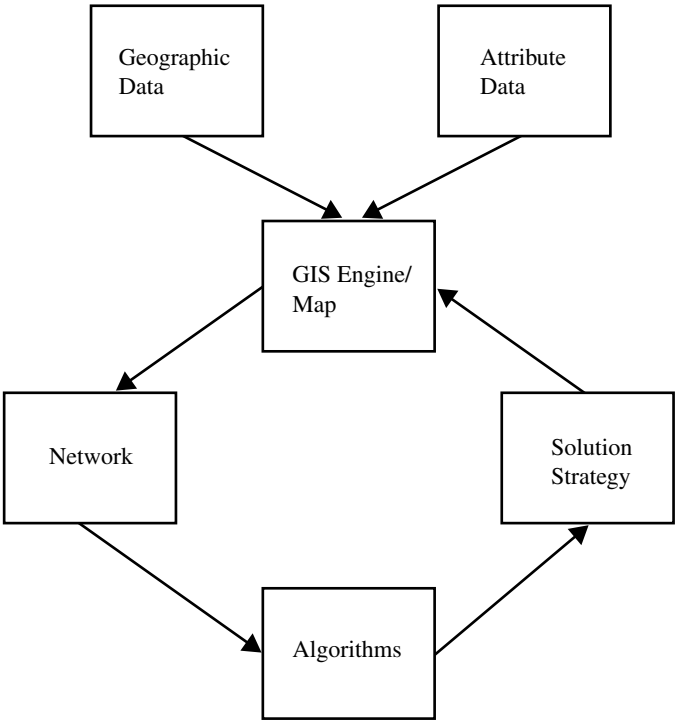

Figure 6 A General Framework for Integrating Algorithms and GIS.

Decennial Census and other Bureau programs. The TIGER/line files are publicly available extracts from the TIGER database. Most GIS vendors allow the user to load these files or distribute their own versions and formats based on this data. There are otherwise no agreed-upon standards for geographic data representation apart from the leading vendors' formats, which can usually be converted from one system to another.

4.3.2. Integrating Algorithms and GIS

As mentioned earlier, GIS has found application in areas important to supply chain management. These include logistics network design, routing, and mode selection. The idea in all these applications is to integrate the GIS with mathematical models and algorithms. Figure 6 provides a schematic representation of such a system.

In such a system, geographic data are provided by the GIS while attribute data, including demand information, costs, production and storage capacities, are downloaded from standard databases. This data is sent to the GIS engine that is the heart of the system. The engine constructs a symbolic network that represents the various relationships among the components of the supply chain. The network is then used by a collection of exact and heuristic algorithms to generate a number of solutions or strategies minimizing various objectives and satisfying all the constraints in the system. These solutions can be viewed, modified, and analyzed by the user so that the most appropriate one is implemented.

What are the advantages of integrating GIS and mathematical models and algorithms?

1. The system allows the user to visualize the data and the model and thus verify that they truly represent the supply chain environment.
2. It provides accurate street-level database (if needed) including one-way streets and turn difficulties.
3. It allows the user to visualize the solution and strategies generated by the system.
4. It allows for sensitivity (what-if) analysis.

5. THE IMPACT OF DECISION SUPPORT SYSTEMS ON LOGISTICS MANAGEMENT

In the last few years, we have seen many companies investing in, and relying on, decision support systems. The reason, of course, is these companies are trying to become best-in-class. As observed recently by PRTM Director Mike Aghajanian, ''For a company with annual sales of $500 million and a 60% cost of sales, the difference between being at median in terms of supply chain performance and in the top 20% is $44 million of additional working capital.''

Of course, the main reason companies use DSS is to reduce cost and increase service level. Indeed, reducing cost in the supply chain is a key challenge because, as observed by Rick L. Adams, VP Logistics, Grainger Industrial Supply, ''A 5% cost decrease has the same impact on profit as a 30% increase in sales.''

Thus, it is no surprise that logistics management has been transformed in the last 10 years from a largely manual process to a more automated one. Major advances in computer and communications technology and the introduction of the Internet and e-commerce have effected this trend. These developments provide new opportunities and increase expectations for a fast and flawless logistics process. The Internet also provides new models in how information systems are deployed. For instance, companies may not need to own the sophisticated DSS—they are able to lease them based on their needs. This mode of deployment is now referred to as application service provider (ASP) and is considered one of the most important trends in information systems, especially for mid-sized companies who cannot afford expensive systems.

We summarize the article with major trends that many experts (see, e.g., Shepard and Lupide 1999) envision for the future in applying DSS for logistics management:

1. The utilization of DSS will increase at all levels of decision making. The DSS will provide decision makers with assistance in quickly making effective decisions.
2. DSS will need to handle real-time data and must have a short processing time so that users can respond in the time frame that drives their business. As we have seen in transportation planning, this is an important issue in operational systems.
3. DSS will become better integrated with user's ERP and other management systems. This will allow users to access DSS information seamlessly in order to provide better customer service.
4. Users require better visibility of their data so that systems will provide users with accessible interfaces to their data in various formats and at different aggregation levels. In order for DSS to become effective, they will need to provide this capability or link with tools that already have that capability.
5. Users require collaborative tools—DSS will need to allow for collaboration in the same company and across different companies. One of the first tools in this area is the forecasting portion of collaborative planning forecasting and replenishment (CPFR), which allows partner companies to collaborate on forecasting and utilizes a DSS that assists in finding discrepancies in the process.
6. DSS at various levels will need to become better synchronized so that decisions at the strategic, tactical, and operational levels are all coordinated and accessible. As we have noted, it is difficult to perform efficient production planning without coordinating with demand planning and distribution planning.

This chapter is based on, and borrows extensively from, two chapters from our book *Designing and Managing the Supply Chain: Concepts, Strategies and Case Studies,* which was written together with Philip Kaminsky and published by McGraw-Hill in 1999. The chapter is also based on material from *The Logic of Logistics,* by Julien Bramel and David Simchi-Levi, published by Springer in 1997. In both cases this has been done with permission from the copyright holders. CHAPTER 77
Demand Forecasting and Planning

ANANTH V. IYER
Purdue University

Our goal in this chapter is to provide a number of possible demand models, and illustrate their use in operational decision making. We cover a number of demand models, ranging from the constant demand model to a model of demand as a distribution to use of information over time to generate adaptive estimates of demand. In each case we provide numerical examples to illustrate use of the technique. For additional technical details see Additional Reading at the end of this chapter.

1. CONSTANT DEMAND FORECAST AND ITS USE IN PLANNING

One of the simplest models of demand is to use an estimate of the average demand. This average demand, assuming a constant rate each period, can then be used to understand the effect of production costs or transport costs on inventory levels. Such models are appropriate when we deal with products in situations with predictable demand, that is, low forecast error. In particular, we will focus on the

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

impact of setup costs and their interaction with holding costs. Our focus in this section is on discussing use of a constant demand rate model in an economic order quantity (EOQ) model. This requires us to define some of the costs that are important in understanding the impact of alternative decisions in an inventory system.

1.1. Inventory Costs

There are three main inventory costs we focus on:

1. *Holding or carrying costs:* These costs, expressed as a cost per unit of inventory per unit of time, model the cost associated with storage facilities, handling, insurance, pilferage, obsolescence, opportunity cost of capital, and so on.
2. *Fixed ordering or setup costs:* These costs are incurred each time an order is placed and model the costs to prepare the purchase or production order, costs associated with equipment setups, or costs associated with transportation (a single delivery truck).
3. *Shortage costs:* These are costs associated with loss of demand or penalties associated with delays.

1.2. An Inventory Policy

The context is the following: An inventory manager faces a constant demand rate that has to be satisfied from inventory. Ordering costs entail a fixed cost per order. Inventory held in the system incurs a holding cost. An *inventory policy* determines the quantity and frequency of orders. Each inventory policy has an associated cost to the organization. The two components of an inventory policy are:

- *Review period:* how often inventory levels are monitored and orders placed
- Order quantity: fixed or variable order quantity

We illustrate this concept through the use of an example.

1.2.1. Example: Choosing an Inventory Policy

Consider the problem of managing the inventory of Xerox paper in a warehouse. Although demands from retailers may fluctuate a bit in their demand, your aggregate demand for the item is fairly constant at 100,000 cases for the year. Due to your volume, your supplier has agreed to provide you an everyday low price of $55.00 a case. You calculate that it will cost about $4.00 per case per year to hold each case. Costs associated with each order and delivery charges by your supplier yield a fixed ordering cost of $75.00.

Consider the following inventory policy:

1. Place an order for Q units.
2. When inventory reaches zero, place another order for Q units and repeat.
3. Assume lead time is zero.

Which inventory policy do you recommend?

- Review daily resulting in daily shipments of about 385 cases each.
- Review weekly, resulting in order sizes of about 1923 cases each.
- Place an order each month at about 8333 cases each.
- Place only two orders per year at about 50000 cases each.

1.2.2. Evaluating the Cost of an Inventory Policy

To calculate costs of each policy, let:

d = yearly demand in units
h = holding costs in dollars per unit per year
s = setup or ordering costs in dollars
Q = quantity of each order
Q = uniquely defines this simple inventory policy

$$\text{Total cost (AHO)} = \text{annual carrying costs} + \text{annual ordering costs}$$

$$\text{AHO} = \frac{Q}{2}h + \frac{d}{Q}s$$

So:

d = 100,000 units/yr
h = 4 dollars/unit-yr
s = 75 dollars

1. $Q = 385$, $\text{AHO} = \dfrac{385}{2}4 + \dfrac{100{,}000}{385}75 = 20{,}250$
2. $Q = 1{,}923$, $\text{AHO} = \dfrac{1{,}923}{2}4 + \dfrac{100{,}000}{1{,}923}75 = 7{,}746$
3. $Q = 8{,}333$, $\text{AHO} = \dfrac{8{,}333}{2}4 + \dfrac{100{,}000}{8{,}333}75 = 17{,}566$
4. $Q = 50{,}000$, $\text{AHO} = \dfrac{50{,}000}{2}4 + \dfrac{100{,}000}{50{,}000}75 = 100{,}150$

From these policies the lowest cost is to order weekly with $Q = 1{,}923$.

1.2.3. Economic Order Quantity (EOQ) Model

Consider the following inventory model:
Place an order for Q units.
When inventory reaches zero, place another order for Q units and repeat.

d = yearly demand in units.
h = carrying or holding costs in dollars per unit per year.
s = setup or ordering costs in dollars.

$$Q^* = \text{economic order quantity (EOQ)}$$

$$Q^* = \text{EOQ} = \sqrt{\frac{2ds}{h}}$$

minimizes the total cost function:

$$\text{AHO} = \frac{Q^*}{2}h + \frac{d}{Q^*}s$$

For:

d = 100,000 units/yr
h = 4 dollars/unit-yr
s = 75 dollars

$$Q^* = \sqrt{\frac{2(100{,}000)(75)}{4}} = 1{,}936$$

$$\text{AHO} = \frac{1{,}936}{2}4 + \frac{100{,}000}{1{,}936}75 = 7{,}746$$

$$\text{Total cost} = \text{AHO} + (cD)$$

1.3. A Service Application—Training Airline Flight Attendants

You manage the training department for airline attendants for a major airline. You have to organize and plan the training sessions for all new hires. Each week personnel sends you a list of the new hires that you must schedule into the next available training session—they are on the payroll and basically idle until they can be trained and put into service. The yearly demand for new attendants

is fairly constant at 1200, and personnel is always interviewing and hiring to keep up with the demand. The new hires, on average, cost the company about $40,000 per year in salary and benefits.

You wonder if there is a way to think about the costs in the system and better manage them. First you realize that personnel and training should coordinate better. Why should personnel put someone on the payroll before they can be scheduled for training? After all, a new hire won't argue about a week here or there on a start date. This seems like an easy thing to accomplish, but it certainly puts the burden on you to schedule the sessions and keep personnel abreast of your plans. Next you wonder how to best plan the training sessions—how often should you hold sessions and how many trainees should you put in each class. You gather the following data: The cost of the teachers, the conference rooms, and so on combine for a fixed cost of $10,000 per training session.

How should you plan the sessions to minimize total cost? Note that given the data, we see that $s = 10{,}000$, $d = 1{,}200$ and $h = 40{,}000$. Thus, the optimal training batch size is

$$\sqrt{\frac{2 \times 10{,}000 \times 1{,}200}{40{,}000}}$$

which is rounded up to 25 per batch. This corresponds to training approximately once a week. The cost associated with this decision

$$\frac{10{,}000 \times 1{,}200}{25} + \frac{40{,}000 \times 25}{2} = 980{,}000$$

1.4. Sensitivity Analysis of the EOQ Model

While the EOQ model provides quick estimates of optimal behavior, it requires knowledge of the costs described earlier. It also requires us to have a good estimate of demand rate. However, the benefit of the model is that it is robust to variation in the assumptions. This is indicated as follows:

*1.4.1. Impact of Using a Q Other Than Q**

Suppose, in practice, the actual Q used in a situation is different from Q^*. We will examine the impact of this difference is Q on average annual costs AHO(Q). We define the average annual costs as

$$AHO(Q) = \frac{sd}{Q} + \frac{hQ}{2}$$

and

$$Q^* = \sqrt{\frac{2sd}{h}}$$

(In this analysis, we thus drop the term cd from both expressions.) Note that

$$\frac{\text{AHO}(Q)}{\text{AHO}(Q^*)} = \frac{1}{2}\left\{\frac{Q}{Q^*} + \frac{Q^*}{Q}\right\}$$

The equation above is obtained by substituting the optimal Q^* in the cost expression for AHO(Q^*)

Note that if Q varies between $Q^*/2$ and $2Q^*$, the impact on average annual cost is less than 25%. Similarly, if Q varies between $0.8Q^*$ and $1.25Q^*$, the average annual costs increase by no more than 2.5%.

These results suggest that the EOQ model is robust, that is, variations in decisions result in small variation in their cost impact as long as we are around the optimal EOQ model.

2. DEMAND MODELED AS HAVING A DISTRIBUTION

In the earlier section, we modeled demand as a constant rate. Often, however, demand is not very predictable but has a significant amount of randomness. To understand the effect of demand forecast error, we first focus on problems where decisions regarding inventory are made once for an entire period. Examples of products that might require inventory decisions that cover demand over a single period include

- Newspapers for which the period refers to one day
- Fruits/flowers for which the period refers to one week

- Fashion products for which the period refers to a season (three months)
- Hotel room reservations for which the period refers to one day
- Airline reservations for which we refer to a particular flight

To illustrate the basic ideas, we start with a numerical example.

2.1. Example—The Fashion Store

The Fashion Store sells fashion items. The store has to order these items many months in advance of the fashion season in order to get a good price on the items. Each unit costs Fashion $100. These units are sold to customers at a price of $160 per unit. Items not sold during the season can be sold to the outlet store at $75 per unit. If the store runs out of an item during the season, it has to obtain the item from alternative sources and the cost including air freight to Fashion is $190 per unit.

Fashion wants help in choosing the initial order quantity to minimize costs to run the store.

Historical data from comparable items over the last few years have generated 100 demand observations as follows:

86	94	90	86	82	84	91	76	85	83	92	82	89	88	79	83	83	85	89	90
73	84	86	90	90	92	83	91	85	85	82	81	81	76	81	81	78	85	84	82
88	86	85	88	86	89	87	84	83	79	90	87	83	87	82	81	85	84	87	89
82	80	92	85	88	85	83	87	84	84	86	80	87	80	89	79	83	80	86	87
81	93	91	89	80	86	87	86	88	84	81	84	84	82	77	93	94	97	87	75

A frequency table of these points and the corresponding cumulative probabilities for each demand value are as follows:

Demand (D)	Frequency	P(demand) P(D)	Cum. Prob. P(Demand ≤ D)
73	1	0.01	0.01
75	1	0.01	0.02
76	2	0.02	0.04
77	1	0.01	0.05
78	1	0.01	0.06
79	3	0.03	0.09
80	5	0.05	0.14
81	7	0.07	0.21
82	7	0.07	0.28
83	8	0.08	0.36
84	10	0.10	0.46
85	10	0.10	0.56
86	9	0.09	0.65
87	8	0.08	0.73
88	5	0.05	0.78
89	6	0.06	0.84
90	5	0.05	0.89
91	3	0.03	0.92
92	3	0.03	0.95
93	2	0.02	0.97
94	2	0.02	0.99
97	1	0.01	1.00
	100	1.0	

The sample mean is 85 units and the standard deviation is 4.43 units.

2.2. The Single-Period Inventory Model

Given the problem described earlier, it turns out that the optimal decision is described using two cost parameters:

1. C_e = cost per unit of an excess item at the end of period
2. C_s = cost per unit of an item short

The optimal service level defined as the probability that all demand is satisfied in a period immediately from primary stock is described as

$$\text{ser}^* = \frac{C_s}{C_s + C_e}$$

From our example we have:

$$C_e = 25$$
$$C_s = 90$$

So,

$$\text{ser}^* = \frac{C_s}{C_s + C_e} = \frac{90}{90 + 25} = 0.782$$

From frequency table we get for a service level of 0.782,

$$r^* \approx 89$$

2.2.1. Suppose Demand Follows a Normal Distribution

Example 1: Fashion Store. If we approximate demand by a normal distribution with mean $m = 85$ and standard deviation $\sigma = 4.43$, we get

$$\text{ser}^* = \frac{C_s}{C_s + C_e} = \frac{90}{90 + 25} = 0.782$$

so

$$r^* = 85 + Z_{0.782}(4.43) = 85 + 0.76(4.43) = 88.45 \approx 89$$

Example 2: Fashion Store. Approximate by Normal with $m = 85$ and $\sigma = 4.43$

Suppose the Fashion Store wants to provide a service level of 90%. What level of inventory is required?

$$r_{0.90} = 85 + Z_{.90}(4.43) = 85 + 1.29(4.43) = 90.7 \approx 91$$

Therefore, if Fashion has an inventory of 91 items with probability 0.90 all the demand in a period is satisfied from primary stock.

3. UNCERTAIN DEMAND OVER MULTIPLE PERIODS

In this section we return to making decisions over continuous time. Demands each period are modeled as following a distribution. We first consider the case where we can only make decisions once each period. The costs consist of the costs of holding inventory each period and the costs of shortage each period. We include the case where there may be a fixed lead time L for the supplier to deliver an order. The basic idea is that in the presence of uncertainty and lead time for delivery, orders have to be placed well in advance of inventory running out in order to guarantee a high level of availability.

3.1. Impact of Lead Time

If we consider the problem in the earlier sections with constant demand and just add in a lead time L between order placement and delivery, note that orders should be placed when the inventory level hits dL. This level is called the reorder level. The order size remains Q as calculated by the EOQ model.

An interesting issue is the fact that in the absence of demand forecast error, lead time has no impact on costs. This is seen by the fact that while the order trigger times are affected by lead time

L, the physical inventory levels and the rate of order placements are unaffected by L. Since these two parameters affect costs in this model, costs are unaffected by lead time.

3.2. Lead Time and Demand Uncertainty

In the presence of lead time and demand uncertainty, the reorder level requires us to decide how much of the demand should be satisfied from stock. This factor can be expressed as *service level.* We express service level as the *probability* of being in stock. This probability is a number that the customers (generating the demand) can use to do their own planning. This probability will depend (intuitively) on the industry and on the extent of competition faced by the company.

If demand follows a normal distribution, then the reorder level requires us to merely generate a Z value that corresponds to the desired cumulative probability.

Then set the reorder level as

$$r = (dL) + (Z\sigma\sqrt{L})$$

where σ refers to the standard deviation of demand per unit time and d is the mean demand per unit time.

3.2.1. Example Problem

The Reliable Hardware Store sells electric pumps. The supplier lead time is one week. Each pump costs Reliable $100. Annual inventory carrying cost is 25% of the investment. If Reliable stocks out, it will fill demand by buying the required pumps elsewhere at an additional cost of $20, that is, Reliable's cost would be $120. Reliable's planned probability of in stock is 91.2%.

Demand recorded for the last 100 weeks shows the following data:

86	94	90	86	82	84	91	76	85	83	92	82	89	88	79	83	83	85	89	90
73	84	86	90	90	92	83	91	85	85	82	81	81	76	81	81	78	85	84	82
88	86	85	88	86	89	87	84	83	79	90	87	83	87	82	81	85	84	87	89
82	80	92	85	88	85	83	87	84	84	86	80	87	80	89	79	83	80	86	87
81	93	91	89	80	86	87	86	88	84	81	84	84	82	77	93	94	97	87	75

The mean demand is 85 units and the standard deviation is 4.43 units. The same data can be plotted as a histogram or as a line graph using a spreadsheet.

Note that when Reliable reorders, there should be sufficient inventory on hand to cover demand during the lead time of one week.

3.3. A (Q, r) Policy

We now formalize our multiperiod inventory system. By convention, some parameters are usually given in annual terms (the EOQ parameters), while other parameters are stated in smaller period terms (the lead time parameters).

s = ordering cost
d = average annual demand
h = annual holding cost per item
L = fixed lead time in periods
ser = planned service level
Z_{ser} = the Z value that generates the required in stock probability
m = mean demand during a period
σ = standard deviation of demand during a period

Then we first calculate:

$$Q = \sqrt{\frac{2ds}{h}}$$

And then the reorder point:

$$r = (mL) + (Z_{\text{ser}}\ \sigma\sqrt{L})$$

$$\text{Average physical inventory level} = \frac{Q}{2} + r - (mL)$$

3.3.1. Another Example Problem

Thus, for the problem faced by Steco, a retailer of titanium rods. Weekly demand for these rods follows a normal distribution with a mean of 100 units and a standard deviation of 5 units per week. These rods cost \$5 each and the cost of holding a rod in inventory for a year is 20% of its cost. The cost to Steco to place an order for replenishment is \$25/order. Delivery lead time is one week. Management wants a less than 6% probability of stocking out. Assume 50 weeks per year.

Develop a (Q, r) policy for Steco.

Answer:

Ordering cost = s = \$25/order
Holding cost = h = \$1/unit/year
Annual demand = $d = 100 \times 50 = 5000$ units/year

$$Q = \sqrt{\frac{2sd}{h}} = 500$$

$m = 100$,
$\sigma = 5$,
$L = 1$,
ser = 0.94, and
$Z_{0.94} = 1.56$ (from the normal table)
$r = 108$

Thus, Steco should reorder Q units whenever the pipeline inventory level falls to below r units.

Steco's average inventory level = $Q/2 + r - (mL) = 258$ units

4. DEMAND AS A MIXTURE OF DISTRIBUTIONS

We now consider an alternative representation of demand that will permit us to incorporate information collected to lower demand uncertainty. The role of the decision maker is to use the best available assessment of the weights to be assigned to each demand model in order to model the demand at that point in time. We do this by representing demand as a mixture of a number of possible demand models. This in effect means that the model of demand will change over time, reflecting the link between information and its role in reducing demand uncertainty. We illustrate this idea using an example problem.

4.1. A Mixture Model of Demand

Consider a retailer (ASSORT) who sells women's dresses. Analysis of the historical data has indicated that at the end of the season, some dresses follow a demand whose distribution is uniform between 1 and 5. Other (in-fashion) dresses follow a demand whose distribution is between 4 and 8 units. About eight months in advance, when the order is placed, the best estimate is that demand for a particular dress will be either of these two distributions with a 50% probability.

These dresses are bought for \$100 and sell for \$200. If ASSORT runs out of dresses, the future profit impact is estimated to be \$200. Dresses that are held through the fashion season incur a holding cost of \$20. Those dresses that do not sell during the season are sold to an outlet store for \$40.

Under this system, what will be ASSORT's order size and associated expected profit if orders have to be placed eight months in advance?

Answer: Given these costs, note that ASSORT will estimate the optimal service level to be

$$\text{Service level} = \frac{r + g - c}{r + h + g - s}$$

where $r = 200$, $c = 100$, $h = 20$, $s = 40$, $g = 200$. Thus, the optimal service level is 78.9%.

The demand distribution at this point in time is

Demand	Probability
1	0.1
2	0.1
3	0.1
4	0.2
5	0.2
6	0.1
7	0.1
8	0.1

With this demand distribution, the inventory of dresses purchased is 6 units. Associated with this inventory purchased, ASSORT's expected profit is as follows:

$(-100*6)$ + (purchase costs)

$((0.1*200*1) + (0.1*200*2) + (0.1*200*3) + (0.2*200*4) + (0.2*200*5) +$
$(0.1*200*6) + (0.1*200*6) + (0.1*200*6))+$ (expected revenue)

$((0.1*20*5) + (0.1*20*4) + (0.1*20*3)+$
$(0.2*20*2) + (0.2*20*1)) +$ (expected salvage − Holding Costs)

$((-0.1*200*1) + (-0.1*200*2))$ (expected penalty costs)

$= 216$

The associated manufacturer revenue is $100 * 6 = \$600$.

4.2. Impact of Information on the Demand Model

The retailer has heard of a new scheme called quick response (QR). Under this scheme, the manufacturer has to receive the order only four months in advance. This enables the retailer to collect data regarding sales of similar products. These similar product sales enable the retailer to further refine the demand distribution estimates. What will be the impact of QR on the retailer?

Answer: Under QR, the retailer observes a draw from the demand distribution. Depending on the value of this observed demand, ASSORT will adjust demand estimates as follows:

Demand	Probability
$1 \le d1 \le 3$	$P(1) = 1, P(2) = 0$
$4 \le d1 \le 5$	$P(1)=1/2, P(2) = 1/2$
$6 \le d1 \le 8$	$P(1) = 0, P(2) = 1$

Thus, the observed demand changes the weights we would place on each of the two demand distributions.

As before, we can then derive the optimal inventory policy and associated expected profit for the retailer as follows:

Demand ($d1$)	Probability	Inventory	Expected Profit
$1 \le d1 \le 3$	0.3	4	144
$4 \le d1 \le 5$	0.4	6	216
$6 \le d1 \le 8$	0.3	7	444
			Total expected profit 262.8

Thus, the retailer's profit increases from 216 to 262.8, an increase of 22%.

What is the expected quantity purchased from the manufacturer?

$$(0.3 * 4) + (0.4 * 6) + (0.3 * 7) = 5.7$$

Thus, manufacturer revenues decreases to \$570, a drop of 5%.

4.3. Quick Response—Service Commitment

Suppose the retailer commits to a service level of 100% in return for the manufacturer providing QR. What will be the impact on the system?

Answer: We will have to change the inventory purchased after observing demand and thus get the following results:

Demand ($d1$)	Probability	Inventory	Expected Profit
$1 \leq d1 \leq 3$	0.3	5	140
$4 \leq d1 \leq 5$	0.4	8	170
$6 \leq d1 \leq 8$	0.3	8	440
			Total expected profit 242.0

The associated manufacturer revenue is

$$100\ [(0.3 * 5) + (0.4 * 8) + (0.4 * 8)] = 710$$

Thus, the manufacturer and the retailer are better off than under the old system.

Where are the retailer's increases in expected profit coming from?

Answer: Consider the service level in the old system and the new QR system with a 100% service level.

Demand ($d1$)	Probability	Old System Service Level	QR System 100% Service Level
$1 \leq d1 \leq 3$	0.3	100%	100%
$4 \leq d1 \leq 5$	0.4	80%	100%
$6 \leq d1 \leq 8$	0.3	60%	100%

By choosing the assortment of dresses closer to the season, ASSORT faces a lower forecast error. This enables the retailer to have fewer stockouts, the manufacturer to have higher revenue, and the customer to have a higher service level. All of this is accomplished without a decrease in retailer profits.

Note that providing a 100% service level in the old system would have decreased retailer pro?ts to \$ 170 because of the increased holding and salvage related costs.

Thus, QR allows the customer service level to be increased without decreasing retailer profits. This example thus illustrates the benefit of using a mixture of demands to represent demand for a product. As information is collected, the weights associated with the possible distributions can be adjusted, thus providing a convenient way to incorporate information into the forecasting process. It also shows the benefit of members of a channel working together to permit information to be incorporated into a decision-making process.

5. USING AN EXPONENTIAL SMOOTHING FORECASTING MODEL

We now illustrate the role of another classic demand-forecasting model—the exponential smoothing model. The exponential smoothing model works as follows: Given a demand forecast from previous periods and an observation this period, and a parameter α, the exponential smoothing model is that

$$\text{Demand forecast} = (\alpha \text{ observed demand}) + ((1 - \alpha) \text{ previous forecast})$$

We now illustrate the role of the exponential smoothing model in a supply chain. The model will

allow us to understand how a supply chain reacts to partial information in adjusting its decisions. We start with a two-level supply chain involving a retailer and a manufacturer with a lead time L. The system operates as follows:

1. Retailer receives deliveries and then faces demand. Thus, the retailer has either too much or too little inventory at the end of the period.
2. Retailer updates demand forecast based on observed demand. This forecast follows an exponential smoothing model with parameter α.

Thus,

$$\text{Demand forecast} = (\alpha \text{ observed demand}) + [(1 - \alpha) \text{ previous forecast}]$$

3. Given a total lead time of L, the base stock level is set as $(L + 1)$ demand forecast
4. Retailer places an order to bring pipeline inventory level up to the base stock level.
5. Orders placed by the retailer reach the manufacturer after an information lead time.
6. The manufacturer receives deliveries and then faces demand. Thus, the manufacturer has either too much or too little inventory at the end of the period. Manufacturer shipments reach the retailer after a delivery lead time.
7. Manufacturer updates demand forecast based on observed demand. This forecast follows an exponential smoothing model with parameter α. Thus,

$$\text{Demand forecast} = (\alpha \text{ observed demand}) + [(1 - \alpha) \text{ previous forecast}]$$

8. Given a total lead time of L, the base stock level is set as $(L + 1)$ demand forecast
9. Manufacturer places an order to bring pipeline inventory level up to the base stock level.
10. Manufacturer orders are filled after a production lead time.

5.1. Sample Calculations for a Demand Forecasting Model

We illustrate the model in the earlier section for a four-level supply chain consisting of a retailer, a wholesaler, a distributor, and a manufacturer. There is a 4-period lead time between successive levels, consisting of 2 periods to transmit an order upstream and 2 periods to deliver downstream between successive levels. Manufacturing lead time is 2 periods. Demand is 4 units at the retailer for the first 10 periods and goes to 8 units from then on. In this section, we summarize the steps in generating values that reflect orders placed at each of the four stages of the beergame in response to demand changes. We will consider the case where each level uses $\alpha = 0.2$. The steps in calculating the order size are outlined below. We will assume that each level uses a base stock level = $(L + 1 + 2) \times$ demand forecast. The parameter L refers to the lead time for order delivery. The value 2 refers to 2 periods of safety stock (assumed).
Retailer—period 11:

1. Observe demand of 8 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 8) + [(1 - 0.2) \times 4] = 4.8$$

3. Base stock level = $(4 + 1 + 2) \times 4.8 = 33.6$.
4. Pipeline inventory level after satisfying period 11 demand = $28 - 8 = 20$
5. Order placed in period 11 = $33.6 - 20 = 13.6$.

Similarly, for period 12, the calculations are as follows:

1. Observe demand of 8 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 8) + [(1 - 0.2) \times 4.8] = 5.44$$

3. Base Stock Level = $(4 + 1 + 2) \times 5.44 = 38.08$.
4. Pipeline inventory level after satisfying period 11 demand = $33.6 - 8 = 25.6$.
5. Order placed in period 11 = $38.08 - 25.6 = 12.48$.

We now consider the orders placed by the wholesaler in period 13.
Wholesaler—period 13:

1. Observe demand of 13.6 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 13.6) + [(1 - 0.2) \times 4] = 5.92$$

3. Base stock level = $(4 + 1 + 2) \times 5.92 = 41.44$.
4. Pipeline inventory level after satisfying period 13 demand = $28 - 13.6 = 14.4$
5. Order placed in period 13 = $41.44 - 14.4 = 27.04$.

Similarly, for period 14, the calculations are as follows:

1. Observe demand of 12.48 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 12.48) + [(1 - 0.2) \times 5.92] = 7.232$$

3. Base stock level = $(4 + 1 + 2) \times 7.232 = 50.624$.
4. Pipeline inventory level after satisfying period 14 demand = $41.44 - 12.48 = 28.96$.
5. Order placed in period 14 = $50.624 - 28.96 = 21.664$.

We now consider the orders placed by the distributor in period 15.
Distributor—period 15:

1. Observe demand of 27.04 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 27.04) + [(1 - 0.2) \times 4] = 8.608$$

3. Base stock level = $(4 + 1 + 2) \times 8.608 = 60.256$.
4. Pipeline inventory level after satisfying period 15 demand = $28 - 27.04 = 0.96$.
5. Order placed in period 15 = $60.256 - 0.96 = 59.296$.

Similarly for period 16, the calculations are as follows:

1. Observe demand of 21.664 units.
2. Update demand Forecast as follows:

$$\text{Demand forecast} = (0.2 \times 21.664) + [(1 - 0.2) \times 8.608] = 11.2192$$

3. Base stock level = $(4 + 1 + 2) \times 11.2192 = 78.5344$.
4. Pipeline inventory level after satisfying period 16 demand = $60.256 - 21.664 = 38.592$.
5. Order placed in period 16 = $78.5344 - 38.592 = 39.9424$.

We now consider the orders placed by the factory in period 17.

Factory—period 17:

1. Observe demand of 59.296 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 59.296) + [(1 - 0.2) \times 4] = 15.0592$$

3. Base stock level = $(2 + 1 + 2) \times 15.0592 = 75.296$.
4. Pipeline inventory level after satisfying period 17 demand = $20 - 59.296 = -39.296$.
5. Order placed in period 17 = $75.296 - (-39.296) = 114.592$.

Similarly, for period 18, the calculations are as follows:

1. Observe demand of 39.9424 units.
2. Update demand forecast as follows:

$$\text{Demand forecast} = (0.2 \times 39.9424) + [(1 - 0.2) \times 15.0592] = 20.0358$$

3. Base stock level = $(2 + 1 + 2) \times 20.0358 = 100.179$.
4. Pipeline inventory level after satisfying period 16 demand = $75.296 - 39.9424 = 35.3536$.
5. Order placed in period 16 = $100.179 - 35.3536 = 64.8256$.

Note that the effect of the information and delivery lags between the stages is to increase a customer demand increase from 4 to 8 units in period 11 to a wholesale order change from 4 to 27.04 in period 13 to a distributor order increase from 4 to 59.296 in period 15 and a factory increase in its brewed cases from 4 to 114.592. Each decision reflects a rational choice given the parameters. This increase in variance or orders as we go up a supply chain is referred to as the bullwhip effect. Demand updating is only one possible reason for the bullwhip effect.

6. SUMMARY

In this chapter we have provided a quick review of four possible approaches to forecast demand and its use in planning. The constant demand model allows for a quick analysis of the effect of ordering costs in a system. The models of demand as a distribution permit details of lead time and demand uncertainty to be included. The modeling of demands as a mixture of distributions enables us to consider the role of information acquired over time. Finally, the exponential smoothing model shows how demand forecast updating can create large swings upstream in a supply chain.

1. INTRODUCTION

The problem of how to allocate a company's resources and material effectively among competing activities over time to optimize the company's market and financial positions is encountered in all industries producing goods or services. Unless a company has significant excess capacity and high inventories, decisions have to be made as to which orders it will accept, which it will turn away, and which products and customers will be given priority over others—in other words, how its available inventory and production capacity will be allocated among revenue-generating activities.

Several factors combine to make this a difficult task. The company must respond to often rapidly changing market conditions and technological developments. A number of different, often conflicting objectives, such as filling customer orders and maintaining low inventory levels and lead times, must be traded off against each other. Different amounts of variability in the production processes and customer demand must be managed. However, there is considerable evidence from various industries that effective execution of this task can provide a significant competitive advantage.

Today a number of trends are combining to render the area of production planning rather more active than it has been for several decades. Increasing competitive pressures have forced companies to forgo the expensive luxury of large amounts of excess capacity and high inventories, making effective allocation of manufacturing capacity and coordination of production activities throughout the supply chain a critical component of market success. The strong demand from industry for these services is demonstrated by the rapidly increasing number of software products and consulting companies specializing in this area that have emerged in the last five years. The explosive expansion of information technology fueled by Moore's law, manifested in the Internet, better databases, and faster, cheaper computers, has rendered feasible a whole range of solutions that could not even be imagined 10 years ago.

In this chapter we shall examine developments in the area of production planning, focusing on the case where a single factory is considered. However, much of the discussion and many of the modeling issues remain valid when production systems involving multiple plants are considered. We do not, however, make any attempt to consider the larger supply chain, which by its nature must consider such aspects as transportation, warehousing, and interactions with other companies. The issue of supply chain management is a fast-growing area of both research and practice and is discussed in more detail in Chapter 82, as well as in Tayur et al. (1998).

We begin by discussing the relationship between the production planning and scheduling functions and their importance to the manufacturing firm. In this context we discuss the effects of congestion on the shop floor and the relationship between workload and lead times, which is fundamental to the relationship between planning and scheduling. We introduce the topic of production planning by discussing at some length the well-known and widely used Material Requirements Planning (MRP) algorithm (Orlicky 1975) and its extensions. This approach is widely used in industry, and much of the current effort in developing advanced planning and scheduling (APS) systems is aimed at remedying its various deficiencies. After defining our view of APS, we present a range of production planning algorithms that have been proposed in industry and academia over the last several years, discussing their strengths and weaknesses. Finally, we identify a number of issues that in our experience must be addressed to implement an APS system successfully.

2. THE PLANNING AND SCHEDULING FUNCTIONS

Generally speaking, planning and scheduling jointly determine how, when, and in what quantity products will be manufactured or purchased. In essence, planning establishes *what* should be done and scheduling determines *how* to do it. The conventional approaches to both these functions are explained below, together with fundamental issues associated with both.

2.1. Planning

Planning determines when to manufacture and purchase parts and how many in order to satisfy future demand for end products. The process is externally focused since the demand comes from both actual and anticipated customer orders. It is controlled by higher-level attributes, such as end-item due dates and order types, and takes an aggregate view of the production process. This aggregation takes several forms: individual machines are aggregated into workcenters for the purpose of representing capacity, time is aggregated into discrete buckets, and the flow time for a number of operations required to produce a component or subassembly is often aggregated into a single lead time. The details associated with how work actually flows through the plant, such as the specific timing of individual operations and production sequences on individual machines, are left unresolved. The time frame, or horizon, over which the plan is made is normally on the order of weeks or months. The result of the process is a time-phased projection of inventory levels, production quantities, and workcenter requirements to satisfy independent demand.

In this incarnation, the production plan serves a number of functions. It represents a decision as to how the company's manufacturing capacity will be allocated among competing products and customers and hence the point where the company's strategy is turned into concrete actions visible by employees and customers. Secondly, it provides management with some visibility into the future status of production, allowing them to identify at least some problematic situations such as mismatches between demand and capacity in time for remedial action to be taken. It thus provides critical information for a number of activities, such as negotiating due dates with customers and deciding the timing and quantity of raw material purchases from suppliers.

It is important to note that the production plan is by nature somewhat tentative, being subject to significant uncertainty. In many companies, at least part of the demand considered in the plan is based on forecasts rather than firm orders and is hence subject to varying degrees of change over time as orders are modified, added, or canceled by customers. Even when demand uncertainty is minimal, the actual execution of the plan on the shop floor is subject to random disruptions such as machine failures, quality problems, and unexpected rush orders. In many companies, production plans are developed and used on a rolling horizon basis, with decisions in the early periods being considered binding but those further out being revised and altered as new information on the realizations of demand and production become available.

It is also important to note that the nature of the planning problem may differ quite substantially depending on the nature of the company's business. At one extreme is the make-to-stock environment, where demand is relatively high and stable. The lead time to produce an end item is sufficiently high that the company maintains substantial finished goods inventory to meet customer orders and produces to replenish this inventory based on demand forecasts. Another situation is a make-to-order environment, where customized items are produced upon receipt of the order. Here the planning system must allow the company to assess intelligently whether or not customer orders can be completed by the requested date and allow detailed coordination of material and other resources to achieve this. Assemble-to-order systems are intermediate in nature, where a number of basic subassemblies are produced to stock and then combined in different ways in response to customer orders. A company's planning and scheduling needs may differ quite substantially depending on the environment in which it is operating. Hendry and Kingsman (1989) discuss the needs of make-to-order companies and the relevance of many planning and scheduling approaches such as kanban (e.g., Monden 1983) and theory of constraints (Goldratt and Fox 1986) in this environment.

An important role in production planning belongs to the master production schedule (MPS), which specifies the quantity of each final demand item required in each time period and drives the requirements planning calculation of how many of each component and subassembly to produce to meet this demand over time and thus the scheduling system that moves the work through the individual operations to meet this plan. Originally MPS was treated as an exogeneous input to the system that developed the quantities and timing of releases to the shop floor. The goal of many APS systems, especially transaction-oriented systems, is to integrate planning and scheduling decisions to a much higher degree. Hence, much of the functionality of the MPS is fulfilled by the plan developed by the APS system.

The MPS, or the planning function that fulfills this role, is a crucial element of the production-planning process for several reasons. First, if the MPS is not realistic with respect to the various constraints such as production and supplier capacity and material availability faced by the manufacturing organization, it is unlikely that the best APS software or shop-floor scheduling package can save the situation. Secondly, the MPS is where a crucial set of decisions determining how the company's limited production capacity will be allocated among competing orders and customers is made. These decisions involve trade-offs whose effective resolution requires an understanding of the strategic and tactical goals of the company as well as negotiation among various functional groups within the company. For example, the manufacturing organization is likely to prefer an MPS that allows them to use equipment efficiently by having long production runs with few setup changes. On the other hand, sales and marketing are likely to push for an MPS that emphasizes delivery to key customers, as well as perhaps to customers who are getting ready to take their business elsewhere. Hence effective, thoughtful procedures for developing an MPS are critical to the company's long-term performance. However, in practice we find that in many cases companies develop their MPS using the intuition and knowledge of a few key employees and simple spreadsheet-based tools for data management. There is currently far more art than science to the development of an MPS, a situation that renders this area attractive for future research.

2.2. Scheduling

While the production plan lays out what mix and quantity of products the company is expected to produce over a certain time horizon, the schedule describes the detailed execution of this plan, giving a step-by-step work list in the form of a dispatch list or a specification of the times at which every operation should start and end. In contrast to the production plan, whose focus is on independent

demand for end items, the scheduling process is internally focused, driven by the need to ensure that all the components, subassemblies, and assemblies needed to produce the end items are completed according to the plan as efficiently (in terms of resource usage) as possible. Inputs to the scheduling process are product definition information (e.g., routes), facility information (e.g., workcenter availability), and shop-floor status. Shop-floor status defines the current state of production, identifying what orders are still open, their current locations (e.g., what machines are working on them), and the yield or scrap rates for each of the operations associated with these orders. Depending on the capabilities of the particular scheduling algorithm used, the process can also address work order resequencing for more efficient workcenter processing and improved plant throughput. The process is controlled by lower-level attributes, such as manufacturing order due dates and work order selection logic at a workcenter. It also takes a more detailed view of the production process, working with individual resources (e.g., machines) vs. workcenters, operational level routes for parts vs. fixed lead times, shift times vs. planned hours, and often even continuous time vs. discrete time buckets. The time horizon is typically short, usually on the order of a shift, a day, or a week. The usefulness of the schedule generally decreases rapidly in the future since responses to shop floor disruptions and changes to the production plan will result in significant revisions.

In summary, planning focuses on allocating production resources and material to various end products or customers, while scheduling focuses on how to meet component level deliveries without sacrificing efficiency. In general, one of these functions tends to dominate, in the sense that its decisions are considered to be more important to satisfy and the other is forced to adhere to them. Many of today's APS systems have their roots in the attempt to remedy the deficiencies of traditional planning systems by integrating planning and scheduling more closely.

3. RELATIONSHIPS BETWEEN PLANNING AND SCHEDULING

It should by now be apparent that planning and scheduling are tightly intertwined. Planning starts with high-level demand and produces a ''schedulable'' plan. Scheduling then generates a time-sequenced allocation of individual resources to tasks over time that efficiently supports this plan. Closing the loop, planning then honors these allocations as it replans. In other words, planning affects scheduling and vice versa.

Effective planning leads to effective scheduling. No amount of clever scheduling can overcome the effects of a poor plan. Another way of saying this is that if a plan calls for the plant to build the wrong things at the wrong time, efficiently executing this plan may still leave the plant in considerable trouble. If the plan is so tightly determined that it does not allow the scheduling procedure to adapt work order (job) sequences to the detailed needs of the shop floor, such as sequence-dependent setup times, then the task of scheduling is obviated and processing efficiency is likely reduced. At the other extreme, a plan that fails to constrain the scheduling task properly risks a decline in on-time performance in the name of efficiency. Planning needs to provide the shop floor enough direction to maintain overall order performance without unduly limiting opportunities for efficient workcenter processing. Recall that planning is where we prioritize orders and customers; the scheduling function does not usually have access to the right information to make these decisions in the company's best interest. However, it is unfortunately quite common to see these decisions being made by scheduling personnel due to dysfunctionalities in the planning system such as inaccurate data on workcenter capabilities.

Just as proper planning leads to good scheduling, proper scheduling leads to good planning. Efficiently rearranging the work on the floor allows production gains to be made that translate into more available capacity in which to plan the work. This also offers the added benefit of closer promise dates. Conversely, poor scheduling can undo the work of a good plan when the inefficiencies incurred on the floor cause exceptions to the plan. These exceptions are often addressed by ad hoc remedies on the shop floor based on local objectives such as machine utilization, resulting in a reduction in global performance.

In spite of this close relationship between planning and scheduling, inherent differences exist between them. These manifest themselves in many ways, including their function, their treatment of capacity, and their representation of the manufacturing process. An interesting discussion of the relation between planning and scheduling can be found in Pritsker and Snyder (1997).

3.1. Function

In manufacturing there is a basic dualism at play between synchronization and sequencing. Synchronization is the process of prioritizing independent demand from customer orders and demand forecasts and deriving all dependent demand for the necessary components, materials, and subassemblies accordingly. Workcenter reservations, allocation of work-in-process to specific orders (pegging), and purchase requisitions are made in support of this coordinated plan. This is an order-driven process and is the primary function of planning. Sequencing, on the other hand, which is the primary function of scheduling, is workcenter driven in that it locally ranks demand on a time-phased basis and projects order completions accordingly.

Under APS, planning, with its synchronization emphasis, dominates and sequencing (or scheduling) is subservient to it. The operations to manufacture a part are initially placed in the plan to support a global criterion, say customer order due date, and then the sequencing of these operations is done to adhere to the plan as closely as possible.

3.2. Treatment of Capacity

Since the basic problem of production planning is that of allocating manufacturing capacity among various customers and products over time, it would seem natural to assume that such a basic notion as capacity should be well understood. However, once one tries to get specific, it turns out that capacity is a remarkably elusive concept. Elmaghraby (1989) gives an insightful discussion of this issue. In this section we first discuss some basic aspects of capacity and its relation to the outputs of the planning process, such as resource utilization, batch sizes, and lead times.

Despite the difficulty of achieving a rigorous definition of capacity, it is widely accepted that the ability to produce a given set of orders on a given set of equipment by specified due dates is affected by product mix, shop-floor scheduling decisions, and the stochastic nature of events on the shop floor. A basic driver of shop-floor dynamics is the phenomenon of congestion, in which the rate of response of the manufacturing system degrades as more work is introduced into the system, even when the demand rate for the system is well below its nominal capacity. This is due to variations in the arrival rates of jobs at workcenters causing short-term saturation, where the workcenter is unable to process all jobs arriving within a short period of time and queues form. These variations arise from the myriad random events that determine the outcome of most manufacturing processes, such as inherent variability in processing and setup times, machine failures, and quality problems.

A fundamental relationship that holds in a broad range of environments states that the average time to process an order at a workstation is a highly nonlinear function of the workload in the system and that as the workload approaches a nominal capacity both the mean and variance of the lead time increase exponentially, as illustrated in Figure 1. A second fundamental relationship is Little's law (Hopp and Spearman 1996), which states that the average work-in-process inventory (WIP) level and the average time to process a job through the system (i.e., lead time or cycle time) are directly proportional.

The most important aspect of congestion for planning purposes is that a plan that is feasible with respect to manufacturing capacity when aggregated over a specified time period may not be capacity feasible at all times during that interval. To see this, consider a situation where the planning time period is a day and we have a single machine that is available for eight hours. In this sense, placing four orders, each of which requires two hours of processing, on this machine on this day is perfectly feasible. However, it may well be that all four jobs arrive at this workcenter at 10 a.m. This causes significant short-term congestion, which renders it impossible to complete all orders in the time period assigned.

Another area in which this shop-floor dynamic is becoming better understood is that of the effect of batch sizes, which has been studied by Karmarkar (1987). This work shows that initially, increasing batch sizes lead to rapid reductions in flow times as excessive setups are eliminated, essentially increasing the capacity of the system. However, as the batch size continues to increase, the flow time begins to increase linearly with batch size due to the additional queueing and processing time incurred by the larger batch sizes.

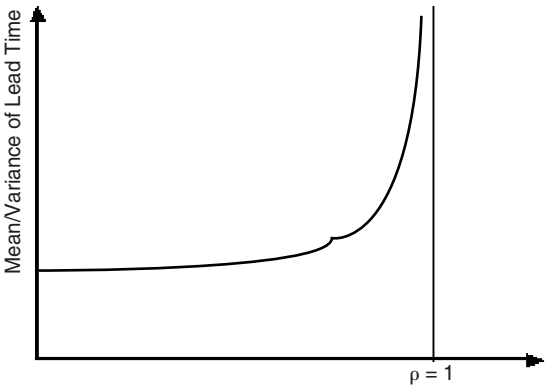

Figure 1 Relationship between Utilization (ρ) and Mean and Variance of Lead Time.

The important aspect of these relationships with regard to planning and scheduling is that both the workload of a given workcenter in a given time and the batch size used in a manufacturing facility are often outputs of the planning process. Hence, the planning process defines to a large extent the basic performance we can realistically expect from the shop floor. The specific scheduling algorithm we use will clearly affect this, at least in the sense that clever job sequencing will make the best possible use of available capacity. However, the high-level response of the system, in the sense of performance measures such as the average lead time, are defined to a large degree by the planning process and cannot be fundamentally altered by scheduling.

Another difference between planning and scheduling stems from their different views of how much capacity should be committed. In planning, it is often desirable to leave some capacity idle to allow time for the workcenters to handle contingencies that may arise, such as failures or rush orders. This is especially true for bottleneck or near-bottleneck workcenters that have demonstrated unreliable performance or whose cycle times vary widely. In planning for these workcenters, it is often advantageous to load the workcenter to a level below that of its nominal availability, yielding a more sparsely populated plan that can tolerate a certain degree of disruption before overall order performance begins to degrade. The extra capacity made available by this undercapacity approach to planning allows the scheduling algorithm, which tries to use the workcenter's full capacity, an opportunity to adjust to the disruptions encountered on the floor. However, while the advantages of this undercapacity planning approach may be significant, too much idle capacity in the plan may well lead to the company making inefficient use of its capacity, quoting overly conservative due dates and hence losing competitive advantage.

3.3. Representation

The advent of the computer and the powerful information technology tools it has brought with it have created many new possibilities for the planning and scheduling process. One area where this is evident is in the level of detail at which the manufacturing process is represented for planning and scheduling. Many more factors can be considered simultaneously with a computerized approach than with a manual one.

Yet even with this ability, planning and scheduling, in practice, still differ in how they represent the manufacturing process. Planning, which coarsely sets the boundaries within which to schedule, can take liberties in its representation. Average setup times, for example, are usually sufficient when generating a plan. The intricate logic that can accompany a setup time calculation is typically superfluous when the objective is to develop a synchronous, as opposed to an executable, plan. Appropriate decisions as to which resources must have their capacity explicitly modeled and which others are nonconstraining and can be treated as having infinite capacity can often improve execution speed without significantly compromising the quality of the plans generated.

This is not to say that detail is not appropriate at the planning level. When capacity is a major determinant of performance, incompatibilities can be introduced as a result of relaxing too many constraints. Consideration of tooling and overlapped operations, for example, may be necessary during planning to obtain a realistic picture of workcenter capacity and provide appropriate goals to the scheduling function. In some industries, such as integrated steel mills, the dynamics of the shop floor affect the capacity of the shop to such a degree that in order to be viable a plan must consider detailed shop-floor dynamics. Again, a well-constructed plan gives scheduling the opportunity to refine the sequence of operations to improve workcenter efficiencies without sacrificing, and hopefully enhancing, global performance to plan. If the plan is wildly inconsistent with the realities of the shop floor, then scheduling may be forced to make radical changes, which in turn cause major adjustments to the plan. This can be viewed as the scheduling function usurping some of the functionality of a dysfunctional planning system, which it may well not have sufficient information to perform adequately.

4. PLANNING ALGORITHMS

We can classify planning algorithms on two basic characteristics. The first of these is how manufacturing capacity is modeled. This yields two basic classes of algorithms: those that consider capacity within a given time period to be unconstraining, that is, essentially infinite, and those that recognize some limitation on the amount of available capacity. We will refer to these two classes of algorithms as infinite capacity and finite capacity, respectively.

The second classification concerns how the algorithm models the timing of production events. Some algorithms do not consider the issue of congestion at all, essentially assuming that the time for a task to be processed at a workcenter is independent of its workload, that is, is a property of the product being manufactured. Note that this does not necessarily imply that the underlying model assumes infinite capacity, only that it is incapable of modeling the congestion effects discussed above. A second set of algorithms considers congestion effects explicitly. We will refer to these two classes of algorithms as noncongested and congested, respectively. While noncongested algorithms work well

when the production system is at low utilization, the ability of this model to predict job completion times accurately deteriorates rapidly as system utilization increases.

We will begin with a discussion of material requirements planning, which is the most widely used infinite capacity algorithm today. We will then introduce a variety of finite capacity algorithms, beginning with enhancements to the basic MRP algorithm and continuing through fundamentally different approaches such as optimization and artificial intelligence techniques.

4.1. Infinite Capacity Algorithms: Material Requirements Planning

Material requirements planning (MRP) was developed in the 1960s to apply the computational power of computers to production and inventory management problems. The basic paradigm adopted was that manufacturing was fundamentally a problem of coordinating the complex material flows involved in producing large, assembled products with deep bills of material. This basic logic, with a number of extensions and additions, is the common ancestor of most of today's enterprise resource planning (ERP) systems (Ptak and Schragenheim 1999). As such, MRP is prevalent in industry and continues to be the basic planning mechanism for many manufacturing companies as well as the driver for a multibillion-dollar software and consulting industry.

We will first briefly describe the basic MRP procedure and then discuss its inherent strengths and weaknesses. Details of this procedure and its many variants and enhancements can be found in texts such as Vollmann et al. (1988) and Nahmias (1993). Efforts to remedy these deficiencies will then lead us to a discussion of several alternative approaches to production planning that form the kernel of several of today's most successful APS systems.

The MRP planning procedure has three main inputs:

1. *The master production schedule (MPS)* or some other planning document that specifies how much of each end product is required in each time period t, over some specified planning horizon involving T periods. In most practical applications, the basic time period is a week, although longer periods of a month or so may be used for periods far in the future where there is more uncertainty in the demand process (e.g., the MPS is based more on forecasts than on firm customer orders). The relationship of the MPS to the production plan was discussed in Section 2.
2. *The bill of material (BOM)*, which specifies the structure of each product in terms of the components, subassemblies, and assemblies that constitute it. This structure is usually represented graphically as a tree whose root node represents the complete product, leaf nodes purchased components or raw materials, and intermediate nodes subassemblies and assemblies. For the sake of brevity we shall refer to these items collectively as modules. An example of such a BOM tree is shown in Figure 2. For each node (i.e., module) the BOM specifies which items are combined to make it and the quantity of each such item. This formalization allows MRP to draw a distinction between two types of demand. Independent demand originates with customers outside the company and is typically for end items. Dependent demand, on the other hand, refers to the demand for the BOM items used to produce the end item. Once the BOM and the independent demand are given, the dependent demand can easily be computed—if we know we need to build four cars, we know we will need four engines, four back seats, and 16 wheels, for instance. This distinction is of great importance since it allows us to focus on forecasting and managing the independent demand with confidence that the dependent demand can be generated easily if the BOM and estimates of independent demand are correct.

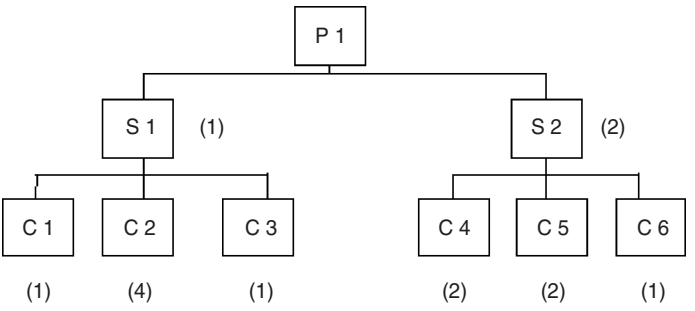

Figure 2 Example BOM Tree.

3. *Inventory status:* This is usually a database specifying the amount of each module on hand or on order. For parts that are on order, it will usually specify when the parts are expected to arrive.

The MRP algorithm combines these three inputs to generate planned order releases for all items in the BOMs of products that occur in the MPS. This will specify how many of each BOM item are needed in each time period covered by the MPS. We will assume that the nodes of the BOM have been indexed such that no node with a lower index occurs at a lower level of the tree than a node with a higher index. Well-defined algorithms to generate this type of indexing, known as level coding, exist. The MRP algorithm can be stated as follows:

For each independent demand item in each time period t, perform the following:

- *Step 1 (initialization):* Set $i = 0$, where node 0 denotes the root node of the BOM tree. Let d_{it} denote the number of item i required in period t.
- *Step 2 (time-phased order releases):* For each descendant j of node i in the BOM tree, perform the following:
  - Calculate the gross requirement $g_{jt} = a_{ij}d_{it}$, where a_{ij} is the number of units of module j required to form module i.
  - Calculate the net requirements for j as $n_{jt} = g_{jt} - l_{it}$, where l_{it} denotes the projected inventory of module j at the beginning of period t. I_{jt} is actually made up of inventory carried over from the last period and items on order expected to arrive in that period. For the sake of brevity, details of how the inventory status is updated can be found in any of several books on this subject (e.g., Nahmias 1993; Vollmann et al. 1988).
  - Generate the planned order release $p_{j,t-L_j} = n_{jt}$, where L_j denotes the number of periods after an order is placed that will elapse before the order is filled. We assume that the L_j are known constants that depend only on the item being ordered. Note that L_j may represent either the production lead time for a part manufactured in house or the supplier lead time for a part or material ordered from a supplier.
  - Once the total quantity of each module to be started in each period has been determined, we can combine the requirements for a number of periods into a release for a single period. This procedure, known as lot sizing, can serve to reduce the amount of setup time required for production changeovers, or may be dictated by process concerns.
- *Step 3 (stopping criterion):* Mark node i as expanded. Select the unexpanded node in the BOM tree with the lowest-level code and go to step 2. If no unexpanded nodes exist, stop.

The basic idea of the above procedure is almost absurdly simple: starting with the requirements for the end product for a given period of the MPS, subtract the estimated amount in inventory in that period to determine how many we actually need to make (the net requirements). Net requirements at one level of the tree become the gross requirements for the next level down. Once we have the net requirements for a given module in a given period, we then schedule the planned order release L_j periods earlier, such that the material will be where it is needed at exactly the right time. This is referred to as backward planning, where the order release date is obtained by working backward from the date the material or product is required and subtracting an estimate of the time needed to complete it.

To illustrate the operation of this algorithm, consider the product whose BOM is given in Figure 2, and let inventory availability and lead times be as listed in Table 1. In addition, we expect 400 units of P1 to become available in week 6, 100 units of S2 in week 4, and 400 units of C4 in week 5.

Based on this information, we can show the results of the MRP calculations in Table 2. Considering the end item P1, we will need 400 units in period 6, but we currently have none available and none expected to become available. Hence, our net requirement for period 6 is 400 units. Since the

TABLE 1 Inventory Status and Lead Times for Example

Item	Lead Time	On Hand
P1	1	–
S2	1	10
C4	2	50

TABLE 2 MRP Calculations for Example

Product P1	0	1	2	3	4	5	6
Gross requirements							400
On hand							
Scheduled receipts							
Net requirements							400
Order releases						400	
Assembly S2	0	1	2	3	4	5	6
Gross requirements						800	
On hand	10	10	10	10	10	110	
Scheduled receipts					100		
Net requirements						690	
Order releases					690		
Component C4	0	1	2	3	4	5	6
Gross requirements					1380		
On hand	50	50	50	50	50		
Scheduled receipts					400		
New requirements					930		
Order releases			930				

lead time is one period, this means that the order must be released at the beginning of period 5 for the end items to be ready when needed at the end of period 6. Since each unit of P1 requires two units of S2, this release causes a gross requirement of 800 units for S2 in period 5. Netting out the 110 units on hand at the beginning of the period, this yields a net requirement for S2 of 690 units, released as an order in period 4. Since, again, each unit of S2 requires 2 units of C4, we obtain a gross requirement of 1380 units of C4 in period 4, resulting in an order for 930 units placed in period 2.

It is interesting to examine the MRP algorithm from a number of different perspectives. First of all, its basic goal appears to be to achieve just-in-time material flow—if the lead times L_j are accurate, material will arrive exactly in the time period in which it will be used. From an optimization standpoint, it attempts to minimize deviation from the MPS (in terms of items completed after their request date) subject to the constraints of the lead times, the BOM structure, and the initial inventory status. Clearly, if the MPS is unrealistic, the backward scheduling procedure in step 2 may indicate a need to release an order in a time period that is already in the past. In this situation, the basic MRP logic offers no help—it is up to the user to revise the MPS to achieve a feasible situation. Many commercial systems provide the option to plan problematic orders forward in time, assuming that required modules at the lowest level of the BOM are started immediately and using the lead times to work forwards to an earliest achievable completion time. In this context, however, it should be noted that neither the backward planning algorithm used by MRP nor the forward algorithm used to remedy deficiencies are rigorously correct. Hence, there may exist a pattern of releases that renders the MPS feasible even though the MRP calculations show them to be otherwise. Moreover, we cannot be certain that if the MRP system claims a plan to be feasible it will indeed turn out to be so when executed on the shop floor.

The basic MRP logic, although widely used and still actively promoted in industry, has a number of fundamental flaws that seriously limit its usefulness as a planning tool. The most important is the treatment of manufacturing capacity. The only reflection of manufacturing capacity in the MRP algorithm is the lead times L_j. These are viewed as being known constants that are an attribute of the module j only. Specifically, they are assumed to be independent of the product mix in the shop and the loading or utilization of the shop at the time the order is released. As we discussed in Section 3.2, the lead time is a function of how the shop is loaded relative to its capacity at the point in time the order is released. Hence, while the fixed lead time assumption may be reasonably accurate for shops at low levels of utilization, as utilization increases, congestion will become more significant. Both the mean and the variance of the time in system at heavily loaded workcenters will increase, rendering the fixed lead times an increasingly inaccurate representation of the actual situation. Inaccurate lead times, in turn, will result in the release of orders to the shop that the factory will not be able to complete on time.

In many environments where the shop is heavily loaded and cannot achieve the lead times quoted in the MRP system, manufacturing will often try to make the case that the lead times should be extended to allow them more time to get work through the plant. However, when the lead times are

extended, we are essentially releasing orders to the shop earlier than we used to, and hence we actually increase the number of orders on the floor. Congestion increases, the actual lead times again increase, and manufacturing goes back to planning to ask for another lead time extension.

Another disadvantage of the MRP algorithm is that when a capacity infeasible plan is recognized, it does not offer any help as to how to repair the problem. In most cases the user has two options—go with the infeasible plan and hope for the best (an option often adopted when the time available for plan revisions expires), or examine the MPS and try to move production requirements between periods so that the MRP algorithm can generate a feasible release plan. The latter is difficult for even an experienced planner to do, especially for a number of products with large, complex BOMs.

On the positive side, MRP correctly distinguishes between dependent and independent demand and provides a useful framework for requirements planning, the calculation of production requirements for dependent demand items given the BOM structure. MRP is also easy to understand, and its adoption forces companies to systematize a great deal of data about their operations, which is a beneficial exercise in and of itself, regardless of what planning algorithm the data are used in. For better or worse, MRP has become a de facto industry standard against which alternative approaches must be measured.

4.2. Finite Capacity Algorithms

The basic source of many of the problems identified with MRP lies in its fundamentally material-centric view of production planning. Other than the extremely indirect representation through the lead times, MRP does not try to represent manufacturing capacity at all. One would expect the infinite capacity approach to work well when capacity is plentiful and the main concern is to coordinate the flow of work through the factory. However, in environments where capacity is expensive and highly utilized, we would expect the infinite capacity model to be increasingly inaccurate in its predictions of job completion times. It did not take long for these problems to be noted in practice, and a number of extensions to the basic MRP procedure have been developed over the years to provide some form of capacity check on MRP calculations. A variety of *finite capacity* algorithms have evolved out of different attempts to address these deficiencies. These algorithms take various approaches to modeling capacity and to generating the actual production plan but are mostly noncongested. We shall present a broad overview of the basic approaches that have been developed in academia and industrial practice.

4.2.1. Extensions to MRP

The two best-known approaches to adding some capacity checks to the basic MRP calculations are rough-cut capacity planning and capacity requirements planning. Both of these approaches have essentially the same philosophy: to estimate the amount of capacity required at each workcenter in each time period and notify the user of any violations. It is up to the user to decide how to modify the MPS to obtain a capacity-feasible order release scheme. They differ in the amount of data required and the accuracy of the capacity profile generated.

Rough-cut capacity planning (RCCP) is intended to be performed on the MPS before the actual MRP run is made. In this approach, we associate a bill of resources with each item in the MPS. These data specify how much time on the various types of resources a given MPS item requires. The RCCP procedure then multiplies each entry in the bill of resources by the number of units required by the MPS in a given time period to estimate the total workload implied for each resource. Note that this calculation is performed before the MRP run, so the timing of planned order releases is unavailable. Hence, lead time information is not used in RCCP. By the same token, neither does it consider the amount of available inventory in estimating this workload. Hence, the accuracy of the workload predictions made by RCCP is often quite poor, although it may allow the user to identify gross capacity violations before the actual MRP run is made. Its chief virtue is that its data requirements are modest and the computations simple.

Capacity requirements planning (CRP) is performed after the MRP run and essentially converts the planned order releases into a capacity profile. This approach in its pristine form considers lead times for individual processing steps rather than for the production of the BOM item and thus requires a lot more data than RCCP. It is also substantially more time consuming to perform. However, being done after the MRP run, it considers both lead times and inventory status. Unfortunately, the arguments above against constant lead times also hold here, rendering the capacity profile generated increasingly inaccurate at high utilization levels.

Another approach to enhancing MRP is the capacitated MRP (MRP-C) approach proposed by Tardif and Spearman (1997). This approach has a number of advantages: it specifically pinpoints the reason for the infeasibility as being due to the current WIP distribution, which does not allow the work in process to be finished in time to meet demand, or lack of capacity at a specific point in time. The basic idea of this approach is that capacity is explicitly considered while doing the calculation itself. Hence, net requirements are calculated in a given time period and are checked against

available capacity to determine whether they can actually be manufactured in that period. If they cannot be produced, then the current plan is infeasible and action must be taken to render it feasible, such as delaying demand or adding overtime. An interesting aspect of this approach is that it identifies infeasibilities as being due to either poor positioning of the WIP in the line or mismatches of demand and capacity in time. The authors show that if their algorithm generates a feasible plan, that plan will minimize the total inventory over the planning horizon. Similarly, they provide algorithms to delay demand or add overtime in a manner that minimizes inventory and lateness costs. This algorithm is of considerable interest in that it integrates the two steps of generating material requirements and checking capacity feasibility that are performed serially under conventional MRP approaches. The fact that it identifies the source of infeasibilities and gives guidance as to what to do about it is also important.

4.2.2. Optimization Approaches

There is a long history of optimization models for production planning, almost all of them based on linear programming. The capacity of each workcenter is recognized to be finite in each time period. The planning problem is then that of assigning orders to time periods, subject to a subset of the relevant resource and relational constraints. Those most commonly considered are workcenter capacity, that is, the number of hours available in each time period and the routing of the products through those workcenters. In most cases the lead times at the workcenters are assumed to be independent of workload. Hence these models are classified as finite capacity noncongested. The objective is usually to maximize some combination of revenue and costs.

A simple model of this form to illustrate the basic types of issues that can be modeled is given below. Let the decision variables x_{it} denote the amount of product i to be produced in period t. We will let I_{it} denote the amount of inventory on hand at the end of period t and S_{it} the amount of backlog at the end of period t. The product j produced in period t is assumed to become available τj periods later, that is, we assume a fixed lead time of τ_j for product j. The model will also determine the amounts of regular and overtime labor to be used, which will be denoted by LR_t and LO_t respectively. Costs are also incurred when we increase and decrease our labor force, and are proportional to the amount of the increase or decrease. Denoting the amount of labor force increase or decrease in period t by λ_t^+ and λ_t^-, respectively, we can then state a basic model as follows.

$$\min \sum_{t=1}^{T} \left[\sum_{i=1}^{n} (p_{it}x_{it} + h_{it}I_{it} + w_{it}S_{it}) + C_{Rt}LR_t + C_{ot}LO_t + c_{lt}\lambda_t^+ + c'_{lt}\lambda_t^- \right]$$

subject to

$$NI_{it} = NI_{i,t-1} + x_{i,t-\tau_i} - c_{it}^i \text{ for all } i, j, t$$

$$NI_{it} = I_{it} - S_{it} \text{ for all } i, t$$

$$LR_t = LR_{t-1} + \lambda_t^+ - \lambda_t^- \text{ for all } t$$

$$LO_t - LU_t = \sum_{i=1}^{n} m_i x_{it} - LR_t \text{ for all } t$$

All variables are assumed to be nonnegative. LU_t is a slack variable denoting the amount of excess labor available in period t. Note that LU_t and LO_t cannot both be positive in the same period. The first set of constraints ensures that the inventory levels are consistent across periods, where NI_{it} is the net inventory of product i in period t. The second set of constraints defines the net inventory to be either positive or negative, since both variables on the right-hand side cannot be positive in any optimal solution. The third set of constraints models the evolution of the labor level over time, while the fourth set indicates the relationship among overtime, undertime, and the amount of regular labor on hand.

While this particular model views the production facility as a single stage whose production capacity is limited by the available workforce, it is easy to extend this approach to situations with multiple products following different routings through multiple-stage production systems. This basic model has been extended in many directions, such as the inclusion of variables and constraints related to working capital, marketing, and promotion decisions (Shapiro et al. 1993).

This model considers capacity at an aggregate level, in the sense of recognizing that the number of hours available on a given resource in a given time period is limited, but the modeling of congestion is still inadequate. As in the MRP algorithm, we are assuming that lead times (the τ_j in the above model) are known a priori and independent of the loading of the shop in that time period. While this may well be an acceptable approximation in lightly utilized facilities, it rapidly degenerates as the

level of resource utilization increases. A number of authors, notably Leachman and his coworkers (Hackman and Leachman 1989; Leachman 1993) have significantly extended the capability of linear programming models in this regard, allowing lead times to vary over time as the workload in time periods changes. Hung and Leachman (1996) use an iterative approach where the results of the linear program are fed into a simulation model of the production facility to obtain updated lead time estimates, which are then input into the linear program for another run.

The model as stated here is also more suitable for MPS generation in that it deals with end-item demand translated into demand for workcenter capacity. Optimization models that explicitly address the multilevel nature of the BOM have been proposed (e.g., Billington et al. 1983) but are generally mixed-integer programs that are significantly more complex than the model above.

A number of authors, such as Graves (1986) and Karmarkar (1989), have attempted to develop models of manufacturing capacity that reflect the effects of congestion using the idea of clearing functions. As the name implies, a clearing function represents the amount of inventory at a workcenter that can be moved out of it in a given period. While a number of different forms for such clearing functions have been suggested in the academic literature, they remain an unexplored possibility in terms of industrial implementation. A particular area of research is how to obtain such clearing functions empirically for specific industrial scenarios.

4.2.3. Artificial Intelligence Approaches

Another approach that appears to be used in some current planning systems is to model the capacity of at least a subset of near-bottleneck workstations in an aggregate manner, as a total number of available hours per planning period. A plan is constructed by calculating the amount of time each operation of the order will require on each workcenter and assigning each operation to a specific planning period. The lead time between nonbottleneck operations is modeled as infinite-capacity, the idea being that these stations have such low utilization that the infinite capacity model is a reasonable approximation. These procedures tend to use quite sophisticated heuristic search procedures to assign orders to periods. Examples of such algorithms are the ReDS system (Hadavi et al. 1989) and the system developed at Texas Instruments described by Fargher and Smith (1994). Smith (1993) presents an excellent review of artificial intelligence approaches to production planning and scheduling problems, and Zweben and Fox (1994) provide a number of case studies.

4.2.4. Congestion Models

All the approaches considered so far have been based on an aggregate model of manufacturing capacity, in the sense that capacity constraints are checked only at an aggregate level over a specified time period. This clearly does not prevent infeasibilities due to mismatches between the arrival and completion of tasks at the workcenters. A number of procedures have been developed to address this problem by making a detailed scheduling model an integral part of the planning algorithm. These models address the congestion effect directly by modeling the operation of the shop in considerable detail. We shall discuss two basic flavors of this approach, asking the reader to bear in mind that in many implementations the distinction between them may become blurred, with any particular procedure exhibiting characteristics of both groups.

4.2.5. Detailed Scheduling as Part of the Planning Process

As discussed above, a major difficulty in most finite-capacity production planning models is that of modeling the nonlinear effects of congestion at the shop floor, caused by variability in the arrival patterns of jobs to the workcenters. A number of planning systems in both the research community and industry have attempted to address this by making the generation of a detailed schedule of shop-floor operations a part of the planning process. The basic idea is to generate a plan using some planning procedure and then try to construct a detailed schedule that meets the deadlines given by the plan. If such a schedule can be generated successfully, it shows that the plan is capacity feasible. In general, one would not expect the schedule generated during the planning process actually to be executed, as both plan and schedule will be revised. Rather, the function of the schedule is to verify that the proposed plan is indeed capacity feasible in the sense that at least one schedule that satisfies its demands can be constructed.

This approach has been illustrated in a research environment by Dauzère-Pérès and Lasserre (1994), who use an optimization algorithm for production planning. Once a plan has been developed, they use a sophisticated optimization-based scheduling heuristic to build a schedule that meets the deadlines set by the plan. In the event that the deadlines cannot be met, they revise the plan and iterate until a satisfactory solution is reached.

While intuitively attractive, this approach has a number of problems. While the idea of using a scheduling algorithm to verify the capacity feasibility of a proposed plan is attractive, the correctness of the conclusion depends on the quality of the scheduling algorithm used. A simple dispatching heuristic may well be unable to find a schedule that satisfies the plan that a more sophisticated exact

solution procedure could identify. Moreover, the essentially discrete nature of the scheduling problem and its well-known computational intractability render the task of generating high-quality schedules very time consuming. This is an important drawback in an environment where the plan must be revised and schedules generated repeatedly before a satisfactory solution is reached.

A common approach widely discussed in industry is to feed the output of an infinite capacity planning system into a detailed discrete-event simulation model of the plant and use the simulation to determine whether the proposed start times will allow all orders to be completed by their due date. If some orders are identified as being late, the plan is modified and the simulation rerun until an acceptable result is achieved. While conceptually attractive, this approach has a number of difficulties. First of all, the time and effort involved in developing and maintaining a detailed simulation model of the facility may be significant. Secondly, the time required to obtain results from the simulation, especially if several replications must be run to obtain statistically valid results, may be quite substantial. Thirdly, if the simulation identifies an infeasibility, the user is often reduced to manual intervention and experimentation to identify a feasible plan, which may be difficult to achieve in the time available for the decision to be made. Finally, this approach requires some fairly detailed assumptions as to how the shop does the scheduling—in effect, the simulation model must generate the schedule as executed on the shop floor to ensure the capacity feasibility of the plan driving the schedule. All in all, this approach may work well in relatively simple manufacturing environments, but is unlikely to be practical in complex multistage environments where the time to make multiple simulation runs is substantial and the effects of changes in the schedules are hard to predict. However, despite the drawbacks of this basic approach, the APS procedures described in the following section are often quite successful using variants of this approach that use scheduling ideas to maintain records of how much capacity is available at each critical resource in a given time period and use this information to drive planning procedures.

5. ADVANCED PLANNING AND SCHEDULING

APS is the process of simultaneously coordinating material and capacity constraints at the operational level to best meet market demand. APS offers the planning function a detailed representation of the production process that was formerly found only in more advanced scheduling systems. As for the scheduling function, it links work orders to customer orders, permitting direct tracking of their progress. Arguably its most important advantage over traditional planning approaches is that material and capacity are *simultaneously* considered as elements that may constrain production. This ensures that the material plan, as it is being generated, is in agreement with the capacity schedule down to the level of individual resources such as machines, and the capacity schedule is in agreement with the material plan throughout all BOMs. This stands in marked contrast to the conventional MRP approach of independently planning material and then subsequently checking this plan against capacity to identify violations.

The computational complexity of this task is quite daunting—to achieve this, one needs to consider detailed scheduling information as well as customer information, essentially creating a detailed schedule in parallel with a production plan to ensure that the plan is indeed achievable. The need to do this for all levels of the potentially complex BOM adds to the difficulty. The computational complexity of scheduling problems on their own is well recognized (Pinedo 1995). Hence, many APS systems do not try to develop plans that are optimal in a rigorous sense. Instead, they are focused on transaction processing, determining at the time the order is placed whether the order can be completed on time or what the earliest possible completion date is if the original request date cannot be met. A complete resynchronization of the plan is then done periodically to optimize resource usage and material plans.

APS systems also differ in how they approach the generation of plans and schedules. In some systems, planning is done periodically in batch mode, with integrated plans being developed for a set of products and workcenters. On the other hand, others are focused on transaction processing, where a plan is constructed and capacity allocated incrementally as orders arrive.

In its pristine form, APS integrates three key processes: advanced planning, advanced scheduling, and order promising.

5.1. Advanced Planning

The goal of advanced planning is the synchronization of constrained material and resources to independent demand. Its purpose is to create a plan that is feasible with respect to all resources required (machines, material, tooling etc.) with sufficient operational slack to permit resequencing of work orders to enhance production efficiency. The independent demand comes from several sources, including customer orders, demand forecasts, master production schedules, transfer orders (i.e., orders from other plants), and the company's policies on safety stock. The advanced planner also considers the work order schedule already released to the shop floor as presented by the advanced scheduler. For each end-item demand, a complete requirements explosion is done using that item's BOM and

backward scheduling dependent demand based on component routes, available resource capacity (not simply workcenter capacity), and available and projected inventory. Some advanced planning engines are refined enough to consider resource and material requests at their point-of-use, which can be helpful in environments where long operation times create extended delays for material usage. Typically, the APS horizon is similar to that of conventional planning tools, ranging from several weeks to months.

5.2. Advanced Scheduling

The second APS component, advanced scheduling, involves the detailed sequencing of operations and material in support of the aforementioned plan. Its purpose is to provide properly sequenced work orders, under possibly more refined constraints than those considered in the plan (e.g., sequence-dependent setups, maintenance schedules, more detailed machining constraints, additional operator restrictions) while still attempting to hold to the plan dates. It serves to efficiently load the workcenters and present a more discriminating schedule to the advanced planner. While advanced planning produces a detailed allocation of resources and material to orders, some applications require further refinement, especially where work sequencing can significantly affect workcenter production rates. Advanced scheduling produces a schedule constrained by both material and capacity. This schedule serves as a projection of what the shop floor should be doing and is used in the advanced planner as a basis for component supply. Exceptions to the advanced plan are identified for resolution in the advanced scheduler or for adjustments to the advanced plan. The advanced scheduling horizon tends to be short, as with conventional scheduling tools, but may need to be extended to support better the needs of the advanced planning process.

The reader should keep in mind that one may not need to run an advanced schedule to produce what the shop floor needs for execution. The main difference between the advanced plan and the advanced schedule is not necessarily the detail used in the representation, but rather the amount of emphasis placed on sequencing. If it is enough to determine what needs to be produced over a given time frame (e.g., a shift) without regard to sequence, then the advanced plan may be sufficient. If, on the other hand, the sequence in which this work is done can significantly affect the workcenter's production rate, an advanced schedule with a more refined sequenced execution list is required. This type of situation often arises in manufacturing systems where the decisions at various stages of production are tightly coupled and setup times between products are significant.

5.3. Order Promising

The third component of APS is order promising, which lies at the center of the transaction-based aspect of APS systems. This component is designed to suggest realistic promise dates for customer orders. The process, sometimes referred to as capable-to-promise (CTP), involves testing the customer's request date for feasibility and, if the date cannot be met, calculating the earliest date that it can be met. This is done based on available and projected inventory and available resource capacity.

CTP functions at two levels: disruptive and nondisruptive. Nondisruptive promising uses available capacity and material to determine the order's projected completion date without altering the planned completion times of orders currently in the system. Disruptive promising, on the other hand, reallocates capacity and material to determine the feasibility of meeting a particular date (presumably earlier than is possible under nondisruptive promising) and identifies what orders are affected as a result. In either case, CTP differs significantly from conventional available to promise (ATP), which considers only the uncommitted inventory balance by period. With CTP, the process extends through the bill of materials and part routings to examine the potential for manufacturing the item if it is not available.

The transaction focus of APS systems renders their speed of execution critical to their effectiveness. Taking advantage of the many advances in hardware and software technology over the last decade, APS systems have execution speeds orders of magnitude faster than those of traditional MRP. Most APS engines have their data downloaded, either in batch or transaction mode, to a dedicated server that is architected to run memory-resident programs and databases. Under this scheme, they are able to deliver real-time order promising and make multiple runs to test various actions in an effort to further improve the plan.

6. APS IMPLEMENTATION ISSUES

Compared to MRP alone, APS has a broader functional impact, is less tolerant of inaccurate and incomplete information, requires more data and in greater detail, and affects more people more directly every day. Beyond this, it causes a cultural change. These factors make APS implementations more challenging than MRP. Nevertheless, remaining cognizant of the value received will enable the technical and organizational hurdles that will inevitably appear throughout the course of the APS implementation to be overcome. Areas in which to be particularly vigilant are described below.

6.1. ERP Integration

The comprehensive nature of today's APS algorithms drives the need for copious amounts of data—data that typically reside in an ERP system. This means that attaining the full benefits of APS is largely predicated on how well it is integrated with ERP. When done well, both systems benefit.

The importance of the ERP system is seen in two key roles it plays. First, ERP provides the necessary infrastructure, holding and managing information about orders, parts, resources, and status. It houses the modules that feed and are fed by the APS system, including forecasting, customer order management, product definition, inventory management, purchase order management, work order reporting, dispatching, and costing. When APS is planning and scheduling, it needs to know what orders to consider, what jobs are finished, what work is in process, what purchased materials are coming in and when, and what capacity is available. Secondly, ERP functions as an execution system, firming and releasing manufacturing orders, cutting purchase orders, and communicating schedules. The orders to be considered are the purview of APS; the actions themselves are the purview of ERP.

This need for ERP integration does, however, pose a number of challenges. First of all, the full benefits of APS can only be realized through a two-way exchange. Closed-loop functionality gives APS the data it needs to plan and schedule and gives ERP the information it needs to take appropriate action. The amount of data transferred and the numerous ERP modules affected require a complex web of communications, as illustrated in Figure 3. Another challenge is the need to disable specific functionality. Some traditional ERP modules, being superseded by APS, are no longer relevant and require circumvention. This must be done with ERP vendor expertise, for these modules often contain utilities that are still germane to the process. This can raise issues of functional ownership.

Finally, determining the type of APS system to be adopted, stand-alone or preintegrated, also deserves some thought. Stand-alone systems, using straightforward handshakes through specially written programming utilities, are less intrusive, require less vendor involvement whenever customized changes are required, and offer well-targeted value. Preintegrated systems, on the other hand, provide a broader range of functionality and are in proven agreement with the ERP system (and in some cases actually share the same database). They may also offer a better upgrade path as improvements in both systems are made. Preintegrated systems also lower the cost and time to implement, thus improving the return on investment.

6.2. Timing, Access, and Quality of Data

6.2.1. Timing

In general, communications between ERP and APS are asynchronous. This means that data are sent to the associated system and no immediate response is required. This is particularly true in systems where the APS engine is transaction oriented. In these systems, updated information is sent on a continual basis in anticipation of a new plan or schedule being generated. Then, at the time of execution, APS knows the current conditions without requiring a time-consuming download, as may be the case with batch-oriented systems. The timing of a full replan or reschedule is often dependent on when the shop floor has consistently reported across the facility (e.g., end of shift) or when a major disruption has occurred (e.g., machine failure). More frequent planning and scheduling is possible with today's technology but is seldom realized given the requirement for the reported information to be consistent.

In the case of order promising, the demands on this timing change. Here, when an order is entered, it triggers the APS engine for the expected completion date and an immediate response is expected. This is a synchronous process. Moreover, as new orders are entered, they need to be promised based on the latest information, including those orders that have just been accepted. Thus, the planning system, upon order acceptance, must immediately reserve materials and capacity so that all future promises can reflect the impact of even the most recently accepted orders.

6.2.2. Access

Planning and scheduling often differ in their data requirements. Capturing some of the subtleties of the production process may be pertinent to scheduling because it seeks to refine the sequence of events, whereas planning may not need to be as precise and thus may not require this same level of detail. In practice, the information required to portray these scheduling subtleties properly usually resides outside the ERP system. For example, traditional ERP systems typically define the manufacturing process at the workcenter level. The scheduling engine, on the other hand, may be forced to examine the detailed differences among the various machines within a workcenter. When more refined information such as this is required, it is imperative that the scheduling system have access to sources of information outside the traditional footprint of ERP or at least be able to circumvent, as necessary, the ERP data definition.

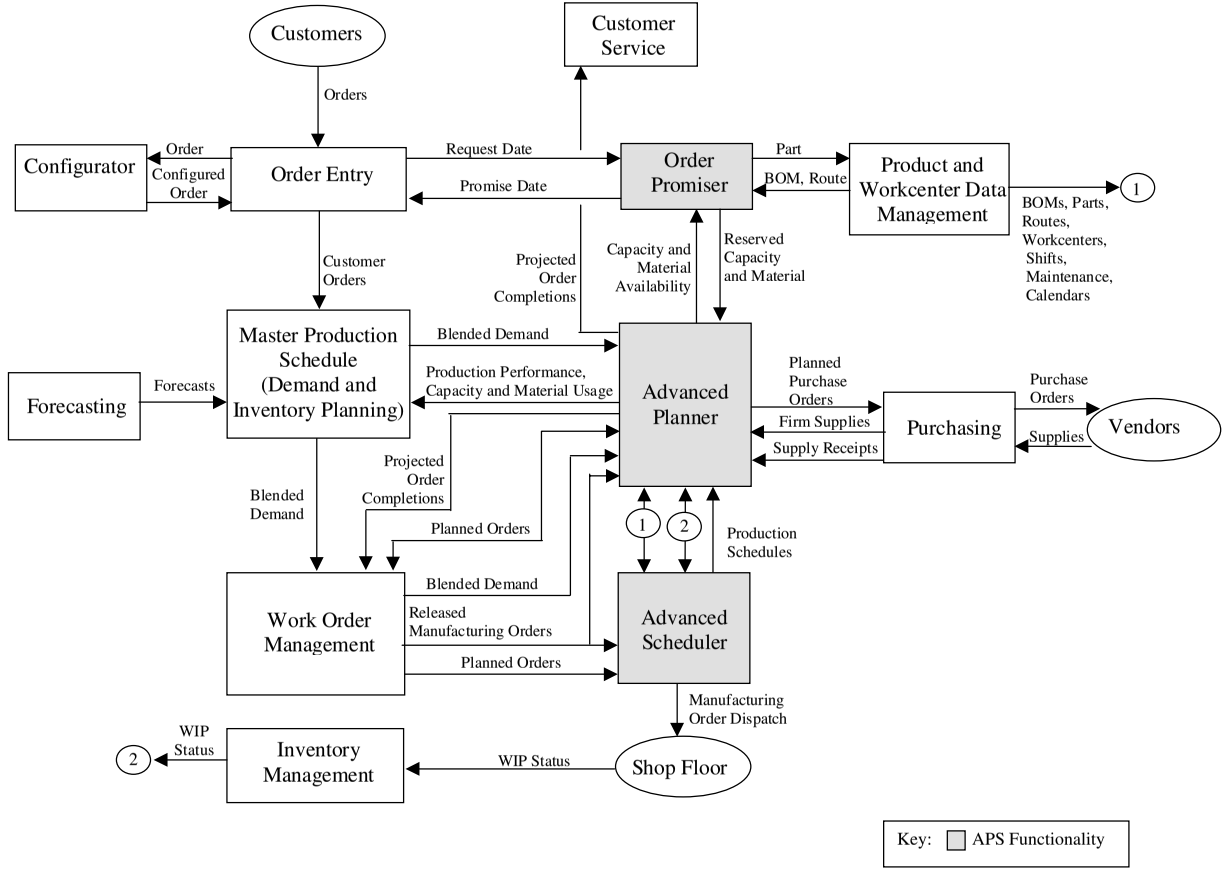

Figure 3 APS/ERP Integration.

6.2.3. Quality

Data quality strongly influences APS results. This is especially true of shop-floor data, which are not always available at the level, at the time, or in the form most appropriate for planning and scheduling.

Work-in-process (WIP) accuracy is particularly problematic. The data-collection system may be, for example, recording only an order's closed operations. Time remaining on partially completed operations may not be known, thus forcing the APS engine to replan and reschedule the operation as if nothing has been done. The significance of this obviously depends on the operation's duration. Similarly, backflushing, which records inventory changes based on assumptive issuing at the end of the process vs. discrete issuing at time of use, can also pose a problem, for it fails to record an order's intermediate progress. If an order's route requires key workcenters for extended lengths of time, this method of capturing status can lead to an erroneous representation of important near-term capacity. Fortunately, advances in data-collection systems have made it easier and more cost effective to track WIP.

Reporting frequency can also adversely affect results. Work accomplished between reports is not recognized until reported. The significance of this misrepresentation increases as the reporting interval widens. More frequent reporting is desirable.

However, frequent reporting does not guarantee valid and consistent status information. False reporting and an inability to hit an order's exact quantity levels at an operation can also mislead the APS engine. As a result, some filtering and interpretation of the shop-floor information may be required. Moreover, where consistent information is a problem (e.g., a downstream station reporting work on an order for which an upstream station has yet to acknowledge), the frequency of the APS resynchronization is forced to match those points in time when the information is most likely to be in agreement across the facility, such as the end of a shift.

Startup conditions (i.e., order and machine status) form yet another critical data source for the planning and scheduling process. As the APS engine is being asked to provide nearer-term dispatch lists (e.g., the next eight hours), the status of resources and WIP at the beginning of the planning and scheduling horizon takes on added importance. This is particularly true in applications where sequence-dependent setups are consequential, for failing to capture a machine's initial state can dramatically alter the resulting sequence. A false start can have a lasting impact.

6.3. Business Process Reengineering

Business process reengineering (Hammer and Champy 1994) is the single biggest factor affecting the success of APS and is what ultimately governs the company's true return on investment. Technology alone cannot guarantee APS success. While APS affords a company the opportunity to improve its order fulfillment process dramatically, it can only happen if the business processes change to accommodate and exploit it. There needs to be a conceptual match between these business processes and the APS system. When the current processes are based on antiquated planning and scheduling practices, changes are in order.

Unfortunately, these changes are not always easily understood and take time to implement. The new planning and scheduling paradigm of APS cuts across organization boundaries and threatens the company's traditional, and now obsolete, mode of operation. The real challenge becomes changing the way people currently think and operate. Confidence is required to move forward. It takes a strong sense of need to implement the procedural changes required. Enlistment of top-level management may be necessary to overcome the pushback that occurs when people are asked to change how they work.

Consequently, the implementation team should take time, in the early stages of the project, to understand better the business processes that will need to be changed in sales, customer service, purchasing, engineering, production planning and scheduling, and manufacturing. Sales will be challenged with sobering promise dates and with reconciling, at the time of order entry, a customer's request with the realities of the production plan. Customer service will wrestle with realistic (and variable) customer order projections. Purchasing will be immediately impacted by sales, and conversely, sales by purchasing. Engineering will be directed to keep BOMs more up to date and more in line with how items are actually built and could be asked to support a configurator to enable order-entry clerks to take direct advantage of the order promise capability. Planning and scheduling will be challenged with having a more comprehensive and integrated view of the production process and with needing improved communications with various departments to better induce the necessary and frequent changes. Manufacturing will be asked to be more disciplined (i.e., follow the schedule and report status) and more flexible (i.e., heedful of new orders and changes to existing orders). In addition, the dynamic reallocation of work will be commonplace.

6.4. A Well-Defined Manufacturing System

Importance must also be placed on properly representing the manufacturing process in the APS engine. This means the manufacturing data need to be brought up to a level of accuracy commensurate

with the APS task. As the manufacturing data deviate from this ideal, the effectiveness of the APS engine (or any other planning and scheduling tools) diminishes accordingly. The data that are most relevant to this process include:

6.4.1. As-Manufactured, Indented Bills of Material

If the item to be produced is not correctly defined, the APS engine is not able to plan and schedule it properly. The issue is usually not whether it is defined (unless in a configure-to-order environment), for most manufacturers have BOMs. Rather, the issue is *how* it is defined. Does an item's BOM reflect the sequence in which that item is to be manufactured, or does it simply represent a listing of what components are required or how the item was engineered? Do the bill's components mirror only those items of importance for planning and scheduling, or do they include a complete listing of all the items in the bill, regardless of their relevance?

6.4.2. Accurate Routes

An item's route directly controls when the requisite resources and materials used in its production are engaged. Obviously, correct identification of these resources and materials is important. This does not mean, however, that every resource or material used in the item's production needs to be identified; only if it supports the representation for purposes of planning and scheduling. Readily available material and secondary as well as tertiary resources at an operation are often not necessary. Furthermore, the operation times themselves are important, for they not only hold the resources for the correct apportionment of time, but they also influence when the other associated operations in the route request their resources and materials.

6.4.3. Supportive Operational Buffer Times

The APS plan may need to allow for the resequencing of work at an operation. When this is the case, operational or resource buffer times are used. This gives a certain degree of latitude to the advanced scheduler for work order resequencing. It is important to set these resequence buffers large enough to allow for some scheduling adjustment, but not so large as to misrepresent the item's lead time.

6.4.4. Consistent Workcenter Definitions

Often, workcenter definitions in ERP reflect a costing orientation more than a planning and scheduling orientation. This can substantially limit the options available to the APS engine. For example, instead of recognizing the more complete set of machines that can actually do a particular operation, the route may only identify a specific (e.g., least-cost) machine, thus misrepresenting the true scheduling options available and potentially artificially extending the time it should take to produce the item. When this is the case, circumvention of the ERP workcenter definition may be required.

6.4.5. Representative Purchasing Lead Times

Purchasing lead times are often inflated to trigger early action by purchasing. In a materially constrained APS application, this can cause overly conservative projections. Flagging an item for early purchase is different than constraining on it. Under a nonconstraining paradigm like MRP, cautious lead times are acceptable, for the purpose is to expose potential problems. In a constraining paradigm like APS, more aggressive (i.e., shorter) lead times generally present a more realistic picture of what is possible.

6.4.6. Appropriate Workcenter and Material Constraints

Bottleneck resources and critically scarce materials need to be modeled in a way that reflects their limited availability, for they are largely responsible for setting the manufacturing flow rate. Failure to represent these limitations properly can render the resulting plans and schedules useless. Nonbottleneck resources and noncritical materials, on the other hand, need not be represented to this same level of detail. This can save on execution time and obviate the need for their precise representation in the model.

6.4.7. Representative Scheduling Rules

Seldom does a manufacturer operate according to one rule (e.g., due date). Rather, each machine or workcenter has its own individualized set of rules (e.g., highest priority, then dynamic slack, and lastly minimum setup). Taken collectively, these rules define the company's manufacturing strategy. Correctly defining these rules and capturing them in the scheduling engine not only ensures valid schedules but also helps APS gain acceptance by those responsible for executing these schedules.

6.5. Usual Suspects

Some APS systems are particularly challenged to represent or work with certain aspects of a manufacturing process adequately. This is not to say it cannot be done, just that it may require additional thought, necessitate extensions to the software, or run counter to their planning and scheduling paradigm. Examples of these challenges include batching, outsourcing, nonsequential operations, flexibility, and early order-release strategies.

Batching, in a discrete process, refers to the combining of like orders for the purposes of processing them together through a portion of their routes. This often surfaces in applications where there are painting or heat-treat operations. The difficulty lies not only with synchronizing these orders appropriately but also with maintaining their unique identities (for these orders may be routed separately after their batched sequence has completed), establishing the batch criteria (e.g., item attributes, timing constraints), associated batching rules (e.g., number in a batch, sum of the batched items' attributes), and gaining access to the requisite information to form the batch.

Outsourcing refers to the practice of having certain operations (or parts) done outside the plant. From a planning perspective, this can be effectively captured. The appropriate delay is simply factored into the item's route. The problem arises when a particular operation or set of operations is done outside the plant before the item reenters for its final set of operations. Precise scheduling of these remaining operations is predicated on having accurate status information from the outside source.

Routing operations that can be done in any order are defined as nonsequential. To bring some structure to the process, an ERP system assumes a specific operational sequence. Since the APS system receives its routing information from the ERP system, the same implied sequence is applied in APS. To function otherwise would require additional information outside the traditional bounds of the ERP system. Nonsequential operations also give rise to significant combinatorial issues.

Most often, the issue of flexibility arises with operators. As more latitude is given to dynamically reassigning people on a line, the demands on the planning and scheduling system increase accordingly. The rules on when to engage a change in assignment and what to change to can be quite complex. Moreover, depending on the number of people assigned, the station times on the line may change. Capturing these dependencies in the planning and scheduling model can be an arduous task and should only be considered when commensurate value results.

Releasing work orders as late as possible is in the best interest of the manufacturing facility and APS. Later releases commit manufacturing at the last possible moment and give planning more flexibility to adjust to ever-changing conditions. Keeping the planning engine in control for as long as possible increases the ability to satisfy ''drop-in'' demand. Unfortunately, many ERP systems require the order to be released before it can be changed. This forces orders to be released early and prevents the planning engine from making last-minute adjustments, since manufacturing is now committed to these orders.

6.6. Implementation Strategies

APS implementation can be a daunting task. The sophistication of the software, the effort to get the necessary data to effectively drive the system, and the need to make fundamental procedural changes across the organization present significant challenges. Moreover, the people involved, their understanding of the business needs, and their willingness to change vary. This makes every APS implementation a unique endeavor. Aside from general project-management guidelines, little is offered to address the challenges that are faced.

Two vastly different APS implementation approaches have been advanced: big bang and evolutionary. With the big bang approach, the strategy is to leap to a complete implementation as quickly as possible. Emphasis is placed on time to value more than fidelity. The approach initially uses the data as it is currently defined rather than going through an extensive modification process to better support the requisite APS functionality. This makes it most appropriate in those environments where the manufacturing data are well defined. With this approach, reliance on the APS system occurs with deliberate speed, immediately exposing opportunities for improvement and abruptly forcing people to work within the new system to effect change. Because of this, procedures need to be in place to quickly and regularly maintain the APS data. This approach usually results in a faster return on investment, but with considerably more trepidation.

With the evolutionary approach, the APS system is initially set up to honor just the BOM constraints, leaving resources and purchased parts unconstrained. If good routing data are not initially available, standard manufacturing lead times are invoked. Under this configuration, the APS system mimics an order-based MRP system. Then, as routes are introduced, key workcenters are constrained, giving an improved representation of the process. As understanding is gained, more constraints are added, such as other workcenters or key purchased parts, until a realistic representation is achieved. This approach, which tends to be more palatable in a proven MRP environment, provides for a more gradual and systematic implementation but extends the time to reach full-value APS functionality and runs the risk of stopping short of this goal.

7. CONCLUSIONS

We have attempted to present a review of the basic planning algorithms, their strengths and weaknesses, and the role of APS in integrating the planning, scheduling, and demand management functions more closely. The issues to be addressed in implementing APS systems have also been addressed. The field of production planning and control has been extremely active in the last several years, and it promises to remain a challenging and interesting area for both researchers and practitioners in the decades to come.

CHAPTER 79

Transportation Management and Shipment Planning

JEFFREY H. FISCHER
United Parcel Service

1. INTRODUCTION

Uncertainty breeds inventory. Managers involved in transportation often have to make planning decisions, like routing, that directly affect the movement of raw materials or finished goods. These decisions often affect other components in the supply chain network, in which case the transportation management team cannot afford to make an incorrect decision. Consequently, any mistakes not only jeopardize other elements within the system but also lead to customer dissatisfaction created by the delay in the delivery times (Quinn 1998).

Beyond routing decisions, however, effective transportation management will assist with solving common transportation and shipping problems by generating various scenarios and simulations in order to arrive at optimal or best solutions for shipment planning, the selection of distribution center sites, and the allocation of resources to critical system components.

2. THE OPTIMIZATION PROBLEM

Often, optimization problems seek a solution where decisions need to be made in a constrained or limited resource environment. The majority of supply chain optimization problems require matching demand and supply when one, the other, or both may be limited. By and large, the most important limited resource is the time required to procure, make, or deliver something. Since the rate of procurement, production, distribution, and transportation resources is limited, demand cannot be im-

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

mediately satisfied. There is always some amount of time required to satisfy demand, and this may not be quick enough unless supply is developed well in advance of demand. In addition to time, other resources, such as warehouse storage space or a vehicle's capacity, may be constrained in meeting demand. All of these factors drive inventory levels, which in turn drive costs.

In achieving optimization, decision variables that are within the control of the planner, such as when to manufacture an order or when and how much of a raw material needs to be ordered, must be balanced with the inherent constraints or limitations that are placed upon supply.

Constraints, such as a supplier's capacity to produce raw materials or components or a customer's distribution center's capacity to handle and process receipts, can be considered either hard or soft constraints. Hard constraints, such as the number of working hours in a shift or the maximum capacity of a transportation vehicle, must be adhered to or satisfied. Soft constraints, on the other hand, can be relaxed or violated. Examples of soft constraints include customer due dates and facility storage limitations. Customer due dates can be modified or product may be temporarily allocated in a warehouse, making constraints less harsh. However, there are cost penalties if a soft constraint is not adhered to, permitting constraints to be weighted by their relative significance. For example, missing a customer due date carries more important consequences than cluttering a warehouse aisle (Lapide and Shepherd 1999).

3. SUPPLY CHAIN MANAGEMENT AND THE TRANSPORTATION ELEMENT

At the center of today's supply chain optimization technology are complex algorithms that can examine millions of variables and solve increasingly complex problems in ever-shortening time frames, enabling solutions in a matter of hours rather than days.

The traditional trade-off in supply chain management has been the maintenance of costly buffers of inventory vs. the ability to meet complex customer prerequisites. Reduce safety stocks and costs will be reduced, but customer service may suffer. Due mainly to advanced planning and scheduling systems and improved forecasting applications, production planners now have the opportunity to reduce reliance on safety stock—while still meeting customer demand—by trading inventory for information.

In transportation management, a similar trend is occurring, but rather than inventory buffers, logistics managers are doing away with time buffers. By using information technology in the elaborate mix of transportation modes, carriers, and shipment consolidation possibilities, manufacturers are obtaining more accurate estimates of the time and cost it will take to deliver goods throughout their supply chains. Transportation management applications are being used to better plan and execute shipments. The software lends visibility, consistency, and economy to the handling of complex variables. Some manufacturers have even begun to integrate their transportation and order management systems, giving transportation optimization an up-front role in supply chain dynamics.

Whether approached on a strategic level or shorter-term tactical and operational levels, transportation management, using new technology, is trimming time and cost. And time, according to most experts, is one of the most precious commodities in today's supply chains. Shortened product life cycles necessitate time-based competition throughout the supply chains (Michel 1997).

For some time now, optimization techniques have been used to solve for least-cost shipping configurations. The classic transportation problem was to solve for the best combination of routes that fulfilled all the demands, subject to all the availability and, naturally, at the least cost. With a considerable number of possible routes, the problem was too complex to solve by hand, and therefore linear programming and network algorithms provide quicker solutions to the problem.

Although times have changed, these methods are every bit as applicable today as they have ever been. While the nature of the model constraints is considerably different and more complex, optimization modeling aids in filling the supply chain more effectively. Thus, transportation vendors have been customizing their delivery systems to meet a more stringent set of customer requirements.

In our global economy, customers are demanding items having exact options, in exact quantities, of zero defect, to be delivered precisely at specific locations, on certain production lines, and at exact times. In light of this new paradigm, we are still confronted with managing transportation costs. As the marketplace demands a far more flexible delivery system, both shippers and carriers are hard pressed to balance these demands against a complicated set of constraints. Fortunately, through mathematical modeling, all the competing requirements in arriving at not only a feasible but also an efficient delivery program can be evaluated and studied.

Linear programming (LP), commonly used to solve a variety of industrial and scientific problems by arriving at an optimal solution, has been around since the 1940s. The early applications for LP that yielded the largest benefits involved creating schedules for massive capital investments such as rail, bus, and airline schedules. With ever-increasing competitive markets, however, additional requirements have been added. Linear programming still remains an effective technique to solve a variety of industrial applications problems (Lustig 1999).

Specific to transportation and logistics issues, some applications include:

1. Transportation and distribution:
   - Shipping plans: Determine optimal shipping assignments from manufacturing facilities to distribution centers or from warehouses to consumers (e.g., customer direct).
2. Site selection:
   - Facilities: Establish the optimal location of a plant or distribution center with respect to total transportation costs between various alternative locations and existing supply and demand sources.
3. Scheduling:
   - Shifts: Solve for the minimum-cost assignment of workers to shifts, subject to varying demand.
   - Vehicles: Allocate available vehicles to jobs and determine the number of trips to make, subject to vehicle size, availability, and demand constraints.
   - Routing: Solve for the optimal routing of a product through a number of sequential processes, each with its own unique capacities and characteristics.
4. Production Planning:
   - Production: Solve for minimum-cost production scheduling for an established workforce, taking into account inventory carrying and subcontracting costs.
   - Production and workforce: Solve for minimum-cost production scheduling, accounting for hiring and layoff costs as well as inventory carrying, overtime, and subcontracting costs, subject to various capacity and policy constraints.
   - Staffing: Determine the appropriate staffing levels for various categories of workers, subject to various demand and policy constraints.

4. TECHNOLOGY REQUIREMENTS

A general trend exists toward increased systems integration within the supply pipeline in order to create and provide better information faster. In turn, this has decreased standard transactional costs but has also led to a fundamental restructuring of industry practices for distributing and supporting goods and merchandise. Over the last few years, decision points, such as supplier selection, price, quantity, routing, and delivery, have required greater coordination throughout the supply chain. Hence, these critical activities have become more and more integrated systems themselves in order to govern the flow of physical goods between shipper and consumer (Lewis and Talayevsky 1997). According to Donald J. Bowersox, the John H. McConnell Professor of Business Administration at Michigan State University, ''technology serves as the primary enabler to facilitate supply-chain-wide integration while simultaneously allowing key business relationships to be conducted on an exclusive enterprise-to-enterprise basis.''

4.1. The Need for Information

As cycle times are reduced and more efficient inventory processes are embraced, transportation buyers have become more increasingly concerned with the location of a shipment in the logistics pipeline than with the shipment itself. Providing information on a shipment, including its contents, its current location, its destination, and its expected time and date of arrival, is critical in transportation planning.

This desire to have timely and accurate shipment information has transportation providers investing millions of dollars each year on high-tech bar coding, communications, and networking equipment. This desire has also made information one of the most important factors in the transportation equation.

The factors that have made shippers demand more information on their shipments reflect major shifts in business practices, new shipping patterns, and the availability of new and more affordable technology.

Advanced manufacturing research (AMR), a market-analysis company that specializes in supply chain technology, estimates that there will be a 48% compound annual growth rate for supply-chain management software until 2003. That will put annual sales of these integrated suites at nearly $19 billion. Transportation management systems, with 1998 sales of $314 million, are expected to reach $1.9 billion by 2003 (Forger 1999).

Simply stated, businesses do not operate the way they used to. Instead of stockpiling finished goods in warehouses, shippers are adopting just-in-time (JIT) and lean manufacturing strategies, which operate with little or no inventory. And this has had a significant impact on transportation management, shipment planning, and the information associated with it.

4.2. Information Exchange

In order for shippers really to improve their operations, they must be willing to share critical information, such as production, supply, and cycle time data, with their transportation providers and other supply chain partners in order to make the entire process more effective.

Sharing this type of information with suppliers allows for many new transportation and distribution alternatives, allowing carriers to reroute loads in transit, consolidate shipments for more efficient distribution, and merge shipments so they arrive to customers as a single order. In the information technology age, sophisticated shippers will know not only where to get accurate data on their shipments but also how to leverage that data to improve operations along their companies' supply chains. This information is being used by shippers and transportation suppliers in the following manner (Minahan 1997):

By shippers:

- Process orders
- Tender freight
- Shop for rate and schedule data
- Generate, transmit, and file shipping documents
- Manage inventory and multiple-point distribution
- Trace shipments
- Measure carrier performance
- Identify supply chain weaknesses
- Process and pay freight bills
- Budget and manage costs

By carriers:

- Receive freight bookings
- Construct rate quotes
- Issue bills of lading
- Track and manage equipment
- Plan routings
- Determine load sequencing
- Manage documentation
- Trace shipments in transit
- Monitor equipment utilization
- Respond quickly to failure situations
- Coordinate consolidated loads and multiple-point distribution
- Confirm pickup and delivery
- Generate performance, accounting, and other reporting
- Issue freight bills

In the context of industrial engineering, many times industrial engineers will be charged with the development, integration, and execution of the complex systems used in supporting these activities.

5. TRANSPORTATION MANAGEMENT SYSTEMS: SUPPLY CHAIN'S FINAL STAGE

The real potential of transportation management systems (TMS), beyond operational efficiencies, is the substantial cost savings that it is capable of generating for shippers. Recognizing the enormous logistics costs that are transportation related, transportation management is as complex and difficult as any other problem associated with an organization's business environment.

Transportation management, an integral part of a firm's logistics strategy, involves purchasing, monitoring, and controlling freight transportation services (Temple, Barker, and Sloane 1982). Considering that, on average, 3.5% of a manufacturer's sales costs and 40–60% of total logistics costs are devoted to the movement of products, transportation management is essential in today's business environment. Therefore, incorporating TMS into a supply chain management strategy is also essential

(Weil 1998). The potential savings from identifying, for example, shipment inefficiencies, excess labor, and other unnecessary costs on a regular basis can be substantial.

The identification of cost-savings opportunities occurs primarily because the system automates the shipping and carrier selection process. In addition, TMS functionality includes load planning, rating, pickup scheduling, shipment consolidation, freight payment, and claims management. With this type of real-time information available, TMS introduces flexibility into a company, allowing the shipping department to make last-minute, but accurate, decisions as priorities and carrier costs shift (Forger 1999).

Standard software packages (see Table 1) are available that directly reduce operating costs by optimizing shipment plans, including freight consolidation, mode/carrier selection, and dedicated fleet routing and scheduling. Other benefits include improved service due to more accurate and timely shipments and the automation of manual processes. The best transportation management software, however, has strong strategic and tactical planning modules, which allow extensive ''what-if'' capabilities to optimize the design of a transportation network. They also aid the planner in the determination of fleet size, the design of fixed/master routes, consolidation strategies, optimal shipment size/frequency, and territory design.

5.1. Pickup, Delivery, and Routing

A primary transportation management concern is the determination of how to utilize a given fleet of vehicles efficiently. To minimize total cost, whether small-parcel, less-than-truckload (LTL), ship-

Source: Tausz 1999.

ments that are typically too large for the package companies and too small for truckload (TL), or carriers that transport trailers direct from origin destination, determining the pickup and delivery sequence of shipments assigned to each vehicle is subject to a variety of constraints (e.g. vehicle capacity and pick-up/delivery times).

This problem can be modeled as a vehicle routing problem (VRP) with numerous side constraints. Recognizing that the VRP is notoriously hard, the size and scope of the real-world data sets can make it impractical to just formulate the problem as an integer program (IP) and use an advanced IP solver to get an optimal solution. Therefore, practitioners usually seek solution techniques that yield acceptable solutions within a reasonable time frame (see Chapter 30). Some of these techniques include:

- Route-building heuristics select arcs greedily in a sequential manner until a feasible solution has been formulated.
- Route-improvement heuristics start with a feasible solution and seek a minor change that reduces cost while maintaining feasibility.
- Mathematical programming-based heuristics solve to optimality some mathematical programming approximation of the problem using several techniques (e.g., Lagrangian relaxation algorithm and column generation).
- Artificial intelligence/self-adaptive methods start with initial feasible solutions, then repeatedly make a local change to the current solution (such as swapping shipments between vehicles). In turn, each new solution is accepted if it satisfies certain criteria. Whereas traditional local improvement methods accept a local change if it strictly decreases the cost and stop when such a change does not exist, taboo search and annealing, for example, allow the selection of nonimproving solutions under certain conditions.

Regardless of the chosen technique, it is important to understand the business rules concerning fleet and vehicle utilization. Therefore, observing current procedures and obtaining real data early in the development process will allow the business rules to be incorporated directly into the model as constraints or applied in a preprocessing step to drastically reduce the problem size. This will make the problem more manageable and help ensure that the plans the transportation management software generates can be implemented in practice (Ergun 1998).

5.2. Case Study: Electronics Industry

An electronics manufacturer had 400 transportation providers within its United States distribution network. Only 42 carriers delivered 98% of the volume. Of this select group, United Parcel Service was the primary carrier handling outbound ground movements, inbound shipments, and less-than-truckload freight to their customers or from suppliers. Due to either the physical product or package constraints, there were few exceptions that prevented them from having a minimum number of carriers within their distribution network. That network consisted of two plants (Syracuse, NY, and Salt Lake City, UT) and four distribution centers (Atlanta, GA, Chicago, IL, Dallas, TX, and San José, CA).

Since transportation represented more than 40% of the company's total logistics expenditures, they began to aggressively pursue opportunities to create additional value through their service providers.

Their primary goal, from a logistics perspective, was to maintain or expand delivery coverage while the number of distribution centers would be potentially reduced to zero. Ultimately, all customers would be served from only the two plants, Syracuse and Salt Lake City, within two days. The offer of a two-day delivery for all products to all customers would be a first within their industry and would give them a tremendous competitive advantage by freeing up cash and generating sales.

Serving customers within two days, however, required an entirely new operating plan for both UPS and the electronics firm. Based upon 18 months of historical distribution data (e.g., traffic lanes, product distribution by customer, mode usage, etc.), various cost scenarios were determined by specific transportation provider, origin, destination, ZIP codes, weight, number of packages, and so on. Every element related to transportation that could be measured was analyzed and associated with a specific product and product group. From this, a plan was developed that met the objectives to lower inventory, reduce overall logistics costs, and improve customer service levels.

The preliminary analysis indicated that a reengineered network and operation, customized to the customer's specific characteristics and requirements, could function with two sites that could deliver 35.5% of the shipments the next day, followed by 63.6% and 0.9% by the second and third day, respectively.

To implement the second-day coverage, the planning team developed a master operating plan divided into phases over a few years. Within each phase were various scenarios that addressed package characteristics, overall volume, pull times, hub sorts, and so on. For example, the plan called for direct loads to be built for final destination hubs, bypassing intermediate hubs, reducing handling and processing time. This reduced costs and increased the geographic coverage. As additional volume

entered the system, more direct loads were made. The plan was highly customized with the manufacturer's and the carrier's requirements, which incorporated shipment origin data, destination ZIP codes, volume adjustments, trailer departure times, linehaul transit times, and hub sort start and stop times.

Their annual logistics costs, with an average inventory of $500 million, was $186 million at the beginning of the project. This was composed of:

- $38 million in transportation
- Inventory carrying costs (including cost of capital, depreciation, obsolescence, damage and shrinkage) at 25% the value of the inventory or $130 million
- Fixed distribution expenses added another $18 million

As mentioned before, management wanted to decrease total logistics costs by reducing warehouses. A consolidated network would reduce inventory levels and other associated costs. Transportation costs could increase since it was estimated that there would be a trade-off in this case between less critical next-day air shipments and stock transfer shipments but more direct and smaller customer shipments.

Although logistics problems such as this one are complex because there are so many possible combinations of the underlying variables, a good solution was found. With two-day service recognized as the only acceptable service level, the key criterion was known. Incorporating the parameter to ship using mostly ground transportation established the overall cost objective. Utilizing optimization-based software to determine the best routing within the UPS ground network identified the necessary geographic coverage. Anything beyond two-day ground capability was supplemented with two-day air shipping (meeting the criterion of eliminating next-day air shipments).

The project was successfully implemented and has achieved the original goals. The reduction of warehouses and the associated inventory resulted in significant savings. With reliable transportation services established throughout the redesigned distribution network, inventory levels dropped to $385 million. In turn, the logistics budget was reduced by approximately 28% to $134 million:

- $32 million in transportation
- Inventory carrying costs (including cost of capital, depreciation, obsolescence, damage, and shrinkage) at 25% the value of the inventory, or $96 million
- Fixed distribution expenses adding another $6 million

The keys to successful implementation of this type of project include:

- *The approach to implementation:* Use a team-based concept for all project implementations, from inception to completion. To accomplish this, immediately identify the most qualified individual to be the project manager and begin formulating the project-implementation schedule itself. The schedule, which will be a mutually agreed-upon timeline, will incorporate the strategies of all parties.
- *The implementation team:* Experienced managers who represent critical areas that will be impacted by any potential changes. For example, industrial engineering, logistics planning, information technology, and finance are all essential functions to be represented in a cross-functional team.
- *Milestones:* Establish significant tasks that must be accomplished and acknowledged by the team before proceeding with other critical assignments. Validation of data and requirements or system testing or training of management and staff, for example, are important steps as the project proceeds. In addition, discussing and validating the original project charter is also critical in order to stay on the intended course.
- *Critical dependencies:* Since each party recognizes that the project must adhere to an aggressive timeline, all critical points must be responded to quickly. To complete the implementation process on time, both parties must reach consensus and respond as soon as possible.
- *Contingency planning:* Although there is an established implementation timeline, adhering to it is challenging. There is always the probability that an issue or a variety of circumstances can delay or jeopardize the final implementation date. Therefore, if changes occur that can potentially affect the optimum design plan, for example, dates should be extended past the date originally set forth in the beginning of the project.

5.3. The Traveling Salesman Problem

The traveling salesman problem (TSP) (Lawler et al. 1985), the classic problem in which a mythical traveler must find a minimum-length cycle through a set of nodes in a completely connected graph,

has an important place in computational complexity theory. But more significant for the transportation and logistics industry is that it has an important place in a continuously expanding field of operations research: vehicle routing.

As an illustration of a TSP application, suppose that a traveler starting from Chicago must visit several U.S. cities exactly once and return to Chicago. A solution to this problem is shown in Figure 1.

A computer scientist would call the TSP a ''hard'' problem because of the long computer times needed to solve large TSPs optimally. Yet transportation dispatchers, faced with the real problem of routing large fleets, would find that their problems include factors that the TSP does not account for, including:

- *Route capacities and times:* Each cycle is constrained by the available space in a vehicle, which might be measured by cubic volume, weight, number of pieces, or floor space (if items are not stackable). The cycle is also constrained by the time in a driver's day, which itself depends on safety regulations, company work rules, and whether the driver has already handled other loads.
- *Time windows:* To remain competitive, companies are much more responsive to their customers' needs and deliver shipments exactly when customers want them. These requirements are stated as time windows, either as rigid lower and upper bounds or as soft time windows, which can be violated with penalty.
- *Dynamic routing:* Planning out the stops in advance is not always possible. Often all stops aren't known until the vehicles are in the field, partway into their routes, forcing them to double back or circulate to finish their tour. In addition, travel times and costs are time dependent because vehicles confront the commuter rush hours on the road, as well as at the loading and receiving docks.
- *Randomness:* Finally, nothing is certain. A shipment that is supposed to have 10 pieces turns out to have 25, and immediately there's not enough space to finish the route. Or perhaps a driver is detained with paperwork and doesn't have time to visit the rest of the stops or get back to the airport gateway in order to connect with the next flight out.

Thankfully, industrial engineers and software developers are aware of these real constraints, which are handled by various extensions of the TSP (Ball et al. 1995; Golden and Assad 1988). For example, route capacities and times are considered by the vehicle routing problem (VRP), while time window constraints are included in the TSP with time windows (TSPTW) and the VRP with time windows (VRPTW). Advances in telecommunications make it now possible to implement models that take into account the dynamic aspects of vehicle routing, while time-dependent vehicle routing problems take into account time-dependent travel times and costs. The stochastic aspects of cost, time, demand

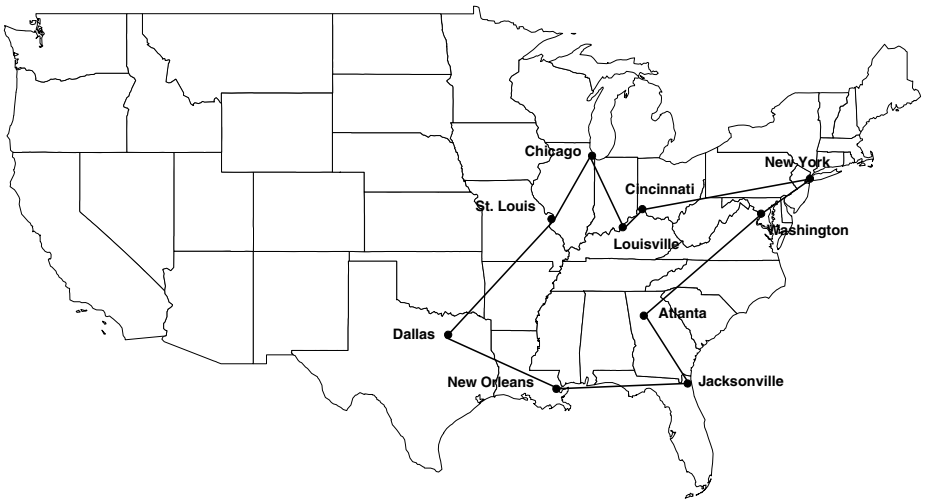

Figure 1 A TSP Tour through 10 U.S. Cities.

size, and even the presence or not of a customer are considered in the stochastic versions of the problems.

Since these problems are very difficult to solve optimally, TMS packages employ a blend of heuristic and optimization algorithms to assist dispatchers in routing their vehicles. In addition to creating more efficient routes, meaning fewer miles, fewer labor hours, and fewer vehicles, not to mention getting stops served on time, today's transportation management software is being integrated into the overall supply chain process to manage the movement of goods from source to destination, tracking the productivity and quality of drivers and generating information for planning purposes, all in a paperless environment.

5.4. The Vehicle Routing Problem

The vehicle routing problem (VRP) (Christofides 1985) is a capacitated version of the TSP. A fleet of vehicles is available at one or more terminals to serve a set of defined stops. A shipment size is associated with each stop, and a cost is associated with the movement between each pair of stops (and between a stop and a terminal). The goal is to deliver the shipments to all the stops at minimum total cost in a set of cycles without violating vehicle capacity. The VRP formulation matches well local pickup and delivery problems where the pickup stops are known before the vehicle starts on the route.

Solving the VRP or its variants may necessitate actually solving additional problems. First, the input to the problem needs to be obtained, such as the distances, travel times, or costs between each pair of stops. This can be achieved either by approximate calculations or by using geographic information systems (GIS). Using approximation, the coordinates of each stop are determined and the distances in a straight line are computed. Since a vehicle cannot drive straight from point to point, the distances must be adjusted upward by about 15% to approximate actual road mileage.

When GIS is used, distances between stops are derived from shortest path algorithms applied to very large networks rather than by simple algebraic calculations. GIS distances are more exact than approximations (especially when stops are separated by bodies of water or mountains), but they are not without flaws. Errors in the input data can occur, and sometimes only an experienced truck driver knows that a fast car route is impossible for a semi-tractor negotiating sharp turns. Nevertheless, GIS are an invaluable source of point-to-point distance and time data, particularly for shorter-length trips, where accuracy becomes even more important. GIS is fast enough to be practical, but GIS data are much more expensive to acquire than by using simple approximations.

From the distances between each pair of stops, travel times are computed assuming specific speeds. Costs are computed assuming vehicle and driver costs particular to each application.

Solving the VRP determines which vehicle serves which stops and in what sequence. There are different solution methodologies for solving the VRP, either optimally or heuristically. Since optimal algorithms can solve only small problems, emphasis is given to heuristics algorithms that aim at finding near-optimal solutions.

Some algorithms assign stops to vehicles and determine the stop sequence concurrently. Other algorithms use the so-called cluster first, route second approach, which consists of the following two steps. First a service area is partitioned into smaller regions, where each region represents a feasible collection of stops for a single route. These regions can overlap, especially when time windows are involved or when requests for pickups arrive dynamically throughout the day. Determining the sequence of stops in a single region amounts to solving a TSP (or a TSPTW, if time windows need also to be satisfied).

If the same 10 cities were considered as in the TSP example but a capacity constraint was added that necessitated the use of three vehicles, the VRP solution could look as in Figure 2.

While the previous description represents a generic implementation, specific vehicle routing applications may have their own individual characteristics, requiring that transportation management and shipment planning software be customized to reflect the operating environment, customer needs, and the characteristics of the transportation mode (Hall and Partyka 1997).

Chapter 30 presents a detailed overview of the VRP and its applications in transportation.

5.5. Other Vehicle Routing Problems

The VRP matches quite well local pickup and delivery routing in the trucking industry. Long-distance truck routing, however, is much more focused on crew-assignment issues, along with balancing interregional freight flows. The problem is much more closely related to transshipment problems than to the VRP, where the objective is to balance the flow of equipment and drivers in and out of terminals while minimizing empty mileage. This must be solved within the context of routes that can take up to several days to complete, requiring driver or equipment exchanges or possibly sleeper/driver teams that operate almost continuously.

Vehicle routing can be divided into three primary categories: service vehicles, passenger vehicles, and freight vehicles. Service vehicles usually do not move things or people from place to place

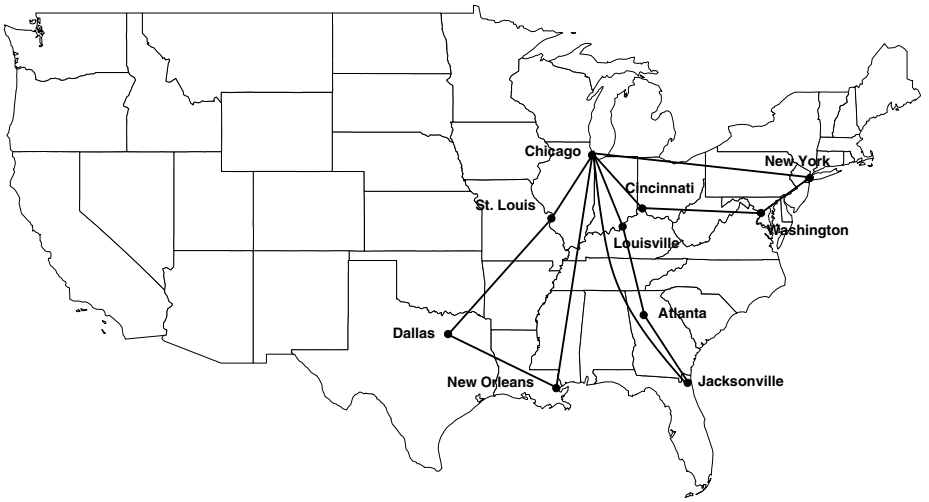

Figure 2 A VRP Solution Using Three Vehicles.

(snow-salting vehicles are an exemption to this) but are used to support jobs in the field (e.g., vans for the copier repair technician or trucks fixing potholes). When service routes are not constrained by shipment sizes and vehicle capacity, the route lengths are constrained only by the time in the driver's day or shift. Local pickup and delivery in the package transportation industry is also dominated by the duration of driver shifts rather than capacities, while time windows are of primary importance to this industry.

In contrast to service vehicles, passenger fleets or carriers carry something from one place to another. Buses and vans, for example, carry people, so the lengths of their routes are constrained by the number of seats, or possibly by a combination of standing and sitting room. Freight vehicles, including ships, trucks, rail, and air, are also capacity limited. When a shipment or passenger is carried from one place to another, it may be transported through a logistics network of terminals connected by a variety of different routes. For example, the less-than-truckload (LTL) industry specializes in shipments that are typically too large for the package companies (such as United Parcel Service) and too small for truckload (TL) carriers, which transport trailers direct from origin to destination.

LTL shipments are commonly handled in at least two, and probably up to four or five, terminals. First the shipment is picked up from the origin and taken to a local end-of-line terminal. Next it may be shuttled to a regional consolidation center, where it is consolidated with shipments originating throughout the general metropolitan area or geographic region. Next the combined load is transported on a long-haul route to another consolidation center, near the final destination. From there, the reverse takes place. The shipment is shuttled to an end-of-line near the destination and finally on a delivery route to the customer's destination.

Each segment of the LTL shipment's journey demands a different kind of route and has a different routing challenge associated with it. Local pickup is a dynamic problem that requires flexibility to serve shipments as they are called in. Shuttle routing necessitates careful driver scheduling to ensure that workshifts are fully utilized. Linehaul routing requires balancing interregional flows to minimize empty equipment miles and reduce driver and fleet downtime. In the end, only the final segment of the trip—the delivery route—closely matches the VRP formulation, while the rest of the problems are solved by a variety of network design and crew-scheduling problems that often need to be customized.

6. SHIPMENT PLANNING

Shipment planning starts with the receipt of orders in the planning system. Transportation management actually begins far in advance of individual shipments. It starts with the configuration of a transportation network.

Recognizing that transportation management is a multidimensional discipline, one must look horizontally at all domains of control that comprise the supply chain and vertically at strategic

planning, tactical planning, and execution. This establishes the business model for a supply chain, including all the physical locations, constraints, and processes. With strategic development modeling tools, a manufacturer can provide a better shipment forecast, by transportation lane, for carriers. With a more accurate model, collaboration between manufacturers and carriers will improve, leading to forecasting tighter carrier commitments and even the planning of sales and promotions around low-cost transportation lanes.

Transportation management systems are able to balance carrier rate, mode, and shipment consolidation variables because they contain carrier rate and equipment data and feature planning algorithms that suggest the fastest or lowest-cost options. Although the planning capabilities of software programs may vary, one of the most basic capabilities is consolidation of small orders into larger shipments. Effective consolidation planning means that multiple orders can be combined to form a full-truckload (TL) shipment rather than having orders go out individually as more costly, less-than-truckload (LTL) shipments.

More advanced shipment planning options in TMS include continuous moves—routing options that seek to keep trucks loaded on all transit legs—as well as sequential loading of shipments to shorten transit times and minimize handling.

Another shipment-planning option built into some transportation management systems is pooling. In pooling, small orders for multiple destinations are combined together and delivered in a full truckload to a cross-docking or distribution facility within the same geographical area as the orders' final destinations. At the pooling point, the freight is separated into small shipments or individual packages and routed to their individual destinations. Other desirable planning features within a TMS and shipment-planning program include the ability to meet short delivery windows, avoiding traffic gridlock at shipment destinations, and restocking options in which replenishment of a shipper's warehouse can ride for free when consolidated with customer orders.

Ultimately, the goal is to understand the trade-off between cost and customer service. Transportation management software strikes a balance between what customers want and what the carriers can deliver (Michel 1997).

6.1. Tactical and Operational Considerations

Transportation management systems can be categorized into three fundamental types:

1. Network planning and modeling applications
2. Transportation resources planning and management (TRPM) applications, which perform tactical planning
3. Transportation administration and management systems, which are operational execution applications

Typical TRPM systems perform some of the same operational tasks as transportation administration and management systems but have the ability to plan and execute enterprise-wide plans rather than single business unit plans. Such systems, therefore, must consider inbound, outbound, and replenishment demands throughout a global supply chain network.

For instance, one inbound and outbound optimization planning software package has the ability to manage shipments from multiple origins to multiple destinations and builds and consolidates loads as orders are imported into the system, using a library of transportation algorithms. Combined with a costing module, it rates, ranks, and selects carriers based on customer needs.

After the system selects the best transportation mode, it determines the best travel path, which loads to deliver first, and which orders should go on the trucks first—an important consideration since customers do not want to hold inventory, making scheduling much more significant due to the pressure to meet on-time delivery (Dilger 1998).

Roadnet Technologies, a leading provider of routing, loading, and planning and dispatch software for the transportation industry, has helped users streamline their supply chains by optimizing their transportation operations with Roadnet 5000 and Territory Planner. (See the Roadnet Technologies website, www.roadnet.com.)

Territory Planner strategically plans delivery and route sales territories. This analytical tool can streamline a company's operation and suggest routes that are in line with the way a shipper does business. Similar tools save reroute time, reduce transportation costs, and improve customer service. Similarly, Roadnet 5000 routes and schedules delivery vehicles by considering the parameters of a company's operation. The consolidated routes that are created provide a competitive advantage by improving driver performance and information management.

Ideally, the optimal TMS will permit transportation and logistics personnel to configure the parameters or rules for processing shipments in relation to the firm's entire customer base (e.g., optimal parcel carriers for each region of the country, discounts applicable to each carrier and region of the country, and carriers available for expedited service, including next-day and two-day delivery). Sub-

sequently, the TMS manages the dynamic characteristics and unique variables of each customer order (e.g., final destination, shipment weight, and delivery date requirements) to make an intelligent rating decision within seconds. In turn, the system alleviates manual ship-rate shopping and guarantees that the shipper is using the least-cost carrier defined within the dynamic parameters of the order.

6.2. The Total Shipping Solution

If shippers incorporate TMS as part of their total supply chain execution solution, they will be able to achieve a strategic advantage and improve supply chain performance. Properly integrated, transportation management software, which can cost between $300,000 and $1 million (Cooke 1998), can enhance numerous areas within the supply chain. Some common areas for improvement include (Weil 1998):

- Order entry/customer service:
  - Real-time rating and routing information with customers on the phone
  - Real-time tracing and tracking of the shipment, including details and value of individual packages
  - Guarantees on customer carrier preference
  - Guarantees that the customer's delivery date will be complied with while still providing a cost-effective order of shipping
- Purchasing:
  - Inbound freight expense and shipment delivery analysis, including back-hauling capabilities or preferred carrier delivery service
- Invoicing:
  - Transportation charge line items automatically added to invoices
  - Ability to configure, maintain, and invoice customer program costs
- Shipping:
  - Increased parcel processing throughput and accuracy via bar code data and scanning to capture package details, package weight, and package tracking numbers
  - Automate carrier and shipment documentation generation, including bills of lading with preassigned carrier freight bill numbers, unique customer reference numbers, shipment labels complete with carrier tracking numbers, retail vendor-compliant data, international documentation, and EDI advanced shipping notice (ASN) bar codes.
- Accounts payable:
  - Automation of freight payment and matching processes
  - Introduction of self-invoicing practices that place claim maintenance in the hands of the carrier, not the shipper.

6.3. Case Study: Manufacturer of Medical Instruments

While many shippers have talked about making changes in their shipping and distribution practices for years, the supply chain service division within a medical instruments organization acted on its beliefs and made changes. In 1998, the company decided to review how small shipments were processed within their distribution centers. Everything had to be considered, from order picking to paying the freight bill. Adding value, taking the cost out of the supply chain, and the desire to improve their logistics network mandated an audit of their entire logistics system.

Their existing routing guidelines and system indicated that small shipments, primarily small parcel freight, were very cost effective based on current transportation rates. However, when all aspects of the shipment process (e.g., picking and packing process, label printing) were incorporated in the analysis, smaller shipments appeared to be less cost effective when compared to, for example, LTL orders. Thus, the planning team reviewed the shipping areas, compared processing times, and identified the costs of each. In addition, their primary carrier, along with the third-party warehouse provider, evaluated proposed warehouse layouts and procedural changes to streamline the shipping process.

Observations and studies were made of the distribution center's activities to quantify current practices. Any assumptions or atypical occurrences observed were evaluated on their individual merit in order not to adversely affect the study. To deliver better alternatives, accurate information was essential for the activity-based costing models utilized in the study. In addition, all exceptions had to be considered to maintain the integrity of the information being supplied to the manufacturer.

In addition, the team identified all the existing procedures inherent to processing a small parcel shipment as well as an LTL shipment. This comparison, which included all aspects of the process, from order entry to packing and transporting the merchandise, was conducted so that each mode of

transportation could be effectively evaluated on its true value. In other words, actual costs would be clearly identified and allocated to processing orders. Since the manufacturer's goal was to improve the overall process within the existing cost structure, they recognized that requesting carriers to lower their transportation prices would produce only minimal gains and not enhance their value to their customers within the market. Focus on transportation rates had been the previous and predominant belief regarding reducing overall costs. Thus, the weight break between small parcel shipments and LTL shipments had been established only to reflect that element. All costs associated with the shipping process were to be included in order to illustrate effectively the actual expenditures. In turn, the weight break for small parcel shipments would be raised from 100 to 150 pounds.

The team's success was successful because they had planned prior to redesigning the procedures within the facility. Relevant data on the products were first gathered, such as:

- Sizes and weights of the products being handled
- Anticipated throughput requirements
- Weighing requirements
- Manifest requirements
- The current and projected packaging and labeling requirements (such as compliance labeling) for the products handled
- The packaging material(s) specified by the customer
- How the products were shipped (pallet loads or loose cartons)
- The company's experience base with various packaging and unitizing methods
- The projected number of inventory turns per year
- EDI or ASN requirements
- Any special handling requirements (e.g., DOT restrictions)

The study revealed that some orders took longer and were actually more costly when processed as a LTL shipment rather than as a small parcel shipment. The primary difference was the consolidation of the cases to a master identification number and application of the shipping labels. While a small parcel shipment underwent a similar procedure, the existing shipping system streamlined several of the steps that were otherwise manually entered for a LTL shipment. Completing the bill of lading, pick/pack time within the warehouse, stretch wrapping, and moving the pallets also contributed to additional time for the LTL order. Additional costs were also realized with the expenditures for pallets, stretch wrap, shipping documents, and administrative costs related to freight payment.

From this base, the planning team considered alternatives that ranged from simple procedural changes that could be implemented immediately to extensive automated sortation designs that required time and capital. With many considerations, the team recognized that the order-selection process was the most labor-intensive activity performed in the customer's warehouse. As a result, it offered the greatest opportunity for improvement. The team identified and implemented several ideas to reduce the order-picking costs:

- Separating broken-case picking from full-case picking to eliminate the need for the selector to change materials-handling equipment.
- Clearly marking the pick-slot numbers in one place eliminated confusion and reduced errors.
- Sequenced slot numbers in a logical pick path reduced travel distance and time.
- Translating quantities ordered into pick quantities on the pick document to eliminate errors from miscalculations (e.g., if the product is packaged in cartons of 12 units, the pick sheet needs to indicate to select 10 cartons, not 120 units).
- Establishing selectors, where appropriate, to pick with labels rather than from a picking sheet. For example, a selector using labels attaches them to each carton picked for an order. The labels indicate one of four in an order, so the selector knows an order is complete when the labels are gone.

The manufacturer quickly benefited from this basic process change and was now well positioned to explore more elegant alternatives to meet future business needs.

This medical instruments company has enjoyed reductions in both the costs of processing and transporting shipments. With all elements assessed, a better conclusion could be drawn in order for the shipment planning process not to affect the outbound shipments adversely. If the manufacturer's original conclusions have been acted upon, the weight break level between small parcel shipments and LTL shipments would have been lowered even further. With a detailed analysis performed, a

new, higher weight break was established. In conjunction with the existing transportation rates, the average cost per shipment was lowered.

7. LOCATION PROBLEMS

The transportation models discussed in this chapter assume that the location of the facilities involved is given. Obviously, the location of various facilities plays an important role in the total transportation costs incurred. The location of factories, warehouses, and distribution centers plays a major role in the quality of service and competitiveness of a manufacturer, while transfer terminals and depot facilities greatly influence the cost structure and effectiveness of a transportation company.

It is to be expected, therefore, that an extensive body of work exists dealing with optimization models that are used to find optimal facility locations (Daskin 1995; Mirchandani and Francis 1990). These optimization models try to provide answers concerning:

- The number and size of facilities
- Where the facilities should be located
- How demand for the facilities is allocated among them to minimize the cost or maximize the profit of satisfying the demand for a commodity

The problems usually involve fixed costs for locating the facilities and distribution costs for transporting the commodities between facilities and customers that are distance related.

A large class of facility location models assumes that facilities can be located on a network composed of nodes and links. Travel can occur only on the links of this network. This is to be contrasted with planar models, which can locate facilities anywhere on the plane. Often, facilities are characterized by capacities (e.g., warehouses) or throughput (e.g., transfer terminals). We present next a qualitative overview of some useful network location models, drawing primarily from Daskin (1995).

- *Set-covering problems:* The set covering problem finds a set of facilities of minimum cost from a finite set of candidate facilities (each with a given cost) so that every demand node is covered. A node is considered covered if at least one facility is located within a given distance of the node. The set-covering problem does not account for possible congestion in the facilities since it does not consider the number of demand nodes that are served by each facility or the size of the demand of each node.
- *Center problems:* The vertex *P*-center problem finds the locations of *P* facilities on the nodes of a network that minimize the maximum distance between a demand node and the nearest facility to the node. A better solution can be obtained if facilities are allowed to also be located on the links of the network, resulting in the absolute *P*-center problem. Center problems are appropriate for locating emergency services like fire fighting, emergency medical vehicles, etc.
- *Median problems:* The *P*-median problem finds the location of *P* facilities on a network that minimize total cost, where the cost of serving demands at a node is represented by the product of the demand at the node and the distance between the node and the nearest facility. It can be shown that at least one optimal solution of the *P*-median problem locates facilities only on the demand nodes of the network. Median problems are appropriate for locating nonemergency services like transportation terminals, post offices, etc.
- *Facility-location problems:* The uncapacitated facility-location problem finds the location of facilities (that have no capacity limitations) so that the total cost of locating the facilities and the operating costs of transporting a commodity between the facilities and clients are minimized. When each candidate facility has a capacity indicating the maximum demand that it can supply, the problem becomes the capacitated facility-location problem. The model is used to locate plants, warehouses, transportation terminals, etc. and is most appropriate for the private-sector type of problem, where both the costs of locating the facilities and the operating costs are borne by the same organization and can be made comparable.
- *Location/routing problems:* The facility-location problems described previously assume that each customer is served on an individual route from the facilities being located. This is sometimes inappropriate, especially for the transportation industry. Location/routing problems refer to problems that involve locating a number of facilities from a candidate set of facilities and establishing delivery routes so that the combined total cost is minimized. The decisions involved in such a problem may include: (1) determining the number and location of the facilities, (2) allocating customers to facilities, (3) assigning customers to routes, and (4) determining the sequence of serving the customers on each route. Location/routing problems are extremely difficult to solve. Problems need to be modeled as location/routing problems only if the stra-

tegic, long-term decision of locating facilities has to be made jointly with the tactical, short-term vehicle routing decisions. Otherwise, the problem can be broken into two separate problems, a location problem and a routing problem.

The problems presented above can be extended further when the facilities are not all similar but are organized hierarchically, resulting in hierarchical facility-location problems. Similarly, when multiple, and sometimes conflicting, objectives are present, multiobjective facility-location problems are obtained. Finally, many models exist that deal with the location of undesirable facilities (e.g., hazardous waste dumps) where instead of wanting to minimize, we want to maximize some measure of the distance between the demand nodes (e.g., population centers) and the facilities.

8. SUMMARY

Transportation management system software is finally getting the attention and recognition it deserves from logistics professionals. Software that aids shipment tendering and carrier selection has become an essential front-line tool in the battle to cut supply chain costs and bolster efficiency. More manufacturers now view TMS as a strategic extension of their enterprise resource planning (ERP) system and no longer delegate it to second-tier status.

The transportation component used to be seen as the stepsister of information technology systems. Only recently, the action was focused on warehouse management systems (WMS) to reduce inventories. Now it is transportation that is getting attention from manufacturers as the last corporate savings frontier.

Since becoming more sophisticated in the past few years because of real-time optimization capabilities (determining the best tender, given pricing and volume discounts, delivery schedules, and consignee), TMS packages will continue to be connected to a company's other business systems.

Interfacing transportation applications with an organization's other business enterprise systems has typically had a quick payback for most organizations. With annual logistics savings of 3–12% in usually less than one year, effectively implementing a TMS (Tausz 1999) for $300,000 and $1 million, as mentioned earlier, is a very economical decision.

Advances in operations research techniques and computing power have revolutionized transportation and shipment planning. Gone are the days of dividing the country into separate regions and assigning a freight planner to each one to find manually the best driver-to-load pairing within the region. Now many carriers are relying on global optimization systems that generate the best possible system-wide matching between drivers and loads, introducing new options to planners that were almost impossible to find using the traditional methods.

As supply chains and logistics cycles become more complex and diverse, transportation and distribution planners are forced to consider multiple points of origin and destination throughout the world. Reduced product life cycles stimulate time-based competition, and customers require better delivery service and inventory-reduction plans. In turn, managers are looking to optimize their transportation and logistics network. Thus, they will continue to define and deploy solutions aimed at finding the most economical means of transporting both inbound and outbound product via shipment and load planning, freight management, consolidation or pooling processing, accounting and analysis, and mileage and location tracking.

CHAPTER 80

Restructuring a Warehouse Network: Strategies and Models

HOKEY MIN
University of Louisville

EMANUEL MELACHRINOUDIS
Northeastern University

1. BACKGROUND

With the advent of the supply chain concept and the growing popularity of electronic commerce (EC), which transcend geographic and business functional boundaries, the traditional roles of warehouses are changing. Traditionally, warehouses have played three main roles in supporting logistics systems: a storage role, which makes long production runs more economical and bridges temporal gaps between demand and supply by making products available for customers on a timely basis; a consolidation role, which reduces total transportation cost by aggregating small orders into large shipments; and a customization (postponement) role, which reduces inventory carrying cost and enhances customer services by delaying the final stage of production and distribution until customers actually demand specific types of products (see, e.g., Maltz 1998). The relative importance or focus of warehousing roles to the entire supply chain network may vary from one warehouse to another due to dynamic shifts in the firm's business environments and strategic priorities. Such shifts include changes in supplier and customer bases, distribution networks, economic outlooks, corporate mergers/acquisition, downsizing, and government legislation.

For instance, many e-businesses (dot-com ventures) are concerned with filling their customers' orders and keeping customers' deliveries up to speed. Consequently, they tend to decentralize ware-

Edited by Gavriel Salvendy

housing operations and increase the number of regional warehouses, which enhances the firms' responsiveness to their online customers. Amazon.com, for example, recently has increased the number and capacity of its warehouses from 2 to a total of 15 facilities. The decentralization of a warehouse network, however, can be costly due to the duplication of safety stocks, reduced freight consolidation opportunities and greater warehousing costs. In an effort to control cost, some companies may downsize or reengineer their corporate structures that involve the consolidation and phase-out of some existing warehouses. According to Ballou and Masters' survey (1993) of 200 logistics executives, 65% of the respondents indicated that they intended to review their current warehouse network and consider restructuring it in the near future. The strategy of consolidating and centralizing warehouses can help the firm save transportation, inventory, and warehousing cost due to economies of scale. Indeed, Ballou (1999) observes that restructuring a warehouse network could generate annual savings of 5–10% of total logistics costs. In the next section, we will elaborate on the pros and cons of different warehouse-restructuring strategies.

2. WAREHOUSE-RESTRUCTURING STRATEGIES

2.1. Warehouse-Centralization Strategy

One of the most noticeable trends in today's warehousing operations is increased inventory velocity. According to the recent study conducted by Speh (1999), the surveyed firms showed the average increase of inventory turns by 30% from 1995 to 1998 and expected to improve inventory turns by 27% between 1998 and 2000. A vast improvement in inventory turns can be attributed to increasing adaptation of more effective inventory management practices such as cross-docking, cycle counting, improved forecast, radio frequency, automated ID systems, and warehouse management systems. Due to significant strides in increasing inventory turns, many firms no longer require a large number of stocking points and consequently allow them to consolidate existing stocking points into fewer locations. In general, warehouse-centralization strategy involves consolidation of regional warehouses into a smaller number of master stocking points and the subsequent phase-out of redundant warehouses. Along with better capacity (or asset) utilization and higher throughput of centralized warehouses, such a strategy often brings substantial amount of savings in warehousing and inventory carrying costs due to the reduced number of warehouses and aggregated inventory. For instance, the square-root rule of inventory consolidation allows the company to estimate the amount of savings in inventory investment as a result of warehouse consolidation. Assuming that the firm relies on economic order quantity (EOQ) rules for inventory management and all stocking points of the firm carry the same amount of inventory, the simplest form of the square-root rule can be mathematically expressed as (Ballou 1999, pp. 352–354):

$$I_T = I_i \sqrt{n}$$

where I_T = the optimal amount of inventory to stock, if consolidated into one location in dollars, pounds, cases, or other units of measurement
I_i = the amount of inventory in each of n locations in the same units of measurement as I_T
n = the number of stocking locations before consolidation

Another benefit includes reduced material-handling costs resulted from bulk storage and picking at centralized locations. Similarly, transportation cost can be reduced due to increased opportunities of large-volume shipments and the subsequent negotiation leverage for better freight rates. In addition, central administrative costs can be reduced through less effort being spent in managing fewer warehouses. On the other hand, warehouse-centralization strategy lengthens lead time and consequently causes deterioration of customer services. With fewer warehouses to serve markets, the accessibility of centralized warehouses to large segments of customer bases and major distribution hubs is critically important. Also, to offset increased distances between centralized warehouses and customers, this strategy may necessitate the more direct shipment of products from master stocking locations to end customers.

2.2. Warehouse-Decentralization Strategy

Forrester Research, Inc. expects that business-to-consumer online sales will reach $184.5 billion in 2004 and business-to-business e-commerce will grow to $1.33 trillion by 2003 (see, e.g., Massie 2000). The explosion of e-commerce will change the way the company distributes its products due to an increasing number of small, unpredictable orders for individual customers. E-commerce requires that warehouses deal with unit quantities of inventories rather than pallet loads of inventories and subsequently accommodate high frequency of small parcel delivery services. Because the role of warehouses has become more of flow-through transshipment facilities intended for quick order fulfillment and product return than traditional storage facilities, their locations need to be dispersed in

wider geographical areas. In other words, warehouses that support e-commerce transactions are likely to be decentralized and located in proximity to each segmented market.

In general, warehouse-decentralization strategy aims to shorten customer response time and improve order-fill rates by positioning inventory locations at the lowest downstream of the supply chain (i.e., end customers). Such a strategy may make sense, particularly when online sales require direct-to-home or store delivery services on a quick-response basis. Despite its merits, the warehouse-decentralization strategy leads to increases in inventory carrying cost and warehousing cost due to a larger number of stocking locations. It can also increase transportation cost due to smaller, more frequent shipping requirements.

2.3. Profile Analysis for a Strategic Choice

To choose a warehouse-restructuring strategy properly between centralization and decentralization, the company may conduct a profile analysis. The profile analysis is intended to provide the management team with a tool to identify the supply chain needs and the degree of fit between the company's network-restructuring decision attributes (e.g., level of investment, time scales, market positioning) and the available restructuring strategy. The profile analysis is composed of four steps (Hill 1994):

1. Select the appropriate aspects of products (e.g., types of product, product range, life cycles) and markets (e.g., sales/promotional tools, delivery service requirements), logistics (e.g., volume shipment via consolidation), investment and cost (e.g., level of investment, level of inventory, shipping cost), and infrastructure (e.g., corporate culture and management styles).
2. Display the trade-offs of strategic choices (centralization vs. decentralization).
3. Develop the profiles of products and targeted market segments to see alignment between those profiles and the strategic choice.
4. Illustrate the degree of consistency between the characteristics of products/markets and the strategic choice. The straighter the profile, the more consistent the chosen strategy is with the characteristics of products/markets.

The excellent example of the profile analysis for the choice of logistics strategy can be found in the recent study conducted by Pagh and Cooper (1998).

3. MODEL DEVELOPMENT

3.1. A Case Scenario of Warehouse Network Restructuring

This section describes a case study of a firm that plans to restructure its warehouse network and reduce total logistics costs. The firm (called Beta hereafter) plans to consolidate 23 warehouses across the United States and Canada into a smaller number of warehouses, while offering a majority of its customers next-day delivery services. Considering hours-of-service regulations stipulated by the Federal Highway Administration (FHA), a majority of Beta's customers should be within 10 hours of driving time from nearest warehouses. Beta's primary mode of transportation is either less-than-truckload (LTL) or truckload (TL) carriers, and consequently compliance with such regulations is important for Beta's distribution operations. However, since Beta's restructuring plan entails the phase-out of some existing warehouses, truck delivery time to a group of isolated customers will likely increase. Therefore, the restructuring plan must smooth away transition to the centralized warehouses in such a fashion that it minimizes the total length of out-of-service dates and any potential disruption of supply chain activities during transition.

Beta has its main manufacturing plant in Terre Haute, Indiana, and currently operates 23 regional public warehouses to serve a total of 281 customers scattered around the United States and Canada (see Figure 1). Beta primarily manufactures and distributes rolls of films and related materials used for packaging such as clear wrappers on the outside of cigarette packages throughout North America. Beta's outbound distribution activities are supported by a single-echelon (or one-tier) warehouse network where all products move from a manufacturing plant through regional warehouses to end customers. To avoid any duplicated distribution efforts and redundant inventory investment with the preexisting warehouses in 14 different U.S. states and 3 Canadian provinces, Beta prefers to maintain a total of less than 15 regional warehouses. The rationale may be that some warehouse locations are within 100 miles of each other and a large number of volume customers are heavily concentrated in certain states and provinces such as Ohio, Wisconsin, Georgia, Illinois, Texas, North Carolina, New Jersey, California, and Manitoba (see Figure 2). Each state or province generates more than 1.2 million pounds of outbound shipping volume. Customers there account for more than 56.6% of the current outbound shipping volume. Seizing increasing market expansion opportunities on the West Coast and the Mexican and Canadian borders, Beta prefers to keep at least one regional warehouse for each of California, Texas, Winnipeg, and Montreal. Beta hopes that its restructuring plan can be

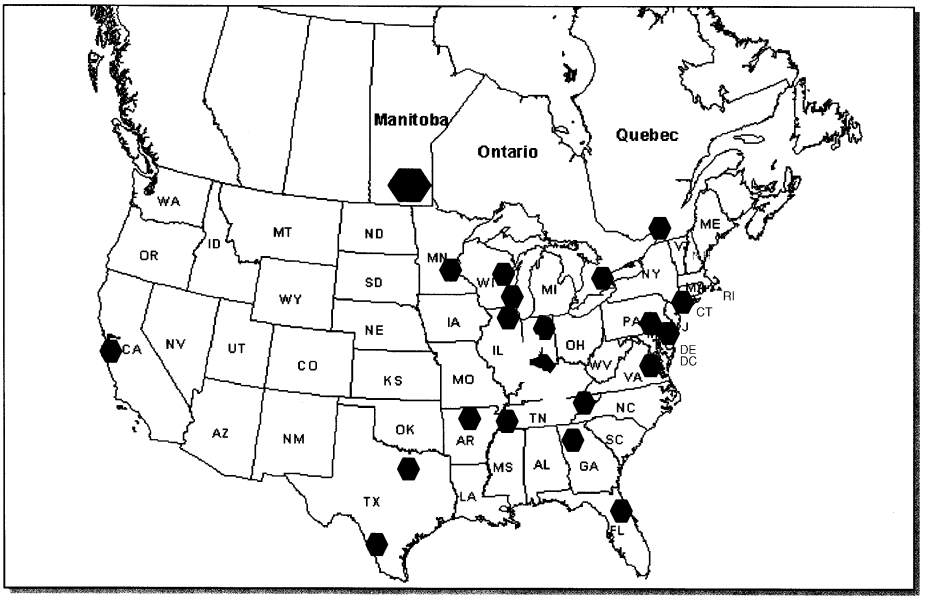

Figure 1 Existing Locations of Regional Warehouses.

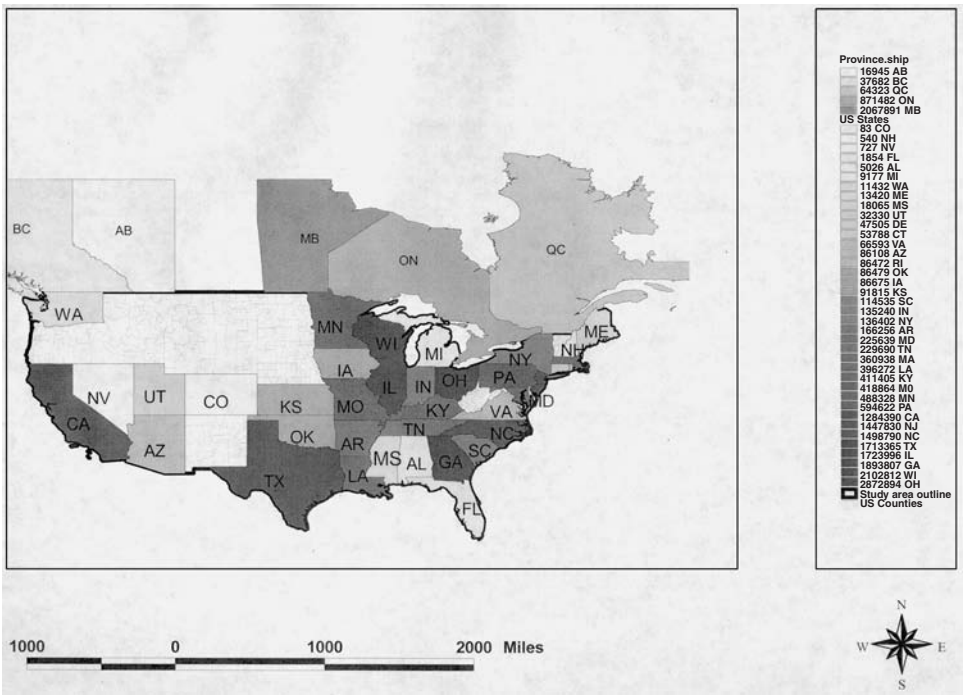

Figure 2 Customer Demand in Shipping Volume.

consistent with the corporate goals of increasing inventory turns and reducing transportation and warehousing costs.

The warehouse network-restructuring problem (WNRP) facing Beta differs from the classical warehouse-location problem in that the former is primarily concerned with determining which warehouses to retain and which warehouses to phase-out among the *existing* locations, whereas the latter is primarily concerned with selecting the optimal site among the alternatives of *new* locations. For excellent discussions of the classical warehouse-location problem, see Baumol and Wolfe (1958), Khumawala (1972), and Meidan (1978). On the other hand, the problems are similar in that both are influenced by the same attributes (or factors), such as warehouse operating cost, transportation cost, delivery access time, and proximity to major customer bases and transportation infrastructure.

In WNRP, each of Beta's consolidated facilities is expected to meet the current demand of all the existing customers and serve its customers within 10 hours of truck-driving time. Some of the existing warehouses, such as two in Terre Haute and one in Indianapolis, Indiana, that Beta considers eliminating may be redundant with their nearest warehouses due to close geographical proximity. But there is no guarantee that elimination of those sites will bring the substantial logistics cost savings without disrupting Beta's supply chain operations. For example, a regional warehouse that gives faster delivery advantages may turn out to be most costly because of its higher inventory taxes. Indeed, the local tax on inventories may vary significantly from one state to another. On the other hand, a warehouse that incurs the lowest cost and provides the best tax incentive packages may be distant from Beta's major customer bases and transportation infrastructure such as break-bulk terminals and major highways.

To deal with this dilemma, systematic decision-aid tools are needed that consider a multitude of conflicting factors affecting the restructuring plan and analyze trade-offs among them. Such decision-aid tools include various mathematical programming techniques such as integer programming (see, e.g., Bradley et al. 1977) and scoring methods such as the analytic hierarchy process (see Cohon 1978; Hwang and Masud 1979; Saaty 1980; Steuer 1986; Harker 1989; Vargas 1990 for excellent discussions of scoring methods). There are comparative advantages and disadvantages associated with the aforementioned decision-aid tools in terms of ease of use, data requirements, computational difficulty, and sensitivity analysis capability.

Considering that Beta's main objective of its restructuring plan is the maximization of a potential cost saving accrued from centralization of warehouses, we propose a single-objective, mixed-integer programming model as our decision-aid tool. The proposed model is designed to find the optimal number of warehouses in the restructured network under capacity limits and service requirements.

3.2. Model Formulation

Under the above scenario, the WNRP addresses the following issues:

1. Which warehouses to retain and which warehouses to eliminate in such a way that Beta's restructured warehouse network minimizes total cost associated with Beta's distribution operations while meeting current customers' demand and delivery service requirements
2. Which customers (or markets) to be served by which consolidated warehouses
3. How to evaluate the sensitivity of restructuring decisions with regard to changing priorities of Beta's restructuring plans

To address the above issues systematically, we develop a mixed-integer programming model that is formulated as follows.

3.2.1. Indices

k = index for manufacturing plants
i = index for warehouses
j = index for customers

3.2.2. Model Parameters

c_{ki} = cost of shipping unit product from manufacturing plant k to warehouse i
s_{ij} = cost of shipping unit product from warehouse i to customer j
v_i = variable cost of operating warehouse i
f_i = fixed cost of maintaining warehouse i
q_i = capacity of warehouse i
d_j = demand of customer j
t_{ij} = truck delivery time (in minutes) from warehouse i to customer j
τ = maximum daily hours of service regulated by FHA
$C(i) = \{j \mid t_{ij} \leq \tau\}$

$D(j) = \{i \mid t_{ij} \leq \tau\}$
M = is a large number

3.2.3. Decision Variables

x_{ij} = amount of products shipped from warehouse i to customer j
y_{ki} = amount of product supplied by plant k to warehouse i

$$z_i = \begin{cases} 1 & \text{if warehouse } i \text{ remains open} \\ 0 & \text{if warehouse } i \text{ is phased out} \end{cases}$$

3.2.4. Mathematical Formulation

$$\text{Minimize} \sum_k \sum_i c_{ki} y_{ki} + \sum_i v_i \sum_{j \in C(i)} x_{ij} + \sum_i \sum_{j \in C(i)} s_{ij} x_{ij} + \sum_i f_i x_i - \sum_i f_i (1 - z_i) \tag{1}$$

Subject to:

$$\sum_{j \in C(j)} x_{ij} \leq q_i \qquad \forall i \tag{2}$$

$$\sum_k y_{ki} = \sum_{j \in C(i)} x_{ij} \qquad \forall i \tag{3}$$

$$\sum_{i \in D(j)} x_{ij} = d_j \qquad \forall j \tag{4}$$

$$x_{ij} + y_{ki} \leq M z_i \qquad \forall k, i, j \in C(i) \tag{5}$$

$$x_{ij}, y_{ki} \geq 0 \qquad \forall k, i, j \in C(i) \tag{6}$$

$$z_i = (0, 1) \qquad \forall i \tag{7}$$

The objective function (1) minimizes total logistics costs composed of shipping costs and warehousing costs while maximizing cost savings resulted from the closure of redundant warehouses. Constraint (2) ensures that the total amount of products shipped to a group of customers does not exceed the capacity of a warehouse serving them. Constraint (3) ensures that the total amount of products supplied by all the manufacturing plants to each warehouse matches the total amount of products shipped from that warehouse to its customers. In other words, inbound shipping volume for each warehouse should be equivalent to its outbound shipping volume. Constraint (4) requires that customer demand be satisfied. Constraint (5) states that unless the warehouse remains open, it cannot serve its customers. Constraint (6) ensures the nonnegativity of decision variables x_{ij}, y_{ki}. Constraint (7) ensures the binary integrality of decision variables z_i.

3.3. Model Application

To demonstrate how the proposed WNRP model works and verify its usefulness, the model was applied to the real-world problem facing Beta. As explained earlier, the Beta management team intended to reduce the number of regional warehouses it was currently operating but had no idea of the ideal number of warehouses to retain. They considered keeping in the range of 7 to 14 warehouses. Although the smaller number of warehouses will reduce Beta's total logistics costs, Beta's management team would like to know the optimal number of warehouses sufficient accommodate current customer demand. Furthermore, Beta would like to offer consistent delivery services to geographically dispersed customers. Therefore, heavy concentration of consolidated warehouses in certain regions is not desirable for Beta's commitment to next-day delivery services. Regardless of cost-saving opportunities, Beta would like to maintain at least one regional warehouse in California and one in Canada.

Given the current warehouse network, however, we (analysts) discover that 11 customers isolated from other clusters of customers cannot be served within 10 hours of delivery time by existing locations of regional warehouses. Herein, we estimated delivery time using actual driving distance between different locations as opposed to Euclidean (straight-line) distance. Most of these isolated customers are located on the West Coast, such as Colorado, Utah, Arizona, Washington, and British Columbia. Since Beta currently has no plan either to relocate its warehouses or to open new warehouses, our task is to find the optimal number and geographic locations of consolidated warehouses that can best serve the remaining customers. In so doing, we run the model specified in Section 3.2

using LINGO's modeling language (LINGO 1995). LINGO is nonprocedural mathematical programming software that provides an environment where analysts can develop, run, and modify mathematical models interactively. Unlike other conventional software, it requires only *what* the modeler wants, rather than *how* it should find the solution (LINGO 1995). The model was run on a TD- 260 personal computer (PC). The total number of feasible warehouse–customer pairs considered by LINGO was 3625. The baseline LINGO model resulted in 23 binary integer variables, 3648 noninteger variables, and 3952 constraints. The execution time of the baseline model and the subsequent runs ranged from 50 seconds to approximately 3 minutes.

The optimal baseline solution suggests to retain consolidated warehouses in four different locations: Paterson, New Jersey; Winnipeg, Manitoba; Memphis, Tennessee; and San Leandro, California (see Figure 3). This solution makes sense in that it covers geographically dispersed areas while preventing any warehousing locations from being too close to each other. It is also congruent with the Beta's management team's wish that the restructured warehouse network include at least one Canadian and one West Coast location. However, in reality, a dramatic reduction in the number of warehouses from 23 to 4 may create confusion among Beta's common carriers, employees, and utility companies (e.g., phone companies) during transition. In addition, such an attempt will likely disrupt customer services during transition because it entails suspension of delivery services, reroutes of shipping, reorganization of load plans, and transfer of some inventory items from phased-out warehouses to consolidated warehouses.

To provide Beta's management team with greater sets of alternatives that allow them to keep the disruption risk to a minimum, we added a constraint that sets the total number of consolidated warehouses prior to running the model. This constraint is mathematically expressed as:

$$\sum_i z_i = p \tag{8}$$

where p = the desired number of consolidated warehouses. The above constraint is common in the prototypical p-median problem (see, e.g., Church 1974; Krarup and Pruzan 1983 for a detailed discussion of the p-median problem). For instance, by setting $p = 5$, we identified five locations of

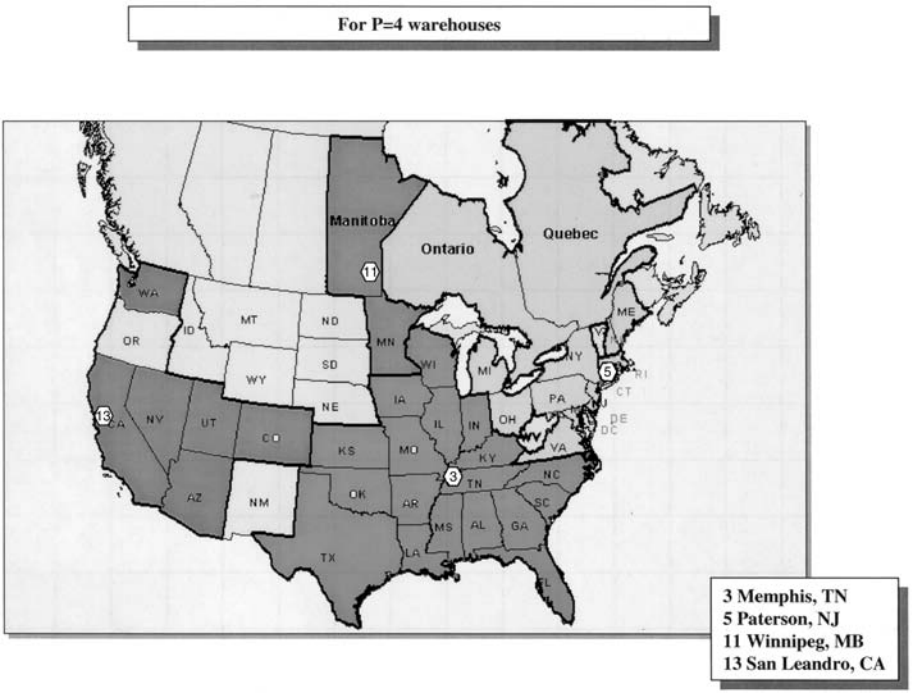

Figure 3 Locations of Consolidated Warehouses and Their Market Boundaries.

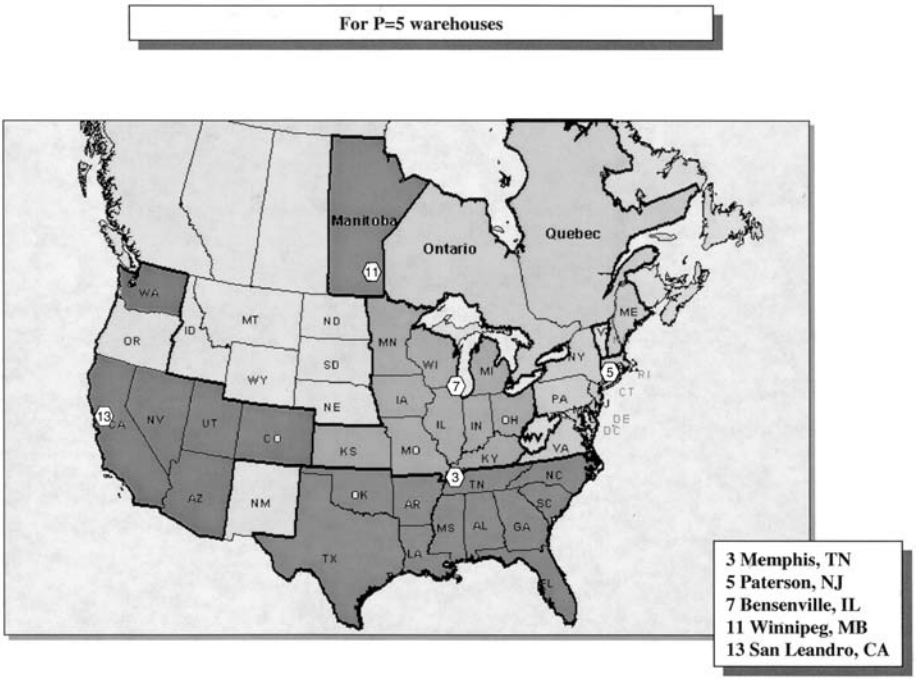

Figure 4 Locations of Consolidated Warehouses and Their Market Boundaries.

consolidated warehouses: Paterson, New Jersey; Winnipeg, Manitoba; Bensenville, Illinois; Memphis, Tennessee; and San Leandro, California (see Figure 4). When we set $p = 6$, the optimal solution suggested retaining six locations: Paterson, New Jersey; Winnipeg, Manitoba; Bensenville, Illinois; Atlanta, Georgia; Dallas, Texas; and San Leandro, California (see Figure 5). Finally, when $p = 7$ was set, we identified seven locations of consolidated warehouses: Paterson, New Jersey; Winnipeg, Manitoba; Toronto, Ontario; Bensenville, Illinois; Atlanta, Georgia; Dallas, Texas; and San Leandro, California (see Figure 6). It is interesting to note that these locations are either at the center or in the vicinity of the center of concentrated customer demand locations. As shown in Figures 3, 4, 5, and 6, among the eight states that originate customer shipping volume in excess of 1.2 million pounds, only three (Ohio, Wisconsin, and North Carolina) do not have consolidated warehouses. However, these states are still within next-day delivery areas from nearest consolidated warehouses such as the ones in Paterson, New Jersey; Atlanta, Georgia; Toronto, Ontario; and Winnipeg, Manitoba.

More interestingly, with the exception of warehouses located in Atlanta, Georgia, and Paterson, New Jersey, all the other warehouses to be retained for consolidation (i.e., Winnipeg, Manitoba; Toronto, Ontario; Bensenville, Illinois; Dallas, Texas; San Leandro, California) were substantially underutilized under the current warehouse network. According to the warehouse-utilization ratio (the number of pallets in the warehouse at the end of a year divided by the theoretical capacity of the warehouse) used by Beta, the Atlanta-based warehouse and the Paterson-based warehouse have an 11% and a 9% utilization ratio, respectively. On the other hand, those in Winnipeg, Toronto, Bensenville, Dallas, and San Leandro have 5% or less utilization ratios. Despite the sustained growth of customer demand in Texas and Mexican border areas, the Dallas-based warehouse has been virtually unused, as evidenced by a less than 1% utilization ratio. Such underutilization may have resulted from redundant warehouses located in Laredo, Texas, and Little Rock, Arkansas, which are within a 500-mile radius from Dallas. If Beta decided to reduce the number of warehouses to 7 from 23, each of the 7 consolidated warehouses would enjoy the average of an approximately 14% utilization ratio, which is a 10% increase from the current average utilization ratio of slightly over 4%.

As shown in Figure 6, the Paterson-based warehouse will serve customers located in Maine, Massachusetts, Rhode Island, New Hampshire, Connecticut, New Jersey, New York, Pennsylvania, Delaware, Maryland, and Virginia. The Winnipeg-based warehouse will serve customers located in Minnesota, Manitoba, and Alberta. The Toronto-based warehouse will serve customers located in

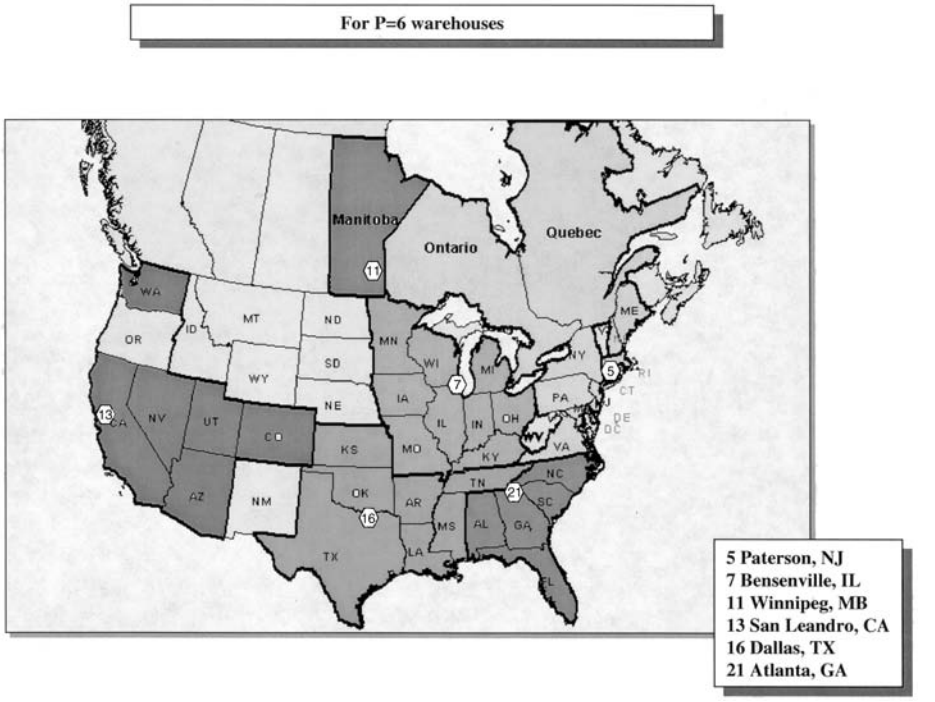

Figure 5 Locations of Consolidated Warehouses and Their Market Boundaries.

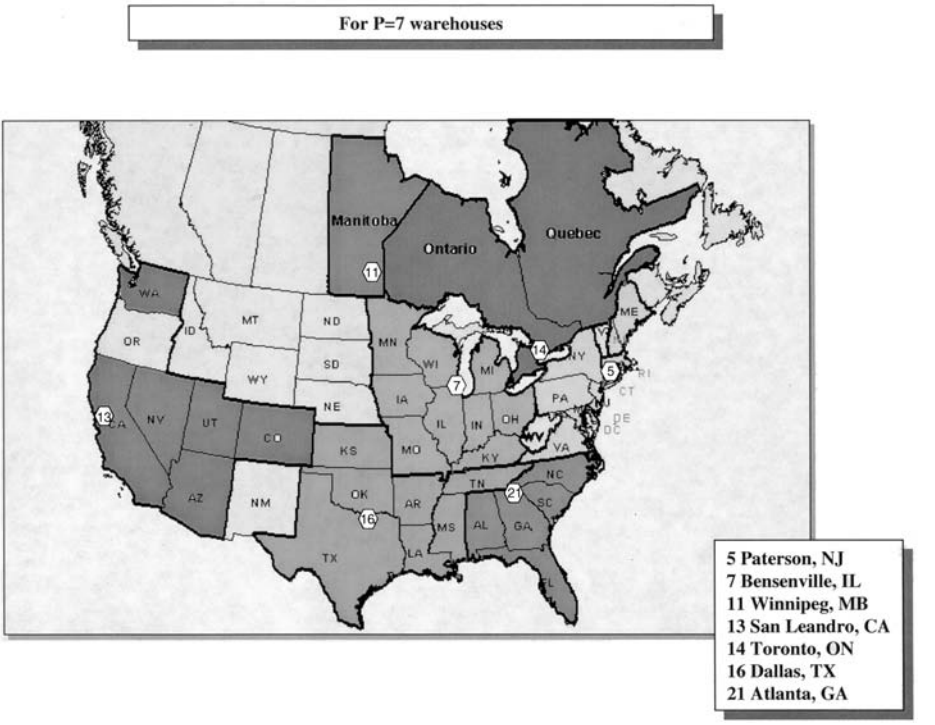

Figure 6 Locations of Consolidated Warehouses and Their Market Boundaries.

upstate New York, Ohio, Michigan, Quebec, and Ontario. The Bensenville-based warehouse will serve customers located in Kentucky, Ohio, Indiana, Michigan, Iowa, Wisconsin, Minnesota, Illinois, Missouri, and Kansas. The Atlanta-based warehouse will serve customers located in North Carolina, South Carolina, Georgia, Florida, Alabama, Tennessee, Kentucky, and Louisiana. The Dallas-based warehouse will serve customers located in Tennessee, Mississippi, Missouri, Kansas, Louisiana, Arkansas, Oklahoma, and Texas. The San Leandro-based warehouse will serve customers located in Colorado, Utah, Arizona, Nevada, California, Washington, and British Columbia. Notice that some warehouses cover overlapped states such as New York, Kentucky, Tennessee, and Louisiana due to heavy geographical concentration of customers in those states. Another thing to note is that, unlike other consolidated warehouses serving at least 30 different customers, the Winnipeg-based warehouse is allocated to serve only three customers. The possible explanation for such an aberration is that it has a huge customer in Winnipeg with its annual order volume in excess of 2 million pounds. That is to say, the Winnipeg-based warehouse is mainly dedicated to the one major customer and consequently its location is contingent upon the continuation of a business relationship with that customer.

4. DECISION SUPPORT SYSTEM FRAMEWORK

Even though the proposed model described in the previous section was designed to help Beta's management team find the minimum cost solution to the problem of determining which warehouses to retain and which warehouses to eliminate, it cannot capture all the complexities and dynamics of the WNRP facing Beta. As such, the proposed model should be embedded within the decision support system (DSS) framework, where the decision maker (e.g., Beta's management team) can freely add, delete, update, and modify the model objective functions, parameters, and constraints. Following three paradigms suggested by Sprague and Carlson (1982), this DSS framework has three components: data-management, model management, and dialogue management.

4.1. Data Management Subsystem

A model is only as good as the quality of the data that support it (Napolitano 1998). To enhance data quality and avoid data redundancy, we developed a database that contains three data sources: external, internal, and governmental. External sources include public data files available from local chambers of commerce, regional economic development agencies, *Site Selection Handbook*, *Industrial Development Magazine*, and websites such as Lycos Roadmaps. Internal sources include the Beta's order history files (e.g., sales shipment data, warehouse shipment data, ZIP code data, statistics reports), inventory record files, accounting data files, bills of lading, and internal customer policy manuals. Government sources include legal documents, regulatory guidelines, and reports issued by federal (e.g., Department of Transportation, Federal Highway Administration, Surface Transportation Board) and state agencies. In addition to raw data that can be obtained from the above sources, Beta may create more specific data categories that are relevant to WNRP. These categories are as follows.

4.1.1. Cost Data

Cost is one of the primary concerns of the WNRP decision. The total logistics costs involved in WNRP encompass annual rental fees for public warehousing, administrative expenses for general office personnel, inventory carrying cost (e.g., local inventory property taxes and insurance premiums on inventory), information-processing cost (e.g., maintenance of warehouse management systems), equipment-handling cost, cost of purchased labor, cost of unloading/loading vehicles, cost of palletizing/sorting, inbound/outbound shipping expenses, freight penalty incurred from delivery route changes, inventory transfer cost, cost of moving value-added services (e.g., packaging, labeling), out-of-service cost, and cost of changing service standards. For additional details of warehousing cost elements, see Speh (1990) and Ackerman (2000).

4.1.2. Traffic Data

Since Beta deals primarily with relatively heavy and bulky products using LTL and TL carriers, it needs to look for a warehouse location that can not only handle the large volume of traffic but can also provide easy access to transportation infrastructure and traffic-related services. Important traffic concerns include proximity to major interstate highways, any overhead construction impairing truck movement, curfew restrictions on hours of traffic operations, close distance to break-bulk terminals, and the availability of freight forwarding and brokerage services. In addition, Beta requires that the warehouse be within a one-day delivery range (approximately a 500-mile radius) of most of its major customers, including food packaging companies in the United States.

4.1.3. Market Data

The profitability of Beta depends heavily on the market potential of the area it serves. In a broad sense, the market potential of a chosen trading area is dictated by its business climate and competition

level. Since Beta's business efforts are geared toward business-to-business transactions, an explicit measure of the local business climate is not readily available. As an indirect barometer for the local business climate, however, we can consider Beta's customers' customers' (e.g., grocery shoppers) aggregated effective buying power and buying power index in the area (metropolitan city or county) that surrounds the warehouse location. Herein, effective buying power is expressed as net gross personal income (= gross personal income − personal taxes − nontax payments). Buying power index is a measure of market ability to buy, expressed as a percentage of U.S. totals. In addition, Beta's past sales volumes and forecasted future business growth in Mexican, Canadian, and West Coast markets can be taken into consideration.

Under the premise that a majority of customers would gravitate toward the Beta's warehouse closest to their market centers, we used proximity to existing customers as part of a surrogate measure of Beta's competitive position in the trading area. Finally, since short inbound delivery to the warehouse can reduce order cycle time for the entire supply chain and subsequently help serve customers better, proximity to Beta's suppliers' locations can be considered as an indicator of Beta's competitiveness in the trading area. Given that the amount of rates (e.g., class rates) for the transportation of freight increases as mileage scales (e.g., rate basis numbers) increase, proximity to Beta's suppliers' locations affects inbound shipping cost.

4.1.4. Local Incentive Data

To increase the return on investment from the consolidated warehouse, local incentives should be taken into consideration. According to the recent Conway Data global survey of development organizations (Venable 1996), local incentives such as labor availability (e.g., annual unemployment rate), labor quality, tax breaks, and loans were considered one of the five most important location factors by thousands of economic development executives. In particular, the Beta management team is greatly concerned with ongoing labor shortage problems. For the last several years, high employee turnover and the subsequent labor shortage have been a key concern in labor-intensive warehousing operations because labor shortages can disrupt continuous distribution of products to customers. In addition, since Beta's product is an important component of distribution packages, which are regarded as a main source of waste, Beta should carefully review local environmental regulations before determining the consolidated warehouse location. Finally, Beta should look for a broad range of tax incentives (e.g., enterprise zone incentives, job creation tax credits or super tax credits for capital investment and job creation) around the consolidated warehouse.

4.2. Model Management Subsystem

The main focus of the model management subsystem is the incorporation of the WNRP model (problem generator) into the DSS. Although the WNRP model can be regarded as a ''black box'' whose algorithm and solution procedures need not be understood by the Beta's management team, it should be integrated with a problem solver such as LINGO. LINGO is standard, commercially available software designed to solve the mixed integer programming problem. To further enhance user-friendliness, we also integrated a geographic information system (GIS) into the model management subsystem. GIS simplifies the data display mechanism by separating data presentation from data storage.

Whereas the WNRP model represents esoteric numbers and symbols, GIS creates a wide variety of visual aids in the form of sound, images, and maps, illustrated in Figures 2, 3, 4, 5, and 6. In general, GIS allows Beta's management team to visualize how distinctive geographic information (e.g., customer shipping volume) from one location is from that from another by superimposing the information on a map. By recognizing geographical differences between one location and another, Beta's management team can choose the warehouse network that is most suitable for their needs. One of the most important advantages of combining the WNRP model with GIS is the enrichment of data quality, because GIS helps analysts visualize database errors that may otherwise go undetected. Particularly, GIS is capable of segmenting customer markets and measuring future market shares. Such an ability can aid the Beta's management team in developing the warehouse network that best serves customers.

4.3. Dialogue Management Subsystem

At best, the model is an abstraction of real-world situations. Consequently, it cannot capture reality without running it more than one time (Dyer and Mulvey 1983; Min 1989). Thus, the model should enable Beta's management team to evaluate ''what-if'' scenarios associated with shifts in Beta's management philosophy (e.g., a shift from cost minimization to quick-response services) and competitive positions (e.g., a shift from domestic to global operations). In other words, the model's successful implementation depends on its flexibility for contingency planning. To enhance the model flexibility, the results of model runs should be reported in user-friendly formats. These formats include

standardized reports such as tables summarizing cost-saving opportunities and figures depicting maximum service radius as a function of the number of warehouses.

5. CONCLUDING REMARKS AND FUTURE RESEARCH DIRECTIONS

The warehouse is in the middle of the supply chain and therefore dictates the efficiency and effectiveness of the supply chain. With the increasing importance of a warehousing role in the supply chain, the warehouse network restructuring strategy can all but determine the success and failure of supply chain operations. This chapter introduces two distinctive warehouse network restructuring strategies: warehouse centralization and decentralization. These two strategies have their pros and cons, depending on the company's strategic focus. This chapter also develops a mathematical model that aims to provide a minimum-cost solution for the real-world warehouse restructuring (centralization) problem. Despite numerous merits, the proposed model points to a number of directions for future work:

1. The model can be expanded to include the element of risk and uncertainty involved in the warehouse-restructuring problem and can be tested for the expanded time periods.
2. The future research theme should include multiobjective treatments of the WNRP that explicitly analyze the trade-offs among cost, traffic access, market potential, and local incentives.
3. The multicommodity problem, which considers both slow-moving and fast-moving products, may be studied in the future.
4. The future network-restructuring problem should look into the possibility that the company will not only phase out some of the redundant warehouses but also relocate others to serve customers better.
5. Pure WNRP research can also continue by incorporating the combined usage of private, public, and contract warehouses into the mathematical modeling process.
6. The multiechelon hierarchical network configuration, which considers the options of both direct shipment from manufacturing plants to customers and indirect shipment through either master distribution centers or regional warehouses, may be an intriguing subject for further studies.

Acknowledgments

The authors wish to thank the senior management team and the vice president of the anonymous company for providing them with valuable data and assistance in the case study reported in this paper.

CHAPTER 81

Warehouse Management

GUNTER P. SHARP
Georgia Institute of Technology

1. INTRODUCTION

Modern warehouses operate with sophisticated equipment for storage, handling, data capture, and communication. A competitive environment requires warehouse managers to have tight control over inventories and orders shipped, with rapid response being the norm. At the same time, efficient strategies for storage and retrieval offer significant operating savings. To satisfy these objectives, an effective warehouse management system (WMS) is essential. A WMS may be a combination of paper-based systems together with computerized inventory records, but the trend clearly is toward an integrated, computer-based system that handles management and automatic identification. The major benefits of a WMS are typically the following:

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

- Improved inventory accuracy, which allows for higher order-fill rates and faster response times
- Increased efficiency as a result of eliminated operations, reduced deadhead travel of workers and vehicles, and sharing of workers across departments
- More timely replenishments of forward pick areas, which result in higher order fill rates
- Better pick wave planning and execution in zone pick systems, which result in better worker utilization and earlier completion of the picking activity

This chapter presents the main concepts of warehouse management. First, there is a functional description of a typical warehouse operation, with emphasis on order picking because that is where most of the labor costs in a warehouse are incurred. This is followed by a discussion of strategic and tactical factors for warehouse operation, and then a discussion of database considerations for WMS. The last part of the chapter describes how users interact with a WMS and what functions they should expect it to perform. The purpose here is not to describe how the WMS is structured, since that varies with the software vendors, but rather to present a user's viewpoint of the major aspects of the system.

A distinction should be made among three different aspects of use of a WMS: planning, executing, and reporting (Rouwenhorst et al. 2000). Once a system is installed, effective reporting feeds back to planning. Although most users focus on the execution aspect, the planning aspect is just as important since that involves strategic (more than six months in the future) and tactical decisions (one to six months in the future) that affect operational effectiveness just as much as short-term planning and execution do.

2. FUNCTIONAL DESCRIPTION OF WAREHOUSE OPERATIONS

2.1. Functional Structure of Warehouse Operations

A functional structure of a warehouse with order-picking activities, as shown in Figure 1, consists of at least 8 functional areas (departments) and more than 15 material flows (represented by arrows) with various load types (Yoon and Sharp 1996). This functional structure is a road map, and not all facilities will contain all departments and flows. The major departments can be categorized as breakdown or consolidation area, based on major functions, and as storage or transfer area, based on the duration of product stay:

- *Receiving area:* incoming shipments are unloaded, and inspected if necessary (transfer area).
- *Pallet reserve area:* an area where products are stored and retrieved in whole pallet quantities, without pallet breakdown (storage area).
- *Carton pick area:* an area from which products are retrieved in carton quantities. Incoming loads and storage units are usually pallets, but may also be cartons and mixed unit loads (storage area).
- *Item pick area:* an area from which products are retrieved in item (less-than-carton) quantities. Incoming loads and storage units are often cartons, but may also be totes and items (storage area).
- *Sorting area:* an area where different items of an order are consolidated, if this function is needed because of orders being split into suborders for picking efficiency (transfer area).
- *Consolidation area:* an area where the different items, cartons, and totes belonging to an order are unitized, such as into a shrink-wrapped pallet (transfer area).
- *Shipping area:* an area where outgoing items are checked and loaded onto vehicles (transfer area). Consolidation and shipping areas are often combined.
- *Auxiliary areas:* may include labeling, repackaging, and processing of items returned from customers.

Material flows can be classified as order and replenishment flows. For replenishment the relevant flows are from receiving to pallet reserve, carton pick, and item pick areas; from pallet reserve to carton pick area; from carton pick to item pick area. The other flows, for customer orders, are relatively more frequent. Consider the flow of a typical high-activity product, which is received in pallets and stored in the pallet reserve area (e.g., the upper levels of pallet rack). It is then moved to the carton pick area (e.g., the lower levels of pallet rack). Individual cartons are removed from the carton pick area and placed in the item pick area (e.g., a gravity flow rack holding cartons). The order pickers selectively retrieve items from the flow racks and place them on conveyors, which carry the items to the sorting area. There the items of each order are sorted into totes, which are then sent to the consolidation area and then to shipping. Some customers may order this product in carton quantities, which may be retrieved directly from the carton pick area. If an order requests a quantity equivalent to 4.2 cartons, then 4 cartons may be retrieved from the carton pick area and the remaining

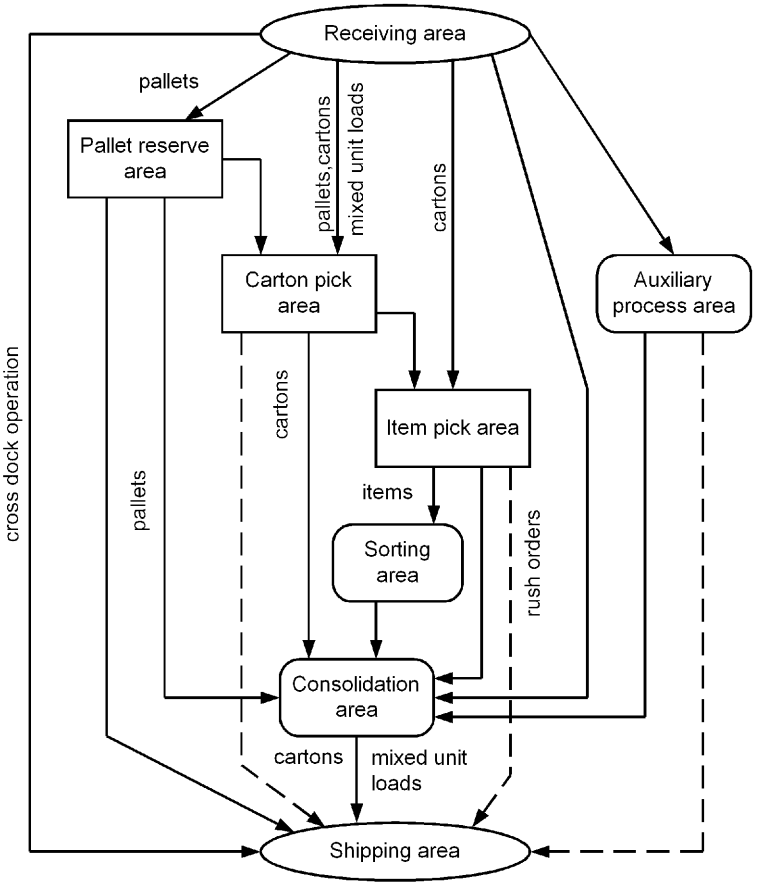

Figure 1 Functional Structure of a Warehouse with Order Picking.

item quantity from the item pick area. Similar logic applies to full pallet quantities of a product on an order.

2.2. Classification of Warehouses Based on Mission

Warehouses differ greatly in purpose and size, even within the same organization, so it is useful to examine some popular types. The purpose and size of a warehouse influence the factors that are important to the user of a WMS in the facility.

2.2.1. Factory Warehouse

A factory warehouse supplying wholesalers might process a small number of large orders daily with advance information about the composition of orders. The definition of ''small number of orders'' is based on the number of consolidation/shipping lanes: if during a process cycle, such as a shift, a packing/shipping lane can be dedicated to an order, we say the number of orders is ''small.'' The definition of ''large order'' refers to the number of different products on an order: if there are 10 or more different products, we say the order is ''large.'' The operating criteria in such a facility are usually cost and accuracy. Response time is often dependent on production scheduling in the factory and thus isusually beyond the control of the warehouse operator. The type of picking is usually pallet retrieval and carton picking, with emphasis on pallets.

2.2.2. Retail Distribution Warehouse

A warehouse serving captive retail units usually has advance information about the composition of orders. Typically, there are more orders per shift than consolidation/shipping lanes. Picking is usually

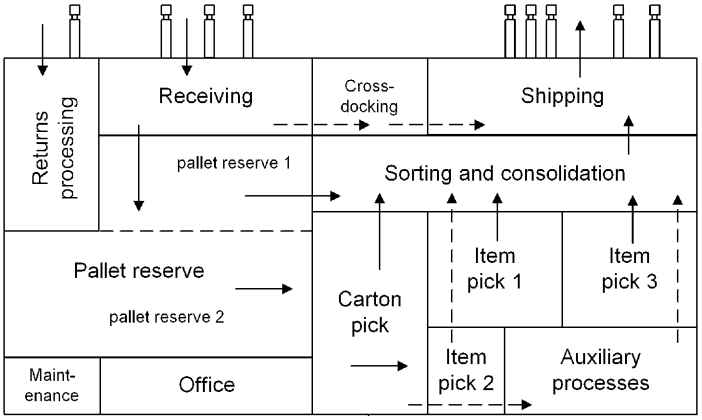

Figure 2 Example Layout of a Retail Distribution Warehouse.

carton and item picking, and usually there is a forward pick area (see Figure 2). Criteria are usually cost, accuracy, and fill rate (fraction of items requested that are actually shipped with the main part of the order). Response times are usually fixed and heavily dependent on truck routing schedules. If the retail units are not captive (not constrained to order from the particular warehouse), then response time becomes an important criterion.

2.2.3. Catalog Retailer

A catalog retailer typically processes a large number of small orders. While the definition of ''small order'' refers to fewer than 10 products, in the catalog retail business it is often closer to 2 or even 1 product per order. The number of orders per day may in the hundreds or even thousands. During the early part of the shift the composition of orders is usually known. Orders that arrive late during the shift may also be rushed through the system. For planning labor and replenishment of the forward pick area there is only statistical information available on these late-arriving orders. The primary criterion is often cost, but response time is also important. The picking here is usually item picking, with some carton picking.

2.2.4. Support for Manufacturing Assembly

A stockroom serving a manufacturing facility might process many small order with perhaps only statistical information about the composition of orders. If the response time is on the order of 30 minutes, then in effect any daily planning must be based on statistical information. The primary criterion is often response time, with cost a secondary criterion. The major types of picking may include item picking and carton picking.

Precise definitions of the descriptors ''small'' and ''large'' are not possible. For example, order size can be determined by cubic volume and/or number of different products on the order (number of line items). It is suggested that a small order be defined as one that contains fewer than 10 line items. If the quantity per line item results in a cubic volume less than 0.01 m^3 (0.35 ft^3), then a small order is also limited roughly to 0.1 m^3 (3.5 ft^3). A large order, containing 10 or more line items, would often have a volume greater than 0.1 m^3. In some situations, a large order might fill a truck. These definitions allow for some awkward, in-between situations. The demarcation based on the number of line items may be more useful because it relates more to operating strategies than a demarcation based on cubic volume.

The difference between advance and statistical information relates to the ability to process the order data for more efficient operation. In the example of a stockroom serving a manufacturing facility, the requirement for fast response (such as 30 minutes) probably would preclude the types of batching strategies used by a catalog retailer, who usually has several hours at night for data processing and a late-afternoon shipping deadline. If there is adequate time for preprocessing, we say there is advance information. Otherwise, the information is statistical. The information availability is directly related to the control rules in the operation of the OPS, since planning and execution based on statistical information may be different from that based on advance information.

2.2.5. Some Terminology

The language used by warehouse designers and operators contains some commonly used terms that need to be defined:

SKU: stock-keeping unit, the type identification of a product for purposes of distribution; for example, Coca-Cola Classic may be sold in 2-liter bottles packed 6 to a carton, 1-liter bottles packed 12 to a carton, 12-ounce cans packed 24 to a carton, 12-ounce cans arranged as 4 6-can inner packs in a carton, and 12-ounce cans packed 24 to a flat; these would all be different SKUs.

Item: the smallest unit of a product sold by the distribution center if many items are contained in a carton; sometimes called piece or each; examples are a 1-liter bottle of soft drink, a 12-pack of inexpensive ball-point pens, a 4-pack of spark plugs, a carton of cigarettes (containing 200 cigarettes in 10 packs of 20 each), a gift pack of stationery and envelopes.

Carton: a paperboard container holding identical product; usually of a size and weight allowing manual handling; example dimensions are $14 \times 10 \times 20$ in. and $300 \times 200 \times 400$ mm; recent trends in some industry sectors are towards a flimsier container, often called a flat, where the upper portion is plastic wrap.

Inner pack: several units of a product secured together (usually by paper or cellophane wrap) and sold by the distribution center as a unit if many items are contained in a carton and purchase quantities per item are large; a carton contains several inner packs.

Pallet: a set of cartons or totes of identical product arranged in a cubical pattern and usually supported by a base that may be of wood or plastic; example dimensions are $40 \times 48 \times 54$ in. and $800 \times 1200 \times 1000$ mm.

Mixed unit load: a set of cartons or totes of different products arranged in a cubical pattern similar to a pallet, often wrapped or strapped for stability.

Overpack: a large carton or tote containing different products; smaller than a pallet but larger than a carton so that manual handling may be difficult.

Tote: a container usually made of plastic and often used for storing and handling different products; usually similar in size to a carton; may be nestable or collapsible, with or without lid.

Order: a document from a customer requesting specific SKUs in specific quantities.

Line item: a ''line'' on an order document relating to a specific SKU and quantity.

Zone: a part of a distribution center to which an order picker is restricted; an example is a 40-aisle system divided into four zones of 10 aisles each, or an aisle-captive person-aboard system with 6 aisles and thus six zones.

Suborder: the portion of a customer order relating to a zone in the distribution center.

Batch: a set of suborders in a zone assigned to an order picker.

Time window: a portion of a day during which an order is processed; for example, an eight-hour day may be split into four two-hour time windows such that an order is processed completely during one of the time windows.

Pick wave: the set of orders processed during a time window; waves are often associated with zone picking.

Order class: a subset of the daily orders with some common characteristic, such as the same customer type, same size of order, or same shipping method.

Product group: a subset of the products in a distribution center with some common characteristic, such as vendor, product type, activity, or brand.

I/O point: the input/output point of a system.

S/R: storage/retrieval.

ASN: advance shipping notice, issued by a supplier to inform the warehouse operator of a shipment to arrive in the near future, usually transmitted electronically.

3. STRATEGIC AND TACTICAL FACTORS IN WAREHOUSE OPERATION

3.1. Classification by Implementation Time

We define strategic factors as those with implementation six or more months in the future. Usually these involve design changes in the physical or operating system where procurement and installation take that much time. Examples include:

- Changing the holding capacity and processing capacity of a functional area
- Changes in hardware for storage, vehicles, conveyors, control system

Tactical factors are defined as those with implementation one to six months in the future. Examples include:

- Modifications to existing storage and handling equipment and major movements of products to new storage or pick positions that cannot be performed with in-house labor on nights and weekends
- Changes in operational rules for storage, retrieval, sorting, and merging that require software modifications
- Negotiating changes in labor mix, that is, the balance between permanent and temporary employees, the balance between regular and overtime

3.2. Operational Planning

In addition to these strategic and tactical factors above, operational planning must be performed on a monthly or more frequent basis. This includes the examples below:

- Reclassification of products based on activity and inventory requirements, including the phase-in of new products and deletion of obsolete ones
- Restructuring of pick zones
- Changing operational settings in the WMS to accommodate a change in volume or change in the mix of orders
- Volume forecasting and labor planning
- Retraining of employees based on performance measures, such as productivity and quality

3.2.1. Space-Planning and Space-Adjustment Factors

The determination of storage space requirements is one of the most fundamental functions in warehouse management. Space utilization in a storage system is affected by several factors:

- *Volumetric efficiency,* F_a, in placing a product load in a storage compartment. This may result from undersized loads and from obstructions in the rack area, such as columns and sprinkler pipes.
- *Utilization,* F_b, of a set of storage compartments by a product lot as withdrawals are made. Deep-lane storage systems are particularly affected by this phenomenon, although it also affects single-deep pallet rack and shelving systems when withdrawals are in small quantities.
- Number of *storage compartments not assigned* for operational flexibility, such as performing dual-command S/R operations. It is usually impossible to occupy every storage position and maintain any type of operational discipline. Some fraction of the spaces, say 5–10%, need to be empty to provide opportunities for activity-based storage when incoming loads arrive. The resulting factor, F_c, will be 90–95% when applied to maximum product storage requirements. For average product storage requirements the factor usually does not apply and can be set to 100%.
- *Cyclical fluctuations* in storage requirements, resulting in factor F_d. Most businesses experience inventory peaks at a particular time(s) of the year. If one designs for the peak (or 90% of the peak) requirement, then at other times of the year the system will be underutilized. One can minimize this effect by renting space from third-party providers during peak inventory periods, by smoothing out deliveries and shipments with incentives, and by more frequent inventory replenishments during peak inventory periods.

The volumetric efficiency, F_a, depends on the matching of load sizes with storage compartment sizes. The storage compartment size must allow for clearances and some load deformation; thus, 100% utilization of the storage compartment would reflect the minimum clearances.

In one case study, pallets in a manufacturer's warehouse were limited in height to 127 cm (50 in.) based on rack spacing, but the average pallet height was 112 cm (44 in.) (Sharp et al. 1994). This gave a factor value of

$$F_a = \frac{112}{127} = 0.88$$

In addition, 50% of the pallets in storage required a height less than 102 cm (40 in.), so for these the factor was

$$F_a = \frac{102}{127} = 0.80$$

Partial pallets that are received and stored without consolidation contribute to low factor values. Columns and other obstructions may cause a loss of 5% or more of the available space. This factor applies to the maximum product storage requirement.

The utilization of a set of storage compartments by a product lot depends on the number of compartments assigned and the withdrawal pattern. For example, if an incoming lot consists of three pallets of identical product, the product is stored in a single-deep rack system, and carton withdrawals occur uniformly, then the average compartment utilization is calculated as shown in Table 1. The calculations assume the ability to reassign empty spaces immediately to other products. The result here is a utilization of 75%, based on the average product storage requirement. If we were to calculate the utilization factor based on maximum product storage requirement, it would be 1.5/3.0 = 50%.

For deep-lane systems the calculations are similar but more involved. Often there is a mismatch between an incoming product lot and the available slots, despite the best efforts of the warehouse designer. One first needs to calculate the optimum lane depth, assuming that empty lanes can be reassigned to other products immediately. Table 2 shows a typical situation in floor stacking, where an incoming lot of 15 pallets may be assigned to a lane depth up to 5, with a stacking height of 3. The best situation requires a floor space of 6.3 m^2, which corresponds to floor space occupied by product (not counting aisle space) of either 3.6 or 4.2 m^2. The incoming lot of 15 pallets requires 5 floor spots of 1 m^2 each, or 5 m^2. The average inventory is 8 pallets (the time for zero inventory is assumed to be negligible), and these require an average of 8/3 = 2.67 m^2. Thus, the utilization based on average product storage requirement is 2.67/3.6 = 74% (for the 2-deep lanes), and 2.67/5 = 53% based on maximum product storage requirement (Tompkins et al. 1996). This underutilization of deep-lane systems is called honeycombing.

The cyclical fluctuations work together with the method (or lack) of shared storage.
Consider the forecasts of inventory requirements (in pallets) over eight time periods for 10 products shown in Table 3. The 10 products have been classified into two groups based on chemical compatibility, and within each group any pallet may occupy any storage position (shared storage). If there is no reorganization of the storage system over the eight time periods, then the positions needed for the groups are 32 and 20, respectively, for a total of 52 pallet positions, as shown in column 15 of Table 4. If the spaces are reorganized every two time periods, then the requirements decrease to a total of 44, for savings of 15%. In this example the reorganization might require some special cleaning to avoid chemical incompatibilities with residues left in the storage compartments. For the case of reorganizing every 8 periods, the sum, over products, of the average storage requirement is 36.75. So the utilization, based on average product storage requirement, is 36.75/52 = 71%; for reorganization every 2 periods, the factor is 36.75/44 = 84%. This dependence of utilization based on reorganization interval is examined in Sharp et al. (1999).

TABLE 1 Method of Calculating Average Storage Compartment Utilization

Col. 1	Col. 2	Col. 3	Col. 4	Col. 5
Number of Spaces Occupied	Percent of Time Number Occupied	(col.1)(col.2)	Average Product Quantity in Storage	(col.4)(col.2)
3	0.333	1.000	2.500	0.833
2	0.333	0.667	1.500	0.500
1	0.333	0.333	0.500	0.167
	Total	2.000	Total	1.500

Average utilization, F_b = 1.500/2.000 = 0.75

TABLE 2 Lane Depth Analysis, Incoming Lot Size = 15 Pallets
Stacking height = 3, pallet dimensions are 1 × 1m, including horizontal clearances

Lane Depth		Modular Width		M^2 per	Lanes Needed		Average m^2	Floor Space
Pallets	Meters	Pallets	Meters	Lane	Maximum	Average	Occupied	Product
1	2.5	1	1	2.5	5	3	7.5	3
2	3.5	1	1	3.5	3	1.8	6.3	3.6
3	4.5	1	1	4.5	2	1.4	6.3	4.2
4	5.5	1	1	5.5	2	1.2	6.6	4.8
5	6.5	1	1	6.5	1	1	6.5	5

Explanation of averages, assuming smooth reduction of inventory:
For 1-deep, each of the 5 situations has equal probability, so average = 3.
For 2-deep, 3 lanes occurs 20% of the time, 2 lanes occurs 20 + 20 = 40% of time.
and 1 lane occurs 20 + 20 = 40% of time. So average is (3)(0.2) + 2(0.4) + 1(0.4) = 1.8.
For 3-deep, 2 lanes occurs 20 + 20 = 40% of time, 1 lane 60%, so average = 1.4.
For 4-deep, 2 lanes occurs 20% of time, 1 lane 80%, so average = 1.2.
For 5-deep, we always need the entire lane.
The time when no lanes are needed is assumed to be negligible.

The overall effect of these four factors can be quite shocking. Using values similar to those in the examples, we might have an overall utilization of storage space, based on average product storage requirements, equal to

$$F_a * F_b * F_c * F_d = 85\% * 75\% * 100\% * 80\% = 51\%$$

Based on maximum product storage requirements, the overall value would be much lower, depending on the method of shared storage. The above examples point to the need for the WMS to report information that enables the warehouse manager to estimate space requirements in a manner consistent with the ability to reallocate that space. Although these types of decisions are often thought of as being part of warehouse design, the ever-changing business conditions in the economy imply that they are also part of warehouse management.

3.2.2. Individual Product Assignment to Storage Positions

A storage rule is defined as a rule for assigning each SKU to storage locations. A primary objective of warehouse design and operation is to minimize the average process time per storage/retrieval (S/R) activity or per order. Even if the total cost of order picking may be the ultimate concern, a significant portion of the total cost is usually proportional to S/R time. Storage rules can be grouped into two broad classifications:

TABLE 3 Example Forecast, 10 Products in Two Groups

		Period							
Product	Group	1	2	3	4	5	6	7	8
1	1	4	5	6	7	9	0	3	4

1. *Dedicated storage:* Each product is assigned a set of storage compartments that no other product is allowed to occupy.
2. *Shared storage:* Each product group is assigned a set of storage compartments that no product in another group is allowed to occupy.

For dedicated storage, the most popular assignment rule is to assign the SKUs with the highest activity (fast movers) to the locations near the input/output (I/O) point(s). The motivation is to reduce average S/R time. This assignment of individual products to storage positions, called slotting, is usually supported by the WMS. The major principles were outlined in the 1960s (Heskett 1963); a more accessible reference is Tompkins et al. (1996). The activity level of a product is measured by its cube-per-order-index (COI), defined as:

$$\text{Cube per order index} = \frac{\text{access trips per period}}{\text{maximum storage space needed}} \tag{1}$$

A shared storage system where any product in any group may occupy a storage compartment is characterized as pure random storage. However, products are usually grouped by size, environmental requirements (temperature, humidity, hazard level, etc.), value, and chemical compatibility, so pure random storage systems are rare. More popular are class-based systems, where products are grouped by activity level in addition to the factors of size, environmental requirements, etc. A typical class-based system allocates products into three classes, usually called A, B, and C, following the principles of Pareto analysis (Tompkins et al. 1996). The left portion of Figure 3 shows a typical result of such ABC analysis for a pallet S/R system, where the 20% most active storage spaces account for 60% of movements, the next 20% of spaces account for 20% of movements, and the remaining 60% of least active spaces account for 20% of movements. The right portion of Figure 3 shows a corresponding grouping of storage compartments in a single-deep pallet system and the resulting assignment of product groups.

A major benefit of shared storage is reduced space needs. Although textbook formulas suggest savings on the order of 45% (Tompkins et al. 1996), in reality the savings are diminished by common seasonality among products, inbound transport consolidation, inherent variability of product inventory, and inability of the warehouse manager to reallocate space. Typical savings for a three-class system with monthly reallocation of space are 20-30% (Sharp et al. 1999).

Referring to Table 4, if the five products in group 1 were stored in a dedicated system, with space needs based on the forecast for eight periods, then a total of 48 spaces would be required (sum of the individual values in column 15). With shared storage for group 1, only 32 spaces are needed, for a savings of $(48 - 32)/48 = 33\%$ just within group 1.

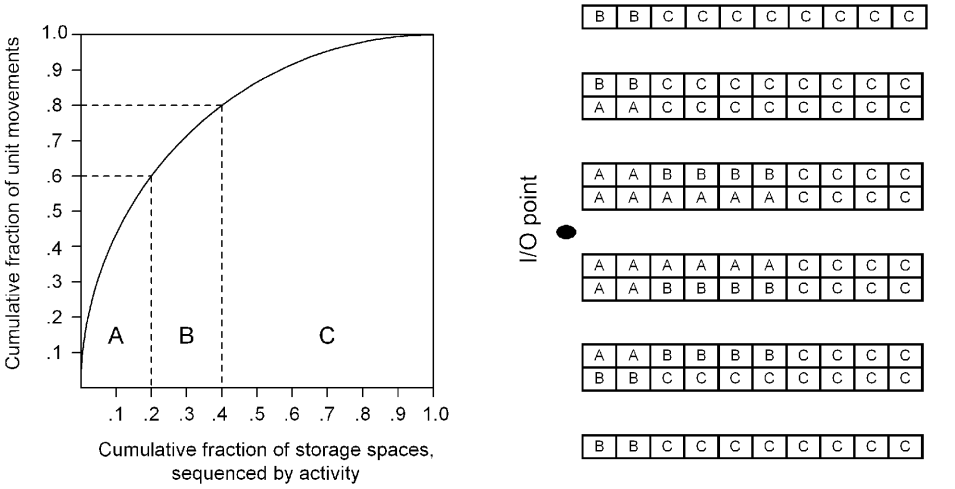

Figure 3 Pareto Analysis and Assignment of Product Groups to Storage Spaces.

A more refined version for pallet storage systems is based on the expected time in storage for each individual pallet (Goetschalckx and Ratliff 1990). For item pick areas a more refined measure is the viscosity of a product (Hackman and Rosenblatt 1990), defined as:

$$\text{Viscosity index} = \frac{\text{retrieval visits per period}}{(\text{cubic volume of product retrieved per period})\text{^}0.5} \tag{2}$$

The concept of family-based storage is sometimes applied in an effort to reduce picker travel time and to simplify order consolidation. The idea is based on identifying items that are likely to be ordered together and then to locate these items near each other. The method has been applied successfully in at least two situations: 1) selecting items based on bills-of-material for manufacturing, and 2) selecting clothing based on size in a catalog retailer operation (Frazelle 1989; Sadiq et al.1996; Amirhosseini and Sharp 1996).

3.2.3. Forward–Reserve Allocation

Referring to Figure 2, one of the crucial decisions in operational planning is deciding which products should occupy positions in the forward pick area and how space should be allocated to each. Depending on the storage technology used in the forward pick area, the total space allocated to it may be a strategic, design decision or a tactical, operational decision. The most commonly used methods use product activity to select products for the forward area and allocate an equal time value of inventory per product. This method, however, is inferior to the recommended method for making these decisions as described in Bartholdi and Hackman (1998). The concept of the viscosity index presented above is used in a recursive algorithm, using the following formula:

$$\text{Fraction of space for product } i = \frac{\sqrt{\text{cubic demand of product } i}}{\sum_j \sqrt{\text{cubic demand of product } j}}\,(V) \tag{3}$$

Dynamic reallocation of products to the forward pick area is practiced by some operators. Using this method, when a pick slot in the forward area becomes empty, it may be reassigned to another product that was previously being picked from the reserve area. Other operators periodically move slow-moving items from the forward area back to reserve.

3.2.4. Zoning and Batching, Order Retrieval

Order retrieval in large and/or busy systems is often characterized by zone picking, where the pick area is divided into smaller areas and a picker is restricted to a zone. An order that requests items from more than one zone is split into suborders, and the picker(s) in each zone selects the respective items. In a grocery distribution center an order may consist of a truckload, and this would be divided into perhaps 20 suborders. In this situation the zone picking would be simultaneous; otherwise it would take too long to complete the order. In a pharmaceutical distribution center the total cubic volume would be less, and the items might be picked into totes. In that situation the zone picking might be progressive, where the picker in the first zone starts the order and passes the partially filled tote to the picker in the next zone, and so forth. Figure 4 illustrates these concepts.

Zone picking is motivated by necessity in the case of large orders and efficiency in terms of operator training with equipment and familiarity with the products. When part-to-picker equipment is used, such as carousel, vertical storage column, and miniload, it is preferable to keep an operator at the retrieval station for that equipment to reduce operator idle time, and thus zones are usually defined by the equipment units.

When the orders or suborders are small relative to the zone size, batch picking is often used: each picker is assigned a set of suborders in the zone, and the items are selected in the most effective manner to reduce picker travel (in picker-to-part systems) or machine travel (in part-to-picker systems). If the pick vehicle has compartments that allow the picker to keep separate the items of the orders (maintain order integrity), then the method is sort-while-pick. Otherwise, downstream sorting is used to reestablish order integrity. The travel time savings from batch picking are discussed in (Armstrong et al. 1979; Choe et al. 1993).

Considering all these options, these are the following logical ways to process orders:

- *Single-order-pick:* One picker works on one order at a time until the order is filled.
- *Sort-while-pick, no zoning:* One picker works on several orders at time with a vehicle that has compartments for maintaining order integrity.

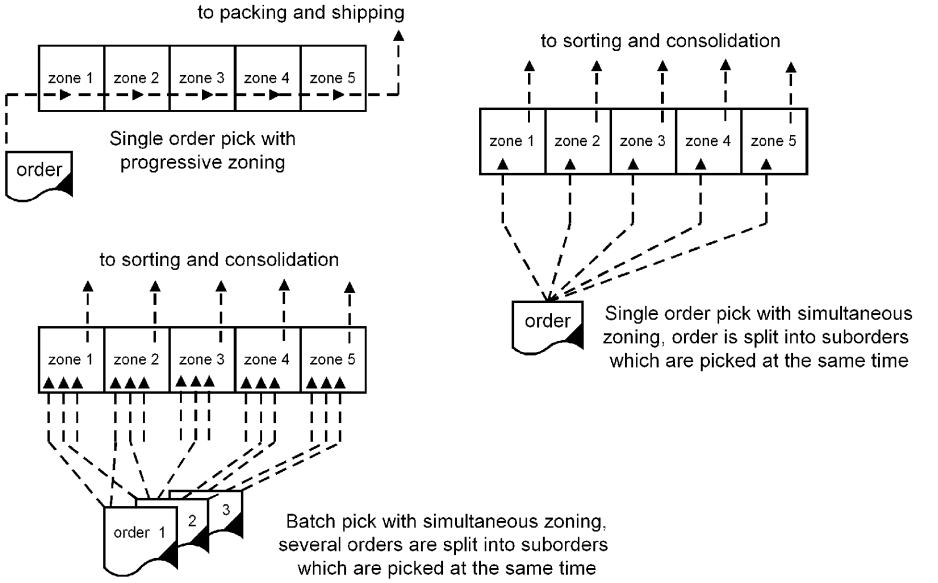

Figure 4 Zoning and Batch Picking.

- *Batch picking with downstream sorting, no zoning:* Several orders are picked by one person completely, often applied with conveyor transport of items to the sorting area.
- *Single-order-pick with zoning:* An order is split into suborders by zone and a picker in each zone fills the corresponding suborder; may be applied with progressive or simultaneous zoning.

Figure 5 Workload Imbalances among Picker Zones.

TABLE 5 Picker Productivity as a Function of Zone Size and Time Window

Line Items per Consolidated Pick List	Number of Pick Waves	Time Window Duration, hr	Average Number of Orders in Process*	Productivity, Line Items per hr	Relative Productivity
50	12	0.5	25	64.6	65.3%
100	12	0.5	25	67.7	68.5%
50	6	1	50	72.7	73.5%
100	6	1	50	76.7	77.6%
200	6	1	50	79.7	80.6%
50	4	1.5	75	75.9	76.7%
100	4	1.5	75	80.2	81.1%
50	3	2	100	77.6	78.5%
100	3	2	100	82.2	83.1%
200	3	2	100	85.7	86.7%
50	2	3	150	79.4	80.3%
100	2	3	150	84.2	85.1%
200	2	3	150	87.9	88.9%
100	1	6	300	98.8	99.9%
200	1	6	300	98.9	100.0%

*Line items per order distributed Poisson with mean of 4.0.

- *Sort-while-pick with zoning:* An order is split into suborders by zone and a picker in each zone fills the corresponding suborders using a set of containers or a vehicle that has compartments for maintaining order integrity.
- *Batch picking with downstream sorting and zoning:* Several orders are split into suborders and the suborders for each zone are filled by the picker(s) operating in that zone, usually applied with simultaneous zoning.

3.2.5. Pick Wave Planning

When there are many orders to be processed daily, it may be desirable to split them into groups, called pick waves. The time for processing a pick wave in the pick area is called a time window. Pick waves may be necessary for one or more of the following reasons:

- Downstream sorting is used, and the design of the sorting system limits the number of orders that may be in process at one time. Note that the number of orders in process can often exceed the number of output chutes of a conveyor sorter (Bozer et al. 1988).
- The capacity of the forward pick area is insufficient to allow the daily orders to be filled without replenishment, and it is desirable to stop the pick process and replenish, for reasons of safety and/or efficiency.

There are some fundamental trade-offs among the size of a pick wave, picking efficiency, and size of the downstream sorting operation. The smaller the time window, the greater the workload imbalances among zones and across time windows. Depending upon the WMS and conveyor accumulation capacity, a picker who finishes early may or may not have to wait until all pickers are finished with the wave. Figure 5 illustrates this phenomenon of induced idle time. Also, smaller pick waves imply more travel per item selected. On the other hand, a small pick wave allows for a smaller and less expensive sorting system and allows for earlier completion of some orders. In the situation where items are sorted according to loading dock doors, the number of doors may limit the size of the wave. For a more complete discussion of these issues see (Choe 1991; Amirhosseini 1999). Table 5 shows some results for picker productivity and number of orders in process at a time for the situation where pickers must work in synchronized mode (pickers who finish early must wait for all to finish the wave).

4. DATABASE CONSIDERATIONS

Although the detailed structure of a WMS varies according to vendor, the WMS will typically be represented by a number of databases and protocols (methods) that reflect operating rules. In this section an overview of the more important databases is given, as well as some of the linkages among them. Further details may be found in Huffman (1985) and Lin (2000).

4.1. Products and Orders

Two important databases relate to products and orders, respectively. The item master defines the products that are handled by the warehouse. Included in this database are product identification, physical characteristics, vendor sources, replenishment and safety stock levels, service level, and so forth (see Table 6). The order master contains the records of customer orders (see Table 7). In addition, closely related tables include a vendor master, a customer master, and an inventory master. The last table should reflect not only quantities and locations of products on hand, but also back-ordered quantities and quantities reserved for customers or other reasons.

4.2. Flow Control

Another series of database tables is used to track the flow of material: advance shipping notice (ANS) table for those receipts that are expected soon, putaway tables for items received that are to be stored, replenish tables for forward pick areas, pick tables for pick waves in each area, load consolidation tables, truck manifest tables, and additional move tables for other moves not specified above. There may be more than one version of each table, one as planned and another as executed, or these characteristics may be captured in one table. These tables, which are often subdivided by priority, are particularly important when automatic identification, such as bar code, is used to control flow. In the situation of batch picking with zoning the pick table needs to contain details on zone, picker, pick wave, sorting area, packing method, and so on. (see Table 8).

4.3. Building, Equipment, and Personnel Assets

The equipment master contains information on the physical characteristics of storage and transport equipment, speeds, compatibilities with respect to products and containers by size, and access times

(see Table 9). This table is usually subdivided into storage media (e.g., racks, shelving), automated storage/retrieval systems, vehicles, and conveyors. This type of information is accessed when decisions on product storage are made. Racks and conveyors are usually divided into zones, and this information is reflected in the tables. Compatibility of storage media with vehicles is also recorded.

The personnel master contains information on the skills of employees, availability by shift, and sometimes their performance (productivity and quality) ratings (see Table 10).

The most important table for building and equipment is the zone master. This table relates building space and equipment units in a logical manner, and it provides the links for inventory, product storage assignment, product retrieval, and flow control. In some applications the table is hierarchical, with overlapping zones. Zone overlap may occur when some areas of a building are used for one purpose, such as single-order-pick during one part of the shift, and another purpose, such as batch-picking-with-zoning, during another part. Table 11 shows some information in an example zone master table.

4.4. Operating Rules

A series of protocols is used to drive the functions in a warehouse according to specified rules. There is an umbrella protocol, called the function flow map, that defines the functions that are allowed to occur in the different zones (areas) of the warehouse. This protocol may be in the form of a table that can be controlled by the warehouse operator, or it may be coded directly into the WMS software. Table 12 is an example where the allowable functions are prioritized. In addition, there are tables that prescribe putaway rules and inventory allocation rules. The rules for picking flow path must reflect the zone structure: one zone, progressive zone picking, or simultaneous zone picking. Rules for picking method reflect single-order-pick and batch-picking. Picking control may be by paper labels, container license plate (e.g., bar code), or radio frequency (RF). Another set of rules applies

TABLE 12 Example Function Flow Map

Function number	Description	Origin Zone	Destinaion Zone, First Choice	Destination Zones, Other
101	receiving, general	none	1	2
102	receiving, R1 only	none	1	
103	receiving, R2 only	none	2	
201	putaway to pallet storage	1	10	20, 30
202	putaway to pallet storage	2	20	10, 30
203	putaway to pallet storage	1	10	
204	putaway to pallet storage	1	20	
205	putaway to pallet storage	1	30	
206	putaway to pallet storage	2	10	
207	putaway to pallet storage	2	20	
208	putaway to pallet storage	2	30	
221	move to cross dock operation	1	90	100
299	putaway to quarantine storage	1	10	20
301	putaway to item pick	1	40	50
302	putaway to item pick	1	50	40
303	putaway to item pick	2	50	40
401	pallet pick	10	100	90
402	pallet pick	20	100	90
501	replenish carton forward area	22	211	
502	replenish carton forward area	22	50	
601	carton picking, one zone only	211	100	
602	carton picking, multiple zones	211	80	
701	item pick, single-line orders	40	95	
702	item pick, single-line orders	50	95	
703	item pick, multi-line orders	40	85	90
704	item pick, multi-line orders	50	85	90
801	carton sorting	80	100	
901	item sorting	85	100	
950	packing	95	100	
960	outbound hold	95	98	
990	loading	100	none	

to consolidation, packing, and loading of orders. If value added functions are performed, such as labeling, pricing, or repackaging for retail display, then rules must be established for them.

4.5. Links to Hardware Controllers

Mechanized and automated equipment units will have their own hardware controllers, and these must be linked to the WMS. The hardware controllers are typically coded in C language in a UNIX operating system. Besides flow-control logic, information on system integrity, battery voltage, conveyor utilization, equipment malfunction, and so on is reported. Automated storage/retrieval systems, high-speed sorting conveyors, and merge conveyors, if present, must be integrated into the overall software system for the warehouse. Conveyor systems have numerous photo-eye detectors, which can send thousands of signals per hour; such high transaction rates must be handled by separate controllers that are linked to the WMS. The interfaces typically involve the transfer of batch instructions between the WMS and the hardware controllers. The main computing platform for the WMS may be a mainframe system, an IBM AS-400 system, or a Windows NT PC-based system. The major WMS vendors support multiple platforms (Seidl 1997; Hahn-Woernle 2000; IT logistiek 2000).

4.6. Data Backups

Systems that attempt to operate in real time require a hot backup or mirror computer operation, augmented by an emergency power generator. In essence, two computer operations run simultaneously, and either one can control the WMS in case the other fails. Otherwise, or in addition, a system of backup data tables should be maintained on an independent computer, so that they may be printed and used for operation in case the WMS computer fails. These backup tables should be updated once every shift or pick wave.

5. DAILY OPERATIONAL FACTORS IN WAREHOUSE OPERATION

5.1. Receiving Operations

It is logical to think of receiving as the first operation in warehousing. The physical receipt of goods, however, is typically preceded by an ASN. This allows for planned cross-dock operations, which are increasing in popularity. Out-of-stock conditions are flagged, and the corresponding goods go directly to packing and shipping for back-orders. Some goods may go to replenishment of forward pick areas directly from receiving (subject to stock rotation policies). Upon receipt of goods from qualified vendors, the inventory values in destination areas may be adjusted, or the goods may be logged into a transient state. Goods from non-qualified vendors may undergo a quality check and/or count. If this is time-consuming, the goods are held in a quarantine inventory status. If the quality check is based on a sample, it is usually possible to move the bulk of the product to another location and control the quarantine status through the WMS. Figure 6 shows the possible logical flows for receiving operations.

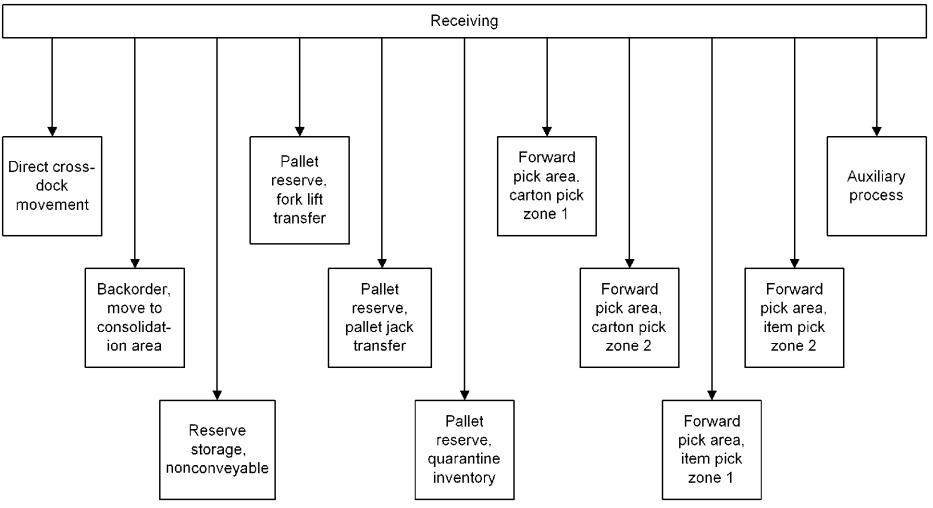

Figure 6 Receiving Operations Material Flows.

There should be the capability to process partial receipts, generate labels for pallets and cartons, and assign storage locations. The assignment of storage locations may follow one of several disciplines:

- *User is completely directed by WMS:* The WMS identifies the location based on product characteristics and available locations. The operator is not allowed to store the item in a different location, except by going through exception routines.
- *User is partially directed by WMS:* An example would be when the WMS directs the user to a zone or a portion of a zone (e.g., an aisle or portion of an aisle), but the user has flexibility within the zone of where to place the item.
- *User has complete flexibility:* The WMS allows the user to place the item in any location, and reports an error only when there is some physical incompatibility, such as compartment too small, compartment contains too much already, etc.

Returns processing is increasingly being assigned to outside operators, but most warehouses still accept some return goods from customers. This is often a labor-intensive operation, involving unpacking, inspecting, repackaging, and labeling. After the last step the goods can be "received" as if they came from a vendor. Manual date entry and error correction are also functions that must be included in receiving.

5.2. Storage and Inventory Control

In addition to the concepts of dedicated vs. shared storage discussed earlier, the WMS should have capability for lot control (typically by date or production run), fractional unit loads, and storage in more than one location. When the incoming quantity of a product is less than a unit load, there is an opportunity for consolidation when the products are stored. Various rules may govern this consolidation, such as same SKU, same SKU and same lot, allow different SKUs in storage compartment, compute remaining compartment capacity by cubic volume, compute remaining compartment capacity by dimensions of items, and so on. When goods that were in a transient state upon receipt are stored, the inventory values are adjusted. In addition, the actual storage location is recorded, or acknowledged in the situation of the user being completely directed by the WMS. Some goods may be reserved for specific customers when they are stored; such stock reservation may also occur later. Cycle counting may be performed when the items are stored; such opportunistic counting helps reduce extra travel for inventory control. Other functions that occur on a regular basis are stock activity reports for fast, medium, slow, and dead stock, and empty location reports. Manual data entry and error correction are also needed.

5.3. Order Processing

The first step in order processing, which is usually performed by the customer service department, is verification of item availability. This is preferably done online, or electronically in the situation of computer-based orders. On-line verification of customer credit status is next, followed by inventory reservation, if appropriate. The pricing structure may reflect quantity restrictions, such as full carton or full pallet, and these are applied at this time. The customer service department should suggest the closest or next quantity multiple, with price breaks if any, to simplify the work in the warehouse. The software used by the customer service department, which may be linked to the WMS, should have flexibility in pricing by customer and order type, flexibility for partial shipments, flexibility in picking and packing orders according to customer needs (including priority class), and flexibility in handling shipping charges (customer pays, price includes transportation, etc.) After the order has been selected, the WMS (or linked software) generates an invoice and bill of lading. Manual date entry and error correction are also included as functions.

5.4. Order Picking

There are several planning functions precede the actual retrieval of products for customer orders. The first of these is to check current inventory levels in the forward pick areas and generate replenishment reports. Most warehouse operators prefer to replenish at the beginning of the shift, for reasons of safety and efficiency. Some replenishments may occur during the pick process, especially if the information about orders is incomplete, or if operators select full cartons from the item pick area when they should be selected from the carton pick area. The WMS should support workload balancing in the pick operation: reflect different picker capabilities according to data in the personnel master (Table 10), and reflect different number of operators according to pick wave and shift. The ability to balance workload over more than one day is desirable, but it is usually not available in the typical WMS.

The WMS must be capable of supporting the different pick methods described in Section 3.2.4, along with estimates of completion times for the major steps, such as the pick waves and sorting and loading operations for waves. For pick wave formation a variety of criteria may apply: group rush orders first, group orders by type (single-order-pick, batch-pick, etc.), group orders by packing method, group orders by loading dock door in reverse sequence based on delivery routes, and group orders by proximity of retrieval locations for sort-while-pick operation (Gibson and Sharp 1992). In zone systems it is desirable to have flexibility for changing the zone configuration, either by pick wave or dynamically. Dynamic adjustment of zones in item-pick operations has proven very effective (Bartholdi and Eisenstein 1996). The routing of pickers in a multi-aisle system is usually accomplished by software according to the number of retrieval stops and the travel metric:

- *Single-command operation:* The operator makes only one stop in the storage system before returning to the I/O point.
- *Dual-command operation:* The operator makes two stops in the storage system before returning to the I/O point. If one stop is for storage and the other for retrieval, as in pallet operations, this method is called interleaving. The rules in the WMS determine the travel savings to be gained by such methods (Graves et al. 1977).
- *Multicommand operation in a sparse system:* The operator makes several stops (more than two) in a system but considerably fewer than the number of pick aisles. For a single block of aisles, called a ladder structure (see Figure 7), an adaptation of the traveling salesman problem may be applied to the routing (Ratliff and Rosenthal 1983). When there are cross-aisles or multiple blocks of aisle, heuristic algorithms are available (Kees 2000).
- *Multicommand operation in a busy system:* When the number of retrieval stops is more than the number of pick aisles, serpentine routing is applied. Here the picker enters each aisle that contains product on the pick document and continues through to the end of the aisle, and then proceeds to the next aisle that contains product to be retrieved. In busy systems, or systems where U-turns or reverse travel in an aisle are not desirable, a one-way flow in each aisle may also be imposed. This may induce unnecessary travel in aisles with no products for the current

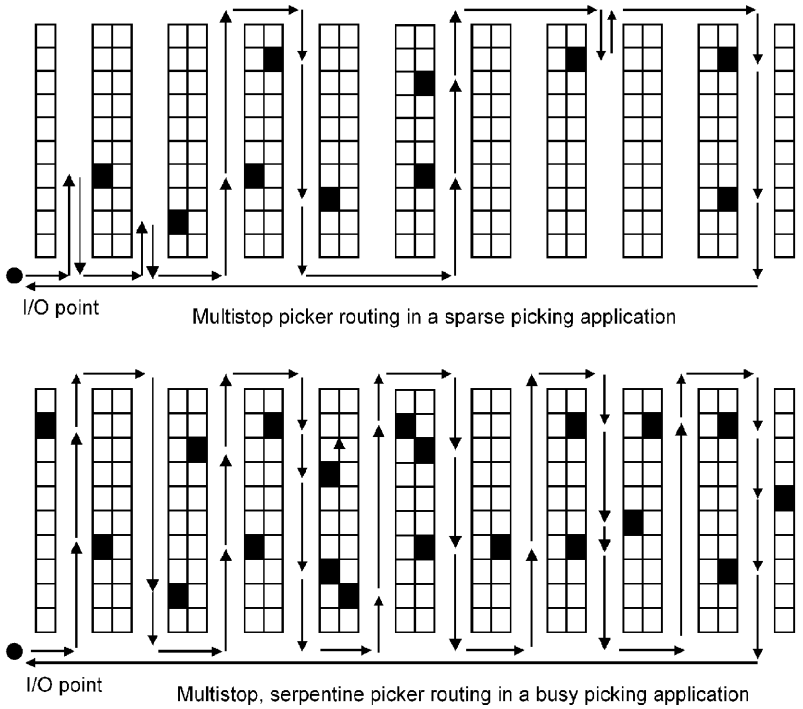

Figure 7 Multistop Picker Routing.

pick document. The expected picker travel in such systems may be obtained using the results in Choe (1991).

- *Multicommand operation with order-picker trucks:* When the vertical travel dimension is added, the picker routing becomes more complicated. Generally, it has been found that the best storage-assignment method is to place the more active items at the lower levels of the rack system. Placing more active items at the end of the aisle doesn't help much, since there is a good chance the picker will travel through the aisle anyway (Krueger 1999).
- *Multicommand operation with automated S/R systems:* In an automated S/R system, the characteristics of the S/R machine usually imply simultaneous movement in the horizontal and vertical dimensions. Most of the technology applications have one S/R machine per aisle. The picker routing then becomes a traveling salesman problem in the Chebyshev metric (Bozer et al. 1990).

The WMS will generate consolidated pick documents for each operator (see Table 8), sequenced by retrieval location. These documents may be paper, electronic, labels or electronic tags, or a combination. They must contain the picker or picker team identification, SKU location, quantity, inner-pack quantity if applicable, zone, wave, packing lane, packing method, and shipping method. Exceptions and interruptions occur frequently in order picking, and a series of protocols must be available to deal with them. The simplest exception decision to execute is to ship an incomplete order: the packing list and invoice are adjusted to reflect actual quantities, and the missing items are placed on back order for the customer if that is the applicable policy. More involved are decisions to substitute items, or to place nearly complete orders temporarily on hold to wait for a missing item. These actions usually require that the products be placed in a temporary storage area, which complicates the sequence of data-processing operations in the flow control tables. The discovery of wrong or damaged items at the loading operation may tie up a loading dock door and disrupt the release of the next pick wave.

5.5. Order Consolidation

After the multiple parts of an order are selected, they must be brought together in one location for packing and consolidation. This may be as simple as consolidating items in a staging lane near the loading dock. In other situations, such as the use of high-speed sorters, accumulation lanes feeding packing lanes are needed. The WMS or linked sorter software controls the flow of goods from picking through sorting and order consolidation and on to packing and loading. Items that differ physically

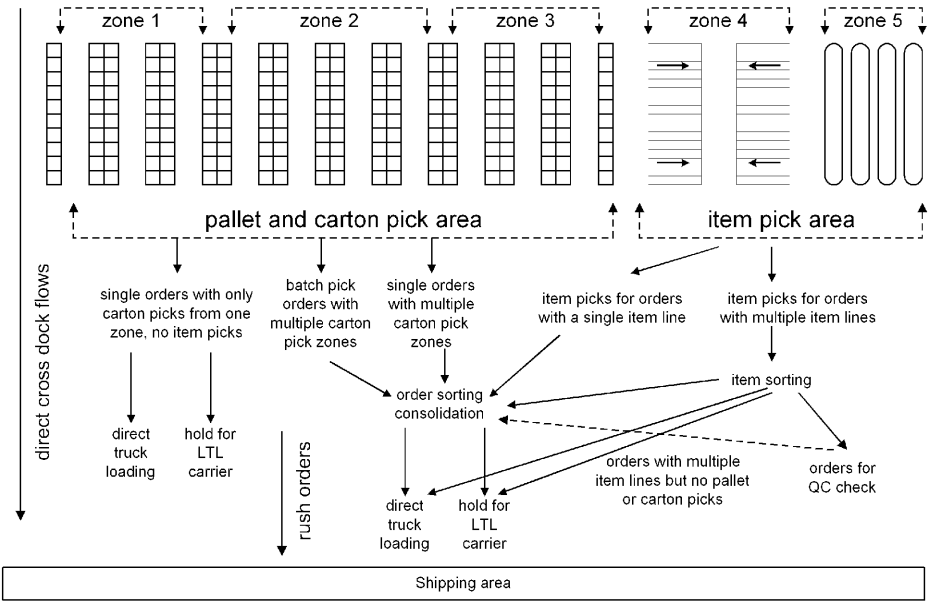

Figure 8 Example of Order-Consolidation Material Flows.

according to shape, such as pallets, nonconveyable items, conveyable items, totes containing multiple items, and so on pose the greatest challenge in this situation. Value-added operations such as labeling, pricing, and repackaging for retail display impose additional tracking and coordination needs. A strict control system, usually involving bar code, and sufficient floor space are necessary ingredients of an effective solution to such problems.

Figure 8 shows some possible flows for order consolidation where pallet and carton picks are sorted manually in a consolidation area and item picks are sorted in a separate area, perhaps with a conveyor.

5.6. Additional Factors

A number of human factor and hardware enhancements are available to increase the productivity and accuracy of order picking, including pick-to-light, voice-guided picking, and voice-recognition systems. Pick-to-light systems (see Figure 9) offer productivity increases of 30–100%, with corresponding error reductions of up to 80% (Sharp et al. 1997). Voice-guided picking allows the operator to use both hands to retrieve products without the need to refer to a paper pick document. Voice-recognition systems enable the picker to interact with the WMS without cumbersome key-entry

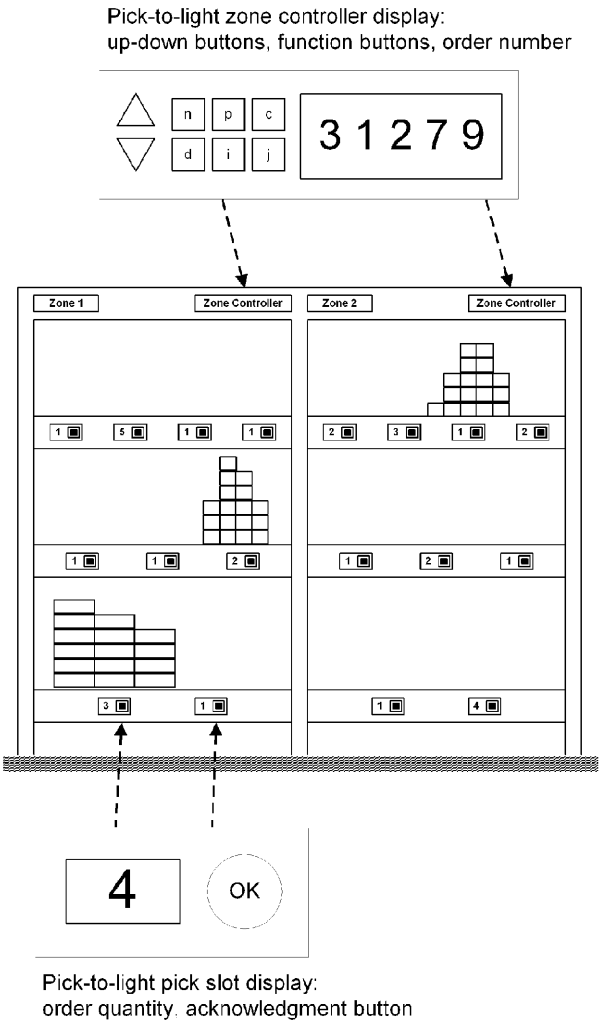

Figure 9 Pick-to-Light System.

devices. Radio-frequency (RF) systems are available to allow bar code readers to interact directly with the WMS from any point in the warehouse. Optical character recognition is available to eliminate the need for operators reading labels (Auto ID 2000). These systems must be integrated with the WMS and tested to ensure functionality.

Implementation should be done in gradual steps. One should not put in more functions and reports initially than can be managed. It may take one or two years for an organization to implement completely a new WMS. Employees should not receive more information than they need to perform their tasks. At the same time, managers should receive summary information on system performance, with details reported only for exceptions. Whenever possible, management reports should include utilization of labor hours by activity type and capacity utilization for equipment.

Linkages to supply chain management systems will occur if the parent organization owns other storage facilities or if the warehouse participates with other firms in a coordinated supply chain. In such cases it is recommended that the WMS vendor provide a unified software package for all relevant facilities. Each separate facility can be represented by one or more zones, and transportation links among them can be represented by transient states. The presence of an enterprise management system will also require linking.

6. CONCLUSION

Warehouse management consists of strategic, tactical, and operational factors. All of these require good information for making decisions: the selection of technologies for storage and retrieval, the assignment of incoming products to storage locations, the retrieval of products for customer orders, the assembly, packing, and loading of orders, the specification of a labor mix consisting of permanent and temporary employees, and the scheduling of labor and equipment. Modern equipment for storage, handling, data capture, and communication enable warehouse managers to have tight control over inventories and orders shipped while achieving short response times to customer orders. At the same time, there are available efficient strategies for storage, retrieval, and order assembly. To take advantage of such opportunities, the facility operator must have an effective, flexible warehouse management system. The trend today is toward an integrated, computer-based system that controls the flow of material and the actions of employees.

CHAPTER 82

Supply Chain Planning and Management*

DOUGLAS M. LAMBERT
The Ohio State University

EDWARD A. SIECIENSKI
JMA Supply Chain Management

*This chapter is adapted from D. M. Lambert and J. R. Stock, ''Supply Chain Management,'' in *Strategic Logistics Management,* 4th Ed., Irwin/McGraw-Hill, Burr Ridge, IL, 2001. Used with permission.

1.0 INTRODUCTION

In any society, industrialized or nonindustrialized, goods must be physically moved or transported between the place they are produced and the place they are consumed. Except in very primitive cultures, where each family meets its own household needs, the exchange process has become the cornerstone of economic activity. Exchange takes place when there is a discrepancy between the amount, type, and timing of goods available and the goods needed. If a number of individuals or organizations within the society have a surplus of goods that someone else needs, there is a basis for exchange. When many exchanges take place between producers and consumers, the alignment of firms that bring products or services to market has been called the supply chain, the demand chain, or the value chain. In this chapter we will use the term *supply chain* to represent this alignment of firms.

2. SUPPLY CHAIN MANAGEMENT VS. LOGISTICS

Supply chain management is a term that has grown significantly in use and popularity since the late 1980s, although considerable confusion exists about what it actually means. Many people use the term as a substitute or synonym for *logistics*. However, the definition of supply chain management used in this chapter is much broader than logistics.

2.1. Definition of Supply Chain Management

"Supply chain management is the integration of key business processes from end user through original suppliers that provides products, services, and information that add value for customers and other stakeholders" (Lambert et al. 1998). There are a number of important differences between this definition of supply chain management and the Council of Logistics Management* definition of logistics.

*The Council of Logistics Management is the leading-edge professional logistics organization, with a current membership of over 15,000.

First and foremost, supply chain management is the management of all key business processes, including customer relationship management, customer service management, demand management, order fulfillment, manufacturing flow management, procurement, product development and commercialization, and returns. Key requirements for successful implementation of supply chain management are executive support, leadership, commitment to change, and empowerment. These requirements will be described along with the key processes later in the chapter.

Thus, supply chain management (SCM) is a systems approach that is highly interactive and complex and requires simultaneous consideration of many trade-offs. As shown in Figure 1, SCM spans organizational boundaries, considering trade-offs both within and among organizations regarding where inventory should be held and where activities should be performed.

In addition to the processes involved in supply chain management, this figure illustrates the product flows and information linkages that must take place in a supply chain. Remember that product flows take place only after information flows are initiated.

Due to the dynamic nature of the business environment, management must monitor and evaluate the performance of the supply chain regularly and frequently. When performance goals are not met, management must evaluate possible supply chain alternatives and implement changes. SCM is particularly important in mature and declining markets, during periods of economic slowdown when market growth cannot conceal inefficient practices, and when product life cycles are extraordinarily short. It is also critical in new product/market development, when the organization is making decisions related to supply chain configuration.

2.2. Difference between Logistics and Supply Chain Management*

The term *supply chain management* (SCM) was originally introduced by consultants in the early 1980s (Oliver and Webber 1982) and has subsequently gained tremendous attention (La Londe 1998). Since 1989, academics have attempted to give structure to SCM (Stevens 1989; Towill et al. 1992; Ellram and Cooper 1993; Bechtel and Jayaram 1997).

Until recently, most practitioners (Davis 1993; Arntzen et al. 1995; Lee and Billington 1995; Camp and Colbert 1997), consultants (Scharlacken 1998; Tyndall et al. 1998; Copacino 1997), and

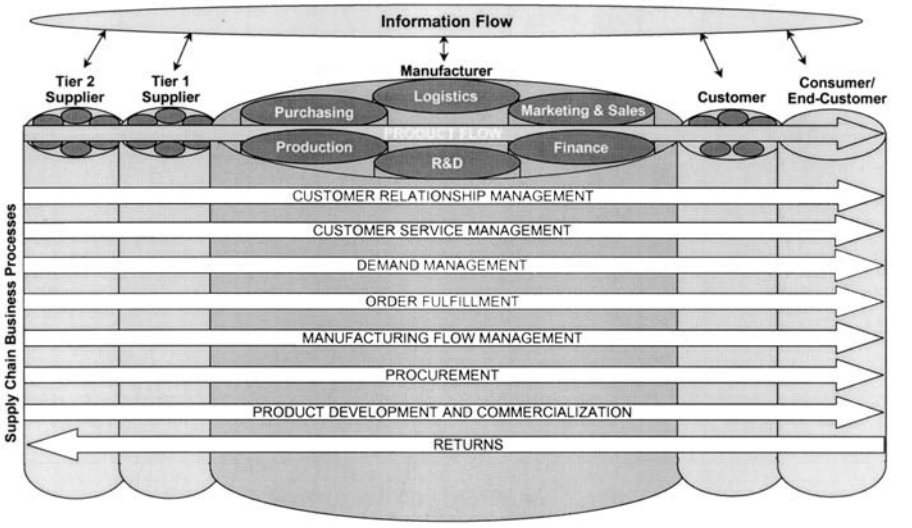

Figure 1 Supply Chain Management: Integrating and Managing Business Processes across the Supply Chain. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, ''Supply Chain Management: Implementation Issues and Research Opportunities,'' *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

*This section is taken from D. M. Lambert, M. C. Cooper and J. D. Pagh, ''Supply Chain Management: Implementation Issues and Research Opportunities,'' *International Journal of Logistics Management,* Vol. 9, 1998, pp. 2–5.

academics (Fisher 1997; Lee and Billington 1992; Handfield and Nichols 1999; Bowersox and Closs 1996) viewed SCM as not appreciably different from the contemporary understanding of logistics management. That is, SCM was viewed as logistics outside the firm to include customers and suppliers. However, in 1986, the Council of Logistics Management (CLM) defined logistics management as ''The process of planning, implementing, and controlling the efficient, cost-effective flow and storage of raw materials, in-process inventory, finished goods, and related information flow from point-of-origin to point-of-consumption for the purpose of conforming to customer requirements.''

Logistics as defined by the Council of Logistics Management always represented a supply chain orientation, ''from point of origin to point of consumption.'' Then why the confusion? Probably because logistics is a functional silo within companies and is also a bigger concept that deals with the management of material and information flows across the supply chain. This is similar to the confusion over marketing as a concept and marketing as a functional area. Thus the quote from the CEO: ''Marketing is too important to be left to the marketing department.'' Everybody in the company should have a customer focus. The marketing concept does not apply just to the marketing department. It is everybody's responsibility to focus on serving the customer's needs.

Executives in companies leading the drive to implement SCM visualize the necessity of integrating all key business operations across the supply chain (Giunipero and Brand 1996; Bowersox 1997a). This broader understanding of SCM is likewise the core message in the following statement by James E. Morehouse, Vice President of A.T. Kearney, management consultants. ''For companies to survive and prosper, they will need to operate their supply chains as extended enterprises with relationships which embrace business processes, from materials extraction to consumption.'' Thus, the understanding of SCM has been reconceptualized from integrating logistics across the supply chain to integrating and managing key business processes across the supply chain (Cooper et al. 1997b). Based on this emerging distinction between SCM and logistics, in 1998, CLM announced a modified definition of logistics. The modified definition explicitly declares CLM's position that logistics management is only a part of SCM: ''Logistics is that part of the supply chain process that plans, implements, and controls the efficient, effective flow and storage of goods, services, and related information from the point-of-origin to the point-of-consumption in order to meet customers' requirements'' (Council of Logistics Management 1998).

Managing the supply chain is a complicated task and even managing logistics from point of origin to point of consumption is a lot easier to write on a piece of paper than actually to do. Imagine the degree of complexity if you are actually going to manage all suppliers back to the point of origin and all products/services out to the point of consumption. It is probably easier to understand why executives would want to manage their supply chains to the point of consumption, because whoever has the relationship with the end user has the power in the supply chain. Intel has created a relationship with the end user by having computer manufacturers place an ''Intel chip inside'' label on their computers. This affects the computer manufacturer's ability to switch chip suppliers. But managing all tier 1 suppliers' networks to the point of origin is an enormous undertaking. Managing the entire supply chain is a very difficult and challenging task, as illustrated in Figure 2.

The early marketing channel researchers, such as Wroe Alderson and Louis P. Bucklin, conceptualized the key factors for why and how channels are created and structured (Alderson 1950; Cox and Alderson 1950; Bucklin 1966). From a supply chain standpoint, these researchers were basically on the right track, particularly in the areas of identifying who should be a member of the marketing channel, describing the need for channel coordination, and drawing actual marketing channels. However, for the last 30 years the channels researchers studied power and conflict with questionable results and ignored two critical issues. First, they did not build on the early contributions by including suppliers to the manufacturer, and thus neglected the importance of a total supply chain perspective. Second, they focused on marketing activities and flows across the channel and overlooked the need to integrate and manage multiple key processes across companies.

Unlike the marketing channels literature, a major weakness of the SCM literature to date is that the authors appear to assume that everyone knows who is a member of the supply chain. Little effort has been given to identifying specific supply chain members, key processes that require integration, or what management must do to successfully manage the supply chain. The SCM framework presented here encompasses the combination of three closely interrelated elements: the structure of the supply chain, the supply chain business processes, and the supply chain management components (see Figure 3). We believe that the combination of these three elements captures the essence of SCM.

The supply chain structure is the network of members and the links between members of the supply chain. Business processes are the activities that produce a specific output of value to the customer. The management components are the managerial variables by which the business processes are integrated and managed across the supply chain. In combination, the SCM definition and this new framework move the SCM philosophy to its next evolutionary stage.

The implementation of SCM involves identifying the supply chain members, with whom it is critical to link, what processes need to be linked with each of these key members, and what type/level of integration applies to each process link. The objective of SCM is to maximize competitiveness

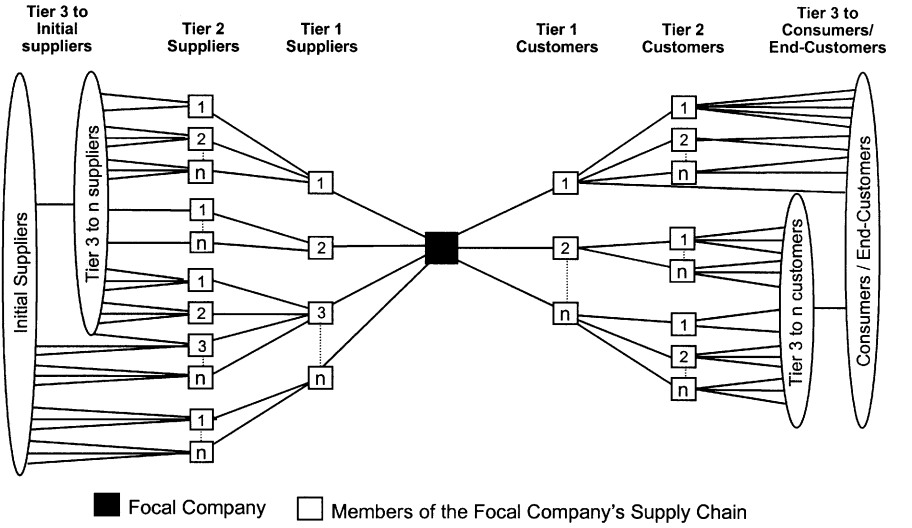

Figure 2 Supply Chain Network Structure. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, "Supply Chain Management: Implementation Issues and Research Opportunities," *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

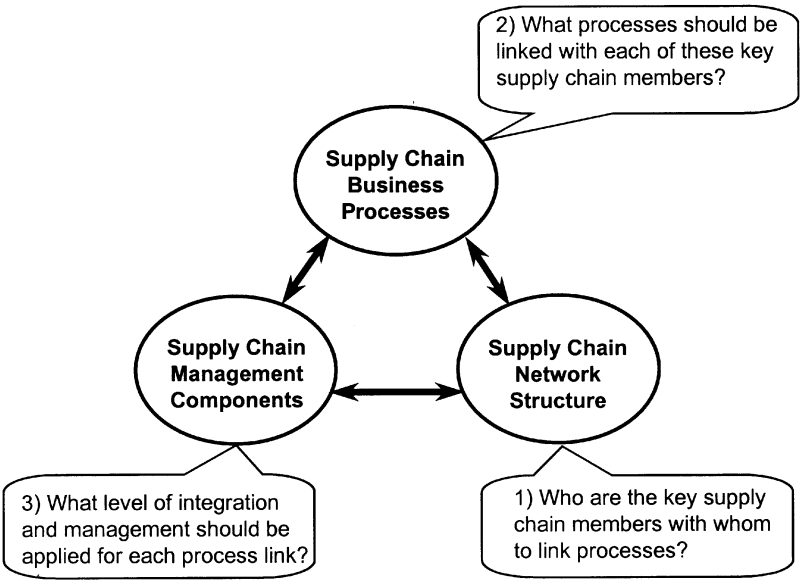

Figure 3 Supply Chain Management Framework: Elements and Key Decisions. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, "Supply Chain Management: Implementation Issues and Research Opportunities," *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

and profitability for the company as well as the whole supply chain network, including the end customer. Consequently, supply chain process integration and reengineering initiatives should be aimed at boosting total process efficiency and effectiveness across members of the supply chain.

3. CHANNEL STRUCTURE

The theory on channel structure described in the marketing literature provides a useful foundation for studying supply chain structure. According to this literature, channel structure may be viewed as a function of product life cycle, logistics systems, effective communication networks (Michman 1971; Ellram and Cooper 1990), product characteristics (Aspinwall 1958), and/or firm size (Weigand 1963). The most detailed theory of channel structure was developed by Bucklin (1966). He stated that the purpose of the channel is to provide consumers with the desired combination of its outputs (lot size, delivery time, and market decentralization) at minimal cost. Consumers determine channel structure by purchasing combinations of service outputs. The best channel has formed when no other group of institutions generates more profits or more consumer satisfaction per dollar of product cost. Bucklin concluded that functions will be shifted from one channel member to another in order to achieve the most efficient and effective channel structure.

Given a desired level of output by the consumer and competitive conditions, channel institutions will arrange their functional tasks in such a way as to minimize total channel costs. This shifting of specific functions may lead to the addition or deletion of channel members.

In deciding when and where to use channel intermediaries, the firm is really considering the make/buy or ''outsourcing'' decision. Does the organization need to develop the required skills and capabilities internally, or can it be done faster and more efficiently by using a third party?

3.1. Outsourcing Pieces of the Supply Chain

Approximately $40 billion of logistics services in the United States are being outsourced. (Piper Jaffray Equity Research 1999). And there are significant opportunities to outsource additional logistics services. Some examples of outsourcing services that are available include:

- A large pharmaceutical company outsources its worldwide distribution, providing on-site pharmacists at some centers to dispense high-value products.
- A third party handles the entire finished goods inventory for a large women's clothing company. When garments are purchased by a retailer, the distributor attaches the store's private label, refreshes the garment, packs it in the store's packaging, and ships to the retailer.
- A mail-order retailer is having FedEx handle not only their shipments, but also storage and management of the inventory and all aspects of distribution.
- In addition to handling store replenishment and delivery of product to consumers for a tool manufacturer, UPS now is going to handle the warehouse. If the retail store needs product, an order that reaches the distribution center by 9:00 p.m. will be at the store by the next morning (Richardson 1994).

Thus, outsourcing represents an opportunity that should be considered in supply chain design and evaluation of existing supply chains. In addition, the role and utility of the distributor are changing. In some cases, consolidation of suppliers and customers has reduced the value and functionality of distributors.

For example, Wal-Mart's large stores, which use direct distribution, replace small stores that may have used distributors. Similarly, advanced technology such as EDI trades information for inventory, reducing the need to hold inventory at distributors as well as at retailers (see Section 6.2). Better information technology and increased service offerings by carriers (such as cross-docking) also reduce the need for distributor's services (Copacino 1994).

3.2. Postponement and Speculation

Bucklin's theory of channel structure is based on the concepts of postponement and speculation (Bucklin 1965). Costs can be reduced by (1) postponing changes in the form and identity of a product to the last possible point in the marketing process and (2) postponing inventory location to the last possible point in time, since risk and uncertainty costs increase as the product becomes more differentiated. Postponement results in savings because it moves differentiation nearer to the time of purchase, when demand is more easily forecast. This reduces risk and uncertainty costs. Logistics costs are reduced by sorting products in large lots in relatively undifferentiated states. Third-party service providers can support postponement by mixing pallets for individual customers as orders are received, repackaging product to fit specific customer or country requirements, and performing final assembly or customization in the field.

Companies can use postponement to shift the risk of owning goods from one channel member to another. That is, a manufacturer may refuse to produce until it receives firm orders; a middleman

may postpone owning inventories by purchasing from sellers who offer faster delivery, purchasing on consignment, or purchasing only when a sale has been made; and consumers may postpone ownership by buying from retail outlets where the products are in stock.

An excellent example of postponement is the mixing of paint colors at the retail store. Rather than having to forecast the exact colors that consumers will want to buy, the retailer mixes paint in any color the consumer wishes to acquire at the time of purchase. Other examples include color panels in the front of built-in kitchen appliances that enable the same unit to be any one of a number of colors; the centralization of slow-selling products in one warehouse location; and the assembly of slow-moving items only after orders have been received.

Speculation is the opposite of postponement: that is, a channel institution assumes risk rather than shifting it. Speculation can reduce marketing costs through (1) the economies of large-scale production; (2) the placement of large orders, which reduces the costs of order processing and transportation; (3) the reduction of stockouts and their associated cost; and (4) the reduction of uncertainty. To reduce the need for speculative inventories, managers in many firms are exploring strategies of time-based competition (Handfield 1991; Rafuse 1995; Christopher and Peck 1997). By using time-based competition, management can reduce significantly the firm's time to manufacture products while reducing inventory, improving inventory turns, reducing cost of ownership, and improving customer satisfaction.

3.3. Time-to-Market Pressures

Speed can be used as a source of competitive advantage. This is true in virtually all market sectors: services, manufacturing, and retailing. Retailers have been leaders in the area of time-based competition, relying heavily on advanced computer systems involving bar coding and EDI to support quick response (this will be described further in Section 6.2). The use of such systems is growing among carriers. But computer systems are not enough to create speed-to-market; fundamental changes in operational relationships are required. This includes information sharing among suppliers, manufacturers, and retailers, including lead times, forecasts of sales, production, and purchase needs, shipping, new product plans, and payment information.

Some of the benefits of effective time-based management include:

- Enhanced customer value through better responsiveness
- Reduced inventory requirements due to shorter lead times
- Reduced cost-added/duplicate functions
- Improved quality/product freshness through reduced handling and lower inventories
- Improved competitive position
- Increased responsiveness to changing market needs
- Improved productivity

3.4. Other Issues Affecting Channel Structure

Additional factors that can influence channel structure include:

- Technological, cultural, physical, social, and political factors
- Physical factors such as geography, size of market, location of production centers, and concentration of population
- Local, state, and federal laws
- Social and behavioral variables

For example, social, cultural, political, and economic variables may support channels that are not necessarily as efficient or effective as they should be.

4. SUPPLY CHAIN NETWORK STRUCTURE*

One key element of managing the supply chain is to have an explicit knowledge and understanding of how the supply chain network structure is configured. The three primary structural aspects of a

*This section is taken from D. M. Lambert, M. C. Cooper and J. D. Pagh, ''Supply Chain Management: Implementation Issues and Research Opportunities,'' *International Journal of Logistics Management,* Vol. 9, 1998, pp. 5–9.

company's network structure are the members of the supply chain, the structural dimensions of the network, and the different types of process links across the supply chain. These three issues are all related to the first element: supply chain network structure, shown in Figure 3. Now each issue will be addressed.

4.1. Identifying Supply Chain Members

When determining the network structure, it is necessary to identify who the members of the supply chain are. Including all types of members may cause the total network to become highly complex, since it may explode in the number of members added from tier level to tier level (Cooper et al. 1997a). To integrate and manage all process links with all members across the supply chain would, in most cases, be counterproductive, if not impossible. The key is to sort out some basis for determining which members are critical to the success of the company and the supply chain and thus should be allocated managerial attention and resources.

Marketing channels researchers identified members of the channel based on who takes part in the various marketing flows, including product, title, payment, information, and promotion flows (Stern et al. 1996). Each flow included relevant members, such as banks for the payment flow and advertising agencies for the promotion flow. The channels researchers sought to include all members taking part in the marketing flows, regardless of how much impact each member had on the value provided to the end customer or other stakeholders.

The members of a supply chain include all companies/organizations with whom the focal company interacts directly or indirectly through its suppliers or customers, from point of origin to point of consumption. However, to make a very complex network more manageable, it seems appropriate to distinguish between primary and supporting members. Primary members of a supply chain are defined to be all those autonomous companies or strategic business units who actually perform operational and/or managerial activities in the business processes designed to produce a specific output for a particular customer or market.

In contrast, the supporting members of a supply chain are companies that simply provide resources, knowledge, utilities, or assets for the primary members of the supply chain.

For example, supporting companies include those that lease trucks to the manufacturer, banks that lend money to a retailer, the owner of the building that provides warehouse space, or companies that supply production equipment or print marketing brochures or provide temporary secretarial assistance. These supply chain members support the primary members now and in the future. Resource, knowledge, utility, or asset providers are important, if not vital, contributors to a company and the supply chain, but they do not directly participate in or perform activities in the value-adding processes of transforming inputs to outputs for the end customer.

The same company can perform both primary and supportive activities. Likewise, the same company can perform primary activities related to one process and supportive activities related to another process. An example from one of the case studies is an OEM that buys some critical and complex production equipment from a supplier. When the OEM develops new products, it works very closely with the equipment supplier, and thus the supplier is a primary member of the OEM's product-development process. However, when looking at the manufacturing flow management process, the supplier is a supportive and not a primary member, since supplying the equipment does not in itself add value to the output of the processes, even though the equipment does add value.

It should be noted that the distinction between primary and supporting chain members is not obvious in all cases. Nevertheless, this distinction provides a reasonable managerial simplification and yet captures the essential aspects of who should be considered key members of the supply chain. The approach for differentiating between types of members is to some extent similar to how Porter distinguished between value-adding and support activities in his value chain framework (Porter 1984).

The definitions of primary and supporting members make it possible to define the point of origin and the point of consumption of the supply chain. The point of origin of the supply chain occurs where no primary suppliers exist. All suppliers to the point of origin members are solely supporting members. The point of consumption is where no further value is added and the product and/or service is consumed.

4.2. The Structural Dimensions of the Network

Three structural dimensions of the network are essential when describing, analyzing, and managing the supply chain. These dimensions are the horizontal structure, the vertical structure, and the horizontal position of the focal company within the end points of the supply chain.

The horizontal structure refers to the number of tiers across the supply chain. The supply chain may be long, with numerous tiers, or short, with few tiers. The vertical structure refers to the number of suppliers/customers represented within each tier. A company can have a narrow vertical structure, with few companies at each tier level, or a wide vertical structure with many suppliers and/or

customers at each tier level. The third structural dimension is the company's horizontal position within the supply chain. A company can be positioned at or near the initial source of supply, at or near to the ultimate customer, or somewhere between these end points of the supply chain.

Different combinations of these structural variables are possible. For example, a narrow and long network structure on the supplier side can be combined with a wide and short structure on the customer side. Increasing or reducing the number of suppliers and/or customers will affect the structure of the supply chain. As companies move from multiple- to single-source suppliers, the supply chain will become narrower. Outsourcing logistics, manufacturing, marketing, or product-development activities is another example of decision making that likely will change the supply chain structure. It may increase the length and width of the supply chain and likewise influence the horizontal position of the focal company in the supply chain network.

Supply chains that burst to many tier 1 customers/suppliers will strain corporate resources and limit the number of process links the focal company can integrate and closely manage beyond tier 1. In general, managers in companies with immediately wide vertical structures actively manage only a few tier 2 customers or suppliers. Some companies have transferred servicing small customers to distributors, thus moving the small customers farther down in the supply chain from the focal company. This principle, known as functional spin-off, is described in the channels literature (Stern et al. 1996) and can be applied to the focal company's network of suppliers as well as to its customers.

Supply chains look different from each company's perspective because management of each company sees its firm as the focal company and views membership and network structure differently. Thus, the perceived supply chain network structure is arbitrary. However, because each firm is a member of the other's supply chain, it is important for management of each firm to understand its interrelated roles and perspectives. This is because the integration and management of business processes across company boundaries will be successful only if it makes sense from each company's perspective (Cooper et al. 1997b).

4.3. Types of Business Process Links

Integrating and managing all business process links throughout the entire supply chain is likely not appropriate. Since the drivers for integration are situational and different from process link to process link, the levels of integration will/should likewise vary from link to link and over time. Thus, some links are more critical than others (Håkansson and Snehota 1995). As a consequence, the task of allocating scarce resources among the different business process links across the supply chain becomes crucial. Four fundamentally different types of business process links can be identified between members of a supply chain (Lambert et al. 1998): managed business process links, monitored business process links, not-managed business process links, and nonmember business process links.

Managed process links. Managed process links are links that the focal company finds important to integrate and manage. This might be in collaboration with other member companies of the supply chain. In the supply chain drawn in Figure 4, the managed process links are indicated by the thickest solid lines. The focal company will integrate and manage process links with tier 1 customers and suppliers. As indicated by the remaining thick solid lines in Figure 4, the focal company is actively involved in the management of a number of other process links beyond tier 1.

Monitored process links. Monitored process links are not as critical to the focal company. However, it is important to the focal company that these process links be integrated and managed appropriately between the other member companies. Thus, the focal company, as frequently as necessary, simply monitors or audits how the process link is integrated and managed. The thick dashed lines in Figure 4 indicate the monitored process links.

Not-managed process links. Not-managed process links are links that the focal company is not actively involved in and are not critical enough to use resources for monitoring. In other words, the focal company fully trusts the other members to manage the process links appropriately, or because of limited resources leaves it up to them. The thin solid lines in Figure 4 indicate the not-managed process links. For example, a manufacturer has a number of suppliers for cardboard shipping cartons. Usually the manufacturer will not choose to integrate and manage the links beyond the cardboard supplier all the way back to the growing of the trees. The manufacturer wants certainty of supply, but it may not be necessary to integrate and manage the links beyond the cardboard supplier.

The three alternatives for integrating and managing links are illustrated in Figure 5. Company A may chose to integrate with and actively manage link 2 (alternative 1). Or company A could chose not to integrate but only to monitor the procedures of companies B and C for integrating and managing link 2 (alternative 2). Both alternatives 1 and 2 necessitate some level of resource allocation from company A. Finally, company A can choose not to be involved and leave the integration and management of link 2 up to companies B and C (alternative 3).

Nonmember process links. Managers understand that their supply chains are influenced by decisions made in other connected supply chains. For example, a supplier to the focal company is also a supplier to the chief competitor. Such a supply chain structure may have implications for the

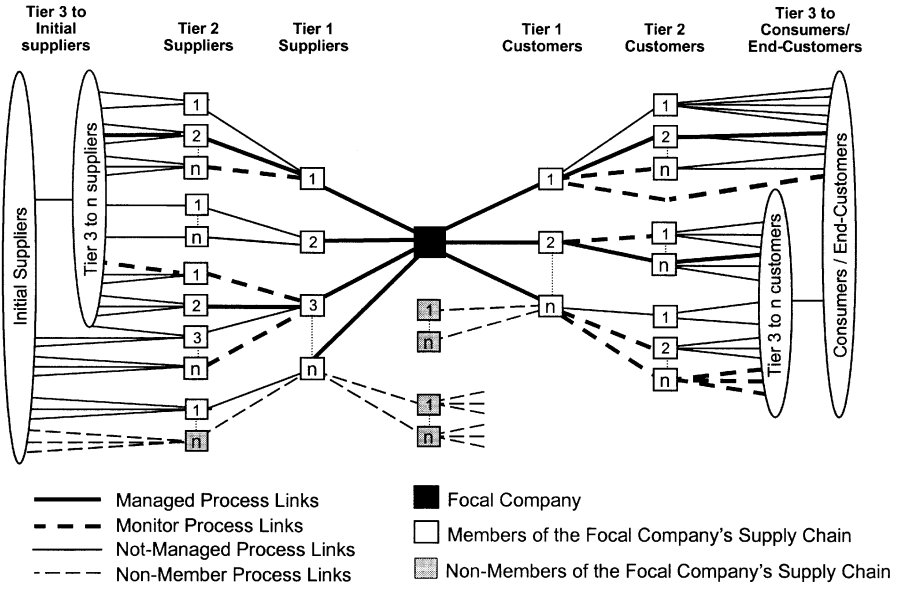

Figure 4 Types of Inter-company Business Process Links. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, "Supply Chain Management: Implementation Issues and Research Opportunities," *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

supplier's allocation of manpower to the focal company's product-development process, availability of products in times of shortage, and/or protection of confidentiality of information. This leads us to identify a fourth type of business link, nonmember process links. Nonmember process links are process links between members of the focal company's supply chain and nonmembers of the supply chain. Nonmember links are not considered as links of the focal company's supply chain structure, but they can and often will affect the performance of the focal company and its supply chain. The thin dashed lines in Figure 4 illustrate examples of nonmember process links.

Based on the process links just described, there is variation in how closely companies integrate and manage links farther away from the first tier. In some cases, companies work through or around

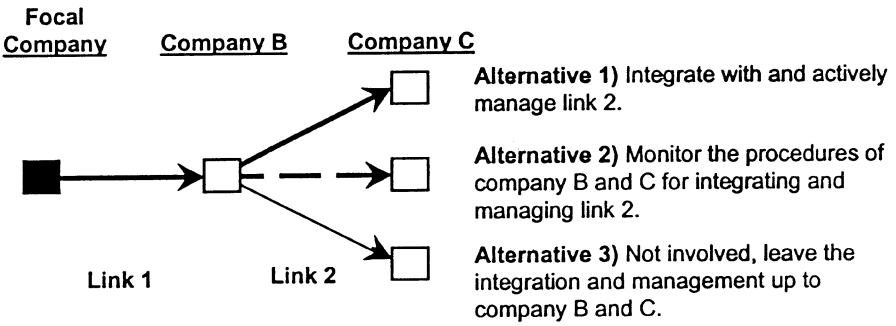

Figure 5 The Focal Company's Alternatives for Involvement with Link 2. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, "Supply Chain Management: Implementation Issues and Research Opportunities," *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

other members/links in order to achieve specific supply chain objectives, such as product availability, improved quality, and reduced overall supply chain costs. For example, a tomato ketchup manufacturer in New Zealand conducts research on tomatoes in order to develop plants that provide larger tomatoes with fewer seeds. Their contracted growers are provided with young plants in order to ensure the quality of the output. Since the growers tend to be small, the manufacturer negotiates contracts with suppliers of equipment and supplies such as fertilizer and chemicals. The farmers are encouraged to purchase their raw materials and machinery using the contract rates. This results in higher-quality raw materials and lower prices without sacrificing the margins and financial strength of the growers.

There are several examples of companies who, in times of shortage, discovered that it was important to manage beyond tier 1 suppliers for critical times. One example involves a material used in the manufacture of semiconductors. The manufacturer had six tier 1 suppliers from which to purchase. However, when shortages occurred, it became apparent that all six tier 1 suppliers purchased from the same tier 2 supplier. It turned out that the most critical relationship was with the tier 2 supplier.

4.4. Supply Chain Mapping Considerations

The mapping of the supply chain for a focal company is an important step in understanding the interrelationships that impact the success of the business. Several important points need to be kept in mind before proceeding with the mapping of the supply chain network:

- Supply chain mapping should begin from the right side (customer side) of the network, as shown in Figure 2. This will bring the correct focus to why the map is being constructed.
- Once the customer segments are identified, each segment should be evaluated in terms of its importance to the success of the focal company. Factors such as sales, profit, contribution margin, and competitive threat can be used to select the priority that each customer or customer segment has in the supply chain.
- Rather than proceeding with comprehensive mapping from right to left (customers to tier *n* Suppliers), it is suggested that the mapping proceed for one or two of the highest-priority customer segments. This process will limit the complexity that can quickly develop by building a complete map that may become weighed down by trivial nodes and a need for vast amounts of information.
- At this point, existing processes and performance can be included in the supply chain map.
- Lastly, performance goals should be established for each customer segment. With performance goals in place, the development of revised intermediate performance metrics and adjusted business processes that support the new goals can proceed.

5. SUPPLY CHAIN BUSINESS PROCESSES*

Successful supply chain management requires a change from managing individual functions to integrating activities into key supply chain processes. Traditionally, both upstream and downstream portions of the supply chain have interacted as disconnected entitles receiving sporadic flows of information over time.

The purchasing department placed orders as requirements became necessary, and marketing, responding to customer demand, interfaced with various distributors and retailers and attempted to satisfy this demand. Orders were periodically given to suppliers and their suppliers, who had no visibility of demand at the point of sale or use. Satisfying the customer often required expedited operations throughout the supply chain as member firms reacted to unexpected changes in demand.

Operating an integrated supply chain requires continuous information flows, which in turn help to create the best product flows. The customer remains the primary focus of the process. However, improved linkages with suppliers are necessary because controlling uncertainty in customer demand, manufacturing processes, and supplier performance is critical to effective supply chain management (SCM). Achieving a good customer-focused system requires processing information both accurately and in a timely fashion because quick-response systems require frequent changes in response to fluctuations in customer demand.

In many major corporations, such as 3M, management has reached the conclusion that optimizing the product flows cannot be accomplished without implementing a process approach to the business. The key supply chain processes are:

*This material is adapted from D. M. Lambert, L. C. Guinipero, and G. Ridenhower, ''Supply Chain Management: A Key to Achieving Business Excellence in the 21st Century,'' manuscript. All rights reserved.

- Customer relationship management
- Customer service management
- Demand management
- Order fulfillment
- Manufacturing flow management
- Procurement
- Product development and commercialization
- Returns

These processes were identified in Figure 1. While the specific processes identified by individual firms may vary somewhat from those above, supply chain management must consider five fundamental processes: selling, customer order fulfillment, manufacturing flow, procurement, and product development.

Of course, performance metrics must be changed to reflect process performance across the supply chain, and rewards and incentives must be aligned to these metrics in order to effect change. Each of the eight processes will now be described.

5.1. Customer Relationship Management Process

The first step towards integrated SCM is to identify key customer or customer groups that the organization targets as critical to its business mission. The corporate business plan is the starting point for this analysis. Customer service teams develop and implement partnering programs with key customers. Product and/or service agreements specifying the levels of performance are established with these key customer groups. In many cases, the product/service agreements will be tailored to meet the needs of key individual customers.

New customer interfaces lead to improved communications and better predictions of customer demand, which leads to improved service for customers. Customer service teams work with customers to identify further and eliminate sources of demand variability. Performance evaluations are undertaken to analyze the levels of service provided to customers as well as customer profitability.

5.2. Customer Service Management Process

Customer service provides the single source of customer information. It becomes the key point of contact for administering the product/service agreement. Customer service provides the customer with real-time information on promised shipping dates and product availability through interface with the organizations' production and distribution operations.

Managing customer service in an SCM environment requires an online, real-time system to provide product and pricing information to support customer inquiries and facilitate order placement. After-sales service is also a requirement. Finally, the technical customer service group must be able to assist the customer efficiently with product applications and recommendations.

5.3. Demand Management Process

Hewlett-Packard's experience with SCM indicates that inventory is either essential or variability driven (Davis 1993). Essential inventory includes work-in-process in factories and products in the pipeline moving from location to location. Time-based and periodic-review systems lead to certain amounts of incoming inventory stock. Variability stock is present due to variance in process, supply, and demand. Customer demand is by far the largest source of variability and stems from irregular order patterns. Given this variability in customer ordering, demand management is a key to an effective SCM process.

The demand management process must balance the customer's requirements with the firm's supply capabilities. Part of managing demand involves attempting to determine what and when customers will purchase. A good demand management system uses point-of-sale and key customer data to reduce uncertainty and provide efficient flows throughout the supply chain.

Marketing requirements and production plans should be coordinated on an enterprise-wide basis. Thus, multiple sourcing and routing options are considered at the time of order receipt, which allows market requirements and production plans to be coordinated on an organization-wide basis. In very advanced SCM systems, customer demand and production rates are synchronized to manage inventories globally.

5.4. Customer Order-Fulfillment Process

The key to effective SCM is meeting or exceeding customer need dates. It is important to achieve high order-fill rates either on a line item or order basis. Performing the order-fulfillment process effectively requires integration of the firm's manufacturing, distribution, and transportation plans. As

previously discussed, partnerships should be developed with key supply chain members and carriers to meet customer requirements and reduce total delivered cost to customer. The objective is to develop a seamless process from the supplier to the organization and then on to its various customer segments.

With the growth of Internet-based businesses that are almost virtual in nature (i.e., no manufacturing or fulfillment assets), the process is carried out by contracted specialists. This implies that information integration becomes the key interaction between the supply chain entities.

5.5. Manufacturing Flow Management Process

The manufacturing process in make-to-stock firms traditionally produced and supplied product to the distribution channel based on historical forecasts. Products were pushed through the plant to meet a schedule. Often the wrong mix of products was produced, resulting in unneeded inventories, excessive inventory carrying costs, mark-downs, and transshipments of product.

With SCM, product is pulled through the plant based on customer needs. Manufacturing processes must be flexible to respond to market changes. This requires the flexibility to perform rapid changeover to accommodate mass customization. Orders are processed on a just-in-time basis in minimum lot sizes. Production priorities are driven by required delivery dates.

At 3M, manufacturing planners work with customer planners to develop strategies for each customer segment. Changes in the manufacturing flow process lead to shorter cycle times, meaning improved responsiveness to customers.

5.6. Procurement Process

Strategic plans are developed with suppliers to support the manufacturing flow management process and the development of new products. Suppliers are strategically categorized based on several dimensions, such as their contribution and criticality to the organization. In companies where operations extend world-wide, sourcing should be managed from corporate on a global basis.

Long-term partnerships are developed with a small core group of suppliers. The desired outcome is a win–win relationship where both parties benefit. This is a change from the traditional bid-and-buy system to involving a key supplier early in the design cycle, which can lead to dramatic reduction in product-development cycle times. Having early supplier input reduces time by getting the required coordination between engineering, purchasing, and the supplier prior to design finalization.

The purchasing function develops rapid communication mechanisms such as EDI and Internet linkages to transfer requirements quickly. These rapid communication tools provide a means to reduce time and cost spent on the transaction portion of the purchase. Purchasers can focus their efforts on managing suppliers as opposed to placing orders and expediting.

5.7. Product Development and Commercialization

If new products are the lifeblood of a corporation, then product development is the lifeblood of a company's new products. Customers and suppliers must be integrated into the product-development process in order to reduce time to market. As product life cycles shorten, the right products must be developed and successfully launched in ever-shorter time frames in order to remain competitive.

Managers of the product-development and commercialization process must:

- Coordinate with customer relationship management to identify customer articulated and unarticulated needs
- Select materials and suppliers in conjunction with procurement
- Develop production technology in manufacturing flow to assess manufacturability and integration into the best supply chain flow for the product/market combination

5.8. Returns Process

Managing the returns channel as a business process offers the same opportunity to achieve a sustainable competitive advantage as managing the supply chain from an outbound perspective (Clendenin 1997). Effective process management of the returns channel enables identification of productivity-improvement opportunities and breakthrough projects.

At Xerox, returns are managed in four categories: equipment, parts, supplies, and competitive trade-ins. ''Return to available'' is a velocity measure of the cycle time required to return an asset to a useful status. This metric is particularly important for those products where customers are given an immediate replacement in the case of product failure. Also, equipment destined for scrap and waste from manufacturing plants is measured in terms of the time until cash is received.

5.9. SCM Process Summary

Focusing efforts on these key business processes, which extend from the end users to original suppliers, provides the foundation for a supply chain management philosophy. The goals or outcomes of these processes are to:

- Develop customer-focused teams that provide mutually beneficial product and service agreements to strategically significant customers
- Provide a point of contact for all customers that efficiently handles their inquiries
- Continuously gather, compile, and update customer demand to match requirements with supply
- Develop flexible manufacturing systems that respond quickly to changing market conditions
- Manage supplier partnerships that allow for quick response and continuous improvement
- Fill 100% of customer orders accurately and on time
- Minimize the return to available cycle time

A responsive, flexible integrated supply chain can accomplish these objectives. Because as previously mentioned, these processes cut across business functions, it is important to examine or reengineer each key process using a systematic approach.

6. BUSINESS PROCESS CHAINS*

Thousands of activities are performed and coordinated within a company, and every company is by nature in some way involved in supply chain relationships with other companies (Bowersox 1997b; Stigler 1951; Coase 1937). When two companies build a relationship, certain of their internal activities will be linked and managed between the two companies (Håkansson and Snehota 1995). Since both companies have linked some internal activities with other members of their supply chain, a link between two companies is thus a link in what might be conceived as a supply chain network. For example, the internal activities of a manufacturer are linked with and can affect the internal activities of a distributor, which in turn are linked with and can have an effect on the internal activities of a retailer. Ultimately, the internal activities of the retailer are linked with and can affect the activities of the end customer.

6.1. Linking Members of the Supply Chain

Håkansson and Snehota (1995) stress that ''the structure of activities within and between companies is a critical cornerstone of creating unique and superior supply chain performance.'' Executives in leading companies believe that competitiveness and profitability can increase if internal key activities and business processes are linked and managed across multiple companies. Thus, ''successful supply chain management requires a change from managing individual functions to integrating activities into key supply chain business processes'' (Lambert et al. 1997).

Companies in the same supply chain may have different activity structures. Some companies emphasize a functional structure, some a process structure, and others a combined structure of processes and functions. Companies with processes often have different numbers of processes consisting of different activities and links between activities. Further, different names are used for similar processes and similar names for different processes. This lack of intercompany consistency is a cause of significant friction and inefficiencies in supply chains. At least with functional silos, there is generally an understanding of what functions like marketing, manufacturing, and accounting/finance represent. If each firm identifies its own set of processes, how do we communicate and link these processes across firms? A simplified illustration of such a disconnected supply chain is shown in Figure 6.

A process can be viewed as a structure of activities designed for action with a focus on end customers and on the dynamic management of flows involving products, information, cash, knowledge, and/or ideas.

In an exploratory study involving 30 successful supply chain redesign practitioners, Hewitt found that companies identified between 9 and 24 internal business processes. The two most commonly identifiable processes were order fulfillment and product development (Hewitt 1994).

A prerequisite for successful SCM is to coordinate activities within the firm. One way to do this is to identify the key business processes and manage them using cross-functional teams. In some cases the internal business processes have been extended to suppliers and managed to some extent between the two firms involved. This may imply that when a leadership role is taken, a firm's internal business processes can become the supply chain business processes. The obvious advantage when this is possible is that each member of the band is playing the same tune.

The number of business processes that it is critical and/or beneficial to integrate and manage between companies will likely vary. In some cases it may be appropriate to link just one key process, and in other cases it may be appropriate to link multiple or all key business processes. However, in

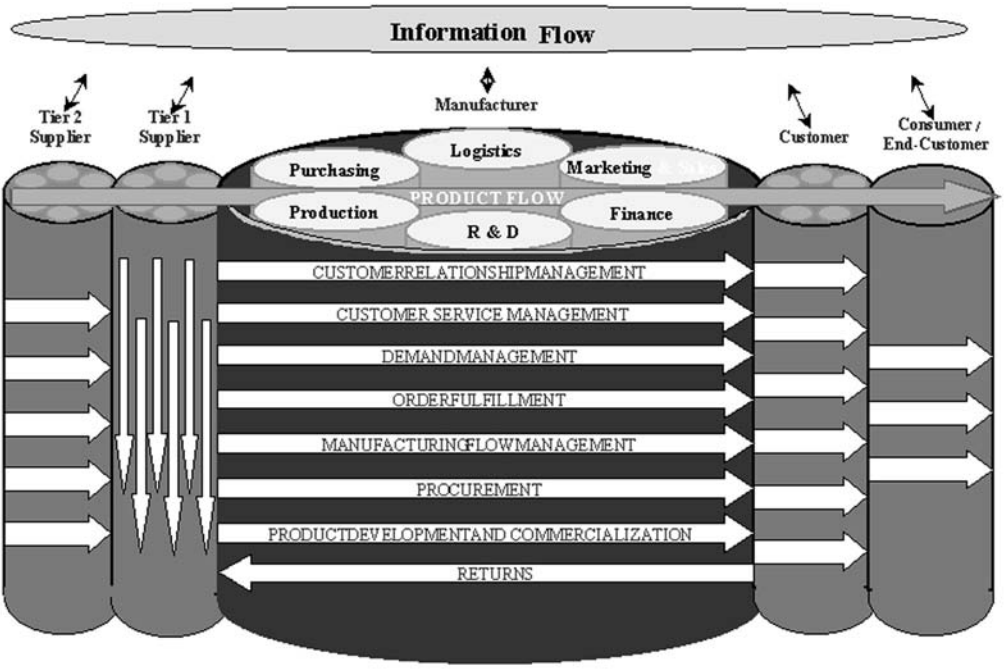

Figure 6 Supply Chain Management: The Disconnects. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, ''Supply Chain Management: Implementation Issues and Research Opportunities,'' *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

each specific case it is important that executives thoroughly analyze and discuss which key business processes to integrate and manage. The major components for integrating and managing a supply chain network are addressed next.

6.2. Information Flow Enablers

Process integration between members of the supply chain is dependent on the timely flow of the information that is identified as critical in the process mapping. Information can be exchanged in many forms, such as a telephone call or a paper report. In today's world of time-based competition, information exchange is normally based on computer-to-computer interaction. For many years, electronic data interchange (EDI), was the most common vehicle for exchanging information between computer systems, primarily between different companies. EDI is simply an agreed-to standardized format for a specific type of business transaction. Several organizations, such as the American National Standards Institute (ANSI), were instrumental in developing these standards. The standards are flexible, which is both a strength and a weakness. Specific details need to be worked out between the supply chain members for each type of transaction (e.g., purchase order or transportation information). This specificity adds cost for systems development as the number of entities is increased. The transmission of EDI information is usually facilitated by a value-added network (VAN) company that acts as an intermediary between the firms.

EDI is still used in many industries. The Internet has also become a transmission medium for transactions; however, newer methods are quickly becoming available for internet data communication. The most promising of these is extensible markup language (XML). The Internet is rapidly becoming the medium of choice for business-to-business e-commerce, and XML is becoming the language of this communication. The flexible structure of the language will allow for more trading partners to establish Internet links economically. At this time, the development of XML is moving so quickly that a good single reference for the reader is available on the Internet at www.xml.com. This source will provide the reader with references that will address the most timely status of XML specification and application.

6.3. Software Packages

Computer software is available for analysis, planning, and operation of various aspects of the supply chain. Since this Handbook will serve as a reference for several years before the next edition, it is not reasonable to mention specific software packages. However, the Council of Logistics Management provides an annual review of commercially available software. This catalog can serve as an important resource for finding potential software tools (Anderson Consulting 1999). Additional information regarding the Council of Logistics Management can be found at its website, www.clm1.org.

7. THE MANAGEMENT COMPONENTS OF SUPPLY CHAIN MANAGEMENT

The SCM management components are the third element of the SCM framework (see Figure 3). An essential underlying premise of the SCM framework is that certain management components are common across all business processes and members of the supply chain (Cooper et al. 1997b). We believe these common management components to be critical and fundamental for successful SCM because they essentially represent and determine how each process link is integrated and managed. The level of integration and management of a business process link is a function of the number and level, ranging from low to high, of components added to the link (Lambert et al. 1996a, b; Cooper et al. 1997a). Consequently, adding more management components or increasing the level of each component can increase the level of integration of the business process link.

The literature on SCM, business process reengineering, and buyer–supplier relationships suggests numerous possible components that must receive managerial attention when managing supply relationships (Cooper et al. 1997b; Lambert, et al 1996a, b; Olsen and Ellram 1997; Turnbull 1990). Each component can have several subcomponents, whose importance can vary depending on the process being managed. But the primary components are planning and control methods; work flow/activity structure; organization structure; communication and information flow facility structure; product flow facility structure; management methods; power and leadership structure; risk and reward structure; and culture and attitude. Each component is briefly described next.

7.1. Planning and Control Methods

Planning and control of operations are keys to moving an organization or supply chain in a desired direction. The extent of joint planning is expected to bear heavily on the success of the supply chain. Different components may be emphasized at different times during the life of the supply chain, but planning transcends the phases (Cooper and Ellram 1993). The control aspects can be operationalized as the best performance metrics for measuring supply chain success.

7.2. Work Flow/Activity Structure

The work flow/activity indicates how the firm performs its tasks and activities. The level of integration of processes across the supply chain would be a measure of organizational structure. All but one of the literature sources examined cites work structure as an important component.

7.3. Organization Structure

Organizational structure can refer to the individual firm and the supply chain. The use of cross-functional teams would suggest more of a process approach. When these teams cross-organizational boundaries, such as in-plant supplier personnel, the supply chain should be more integrated.

7.4. Communication and Information Flow Facility Structure

The information flow facility structure is key. The kind of information passed among supply chain members and the frequency of information updating has a strong influence on the efficiency of the supply chain. This may well be the first component integrated across part or all of the supply chain.

7.5. Product Flow Facility Structure

Product flow facility structure refers to the network structure for sourcing, manufacturing, and distribution across the supply chain. With reductions in inventory, fewer warehouses would be needed. Inventory is necessary in the system, but some supply chain members may keep a disproportionate amount of inventory. Since it is less expensive to have unfinished or semifinished goods in inventory than finished goods, upstream members may bear more of this burden. Rationalizing the supply chain network has implications for all members.

Product structure issues include how coordinated new product development is across the supply chain and the product portfolio. Lack of coordination in new product development can lead to inefficiencies of production, but there is also the risk of giving away corporate competence. The com-

plexity of the product will likely affect the number of suppliers for the different components and the challenge of integrating the supply chain.

7.6. Management Methods

Management methods include the corporate philosophy and management techniques. It is very difficult to integrate a top-down organization structure with a bottom-up structure. The level of management involvement in day-to-day operations can differ across supply chain members.

7.7. Power and Leadership Structure

The power and leadership structure across the supply chain will affect its form. One strong leader will drive the direction of the supply chain. In most supply chains studied to date, there are one or two strong leaders among the firms. The exercise of power, or lack of it, can affect the level of commitment of other supply chain members. Forced participation will encourage exit behavior, given the opportunity (Macneil 1980; Williamson 1975).

7.8. Risk and Reward Sharing

The anticipation of sharing of risks and rewards across the supply chain affects the long-term commitment of its members. The recent fire at a Toyota supplier demonstrated Toyota's commitment to its suppliers and the assistance from other members of the chain.

7.9. Culture and Attitude

The importance of corporate culture and its compatibility across supply chain members cannot be underestimated. Meshing cultures and individuals' attitudes is time consuming but is necessary at some level for the supply chain to perform as a coordinated network. Aspects of culture include how employees are valued and incorporated into the management of the firm.

Figure 7 illustrates how the management components can be divided into two groups, to point out some basic differences. The first group is the physical and technical group, which includes the most visible, tangible, measurable, and easy-to-change components. Much of the literature on change management (Jaffe and Scott 1998; Andrews and Stalick 1994; Hammer 1990; Hammer and Champy

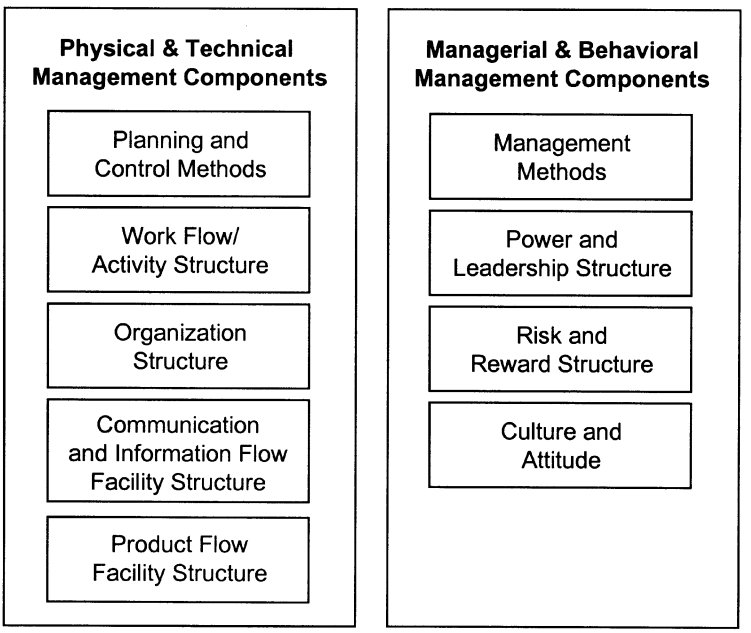

Figure 7 Supply Chain Management: Fundamental Management Components. (From D. M. Lambert, M. C. Cooper, and J. D. Pagh, "Supply Chain Management: Implementation Issues and Research Opportunities," *International Journal of Logistics Management,* Vol. 9, No. 2, 1998, pp. 1–19. Reprinted with permission)

1993; Towers 1994) shows that if this group of management components is the only focus of managerial attention, managing the supply chain will most likely be doomed to fail.

The second group is composed of the managerial and behavioral components. These components are less tangible and visible and are often difficult to assess and alter. The managerial and behavioral components define the organizational behavior and influence how the physical and technical management components can be implemented. If the managerial and behavioral components are not aligned to drive and reinforce an organizational behavior supportive of the supply chain objectives and operations, the supply chain will likely be less competitive and profitable. If one or more components in the physical and technical group are changed, management components in the managerial and behavioral group likewise may have to be readjusted. Consequently, the groundwork for successful SCM is established by understanding each of these management components and their interdependence. Hewitt states that true intra- and intercompany business process management, or redesign, is likely to be successful only if it is recognized as a multicomponent change process, simultaneously and explicitly addressing all SCM components (Hewitt 1994).

The physical and technical components are best understood and applied/managed the farthest up and down the supply chain. For example, in one case, the focal company had integrated its demand management process across four links by applying the following components: planning and control methods, work flow/activity structure, communication and information flow facility structure, and product flow facility structure. The managerial and behavioral management components are, in general, less well understood, and more difficulties are encountered in their implementation.

8. SUPPLY CHAIN DESIGN

Even though leading-edge firms are doing more planning of their supply chains, evidence suggests that the majority of supply chains were not designed but developed over time. For example, companies like Hewlett-Packard (Lee and Billington 1992; Davis 1993) and Digital Equipment (Arntzen et al. 1995) plan new channels/supply chains and use supply chain management strategies to modify existing networks. However, these examples appear to be the exception rather than the rule.

Current practice reveals a lack of planning by most firms. Better management of supply chains can create many benefits. For example, in many cases not all supply chain alternatives are known when structural arrangements are initially negotiated; these decisions may later prove to be less than optimal. Identifying suboptimal supply chain arrangements and making structural changes will lead to increased profitability.

In addition, unanticipated changes in the environment may make it necessary to reconsider the supply chain and reevaluate partnership arrangements. Environmental factors may include changes in end-consumer needs, markets, products and product lines, the competitive situation, the economic environment, and government regulation and incentives.

Supply chain strategy must be aligned with overall corporate strategy. Supply chain performance goals must be stated in operational terms, such as projected market coverage, sales and service support, sales volume, profitability, inventory turns, cash-to-cash cycle times, and return on investment. The supply chain strategy includes decisions regarding intensity of distribution, use of direct or indirect channels, the services of intermediaries in each geographic area, and implementation plans.

A firm must become involved in the supply chain design process when it is considering entering the market with a new product or when existing supply chains are falling short of performance objectives. The supply chain design process consists of the following steps (Lambert 1978):

1. Establish supply chain objectives.
2. Formulate a supply chain strategy.
3. Determine supply chain structure alternatives.
4. Evaluate supply chain structure alternatives.
5. Select supply chain structure.
6. Determine alternatives for individual supply chain members.
7. Evaluate and select individual supply chain members.
8. Measure and evaluate supply chain performance.
9. Evaluate supply chain alternatives when performance objectives are not met or attractive new options become available.

The manufacturer, wholesaler, or retailer may lead the design process, depending on the relative market power, financial strength, and availability of desired supply chain members.

8.1. The Manufacturer's Perspective

A manufacturer has market power when customers demand its product. When consumers demand a manufacturer's brand, retailers and consequently wholesalers are anxious to market its existing and

new products because such products will draw customers. Increasingly the consolidation of manufacturers, wholesalers, and retailers on a national and global basis has resulted in a power shift to retailers since they have access to consumers. The consolidation of manufacturers results in a reduced set of global suppliers that produce brands which are increasingly viewed as substitutable by consumers. The store brands of retailers such as Wal-Mart become national and some cases global brands themselves, which has further contributed to the weakening of traditionally strong manufacturer brands.

A small manufacturer of a little-known brand may find it difficult to attract supply chain members for its existing or new product offerings. Such a manufacturer lacks market power when entering supply chain negotiations. Also, since financial resources determine a manufacturer's ability to perform marketing functions internally, small manufacturers usually cannot afford to distribute directly to retailers or geographically dispersed industrial customers and must rely on wholesalers. Furthermore, in some locations acceptable middlemen may not be available in every line of trade. Firms in this situation include some manufacturers of electrical supplies and small hand tools.

Even the manufacturer of a full line of products who has geographically concentrated customers may find direct channels less profitable than indirect channels for some of the products and customers. For example, many pharmaceutical companies have increased their use of wholesalers, even in concentrated market areas, because of the high customer service levels required.

8.2. The Wholesaler's Perspective

Wholesalers make it possible to provide possession, time, and place utility efficiently. Wholesalers are economically justified because they improve distribution efficiency by breaking bulk, building assortments of goods, and providing financing for retailers or industrial customers.

Wholesalers' market power is greatest when retailers order a small amount of each manufacturer's products or when the manufacturers involved have limited financial resources. For some products, such as Whirlpool appliances and some lines of jewelry and fashion apparel, per-unit prices and margins may be large enough to enable the manufacturer to sell directly to retailers, even when the number of items sold to each retailer is small. But manufacturers of low-value or low-margin items such as cigarettes and some food items may find it profitable to sell only through wholesalers, even though each retailer may order in relatively large quantities.

Wholesalers' and distributors' financial strength determines the number of services they can perform. Each service represents a profit opportunity as well as an associated risk and cost. The presence or absence of other firms offering comparable services influences the market power of individual wholesalers. Traditionally, wholesalers have been regional in scope. In some industries, such as pharmaceutical, wholesaler mergers have occurred. Cardinal Heath, McKesson, and Bergen Brunswig are large pharmaceutical wholesalers that have become national in scope. Together they control over one-half of the drug store wholesale business in the United States.

8.3. The Retailer's Perspective

Retailers exist when they provide convenient product assortment, availability, price, and image within the geographic market served. The degree of customer preference (loyalty due to customer service and price/value performance) that a retailer enjoys in a specific area directly affects its ability to negotiate supply chain relationships. The retailer's financial capability and size also determine its degree of influence over other supply chain members.

9. SUPPLY CHAIN DESIGN CONSIDERATIONS

Among the factors management must consider when establishing a supply chain are market coverage objectives, product characteristics, customer service objectives, and profitability (Bowersox et al. 1980).

9.1. Market Coverage Objectives

In order to establish market coverage objectives, management must consider consumer/customer buying behavior, the type of distribution required, supply chain structure, and the degree of control necessary for success.

9.1.1. Customer Buying Behavior

The buying motives of potential customer segments must be determined in order to design a supply chain that can perform most efficiently and effectively. This analysis enables the designer to determine the retail segment or segments most capable of reaching the target market or markets. Industrial marketers also must identify potential users and determine how these customers will make the purchase decision. The industrial purchaser's decision-making process depends on whether the firm is a user, an OEM, or a distributor.

9.1.2. Type of Distribution

There are basically three types of distribution that can be used to make product available to consumers: intensive distribution, selective distribution, and exclusive distribution. In intensive distribution, the product is sold to as many appropriate retailers or wholesalers as possible. Intensive distribution is appropriate for products such as chewing gum, candy bars, soft drinks, bread, film, and cigarettes, where the primary factor influencing the purchase decision is convenience. Industrial products that may require intensive distribution include pencils, paper clips, transparent tape, file folders, typing paper, transparency masters, and screws and nails.

In selective distribution, the number of outlets that may carry a product is limited, but not to the extent of exclusive dealing. By carefully selecting wholesalers and/or retailers, the manufacturer can concentrate on potentially profitable accounts and develop solid working relationships to ensure that the product is properly merchandised. The producer may also restrict the number of retail outlets if the product requires specialized servicing or sales support. Selective distribution may be used for product categories such as clothing, appliances, televisions, stereo equipment, home furnishings, and sports equipment.

When a single outlet is given an exclusive franchise to sell the product in a geographic area, the arrangement is referred to as exclusive distribution. Products such as specialty automobiles, some major appliances, some brands of furniture, and certain lines of clothing that enjoy a high degree of brand loyalty are likely to be distributed on an exclusive basis. This is particularly true if the consumer is willing to overcome the inconvenience of traveling some distance to obtain the product. Usually, exclusive distribution is undertaken when the manufacturer desires more aggressive selling on the part of the wholesaler or retailer or when channel control is important. Exclusive distribution may enhance the product's image and enable the firm to charge higher retail prices.

Sometimes manufacturers use multiple brands in order to offer exclusive distribution to more than one retailer or distributor. Exclusive distribution occurs more frequently at the wholesale level than at the retail level. Anheuser-Busch, for example, offers exclusive rights to distributors, who in turn use intensive distribution at the retail level (in states such as Florida where this is allowed). In general, exclusive distribution lends itself to direct channels (manufacturer to retailer). Intensive distribution is more likely to involve indirect channels with two or more intermediaries.

9.1.3. Channel Structure

With customer requirements and the type of distribution determined, management must select supply chain institutions for both inbound and outbound portions of the supply chain. Factors to consider when selecting supply chain members include financial strength, capabilities; ability to link up processes, ability to grow with the business, and competing supply chains.

9.1.4. Control

In many cases a firm may have to exercise some control over other members of the supply chain to ensure product quality and/or post-purchase services. The need for control stems from management's desire to protect the firm's long-term profitability.

9.2. Product Characteristics

Product characteristics are a major consideration in supply chain design. Nine product characteristics should be analyzed by the designer: the product's value, the technicality of the product, the degree of market acceptance, the degree of substitutability, the product's bulk, the product's perishability, the degree of market concentration, seasonality, and the width and depth of the product line.

9.2.1. Value

Products with a high per-unit cost require a large inventory investment. Consequently, high-value products typically will require shorter supply chains (fewer members) in order to minimize total inventory investment. But supply chains tend to be longer when the unit value is low, unless sales volume is high. In general, intensive distribution is used for low-value products.

The product's value also influences its inventory carrying cost and the desirability of premium transportation. Low-value, low-margin grocery products may be shipped by rail car and stored in field warehouses. High-value component parts and products such as high-fashion merchandise may be shipped by air freight to minimize in-transit inventories and reduce inventory carrying costs and markdowns.

9.2.2. Technicality

Highly technical products usually require demonstration by a salesperson as well as prepurchase and postpurchase service that often requires that repair parts be stocked. Technical products include such items as computers, high-priced stereo components, expensive cameras and video equipment, im-

ported sports cars, and a multitude of industrial products. Generally, direct channels and selective or exclusive distribution policies are used for these kinds of products.

9.2.3. Market Acceptance

The degree of market acceptance determines the amount of selling effort required. If a leading manufacturer offers a new product and plans significant introductory advertising, customer acceptance will be high and intermediaries will want to carry the product. But new products with little market acceptance and low brand identification require aggressive selling.

9.2.4. Substitutability

Product substitutability is closely related to brand loyalty. When brand loyalty is low, product substitution is likely and intensive distribution is required. Firms place a premium on point-of-purchase displays in high-traffic areas. To gain support from wholesalers and/or retailers, the producer may offer higher-than-normal margins. Selective or exclusive distribution makes product support easier.

9.2.5. Bulk

Generally, low-value, high-weight products are restricted to markets close to the point of production. These products often require special materials-handling skills. With low weight and small cubes, more units can be shipped in a truck, rail car, or container, thereby reducing the per-unit cost of transportation. Tank truck shipment of orange juice concentrate from Florida to northern markets for packaging is an example of moving a product closer to the point of consumption to overcome value and bulk restrictions.

9.2.6. Perishability

Perishability refers to physical deterioration or to product obsolescence caused by changing customer buying patterns or technological change. Perishable products are usually sold on a direct basis in order to move product through the supply chain more quickly and reduce the potential for inventory loss.

9.2.7. Market Concentration

When the market is concentrated in a geographic area, short supply chains may be the most effective and efficient method. When markets are widely dispersed, however, specialized intermediaries are necessary; they can capitalize on the efficiencies associated with moving larger quantities. Because of widely dispersed markets, many food-processing companies use brokers to market their products. This factor also explains the existence of pooling agencies, such as freight forwarders and local cartage firms, that aggregate small shipments into truckload or carload units for movement to distant points.

9.2.8. Seasonality

Seasonality must be considered when applicable. For some products, sales volumes peak at certain times of the year (such as toy sales at Christmas); in other cases, raw materials, such as fresh fruits and vegetables, may only be available at specific times. Both cases require out of-season storage. Manufacturers must invest in warehouses, use third parties, or provide incentives to intermediaries so they perform the storage function. For example, manufacturers might offer a seasonal discount or consignment inventories to wholesalers or retailers who agree to take early delivery.

9.2.9. Width and Depth

The width and depth of a supplier's product line influence supply chain design. A manufacturer of products with low per-unit values may use intensive distribution with direct sales if the product line is broad enough to result in a relatively large average sales volume. Grocery manufacturers such as Kellogg's and General Foods are examples. Usually, a manufacturer of a limited line of products will use wholesalers to achieve adequate market coverage at a reasonable cost.

9.3. Customer Service Objectives

Customer service represents the place component of the marketing mix. Customer service can be used to differentiate the product or influence the market price—if customers are willing to pay more for better service. In addition, the supply chain structure will determine the costs of providing a specified level of customer service.

Customer service is a complex subject. However, it is usually measured in terms of the level of product availability, speed and consistency of the customer's order cycle, and communication that takes place between seller and customer. Management should establish customer service levels only after carefully studying customer needs.

9.3.1. Availability

The most important measure of customer service is inventory availability within a specified order cycle time. A common measure of availability is the number of orders shipped complete within a specified time period as a percentage of total orders received. The measure(s) selected should reflect the customer's view of customer service. The best measure of customer service reflects the product's importance to the customer and the customer's importance to the company.

9.3.2. Order Cycle

The order cycle is the time that elapses between the customer's order placement and the time the product is received. The ability to achieve the targeted order cycle time consistently influences the amount of inventory held throughout the supply chain. Consequently, the speed and consistency of the order cycle are prime factors in supply chain design. Most customers prefer consistent service to fast service because the former allows them to plan inventory levels to a greater extent than is possible with a fast but highly variable order cycle.

9.3.3. Communication

Communication refers to the firm's ability to supply timely information to the customer regarding such factors as order status, order tracking, back-order status, order confirmation, product substitution, product shortages, and product information requests. The use of automated information systems usually results in fewer errors in shipping, picking, packing, labeling, and documentation. The ability of supply chain members to provide good communications systems is a major factor in supply chain design.

10. SUPPLY CHAIN PERFORMANCE MEASUREMENT

The literature rarely focuses on measuring supply chain performance, for a number of reasons:

1. Measuring supply chain performance is difficult.
2. Some aspects of supply chain performance are difficult to quantify, making it difficult to establish a common performance standard.
3. Differences in supply chains make it difficult to establish standards for comparison.

One measure of supply chain performance is the extent to which the company's target market(s) are being satisfied, given the firm's goals and objectives. This would include measures of product availability, adequacy of customer service, and strength of brand image.

Next, management must analyze supply chain structure to determine whether the corporate strategy has been successfully implemented. Measures of structure efficiency include member turnover, competitive strength, and related issues. When management evaluates supply chain structure, it must compare the firm's ability to perform the functions/activities internally with another member's ability to perform these functions/activities.

Some potential quantitative measures of supply chain performance include logistics cost per unit, errors in order filling, and percent of damaged merchandise. Qualitative measures that managers may use when reevaluating the supply chain and specific members include degree of coordination, degree of conflict, and availability of information as needed. Management should set objectives for the supply chain and individual members and measure actual performance against planned performance. Also, evaluation measures should be developed over time and used to isolate potential problem areas. Perhaps the best measures of performance are the value created for customers and the profitability of the supply chain and its members.

For the individual firm, the goal is to find the most efficient way to offer the desired level of customer service (see Figure 8). For the supply chain, the goal is to improve overall efficiency by reallocating functions, and therefore costs, among its members. The level of customer service offered by the individual member firms, for example, will have a significant impact on other members and total supply chain performance.

For example, a manufacturer whose product availability is poor and order cycle times inconsistent may force wholesalers to carry more inventory as safety stock in order to offer an acceptable level of service to the retailers. In this case, lower logistics costs for the manufacturer were achieved at the expense of other members of the supply chain, and the entire supply chain may be less efficient.

However, if management concentrates on systems changes that improve logistics efficiency or effectiveness, it may be possible to satisfy all of the firm's objectives. For example, by linking members of the supply chain, using advanced information technology and sharing key data, a firm may be able to achieve some or all of the following: increased customer service levels, lower inventories, speedier collections, decreased transportation costs, lower warehousing costs, improvement in

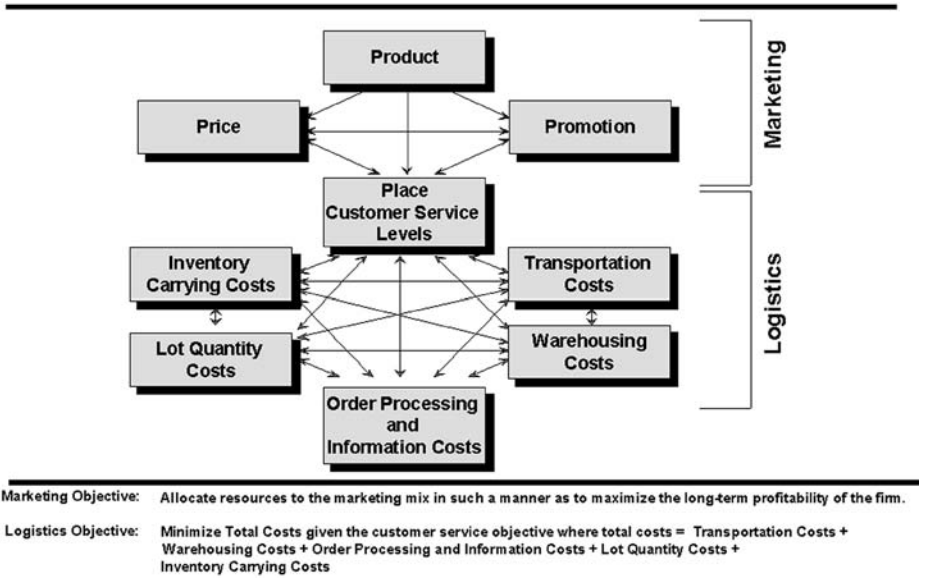

Figure 8 Cost Trade-offs Required in Marketing and Logistics. (From D. M. Lambert, *The Development of an Inventorry Costing Methodology: A Study of the Cost Associated with Holding Inventory,* National Council of Physical Distribution Management, Chicago, 1976. Reprinted with permission)

cash flow, and high return on assets. Thus, all supply chain decisions are best viewed from a systems perspective, as an integrated whole.

A manufacturer has minimal additional cash invested in inventory held by the customer rather than in the manufacturer's warehouse. Furthermore, the non-cost-of money components of inventory carrying cost are shifted to the next level of the supply chain. However, this may not be most efficient for the supply chain as a whole, as the value of inventory increases as it gets closer to the consumer because of mark-ups by each subsequent member and/or value added at various stages in the supply chain. The supply chain would be better off as a whole to have inventory held in the least valuable forms. In addition, the less differentiated the inventory has become, the more likely, in general, that it can be used in a different application.

In addition to rethinking traditional strategies for improving supply chain cash flow and return on assets, supply chain leaders may wish to consider automating and integrating the information systems within the supply chain. This can reduce lead-time variability and create time for planning. If communications flows throughout the supply chain are improved, all members will be able to reduce inventories while improving customer service.

In addition, the extra planning time that results due to increased communication speed will allow freight consolidations, warehousing cost savings, and lower lot quantity costs. Customer service levels can be improved and total operating costs reduced—truly a unique opportunity.

11. REENGINEERING IMPROVEMENT INTO THE SUPPLY CHAIN

A critical part of streamlining supply chains involves reengineering the key processes to meet customer needs. Reengineering is a process aimed at producing dramatic changes quickly. Hammer and Champy (1993) define it as the fundamental rethinking and radical redesign of business processes to achieve dramatic improvements in critical contemporary measures of performance such as cost, quality service, and speed. Improvement through reengineering cannot be accomplished in a haphazard manner. These changes must be supported at the top and driven through an overall management plan.

A typical reengineering process proceeds through three stages: fact finding, identifying areas for improvement to business process redesign, and creative improvements. The fact-finding stage is a very detailed examination of the current systems, procedures, and work flows. Key focus is placed on separating facts from opinions.

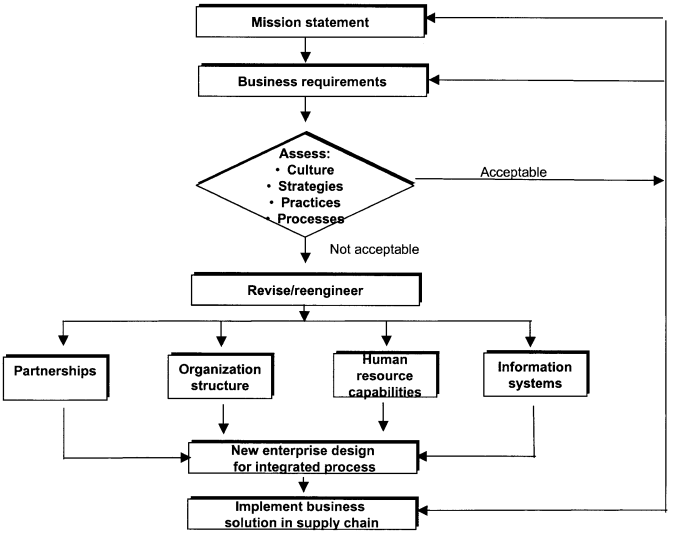

Figure 9 Reengineering SCM Process Flow Chart. (From D. M. Lambert, L. C. Guinipero, and G. J. Ridenhower, "Supply Chain Management: A Key to Achieving Business Excellence in the 21st Century," manuscript. All rights reserved)

Armed with the facts collected in the first stage, reengineering teams identify areas for improvement. They analyze where value was added for the final customer, with particular emphasis on customer contact points and product information transfers that are currently ineffective or inefficient. After identification of improvement points the creative phase of redesigning business process and information flow begins. The outcomes of the creative phase will fundamentally change both the nature of the work and how it is performed.

Figure 9 illustrates a general plan when undertaking a process reengineering approach. Organizational energy needs to focus on the firm's mission statement. The mission statement drives the business requirements in the organization. A complete assessment is made of the firm's culture, strategies, business practices, and processes.

If this analysis proves acceptable, management implements its business solution across the supply chain. Typically, improvements are required in one of the areas to enhance supply chain performance. An example of this reengineering is the new Mercedes-Benz microcar, which is based on the principle of systems supply (Coleman et al. 1995). This reengineering of the process results in delegating more design activities to suppliers, reducing the amount of engineering and labor at the primary manufacturer. The result is passing the savings of these efficiencies along to the customer in the form of increased value.

12. IMPLEMENTING INTEGRATED SUPPLY CHAIN MANAGEMENT

Implementing SCM requires making the transition from a functional organization to a focus on process. Figure 10 illustrates how each function in the organization maps with the seven key processes.

In the customer relationship management process, sales and marketing provides the account management expertise, engineering provides the specifications that define the requirements, logistics provides knowledge of customer service requirements, manufacturing provides the manufacturing strategy, purchasing provides the sourcing strategy, and finance and accounting provides customer profitability reports. The customer service requirements must be used as input to manufacturing, sourcing, and logistics strategies.

If the proper coordination mechanisms are not in place across the various functions, the process will be neither effective or efficient. Taking a process focus means that all functions that touch the product or provide information must work together. For example, purchasing depends on sales/marketing data fed through a production schedule that are used to assess specific order levels and timing of requirements. These orders drive production requirements, which in turn are transmitted upstream to suppliers.

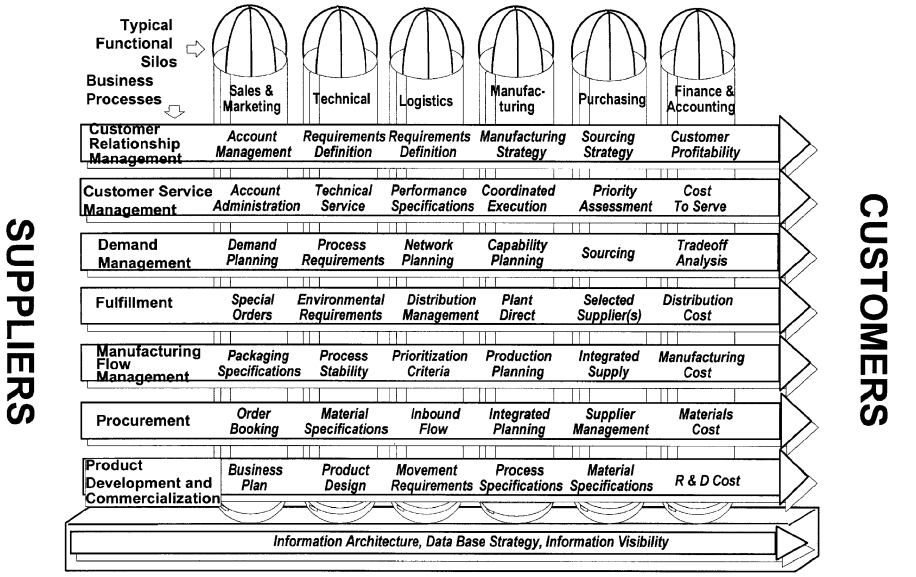

Figure 10 Implementation of Supply Chain Management. (From D. M. Lambert, L. C. Guinipero, and G. J. Ridenhower, "Supply Chain Management: A Key to Achieving Business Excellence in the 21st Century," manuscript. All rights reserved)

The increasing use of outsourcing has accelerated the need to coordinate supply chain processes because the organization becomes more dependent on outside contractors' suppliers. Consequently, coordination mechanisms must be in place within the organization. Where to place these coordination mechanisms and which team and functions are responsible become critical decisions.

Several process redesign and reengineering techniques can be applied to the seven key processes. Chrysler Corporation's development of Neon was accomplished through the efforts of 150 internal employees. This core group leveraged its efforts to 600 engineers, 289 suppliers, and line employees. Concurrent engineering techniques required the involvement of personnel from all key functional areas working with suppliers to develop the vehicle in 42 months. The use of concurrent engineering resulted in the avoidance of later disagreements, misunderstandings, and delays.

All firms within the supply chain will have their own functional silos that must be overcome and a process approach that must be accepted in order to successfully implement SCM. The requirements for successful implementation of SCM include:

- Executive support, leadership, and commitment to change
- An understanding of the degree of change that is necessary
- Agreement on the SCM vision and the key processes
- The necessary commitment of resources and empowerment to achieve the stated goals

13. MANAGING SUPPLIER RELATIONSHIPS

Supplier partnerships have become one of the hottest topics in interfirm relationships. Business pressures such as shortened product life cycles and global competition are making business too complex and expensive for one firm to go it alone. Despite all the interest in partnerships, a great deal of confusion still exists about what constitutes a partnership and when it makes the most sense to have one. This section will present a model (Lambert et al. 1996a, b) that can be used to identify when a partnership is appropriate as well as the type of partnership that should be implemented.

While there are countless definitions for partnerships in use today, we prefer the following definition: "A partnership is a tailored business relationship based on mutual trust, openness, shared risk and shared rewards that yields a competitive advantage, resulting in business performance greater than would be achieved by the firms individually" (Lambert et al. 1996a, b).

13.1. Types of Partnerships

Relationships between organizations can range from arm's-length relationships (consisting of either one-time exchanges or multiple transactions) to vertical integration of the two organizations, as shown in Figure 11. Most relationships between organizations have been at arm's length where the two organizations conduct business with each other, often over a long period of time and involving multiple exchanges. However, there is no sense of joint commitment or joint operations between the two companies. In arm's-length relationships, a seller typically offers standard products/services to a wide range of customers, who receive standard terms and conditions. When the exchanges end, the relationship ends. While arm's length represents an appropriate option in many situations, there are times when a closer, more integrated relationship, called a partnership, would provide significant benefits to both firms.

A partnership is not the same as a joint venture, which normally entails some degree of shared ownership across the two parties. Nor is it the same as vertical integration. Yet a well-managed partnership can provide benefits similar to those found in joint ventures or vertical integration. For instance, Pepsi, by acquiring restaurants such as Taco Bell, Pizza Hut, and KFC, ensured that Coca-Cola would never be served in these outlets. Coca-Cola has achieved a similar result without the cost of vertical integration through its partnership with McDonald's.

While most partnerships share some common elements and characteristics, there is no one ideal or benchmark relationship that is appropriate in all situations. Because each relationship has its own set of motivating factors as well as its own unique operating environment, the duration, breadth, strength, and closeness of the partnership will vary from case to case and over time. Research (Lambert et al. 1996) has indicated that three types of partnerships exist.

- *Type 1:* The organizations involved recognize each other as partners and, on a limited basis, coordinate activities and planning. The partnership usually has a short-term focus and involves only one division or functional area within each organization.
- *Type II:* The organizations involved progress beyond coordination of activities to integration of activities. Although not expected to last forever, the partnership has a long-term horizon. Multiple divisions and functions within the firm are involved in the partnership.
- *Type III:* The organizations share a significant level of integration. Each party views the other as an extension of their own firm. Typically no end date for the partnership exists.

Normally, a firm will have a wide range of relationships spanning the entire spectrum, the majority of which will not be partnerships but arm's-length associations. Of the relationships that are partnerships, the largest percentage will be type I, and only a limited number will be type III partnerships. Type III partnerships should be reserved for those suppliers or customers who are critical to an organization's long-term success. The previously described relationship between Coke and McDonald's has been evaluated as a type III partnership.

13.1.1. The Partnership Model

The partnership model shown in Figure 12 has three major elements that lead to outcomes: drivers, facilitators, and components. Drivers are compelling reasons to partner. Facilitators are supportive corporate environmental factors that enhance partnership growth and development. Components are joint activities and processes used to build and sustain the partnership. Outcomes reflect the performance of the partnership.

13.1.1.1. Drivers Both parties must believe that they will receive significant benefits in one or more areas and that these benefits would not be possible without a partnership. The primary potential benefits that drive the desire to partner include asset/cost efficiencies, customer service improvements, marketing advantage, and profit stability/growth (see Table 1 for examples). While the presence of strong drivers is necessary for successful partnerships, the drivers by themselves do not ensure success. The benefits derived from the drivers must be sustainable over the long term. If, for instance,

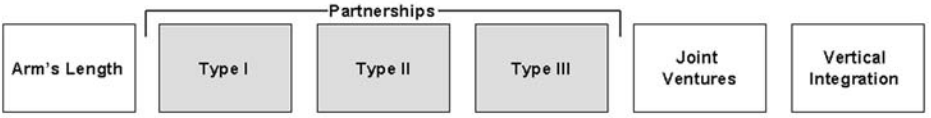

Figure 11 Types of Relationships. (From D. M. Lambert, M. A. Emmelhainz, and J. T. Gardner, "Developing and Implementing Supply Chain Partnerships," *International Journal of Logistics Management,* Vol. 7, No. 2, 1996, pp. 1–7. Reprinted by permission)

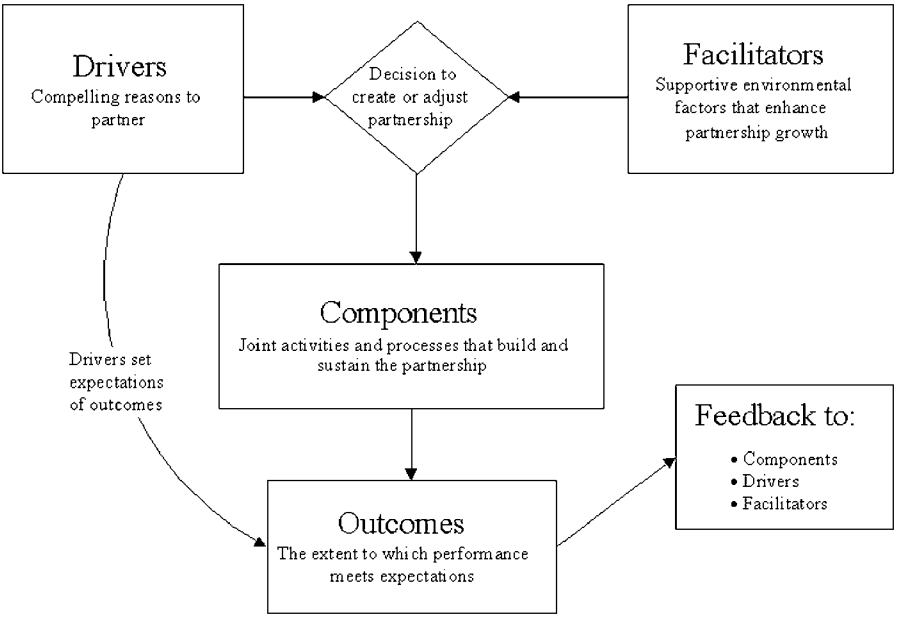

Figure 12 The Partnering Process. (From D. M. Lambert, M. A. Emmelhainz, and J. T. Gardner, "Developing and Implementing Supply Chain Partnerships," *International Journal of Logistics Management,* Vol. 7, No. 2, 1996, pp. 1–7. Reprinted by permission)

the marketing advantage or cost efficiencies resulting from the relationship can be easily matched by a competitor, the probability of long-term partnership success is reduced.

In evaluating a relationship, how does a manager know if there are enough drivers to pursue a partnership? First, drivers must exist for each party. It is unlikely that the drivers will be the same for both parties, but they need to be strong for both. Second, the drivers must be strong enough to provide each party with a realistic expectation of significant benefits through a strengthening of the relationship. Each party should independently assess the strength of its specific drivers and present its drivers to the other party. One of the reasons that partnerships fail is that one or both of the parties have unrealistic expectations. The process of evaluation of the drivers helps the parties set realistic expectations.

13.1.1.2. Facilitators Drivers provide the motivation to partner. But even with a strong desire for building a partnership, the probability of success is reduced if the corporate environments are not supportive of a close relationship. Just as the relationship of a young couple with a strong desire to marry can be derailed by unsupportive in-laws, different communication styles, and dissimilar values, so can a corporate relationship be sidetracked by a hostile environment. On the other hand, a supportive environment that enhances integration of the two parties will improve the success of the partnership. Facilitators are elements of a corporate environment that allow a partnership to grow and strengthen. They serve as a foundation for a good relationship. In the short run, facilitators cannot be developed; they either exist or they don't. And the degree to which they exist often determines whether a partnership succeeds or fails. Facilitators include corporate compatibility, similar managerial philosophy and techniques, mutuality, and symmetry (see Table 1 for details).

Facilitators apply to the combined environment of the two potential partners. Therefore, unlike drivers, which are assessed by managers in each firm independently, facilitators should be assessed jointly. The discussion of corporate values, philosophies, and objectives often leads to an improved relationship even if no further steps toward building a partnership are taken. The more positive the facilitators, the better the chance of partnership success.

If both parties realistically expect benefits from a partnership and if the corporate environments appear supportive, then a partnership is warranted. The appropriateness of any one type of partnership is a function of the combined strength of the drivers and facilitators. A combination of strong drivers and strong facilitators would suggest a type III partnership, while low drivers and low facilitators

TABLE 1 Partnership Drivers, Facilitators, and Components

Partnership Drivers
- Asset/cost efficiency: What is the probability that this relationship will substantially reduce channel costs or improve asset utilization, for example, product costs, distribution costs savings, handling costs savings, packing costs savings, information handling costs savings, managerial efficiencies, and assets and devoted to the relationship?
- Customer service: What is the probability that this relationship will substantially improve the customer service level as measured by the customer, for example, improved on-time delivery, better taking of movement, paperless order processing, accurate order deliveries, improved cycle times, improved fill rates, customer survey results, and process improvements?
- Marketing advantage: What is the probability that Ns relationship will lead to substantial marketing advantages, for example, new market entry, promotion joint advertising, sales promotion), price (reduced price advantage), product jointly developed product innovation, branding opportunities), place (expanded geographic coverage, market saturation), access to technology, and innovation potential?
- Profit stability/growth: What is the probability that this relationship will result in profit growth or reduced variability in profit, for example, growth, cyclical leveling, seasonal leveling, market share stability, sales volume, and assurance of supply?

Partnership Facilitators
- Corporate compatibility: What is the probability that the two organizations will mesh smoothly in terms of (1) culture, for example, both firms place a value on keeping commitments, constancy of purpose, employees valued as long-term assets, and external stakeholders considered important, and (2) business, for example, strategic plans and objectives consistent, commitment to partnership ideas, and willingness to change?
- Management philosophy and techniques: What is the probability that the management philosophy and techniques of the two companies will match smoothly, for example, organizational structure, use of TQM, degree of top management support, types of motivation used, importance of teamwork, attitudes toward ''personnel churning,'' and degree of employee empowerment?
- Mutuality: What is the probability both parties have the skills and predisposition needed for mutual relationship building? Is management skilled at two-sided thinking and action, taking the perspective of the other company, expressing goals and sharing expectations, and taking a longer-term view, for example, or is management willing to share financial information and integrate systems?
- Symmetry: What is the probability that the parties are similar on the following important factors that will affect the success of the relationship: relative size in terms of sales, relative market sham in their respective industries, financial strength, productivity, brand image/reputation, and technological sophistication?

Partnership Components
- Planning (style, level, and content)
- Joint operating controls (measurement and ability to make changes)
- Communications (non-routine and day-to-day: organization, balanced flow, and electronic)
- Risk/reward sharing (loss tolerance, gain commitment, and commitment to fairness)
- Trust and commitment to each other's success)
- Contract style (time frame and coverage)
- Scope (share of partner's business, value added, and critical activities) Investment (financial, technology, and people)

Partnership Outcomes
- Global performance outcomes (enhancement of profits, leveling of profits over time)
- Process outcomes (improved service, reduced costs)
- Competitive advantage (market positioning, market share, access to knowledge)

suggest an arm's-length relationship. While it might seem, from all of the press on the importance of integrated relationships and alliances, that managers should attempt to turn all of their corporate relationships into type III partnerships, this is not the case. In partnering, more is not always better. The objective in establishing a partnership should not be to have a type III partnership; rather, it should be to have the most appropriate type of partnership given the specific drivers and facilitators.

In fact, in situations with low drivers and/or facilitators, trying to achieve a type III partnership is likely to be counterproductive. The necessary foundation is just not there. Once it has been determined that a partnership of a specific type is warranted and should be pursued, the next step is actually to put the partnership into place. This is done through the components.

An assessment of drivers and facilitators is used to determine the potential for a partnership, but the components describe the type of relationship that has actually been implemented.

13.1.1.3. Components Components are the activities and processes that management establishes and controls throughout the life of the partnership. Components make the relationship operational and help managers create the benefits of partnering. Every partnership has the same basic components, but the way in which the components are implemented and managed varies. Components include planning, joint operating controls, communications, risk/reward sharing, trust and commitment, contract style, scope, and financial investment. Table 1 summarizes the drives, facilitators, and components of partnership.

13.1.1.4. Outcomes and Feedback Whatever type of supplier partnership is implemented, the effectiveness of the relationship must be evaluated and possibly adjusted. The key to effective measurement and feedback is how well the drivers of partnership were developed at the outset. At this beginning point, the measurement and metrics of relating to each driver should have been made explicit. These explicit measures then become the standard in evaluation of the partnership outcomes. Feedback can loop back to any step in the model. Feedback can take the form of periodic updating of the status of the drivers, facilitators, and components.

Additional information on the partnership model can be found in Gardner et al. (1999). Information on this book and other current developments in the partnership research can be found at the website of the International Journal of Logistics Management at www.logisticssupplychain.org.

14. SUMMARY

In this chapter we saw that:

1. Supply chain management is different from managing logistics in the supply chain.
2. Various supply chain structures are used.
3. Supply chain management is a process-oriented approach to manage relationships in the supply chain, and leading-edge firms such as 3M are implementing SCM.
4. Communications can improve the efficiency and effectiveness of the supply chain.
5. A number of factors influence supply chain design, evolution, and performance.
6. The implementation of integrated supply chain management requires a process management team structure.
7. Partnerships with key suppliers and customers are an important part of supply chain management.

CHAPTER 83
Stochastic Models

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

1.1. Overview

Many systems of interest to industrial engineers involve randomness or unpredictability; for example, in the arrival of jobs requiring processing, or in machine breakdowns. In attempting to understand these systems for the purpose of design or control, a mathematical model is needed. Often, randomness and uncertainty must be captured explicitly in the model in order to represent the system reasonably faithfully. Such a model is called a *stochastic model*. The value of these models is that they enable us to predict the performance of a new system or the effect of a change in an existing system.

This chapter is a tutorial covering those aspects of the theory of stochastic models that are of greatest importance for applications in the manufacturing and service industries. After some preliminaries in this section, we cover four families of stochastic models. *Point processes,* treated in Section 2, are collections of random times, representing, for example, arrival times of jobs at a service facility. *Markov chains* are treated in Section 3. These offer both mathematical tractability and the flexibility to model a broad range of systems. *Queueing systems,* treated in Sections 4 and 5, capture the phenomenon of waiting. These are the central focus of this chapter. Indeed, the primary reason for treating point processes and Markov chains is to provide a foundation from which to build and analyze useful queueing models. Queueing networks, treated in Sections 6 and 7, are models of two or more interacting queues.

This chapter deals only with the simplest and most basic stochastic models and their mathematical analysis. Among the many excellent sources for the introductory material discussed here are the books by Ross (1997) and Wolff (1989), who treat the subject fairly mathematically, and Hall (1991), who focuses more on practical considerations. Ross (1996) is more advanced. For a comprehensive treatment of stochastic models of manufacturing systems, see Buzacott and Shanthikumar (1993). Larson and Odoni (1981) and Hall (1991) cover a variety of examples of stochastic modeling for service industries. Other chapters of the Handbook with a substantial stochastic modeling component are Chapters 60, 72, and 94.

1.2. Simulation vs. Mathematical Analysis

One of the primary applications of stochastic models is in discrete-event simulation of engineering systems that are subject to randomness. The first step in this methodology is to develop a stochastic model of the system in question. Simulation is used to analyze the model because models of real systems are usually too complex for direct mathematical analysis. Simulation is treated thoroughly in Chapters 93–96 of the Handbook.

Only relatively simple stochastic models may be examined in any detail using mathematical analysis, whereas almost any stochastic model may be analyzed using simulation. Because of this, it is necessary to state clearly what benefits are derived from mathematical analysis of stochastic models. These are as follows.

1. The mathematics yields insights and general principles, such as Little's law (see Section 5.1), which cannot be readily discovered from simulations.
2. The mathematics can be used to validate simulation results. This may be especially important in designing a new system, when one cannot validate the simulation by comparison with observations on an existing system. The goal of validating simulations motivates much of the interest in stochastic models; see Subsection 5.4 and Section 7 below.
3. The mathematics can sometimes show explicitly how performance is affected by system parameters and configuration choices. This is true for certain special families of models, including many of those treated in Sections 4 to 6 below. To get similar information through simulation may require a large amount of computation.
4. The mathematics may help us to understand a system that is fundamentally hard to simulate. Examples of this include models involving queues in heavy traffic (Subsection 5.4) or problems in which a very small probability must be estimated. Long simulation runs may be needed to get any accuracy in such situations, whereas various limit theorems in probability theory often give very accurate results.

1.3. Preliminaries on Probability

Here we briefly review some of the fundamental concepts in probability used in later sections. To define probabilities, we begin with an *experiment,* which may be thought of as some process leading to one of a collection of *outcomes.* This collection of outcomes is called the *sample space*. An *event* is a subcollection of outcomes. We say that an event *occurs* if the outcome that results from the experiment is in the event. Events are precisely the objects to which probabilities are assigned. The probability of an event E is denoted by $P(E)$.

The *conditional probability* of an event A given an event B is the probability that they both occur divided by the probability that B occurs:

$$P(A|B) = \frac{P(A \text{ and } B)}{P(B)} \tag{1}$$

This is also called simply the probability of A given B. One of the most important concepts in probability is the formal notion of independence or ''unrelatedness''—that one event has no bearing on another. Formally, two events A and B are said to be *independent* if either of the following holds.

$$P(A|B) = P(A) \text{ or } P(A \text{ and } B) = P(A)P(B) \tag{2}$$

The first of these may be expressed by saying that the knowledge that B will occur has no effect on the chance that A will occur.

A *random variable* X is a quantity whose value depends on the outcome of an experiment. The *distribution* of a random variable is any specification of all probabilities associated with that random variable. One such specification is the *distribution function* F of X, which is defined by

$$F(x) = P(X \leq x), \ -\infty < x < \infty \tag{3}$$

If X is *discrete*, which is to say its possible values may be written as a list $x_1, x_2, x_3, \ldots$, we may specify its distribution through its *probability mass function,* f, defined by

$$f(x) = P(X = x), \ -\infty < x < \infty \tag{4}$$

Note that $f(x) = 0$ unless x is one of the possible values x_i of X. To say that X is a *continuous random variable* is to say that there is a function f for which

$$P(X \leq x) = \int_{-\infty}^{x} f(u)\, du, \ -\infty < x < \infty \tag{5}$$

In this situation, f is called the *probability density function* of X, and f is the derivative F' of the distribution function F of X.

The *expected value* $E(X)$ of a random variable X is its weighted average value, in which each possible value of X is weighted by its probability. This has the interpretation of being a central value, sometimes also a typical value, of X. It may be written in the following ways, depending on whether the random variable is discrete or continuous.

$$E(X) = \sum_{x} xf(x) \text{ in the discrete case, and}$$

$$E(X) = \int_{-\infty}^{\infty} xf(x)\, dx \text{ in the continuous case} \tag{6}$$

Sometimes it is convenient to use the Steiltjes integral notation to combine these into the single formula

$$E(X) = \int_{-\infty}^{\infty} x\, dF(x) \tag{7}$$

The *variance* of a random variable is its *expected squared deviation* from its mean, or

$$\text{Var}(X) = E[(X - E(X))^2] = \int_{-\infty}^{\infty} (x - E(X))^2 f(x)\, dx \tag{8}$$

the integral form being valid in the case of a continuous random variable only. The *standard deviation* $\text{SD}(X)$ is the square root of the variance. This has the interpretation of being a ''typical distance'' between the value of the random variable and its mean. Because of this simple interpretation, the standard deviation may be considered a natural measure of variability of a random variable. In the context of stochastic models, another measure of variability is often more convenient to work with than the standard deviation. This is the *coefficient of variation,* or CV, defined as the ratio $\text{CV}(X) = \text{SD}(X)/E(X)$ of the standard deviation to the mean. The CV may be interpreted as a typical deviation of a random variable from its mean, expressed relative to that mean. The squared coefficient of variation, or SCV, is often used below also.

We briefly discuss three distributions of importance, the *Poisson distribution,* the *exponential distribution,* and the *normal distribution*. A random variable X has the Poisson distribution with mean m if

$$P(X = x) = e^{-m}\frac{m^x}{x!} \text{ for } x = 0, 1, 2, \ldots \tag{9}$$

This is a discrete distribution, over the non–negative integers. Its expected value and variance are equal:

$$E(X) = \text{Var}(X) = m \tag{10}$$

See Subsection 2.1 for an explanation of how the Poisson distribution arises naturally.

A random variable Y is said to have the exponential distribution with *rate* λ if its probability density function is

$$f(y) = \lambda e^{-\lambda y} \text{ for } y \geq 0 \tag{11}$$

The mean and variance are

$$E(Y) = \frac{1}{\lambda} \text{ and } \text{Var}(Y) = \frac{1}{\lambda^2} \tag{12}$$

It follows from this that the CV of the exponential distribution is 1. The exponential distribution has the remarkable *memoryless property,* which states that

$$P(Y > s + t | Y > s) = P(Y > t) \text{ for all } s, t \geq 0 \tag{13}$$

Thinking of Y as a random time, this says that the conditional distribution of the excess of Y over a fixed time s, given that Y does indeed exceed s, is the same as the unconditional distribution of Y. To express this in a more down-to-earth way, suppose that Y is the time at which a train will come and that Y has the exponential distribution. Then, no matter how long we have waited for the train, the distribution of the time we have left to wait is always the same. If this seems counterintuitive, then it may help to consider the memoryless property as it arises in a "discrete-time" setting. If you keep tossing a coin until you first get a head, then as long as you have not yet got a head, it is clear that the distribution of the number of tosses you have left to go is always the same. The number of tails before the first head here has the *geometric distribution*, which is a discrete-time analog of the exponential distribution. See Eq. (24) for its probability mass function.

A random variable Z is said to have the *standard* normal distribution if it has probability density function

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}, \text{ for } -\infty < z < \infty \tag{14}$$

The mean and variance are 0 and 1, respectively. A random variable X is said to have the normal distribution with mean m and variance σ^2 if $(X - m)/\sigma$ has the standard normal distribution.

To understand how the normal distribution arises, we must introduce another basic concept, that of *independent random variables*. Two random variables, X and Y, are said to be independent if

$$P(X \leq x \text{ and } Y \leq y) = P(X \leq x)P(Y \leq y), \; -\infty \leq x, y \leq \infty \tag{15}$$

This is equivalent to saying that any event defined in terms of X is independent of any event defined in terms of Y. For independent random variables X and Y, the variance of the sum is the sum of the variances:

$$\text{Var}(X + Y) = \text{Var}(X) + \text{Var}(Y) \tag{16}$$

This simple formula often makes it easy to compute variances. So while it is the standard deviations that are most easily interpreted, typically the variances are the first quantities to be calculated. A significant analogy is that it is the *squared* length of the hypotenuse of a right-angled triangle that is got by adding the *squared* lengths of the other sides—throughout it is squared lengths, not the lengths themselves, that have this simple additive behavior. Often in stochastic models and statistics, collections $X_1, X_2, X_3, \ldots$ of independent and identically distributed random variables play a key

role. See, for example, Subsection 2.2. For such random variables, with $m = E(X_1)$ and $\sigma^2 = \mathrm{Var}(X_1)$ denoting the common expected value and variance, and with $\overline{X}_n = (X_1 + X_2 + \ldots + X_n)/n$ denoting the mean of the first n of the X_i's, we have

$$E(\overline{X}_n) = m \text{ and } \mathrm{Var}(\overline{X}_n) = \frac{\sigma^2}{n} \tag{17}$$

Thus, $\mathrm{SD}(\overline{X}_n) = \sigma/\sqrt{n}$, and so, while an individual X_i is typically about σ in distance from m, the mean $\overline{X}_n$ is typically only about $\sigma/\sqrt{n}$ from m. This result quantifies the manner in which the individual deviations of the X_i's from their common expected value tend to cancel one another out as they are added together in the process of forming the "sample mean" $\overline{X}_n$. Furthermore, the *central limit theorem* states that the distribution of $\overline{X}_n$ is *asymptotically normal* with mean and variance (17). Roughly speaking, this means that $(\overline{X}_n - m)/(\sigma/\sqrt{n})$ is approximately standard normal. This is one of the most fundamental results in probability and one of the key consequences of independence.

2. POINT PROCESSES

In the applications we consider, a point process is a model for a collection of random times. Typical examples are the arrival times of parts at a machine in a manufacturing system or the times at which 911 emergency calls are made in a city. Point processes are also sometimes known by the more informal term *streams*. Mathematically, a point process may be described as a collection of increasing times $0 \leq T_1 < T_2 < T_3 < \ldots$. We often refer to these times generically as arrival times, even though in a given application they may represent departure times or times of some other type of occurrence. Another way to describe a point process is to specify the corresponding *counting process*, which is defined by

$$N(t) = \text{the number of arrivals in the interval } [0, t],\ t \geq 0$$

So N "counts" the number of arrivals up to time t. Yet another way to present a point process is through the *interarrival times* $X_1 = T_1$, $X_2 = T_2 - T_1$, $X_3 = T_3 - T_2$, . . . In summary, there are three natural ways to specify a point process: using the arrival times T_i themselves, using the counting process N, or using the interarrival times X_i. For any particular point process, one or another of these views may give a special insight.

2.1. The Poisson Process

The Poisson process is a process of completely random arrivals. It may be described informally as follows. Suppose we break up time into small intervals of length, say, h. Suppose that in each time interval we toss a coin with probability of heads p, again a small value. (Generally we think of coin tosses as fair in that each outcome has an equal 50% chance. Here we need an unfair coin, but we keep two other properties of coin tossing: that the outcomes of different tosses are independent and that on each toss there is the same probability p of heads.) For example, if we take h to be one second and $p = 1/3600$, then we get one head per hour on average. If a given toss results in heads, we place an arrival at the center of the corresponding interval. Otherwise, there is no arrival in the interval. That this process represents arrivals completely at random is because of two observations: the probability of having an arrival in any one of these one-second intervals is the same, and what happens in one interval is independent of what happens in all the other intervals. On average, this model produces arrivals at rate p/h per unit time, or p arrivals per second. Using the standard symbol λ for an arrival rate, we have $\lambda = p/h$. To define the true Poisson process of rate λ, we must take a limit as $h \to 0$ and $p \to 0$ in such a way that the overall arrival rate p/h is always λ.

The main properties of the Poisson process are:

1. $N(t)$, the number of arrivals by time t, has the Poisson distribution with mean λt, which is given by (9) with $m = \lambda t$.
2. The numbers of arrivals in several nonoverlapping time intervals are independent of one another.
3. The interarrival times $X_1, X_2, X_3, \ldots$ are independent with the exponential distribution, given by (11).

If, for a given point process N, the expected number of arrivals in any interval is proportional to the length of the interval, then we say that *the arrival rate of N is constant*. This is equivalent to the property that $E(N(t)) = \lambda t$ for all $t \geq 0$. It is a remarkable fact that if a point process has a constant arrival rate and satisfies property 2 above, then it is a Poisson process. The Poisson process arises naturally in many ways. For example, it holds quite generally that if a large number of independent

point processes are combined, or superposed, each having a constant arrival rate and each making a small contribution to the total, then the superposition is approximately a Poisson process. The arrival times of telephone calls at a telephone exchange typically behave like a Poisson process, over any period where the overall arrival rate is fairly constant, because they are in fact the superposition of point processes generated by a great many people and computers acting somewhat independently. Similar effects are sometimes seen in manufacturing systems. For example, in a job shop with highly diverse routing (Buzacott and Shanthikumar 1993), arrival streams tend to behave like Poisson processes.

2.2. Renewal Processes

If the interarrival times $X_1, X_2, X_3, \ldots$ of a point process are independent and identically distributed, then it is called a *renewal process*. To motivate the use of renewal processes in modeling, consider the standard example of replacing light bulbs as they burn out. If the lifetimes X_i, $i = 1, 2, \ldots$ of the bulbs are independent and have the same distribution, then the times of replacement form a renewal process. By property 1 of Subsection 2.1, the Poisson process is a renewal process with exponentially distributed interarrival times.

Renewal processes, being a larger class than the Poisson processes, are more difficult to analyze. We do not have a simple description of the distribution of the number of arrivals by time t, $N(t)$, for a renewal process. However, we do have approximations for its mean and variance for large t. Let $m = E(X_1)$ and $\sigma^2 = \text{Var}(X_1)$ denote the common mean and variance of the X_i's, and let c^2 denote the SCV $(\sigma/m)^2$ (see Subsection 1.3). Then the (long-run) *arrival rate* and *asymptotic variance* of the counting process N are defined in general and evaluated in the case of the renewal process in the following:

$$\lambda = \lim_{t\to\infty} \frac{E(N(t))}{t} = \frac{1}{m} \text{ and } \lim_{t\to\infty} \frac{\text{Var}(N(t))}{t} = \lambda c^2 = \frac{\sigma^2}{m^3} \tag{18}$$

The first result here is known as the *elementary renewal theorem*. Simply put, it says that if the average time between arrivals is a half-hour, then on average there will be two arrivals per hour ($\lambda = 2$) in the long run. To enhance the results (2.18), we may invoke an extension of the central limit theorem of Subsection 1.3, stating that $N(t)$ is asymptotically normally distributed with mean λt and variance $\lambda c^2 t$ for large times t. This fact is useful in understanding queues in heavy traffic; see Subsection 5.2.

Example 2.1: Suppose that 911 calls arrive in a Poisson process of rate one per minute. The probability of more than 80 calls in a 60-minute period may be calculated approximately as follows. Let Z denote a standard normal random variable. By (12) and (18), the mean and variance of $N(60)$ are both approximately equal to 60, and so we have $P(N(60) > 80) \approx P(Z > (80 - 60)/\sqrt{60}) = P(Z > 2.582) = 0.005$. Of course, in this case we are dealing with a special renewal process, namely the Poisson process. Therefore, property 1 of Subsection 2.1 may be used as an alternative approach to computing this probability.

3. MARKOV CHAINS

A stochastic process is a collection of random variables X_t defined for a set of times t. The counting processes of Section 2 were our first examples of stochastic processes. The term *stochastic model* refers simply to a stochastic process used to model something. There is a large family of stochastic processes, known as the Markov chains, or simply chains, that have enough generality to be genuinely useful in applications and yet enough structure to be mathematically tractable. Markov chains may be thought of as the simplest processes that allow some level of dependence over time. We begin with a simple example to illustrate the Markov property in the context of building a stochastic model.

3.1. The Markov Property

Consider a machine that at any given time is either operational or not. We observe it in successive time periods and record a 1 if it is operational and a 0 if it is not. Over time, this produces a sequence of observations, perhaps in this example 1, 1, 1, 0, 0, 1, . . . , indicating that the machine ran for three periods, was then down for two, and so forth. If these observations cannot be predicted with certainty in advance, we may wish to model them as a sequence of random variables $X_1, X_2, \ldots, X_T$, each taking as its value either 0 or 1, with T denoting the number of observation periods. Then the collection of random variables $(X_1, X_2, \ldots, X_T)$ is an example of a stochastic model. It is convenient to denote the entire process simply by X. X_t is referred to as the state of the process X at time t. The set $S = \{0, 1\}$ of possible values of the X_t's is called the *state space* of the process. The

observations 1, 1, 1, 0, 0, 1, . . . constitute a *realization* or *path* of X. If we observe the process for T time periods, then each path is a sequence of T zeroes and ones.

A specification of the probabilities associated with a stochastic model is called the *law* or *distribution* of the model. To define the law of X, we must assign a probability to each possible path of X. Doing this directly is often cumbersome, and the first step in developing stochastic models is to find natural ways of specifying the probabilities of the paths. The simplest specification is to assume that the states at different times are independent and that the probability that the machine is operational at any fixed time t is some constant p. Then $1 - p$ is the probability that the machine is inoperational at a time t. The probability of any particular path is then $p^r (1 - p)^{T-r}$, where r is the number of time periods for which the machine is operational on this path (and so $T - r$ is the number of time periods for which it is inoperational). This comes from independence of all the X_t's, using an extension of (2) to the effect that the probability of several independent events all occurring is the product of their probabilities.

In the model for machine failures just described, if we have observed the machine up to some time period t, these observations are irrelevant from the point of view of predicting the state of the machine in the next time period, period $t + 1$. This is because the model assumes that the successive states of the machine are independent. However, it is quite common in practice that the history of a process is informative regarding its future behavior. In the present example, it may be that when the machine is operational in one time period, it has a better than average chance of being operational in the next time period also. But to allow complete generality in the manner in which future states depend on present and past states would leave us with the problem of overchoice. We will never have enough data to fit such a detailed model. So we make an assumption that allows some dependence, but not too much. We suppose that, having observed the machine for periods 0, 1, 2, . . . , t, the distribution of the state of the machine in period $t + 1$ depends only on its state in period t, the immediately preceding period. In other words, if we know the condition of the machine at the "present" time t, the past conditions are uninformative as to future conditions. This is the *Markov property*. Mathematically, it is expressed by the condition

$$\begin{aligned} &P(X_{t+1} = j | X_t = i, X_{t-1} = i_{t-1}, \ldots, X_1 = i_1) \\ &\quad = P(X_{t+1} = j | X_t = i) \\ &\quad \text{for all states } i_1, i_2, \ldots, i_{t-1}, i, j \in S \text{ and times } t \geq 0 \end{aligned} \tag{19}$$

This conditional probability is called the *transition probability* from state i to state j at time t. Once these quantities are specified, the entire law of the Markov process is specified. The Markov process is said to have *stationary transition probabilities* if $P(X_{t+1} = j | X_t = i)$ does not depend on t, in which case it is denoted simply by p_{ij}. We assume this property from now on, as this is the most important situation in applications, being the situation where the least number of parameters is needed to specify the model.

3.2. Transition Matrices

For a Markov chain $X = (X_0, X_1, X_2, \ldots)$ observed at all times $t = 0, 1, 2, \ldots$ and having state space $S = \{1, 2, \ldots, n\}$, the matrix P with entries p_{ij} is called the *transition matrix*. This is an $n \times n$ matrix whose rows add to 1. In the example of the machine above, where the state space $S = \{0, 1\}$ has only two states, the transition matrix is a 2×2 matrix

$$P = \begin{pmatrix} p_{00} & p_{01} \\ p_{01} & p_{11} \end{pmatrix}$$

Here, for example, p_{01} is the conditional probability that the machine is operational in the next time period, given that it is now inoperational. The other entries have parallel interpretations.

With the introduction of P, it is natural to define the vectors

$$\pi(t) = [\pi_1(t), \pi_2(t), \ldots, \pi_n(t)] = [P(X_t = 1), P(X_t = 2), \ldots, P(X_t = n)]$$

which give the distribution of the chain at time t. These may all be computed, once the initial distribution $\pi(0)$ of the chain is known, using the following:

$$P(X_{t+1} = j) = \sum_{i=1}^{n} P(X_{t+1} = j | X_t = i) P(X_t = i) = \sum_{i=1}^{n} \pi_i(t) p_{ij} \tag{20}$$

In matrix form, this is the recurrence relation $\pi(t + 1) = \pi(t)P$, repeated application of which gives

$$\pi(t + s) = \pi(t)P^s. \tag{21}$$

It is the compactness of (21) as compared to (20) that motivates the use of vector and matrix notation in dealing with Markov chains. The matrix P^s, which is the sth power of the matrix P, is known as the *s-step transition matrix,* its entry $p_{ij}(s)$ being the probability that the chain, when initialized in state i, enters state j upon the sth transition.

3.3. Irreducibility and Steady State

A *steady-state distribution* of a Markov chain is a distribution $\pi = (\pi_1, \pi_2, \ldots, \pi_n)$, say, such that if X_0 has the distribution π, then X_1 also has that distribution, as do X_2, X_3, and so forth. This is also known as a *stationary distribution*. Using (21), the condition that π be a stationary distribution may be expressed in the form

$$\pi P = \pi \tag{22}$$

These are called the *steady-state equations*. A Markov chain is said to be irreducible if any state can be reached from any other through a sequence of transitions whose probabilities are positive. For irreducible chains, there is precisely one steady-state distribution π, and it is the only vector x that satisfies the steady-state equations $xP = x$ and also satisfies the condition $x_1 + x_2 + \ldots + x_n = 1$.

Example 3.1: Figure 1(*a*) represents a Markov chain on the state space $S = \{1, 2\}$ with transition matrix

$$P = \begin{pmatrix} 0.5 & 0.5 \\ 1 & 0 \end{pmatrix}$$

This chain is irreducible because each state may be reached from the other. Its steady-state distribution may be computed by solving (22) to give $\pi_1 = 2/3$ and $\pi_2 = 1/3$. Figure 1(*b*) represents a Markov chain that is not irreducible because, for example, state 1 cannot be reached from state 3.

Another important concept related to long-run behavior is that of a *limiting distribution* of a chain. This is a limit of the form

$$\pi_j(\infty) = \lim_{t\to\infty} P(X_t = j) \text{ or, using vectors and matrices,}$$
$$\pi(\infty) = \lim_{t\to\infty} \pi(t) = \lim_{t\to\infty} \pi(0)P^t \tag{23}$$

when we have convergence. We see that a steady-state distribution π is also a limiting distribution by taking $\pi(0) = \pi$ here and using (22). Conversely, any limiting distribution is also a steady-state distribution. To establish this, we have

$$\pi(\infty)P = (\lim_{t\to\infty} \pi(0)P^t)P = \lim_{t\to\infty} \pi(0)P^{t+1} = \pi(\infty)$$

showing that $\pi(\infty) = \pi(\infty)P$. Because of this, in later sections of this chapter we do not carefully distinguish between steady-state distributions and limiting distributions.

For some chains, the limit in (23) may fail to exist. Existence is guaranteed by irreducibility along with a new property, *aperiodicity,* which requires that, for sufficiently large s, every entry of P^s is positive. Under irreducibility and aperiodicity, the limits of (23) exist and are equal for any initial distribution. The common limit is the unique steady-state distribution π. In what follows, we always assume aperiodicity and irreducibility, unless otherwise stated.

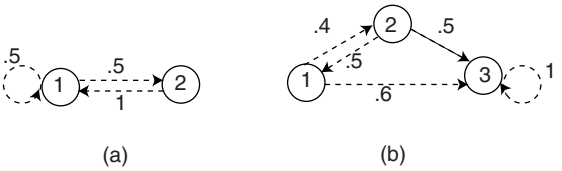

Figure 1 Two Simple Markov Chains.

Given a Markov chain, a natural question to ask is What is the long-run fraction of time that the chain spends in a given state $i \in S$? The idea of long-run behavior is quite different from that of steady-state/limiting distributions. In the latter, the motivating idea is to understand the behavior of the chain at some fixed time very far in the future. But the question of long-run behavior concerns what happens to the chain over a very long time interval. This distinction will be discussed further in the context of queues in Subsection 5. The answer to the question above is again the solution π to the steady-state equations (22), as long the chain is irreducible. To illustrate, the chain of Example 3.1 spends two-thirds of its time in state 1 and one-third in state 2, in the long run.

We summarize the discussion of steady-state behavior of Markov chains as follows. For ''well-behaved'' chains, such as irreducible, aperiodic, finite-state chains, there is a unique steady-state distribution that is also the limiting distribution. Furthermore, this distribution gives the long-run fraction of time spent in each state. It may be computed easily, by solving the steady-state equations (22). The steady-state behavior of the chain does not depend on the initial state.

Many interesting models require an infinite state space. The results just stated for the finite-state case extend to the infinite-state case once we adopt the condition of *positive recurrence* in addition to irreducibility and aperiodicity. A chain is positive recurrent if the expected time to return to any state is finite. We now turn to a simple infinite-state example.

3.4. Analysis of a Simple Discrete-Time Queue

In this subsection, we develop a very simple queueing model. This model is a Markov chain $L(t)$ representing the number of jobs present in a queueing system observed at regular discrete times $t = 0, 1, 2, \ldots$. The state space is $\{0, 1, 2, \ldots\}$. There are two types of transitions possible: arrivals and departures. We write p for the probability that a job arrives in the next time step. We write q for the probability that a job will complete service in the next time step, assuming that there is at least one job present ($L(t) > 0$). If we write r for $1 - p - q$, which is the probability of no state change when there is at least one job present, then the transition matrix of the chain is

$$P = \begin{pmatrix} 1-p & p & 0 & 0 & \ldots \\ q & r & p & 0 & \ldots \\ 0 & q & r & p & \ldots \\ 0 & 0 & q & r & \ldots \\ \ldots & \ldots & \ldots & \ldots & \ldots \end{pmatrix}$$

If there are no jobs present, then there cannot be a departure, and this is why the first row of P does not follow the same pattern as the others. In the case of this chain, the steady-state equations (22) become

$$\pi_0(1-p) + \pi_1 q = \pi_0 \text{ and, for } i > 1,\ \pi_{i-1} p + \pi_i(1-p-q) + \pi_{i+1} q = \pi_i$$

These may be reorganized as

$$-p\pi_0 + q\pi_1 = 0, \text{ and, for } i > 1,\ -p\pi_{i-1} + q\pi_i = -p\pi_i + q\pi_{i+1}$$

Thus $p\pi_i = q\pi_{i+1}$ for all i, and, once we require that the π_i's sum to 1, we get the following unique solution:

$$\pi_i = (1-\rho)\rho^i,\ i = 0, 1, 2, \ldots, \text{ when } \rho = \frac{p}{q} \tag{24}$$

From this, the steady-state probability that the system is empty is $\pi_0 = 1 - \rho$. This is also the long-run fraction of time that the system is empty (see Subsection 3.3). The probability that the system is not empty is $1 - \pi_0 = \rho$. Fleshing out the interpretation of the model, we imagine that the server is busy as long as there is at least one job in the system. Then ρ may be interpreted as the long-run proportion of time that the server is busy. This is known as the *server utilization*. The distribution (24) is called the *geometric distribution with parameter* ρ. Its mean is given by

$$\frac{\rho}{1-\rho}, \tag{25}$$

and this may be described as the steady-state expected number of jobs in the system. As the utilization ρ approaches 1, the expected number of jobs in the system increases in approximate inverse proportion to $1 - \rho$. If the utilization is 99%, then the expected number of jobs waiting is 99. This quantifies

the trade-off between utilization of the server, which we would like to keep high, and work-in-process, which we would like to keep low. This is a significant insight into the behavior of queues, gained from a very simple model.

3.5. Markov Chains in Continuous Time

Suppose now that we have a stochastic process $X(t)$, $t \geq 0$, observed for all times, not just integer times. We take the state space to be the finite set $\{1, 2, \ldots, n\}$ as before. The Markov property in this situation is just as described in Subsection 3.1 for the discrete-time case: knowing the state of X at a time t, its evolution after time t is independent of its history before time t. Briefly, the future is independent of the past, given the present.

Just as the rule whereby a discrete-time chain evolves is defined by a matrix P, the transition matrix, the rule whereby a continuous-time chain evolves is defined by a matrix Q, the generator matrix. The off-diagonal entry q_{ij}, $i \neq j$, of Q has the interpretation that $q_{ij}h$ is approximately the probability that the chain, starting from state i at a time t, makes a transition to state j by time $t + h$, where h is small:

$$P(X(t + h) = j | X(t) = i) \approx q_{ij}h \quad \text{for} \quad i \neq j \tag{26}$$

(The error in this approximation is small compared to h.) Because of this, q_{ij} is called the *transition rate* from state i to state j. It may be described more precisely as the rate of transitions into state j while the process is in state i. The diagonal entries q_{ii} of Q are determined by the condition that the rows of Q must add to 0, which is analogous to the property that the rows of a transition matrix add to 1. So q_{ii} is negative and we denote it by $-q_i$, where

$$q_i = \sum_{j|j\neq i} q_{ij} \tag{27}$$

the sum on the right being over all states except i. (A technical condition assumed throughout is that these quantities are finite.) The transition matrix of X over a time t is defined by

$$P(t) = (p_{ij}(t)), \quad \text{where } p_{ij}(t) = P(X(t) = j | X(0) = i) \tag{28}$$

(Here and below, the notation (a_{ij}) means the matrix of the a_{ij}'s.) Soon we shall develop a simple formula for $P(t)$ in terms of the basic data of the chain, its generator Q.

By the Markov property of X, the process $X(0)$, $X(h)$, $X(2h)$, . . . that results when we observe X at intervals of length h is a discrete-time Markov chain with transition matrix $P(h)$. If we think of h as a small time interval, then equation (26) shows that the transition probabilities of this discrete-time chain are given approximately by

$$\begin{aligned} &p_{ij}(h) \approx q_{ij}h \quad \text{for} \quad i \neq j, \text{ and } p_{ii}(h) \approx 1 - q_ih, \text{ or,} \\ &\quad \text{in matrix form, } P(h) \approx I + hQ \end{aligned} \tag{29}$$

The rows of the matrix $I + hQ$ add to 1 because those of Q add to 0.

We have related the continuous-time chain to a discrete-time chain with a fast clock, whose time unit is the small quantity h but whose transition probabilities $p_{ij}(h)$ are proportionately small for $i \neq j$ by (29). This allows us to analyze the continuous-time chain using discrete-time results. All the basic calculations for continuous-time, finite-state Markov chains may be carried out by taking a limit as $h \to 0$ of the discrete-time approximation. For example, the transition matrix $P(t)$, defined in (28), may be derived as follows. We divide the time interval $[0, t]$ into a large number N of short intervals of length $h = t/N$, so that the transition matrix $P(t)$ is the N-step transition matrix corresponding to $P(h)$. It follows from (29) that $P(t)$ is approximately the N-step transition matrix corresponding to the transition matrix $I + hQ$. This approximation becomes exact as $h \to 0$, and we have

$$\begin{aligned} P(t) &= (p_{ij}(t)) = (P(X(t) = j | X(0) = i)) \\ &= \lim_{h\to 0} (I + hQ)^N = \lim_{N\to\infty} \left(I + \frac{tQ}{N}\right)^N = e^{tQ} \end{aligned} \tag{30}$$

In the final equality here we are using the well-known limit $\lim_{N\to\infty} (1 + x/N)^N = e^x$, which holds even when x is replaced by a matrix, here by tQ. The exponential of a matrix is defined by the Taylor series

$$e^A = I + A + \frac{A^2}{2} + \ldots = \sum_{n=0}^{\infty} \frac{A^n}{n!}$$

Now, some consequences of (30). If we differentiate with respect to t we get

$$\frac{d}{dt} e^{tQ} = Qe^{tQ} \quad \text{or} \quad P'(t) = QP(t), \text{ and similarly } P'(t) = P(t)Q \tag{31}$$

These are called *Kolmogorov's backward and forward equations,* respectively. The *Chapman–Kolmogorov equations* $P(s + t) = P(s)P(t)$ may be deduced from (30) as follows:

$$P(s + t) = e^{(s+t)Q} = e^{sQ+tQ} = e^{sQ}e^{tQ} = P(s)P(t) \tag{32}$$

The generator Q determines how a continuous-time Markov chain evolves via (26). There is another, more direct prescription for the evolution of the chain in terms of Q. If the chain is now in state i, then the time T until the next change of state has the exponential distribution with rate q_i:

$$P(T \leq t) = 1 - e^{-q_i t}, \; t \geq 0 \tag{33}$$

When the chain does leave state i, it chooses its next state $j \neq i$ according to the probabilities q_{ij}/q_i. Why is the time T exponentially distributed? Because the Markov property of X implies that T must have the memoryless property (13), and this in turn implies that T has the exponential distribution.

Example 3.2: Let us illustrate this using the machine-failure example introduced in Subsection 3.1, now reworked in continuous time. The state space $S = \{0, 1\}$ has two states, representing inoperational and operational, as before. The order-2 generator matrix is of the form

$$Q = \begin{pmatrix} -q_0 & q_0 \\ q_1 & -q_1 \end{pmatrix}$$

Here, q_0 may be interpreted as the rate of repair when the machine is inoperational, and q_1 as the rate of breakdown when the machine is operational. In other words, the chain evolves with alternating exponentially distributed inoperational and operational periods, the inoperational periods having rate q_0 and the operational periods having rate q_1.

The Poisson counting process of Section 2 is a continuous-time Markov chain N on the infinite state space $\{0, 1, 2, \ldots\}$, with generator

$$Q = \begin{pmatrix} -\lambda & \lambda & 0 & 0 & \ldots \\ 0 & -\lambda & \lambda & 0 & \ldots \\ 0 & 0 & -\lambda & \lambda & \ldots \\ 0 & 0 & 0 & -\lambda & \ldots \\ \ldots & & \ldots & & \ldots \end{pmatrix} \tag{34}$$

Thus, the transitions are always from a state n to the state $n + 1$. The transitions are, of course, arrivals because they cause the count N to increase by 1. The probability of a transition in a short interval of time h is approximately λh for any n by (26). This observation corresponds precisely with the description of the Poisson process in terms of coin tossing in Section 2. Moreover, the fact that the time between arrivals in a Poisson process is exponential may be seen now as a consequence of the fact, expressed in (33), that the holding times in any continuous-time Markov chain are exponentially distributed.

Let us briefly describe the long-run behavior of continuous-time, finite-state Markov chains. We assume irreducibility as before, which in this case means simply that the entries of $P(t)$ are all positive for $t > 0$. Periodicity does not arise in continuous time. There is a unique distribution π satisfying

$$\pi P(t) = \pi \text{ for all } t \geq 0$$

This is the steady-state distribution of the chain. By differentiation at $t = 0$ using (31), we find that

$$\pi Q = 0, \text{ or } \pi_j q_j = \sum_{i|i \neq j} \pi_i q_{ij} \text{ for all states } j = 1, 2, \ldots, n \tag{35}$$

This relates π to the parameters of the chain—the entries of its generator Q. These are the steady-state equations in the continuous-time case. For finite-state irreducible chains, these equations have a unique solution whose components add to 1, and this solution is the steady-state distribution π. As in the discrete-time case, π is also the limiting distribution of the Markov chain and gives the long-run proportion of time spent in each state. These results extend to the infinite-state case, assuming positive recurrence, as in Subsection 3.3.

Example 3.3: The steady-state distribution of the machine-failure model of Example 3.3 is given by

$$\pi_0 = \frac{q_1}{q_0 + q_1} \text{ and } \pi_1 = \frac{q_0}{q_0 + q_1}$$

This may be seen by solving the equations (35) or by noting that the steady-state probabilities must be proportional to the mean times spent in the states, which are given by (12) as $1/q_0$ and $1/q_1$.

3.6. Reversible Markov Chains and Birth-and-Death Models

Now we consider some special continuous-time Markov chains that arise in discussing simple queueing models. We restrict attention to the continuous-time case, as this is the setting of most of the practical models treated later.

Let X be a continuous-time Markov chain with generator Q and steady-state distribution π. The quantity $\pi_i q_{ij}$, sometimes called the *flux from i to j*, is the rate at which transitions from i to j occur in steady state. Contrast this with the transition rate q_{ij} itself, which is the rate of transitions from i to j when the chain is in state i.

Suppose now that X has state space $S = \{0, 1, 2, \ldots\}$ and each transition is to a neighboring state: the chain goes either up by one or down by one on any transition. Such a process is known as a *birth-and-death process* and is characterized by the *birth rates* $\lambda_i = q_{i,i+1}$ and *death rates* $\mu_i = q_{i,i-1}$. The generator of a birth-and-death process takes the form

$$Q = \begin{pmatrix} -\lambda_0 & \lambda_0 & 0 & 0 & \ldots \\ \mu_1 & -\mu_1 - \lambda_1 & \lambda_1 & 0 & \ldots \\ 0 & \mu_2 & -\mu_2 - \lambda_2 & \lambda_2 & \ldots \\ 0 & 0 & \mu_3 & -\mu_3 - \lambda_3 & \ldots \\ \ldots & & \ldots & & \ldots \end{pmatrix} \tag{36}$$

Now, in the long run, the rate of transitions from state i to $i + 1$ must equal the rate from $i + 1$ to i, because the number of the former type of transition must always be within 1 of the number of the latter type, and therefore

$$\pi_i q_{ij} = \pi_j q_{ji} \tag{37}$$

for $j = i + 1$. This equation states that the flux from i to $j = i + 1$ equals the flux from j to i. This is easily seen to be true not just for neighboring pairs i, j, but for all pairs of distinct states $i \neq j$. The equations (37) are called the *detailed balance equations*. It is easy to deduce the steady-state distribution from (37), the result being

$$\pi_n = C \frac{\lambda_0 \lambda_1 \ldots \lambda_{n-1}}{\mu_1 \mu_2 \ldots \mu_n}, \; n = 0, 1, 2, \ldots \tag{38}$$

where C is a constant chosen to ensure that the π_n's add to 1. (If no such constant exists, then the process is not positive recurrent.) This formula determines the steady-state distribution of a great many simple queueing models, several of which will be discussed in the next section.

A Markov chain satisfying (37) for all pairs of distinct states $i \neq j$ is said to be *reversible,* a somewhat unfortunate choice of term referring to the fact that, if viewed in reverse time while in steady state, it is probabilistically indistinguishable from its forward-time version. (Such a chain might be described more precisely by saying that it is unchanged by time reversal rather than reversible.) Many of the queueing models to be treated later are in fact Markov chains satisfying the property (37) or some related property. See Kelly (1979) for a thorough treatment of such chains.

4. SIMPLE QUEUEING MODELS

Of central interest in designing industrial and service systems is the problem of providing service to a stream of arriving customers or jobs. Because of irregularities in the arrival or service processes, there are times when too much work has arrived in too short a time and so jobs have to wait for service. Even though the system has the capacity to serve all arrivals, randomness generally results in some waiting. Waiting could be eliminated if the irregularity could be eliminated, without increasing overall service capacity or diminishing the overall flow of arriving work. Waiting is therefore a consequence of irregularity. This waiting is central: it occupies resources in the form of waiting space, contributes to work-in-process, causes due dates to be missed, and may cause machines and workers to be starved of work. Much system design focuses on minimizing waiting time. Therefore, many stochastic models also focus on waiting, and models of waiting are called queueing systems, or simply queues.

A queueing system may be divided loosely into three subsystems: the arrival process, the waiting area, and the service system. Each of these subsystems can operate in a variety of ways. The following are some of the more common possibilities. The arrival process specifies a sequence of jobs or batches of jobs and the times at which they enter the system. The arrival times may constitute a Poisson process or a renewal process, for example. The jobs may be indistinguishable from one another, or they may be of several classes, to be treated differently in the waiting or service area. The waiting area may be managed in various ways. Jobs may be ordered according to time of arrival, the most recent arrival being the first to be served (first-in-first-out, or FIFO). This is the most common discipline used in serving people because of the sense of fairness it engenders. To give some simple alternatives, jobs may be served in random order (SIRO) or last-in-first-out (LIFO). Under the processor sharing (PS) discipline, all jobs present share the server's attention equally. Jobs may also be served according to priorities determined based on job class or service needs. Preemption, in which an arriving high-priority job ejects a low-priority job from service, may or may not be allowed. The service system is where the jobs receive what they have waited for. There may be one or many servers, and the servers may be subject to breakdowns. Jobs may be served singly or in batches, and service times may depend on job class. See Hall (1991) for a discussion of modeling real systems as queues, with a careful treatment of the role of these three subsystems.

4.1. Notation

The queues of this section all belong to the class $G/G/s/K$. The four elements in this notation have the following meanings. The first element refers to the arrival process, G indicating generally distributed interarrival times. Independence of these times is assumed. Thus, the first G indicates that arrivals form a renewal process. The second element describes the service times, the G again indicating a general distribution. Independence is again assumed, and moreover, it is assumed that interarrival times are independent of service times. The third element, s, is the number of servers, and the last element, K, is the capacity of the system. $K - s$ is therefore the capacity of the waiting area. If the parameter K is not present, an unlimited capacity is assumed. If one of the G's is replaced by M, this indicates that the corresponding distribution is exponential. The M connotes the property of memorylessness (13). For example, the $M/M/1$ queue is the special case of the $G/G/1$ queue in which the arrivals are Poisson and the service distribution is exponential. D, standing for deterministic, is used to indicate constant service or interarrival times.

It is standard to denote the long-run arrival rate of a queue by λ and the long-run service rate (of one server) by μ. To avoid having to deal with unimportant special cases, we always assume that these rates are positive—that is, that they are not zero. In the case of renewal arrivals and independent, identically distributed service times, the expected interarrival time is then $1/\lambda$ and the expected service time is $1/\mu$. Throughout, ρ denotes the *traffic intensity* λ/μ of the arriving stream of jobs, which is the rate at which work arrives, work itself being measured in terms of the time it takes a server to perform it. Another quantity of importance is the server utilization, which is the proportion of time that a server is busy. For a single-server queue, the utilization and the traffic intensity are equal.

$L(t)$ will denote the load, or number of jobs in the system, waiting or being served, at time $t \geq 0$. For each model considered in this section, the distribution of $L(t)$ approaches a limit as $t \to \infty$, and the limit is referred to as the steady-state distribution of the number in the system. (As we said in Subsection 3.3, we do not distinguish carefully between steady-state and limiting distributions.) We denote by L a random variable whose distribution is this steady-state distribution. Let W_n denote the time-in-system or *flow time* of the nth arrival to the system. Then, for the models considered here, the distribution of W_n also has a limit as $n \to \infty$, which we call the *steady-state flow-time distribution*. We denote by W a random variable with this distribution. In the same way we can define a random variable W_Q whose distribution is the steady-state distribution of waiting time. Flow time and waiting time differ only in that the latter does not include service time. Most of the results given here concern the expected values of the random variables L, W, and W_Q for various queues. These

expected values are called *steady-state expected values.* For some technicalities concerning steady-state and long-run averages, see Subsection 5.1. For more on these models, see the books referred to in Subsection 1.1 or any of the many introductory texts on queues.

4.2. Simple Markovian Queueing Models

In this subsection we treat several queues of the $M/M/s/K$ type. These queues have Poisson arrivals, exponential service times, s servers, and capacity K. For these queues, the number-in-system $L(t)$, $t \geq 0$, is a continuous-time Markov chain, in fact, a birth-and-death process (Subsection 3.6). The Markov property arises from the exponentiality of service and interarrival times—see the discussion following (33). The queueing discipline is taken to be FIFO in every case. The results presented here follow fairly directly from (38).

4.2.1. M/M/1 Queue

This is the single-server queue with Poisson arrivals and exponential service. It is the continuous-time analog of the simple queue treated in Subsection 3.4. It may be viewed as a birth-and-death process, with generator (36) where $\lambda_n = \lambda$ and $\mu_n = \mu$ for all $n \geq 0$. The fact that the birth rates are constant is what makes the arrival process Poisson. Suppose that the traffic intensity $\rho = \lambda/\mu$ is less than 1. This condition is an example of the general *capacity condition* (57) below, as it concerns the capacity of the server to handle the arriving work. It implies that the process is positive recurrent. The steady-state distribution of the number in the system L may be derived directly from (38) and is the same geometric (ρ) distribution that arose in (24) for the discrete-time queue of Subsection 3.4. The steady-state distribution of flow time W is exponential with rate $\mu(1 - \rho)$. The steady-state expected number-in-system, time-in-system, and waiting time are

$$E(L) = \frac{\rho}{1 - \rho}; \; E(W) = \frac{1}{\mu(1 - \rho)}; \; E(W_Q) = \frac{\rho}{\mu(1 - \rho)} \tag{39}$$

4.2.2. M/M/2 Queue

Here we increase the number of servers to two. Assume now that $\rho < 2$, so that the two servers are sufficient to handle the arriving work. The $M/M/2$ queue is the birth-and-death process with $\lambda_n = \lambda$ for all $n \geq 0$, $\mu_1 = \mu$, and $\mu_n = 2\mu$ for $n \geq 2$. The new μ_n's express the idea that when there are two or more jobs in the system, both servers are busy and so the overall rate at which service is provided is doubled. The steady-state probabilities are given by

$$\pi_0 = \frac{2 - \rho}{2 + \rho}; \; \pi_n = 2\pi_0 \left(\frac{\rho}{2}\right)^n, \; n > 0 \tag{40}$$

For this queue we record the steady-state expected number-in-system and flow time:

$$E(L) = \frac{\rho}{1 - \rho^2/4}; \; E(W) = \frac{1}{\mu(1 - \rho^2/4)} \tag{41}$$

4.2.3. M/M/∞ Queue

This is the birth-and-death process with $\lambda_n = \lambda$ and $\mu_n = n\mu$ for all $n \geq 0$. The service rate is proportional to the number of jobs in the system, and this captures the idea that each job is being served simultaneously at the same rate, μ. The steady-state distribution of the number in the system is Poisson (ρ), again by (38), where $\rho = \lambda/\mu$ is the traffic intensity as usual. Thus, the expected number in the system is simply $E(L) = \rho$. Since there is no waiting in this system, other quantities are easy to derive but perhaps not very informative. For example, the distribution of the steady-state time-in-system W is the same as the service distribution, namely, exponential with rate μ.

4.2.4. Erlang Loss System M/M/s/s

Although this model is associated with telephony rather than industrial engineering, its historical importance and simplicity justify mentioning it. Suppose we have a telephone exchange with s circuits, meaning that it can handle at most s simultaneous calls. The key measure of performance of this system is the fraction of calls that are "lost," i.e., that arrive to find all circuits busy. Erlang modeled this system as an $M/M/s/s$ queue in which calls arrive in a Poisson process of rate λ and last an exponential time with mean $1/\mu$. The servers here are the circuits. This may be viewed as the birth-and-death process with $\mu_n = n\mu$ for $n \geq 0$, $\lambda_n = \lambda$ for $n \leq s$, and $\lambda_n = 0$ for $n > s$. The steady-state distribution π may be found from (38), giving

$$\pi_n = \frac{\lambda^n/n!}{1 + \lambda + \lambda^2/2! + \ldots + \lambda^s/s!}, \; n = 0, 1, \ldots, s \tag{42}$$

With $n = s$, this is the proportion of time that all s circuits are busy. This is also the proportion of arriving calls that are lost, because of the PASTA property to be discussed below in Section 5.5. Equation (42) in the case $n = s$ is the celebrated *Erlang loss formula*.

4.3. A Comparison of Systems

To illustrate what can be gained from the mathematical results of the previous subsection, we present a comparison of three systems. The three systems are identical in the load that must be served and in the service capacity available, but differ slightly in the queueing discipline. Here are the systems.

- *System 1* consists of two separate single-server queues, each having arrivals at rate λ and service at rate μ. This system is modeled as two independent $M/M/1$ queues.
- *System 2* consists of a single queue served by a pair of servers. The arrival stream has rate 2λ, and each server serves at rate μ. This is modeled as an $M/M/2$ queue.
- *System 3* consists of a single queue with an arrival stream of rate 2λ and a single server serving at rate 2μ. This is modeled again as an $M/M/1$ queue.

Denoting λ/μ by ρ, the overall traffic intensity in each case is 2ρ (not ρ). Using formula (39) above for the first and third systems and (41) for the second, the steady-state mean numbers-in-system for the three cases may be found, leading to

$$E(L_1) = 2\,\frac{\rho}{1 - \rho} \geq E(L_2) = \frac{2\rho}{1 - \rho^2} = \left(\frac{2}{1 + \rho}\right)\frac{\rho}{1 - \rho} \geq E(L_3) = \frac{\rho}{1 - \rho}$$

Thus, from the viewpoint of work-in-process, the third system is the most favorable and the first is the least favorable. This has a simple explanation. System 1 compares poorly to system 2 in that the former may have an idle server when there are two jobs in the system, whereas this cannot occur in the latter. Also, system 2 compares poorly to system 3 in that the former serves at half the rate of the latter when there is only one job in the system. Combining the queues almost halves average work-in-process for high traffic intensities. Using a single fast server to serve the combined queue halves average work-in-process for all traffic intensities. The comparison is intuitive. The process of modeling has led to quantification of the intuition that is satisfying and natural, even if the assumptions of the models, such as exponentiality, are somewhat arbitrary. The advantage of maintaining a single queue served by several servers over having a separate queue for each server, demonstrated here in the comparison of system 1 and system 2, is well known and is put to good use in many retail banks and at airline check-in counters.

4.4. Models Based on the $M/G/1$ Queue

The $M/G/1$ queue is a single-server queue with Poisson arrivals and independent, identically distributed service times having an arbitrary distribution. Here we analyze this queue and several of its variants. The results show that quite a broad range of phenomena can be modeled simply enough to allow basic performance measures to be given by explicit formulas. As always, λ and μ denote the arrival and service rates, respectively.

4.4.1. M/G/1 Waiting Time Formula

The *Pollaczek–Khintchine formula* gives the steady-state expected waiting time for this queue as

$$E(W_Q) = \frac{\lambda E(S^2)}{2(1 - \rho)} = \frac{\rho(1 + c_s^2)}{2\mu(1 - \rho)} \tag{43}$$

where S is a random variable whose distribution is the service distribution and c_s^2 is its SCV. The $M/M/1$ queue is a special case, for which $c_s^2 = 1$. See (39).

4.4.2. M/G/1 under a Priority Discipline

Suppose that, instead of a homogeneous stream of arriving jobs, the jobs are of different classes that are treated differently in the queue. The classes range from 1 to p, say, and jobs of class k, $1 \leq k \leq p$, are given priority k. This means that a job of class k in the queue would be allowed to enter service only if there were no higher priority jobs (i.e., jobs of class $k' < k$). The discipline is taken

to be nonpreemptive, so that a low-priority job in service will complete service rather than being ejected by an arriving high-priority job. Jobs of class k are assumed to arrive in a Poisson process, with rate λ_k, and are assumed to have their own characteristic service distribution function G_k. We write λ for the overall arrival rate, ρ_k^+ for the traffic intensity of jobs of priority k or higher, and μ_k for the service rate of class k:

$$\lambda = \sum_{i=1}^{p} \lambda_k,\ \rho_k^+ = \sum_{i=1}^{k} \frac{\lambda_i}{\mu_i} \text{ and } \frac{1}{\mu_k} = \int_0^\infty x dG_k(x)$$

We also introduce S, a random variable with the aggregated service distribution, whose distribution function is defined as $G = \Sigma\ \lambda_k G_k/\lambda$. With this notation, we have the following formulas for the steady-state expected waiting time of jobs of each class.

$$E(W_Q^1) = \frac{\lambda E(S^2)}{2(1 - \rho_1^+)} \text{ and, for } k > 1,\ E(W_Q^k) = \frac{\lambda E(S^2)}{2(1 - \rho_k^+)\ (1 - \rho_{k-1}^+)}$$

It may be shown from this that, in order to minimize the expected number of jobs in the system (work-in-process), the shorter jobs should receive higher priority. This is a manifestation of the general principle that short jobs should be served first. For details, see for example Buzacott and Shanthikumar (1993). This underlies the idea of having express checkout lines in supermarkets.

4.4.3. The M/G/1 Queue with Batch Arrivals

Suppose that, instead of jobs arriving singly at the Poisson arrival times, they arrive in batches. Suppose that the batch sizes are independent and identically distributed. This arrival process is known as a *compound Poisson process* and is fundamentally more variable than the Poisson process. We assume the FIFO discipline. We write m_B and c_B^2 for the mean and SCV of batch size. Then the traffic intensity is $\rho = \lambda m_B/\mu$, where λ is the arrival rate of batches and μ is the service rate of individual jobs. It is easy to derive the steady-state expected waiting time in this system. The nth *batch waiting time* is the time between the arrival of the nth batch and initiation of service for the first job in the batch. By treating an entire batch as a single job, the steady-state batch waiting time may be deduced directly from the Pollaczek–Khintchine formula (43) as

$$E(W_{Q(\text{Batch})}) = \frac{\rho(1 + c^2)}{2\mu(1 - \rho)} \tag{44}$$

where c^2 is the SCV of the service time of an entire batch, which may be expressed in terms of the SCV of service for a single job as $c^2 = c_B^2 + c_s^2/m_B$. The expected waiting time for a job, rather than a batch, is found by adding to (44) the expected total service time of all jobs ahead of a typical job in a batch, and this gives

$$E(W_Q) = \frac{\rho(1 + c^2)}{2\mu(1 - \rho)} + \frac{1}{\mu}\frac{E(B(B - 1))}{2m_B} \tag{45}$$

where B is a random variable having the batch-size distribution.

4.5. Examining the Assumptions of a Simple Queueing Model

In building a stochastic model for a real system, we make various simplifying assumptions for reasons of tractablility or parsimony. To be effective in modeling, we must appreciate the consequences of these assumptions. In this subsection we illustrate what is involved in this aspect of model building by considering an idealized example. We consider the $M/M/1$ queue as a model for a single worker performing an operation on arriving workpieces. The primary reason for adopting such a model is the mathematical tractability that comes as a consequence of the Markov property. Now we consider the implications of this model.

As we saw in Section 2, Poisson arrivals may be thought of as completely random arrivals in a very exact sense. They are neither too regular, as for example if they came once every five minutes, nor too irregular, as for example if they came in batches of between 1 and 20 with highly variable interarrival times. The Poisson process implies memorylessness, in that observations of past arrivals give no hint as to future arrivals. To expand on this property, if the arrivals to the real system have been unusually heavy recently, this is no indication that they will continue to be heavy, nor is it an indication that they will become less heavy. If actual arrivals tend to come in clusters, or if the arrival rate fluctuates throughout the workday, the Poisson model may be inappropriate. The qualitative

behavior of the Poisson process may or may not be consistent with the actual nature of the system. The success of the model may depend heavily on having consistency here.

The assumption that the service times are independent implies, for example, that knowledge of one service time tells us nothing about the next service time. If one service time is particularly long, then this gives us no reason to expect the next one to be long, or short, or unusual in any way. In reality, there may be serial correlations between the service times, caused for example by fluctuations in the attentiveness of the worker or in the quality of the arriving workpieces. This, of course, violates the assumption of independent service times. These effects may give rise to a tendency to have several long or short service times in a row, which would tend to increase waiting times.

Service times are also assumed to follow the exponential distribution in the $M/M/1$ model. One feature of the exponential distribution is that it is highly variable. For this distribution, 14% of service times are over twice the average service time and 39% of service times are less than half the average. This variability is inconsistent with a routine manual task performed on uniform parts. It may be consistent with a cognitive task, such as diagnosis of the cause of a malfunction. So whether this assumption is reasonable depends heavily on the nature of the task being performed.

Good modeling requires that we understand the qualitative consequences of modeling assumptions and that we use this understanding to make choices consistent with the reality we are trying to model.

5. SOME GENERAL PRINCIPLES

5.1. Long-Run Behavior

The first focus of the mathematics of stochastic models is to determine long-run or steady-state behavior. This is because long-run behavior requires less detail to describe than the full evolution of the system, and it often gives a good sense of the overall behavior of the system over the time frame for which it is to be in operation. In interpreting results on long-run behavior, one must bear in mind a sense of how long a time interval is needed before average performance may be approximated by long-run performance.

5.1.1. Steady-State vs. Long-Run Averages

As we saw in Subsection 3.3, there are several competing descriptors of long-run behavior, including steady-state expected values, which are averages with respect to the steady-state or stationary distribution, and long-run or time averages. Usually, the mathematics leads most easily to steady-state averages. This is exemplified by the fact that, in a Markov chain, the steady-state distribution π is easy to characterize and to compute. *Ergodic properties* are equalities between these two kinds of averages. To relate this to queues, as before let us denote by $L(t)$ the number-in-system at time t for a certain queueing system, and by W_n the time-in-system for the nth job to arrive. Define the long-run average number-in-system by

$$\overline{L} = \lim_{T\to\infty} \frac{\int_0^T L(t)\, dt}{T} \tag{46}$$

Similarly, define the long-run average time-in-system by

$$\overline{W} = \lim_{n\to\infty} \frac{W_1 + W_2 + \ldots + W_n}{n} \tag{47}$$

Let L and W be random variables whose distributions are the steady-state distributions of the number-in-system and time-in-system for the queue, respectively. Then, in great generality, we have the ergodic properties

$$\overline{L} = E(L) \text{ and } \overline{W} = E(W) \tag{48}$$

The difficulty in understanding these statements is not to see that they are true but to distinguish between the concepts represented by the two sides of the equalities.

5.1.2. What Goes In Must Come Out

This simple principle, more formally expressed, says that the long-run arrival rate to a system equals the long-run departure rate. The reason is clear: the difference between the number of arrivals and the number of departures over a time interval equals the change in the number of jobs actually in the system, and, as long as the number in the system is not allowed to grow relentlessly, the numbers

of arrivals and departures cannot differ by very much. This simple fact leads quickly to the important *traffic equations* (53) for a queueing network.

5.1.3. Little's Law and Other Conservation Laws

Suppose jobs arrive at a system, spend some time there, perhaps waiting and being served, and then depart. The system may be a warehouse or other storage system, a queueing system, or perhaps something more complex, such as a queueing network. Using the notation of (46) and (47), it may be shown in great generality that

$$\overline{L} = \lambda \overline{W} \tag{49}$$

This is *Little's law*. Illustrations of it may be seen in (39) and (41), once the ergodic relations (48) are taken into account. To justify (49) heuristically, following Ross (1997), if jobs arrive at rate λ and on average spend time $\overline{W}$ in the system, then demand for occupancy of the system arrives at a rate of $\lambda\overline{W}$, and so occupancy must be supplied at a rate of $\lambda\overline{W}$ also, meaning that $\lambda\overline{W}$ jobs must be present on average.

This simple fact may be applied to various systems. For example, in the context of a queue, the "system" could be taken to mean the waiting area or the service area rather than the entire system. If applied to the service area of a single-server queue, Little's law yields

$$1 - P(L = 0) = \lambda \left(\frac{1}{\mu}\right), \text{ or } P(L = 0) = 1 - \rho \tag{50}$$

To see that this is a special case of (49), note that $1 - P(L = 0)$ is not only the steady-state probability that the server is busy, it is also the steady-state expected number of jobs in service, which in turn, by an ergodic property, is the time-average number of jobs in the system in question. Of course, $1/\mu$ is the expected time in service and plays the role of $\overline{W}$ in (49). When Little's law is applied to the waiting area, it tells us that the expected number of jobs waiting is the product of the arrival rate and the average waiting time.

5.2. Behavior of a Bottleneck Queue

A bottleneck station is a station with sufficiently high server utilization to cause substantial delays. These are also called stations in *heavy traffic*. In a manufacturing system, such stations are often the ones of greatest interest. They typically represent the critical resources and may be responsible for most of the work-in-process and waiting. Despite the complexity of the exact analysis of the $G/G/1$ queue, in heavy traffic the behavior is somewhat simple. It may be shown that the steady-state expected waiting time satisfies

$$E(W_Q) \approx \frac{\rho(c_a^2 + c_s^2)}{2\mu(1 - \rho)} \tag{51}$$

in the sense that the ratio of the two sides of the approximation converges to 1 as $\rho \to 1$. Here, c_a^2 and c_s^2 are the SCVs of interarrival and service time, respectively. For a more precise statement, see Asmussen (1987). This approximation is exact for the $M/G/1$ queue, in which case $c_a^2 = 1$. See (43).

A common feature of all the waiting-time formulas we have had, from the simple (25) to the general (51), is the presence of the factor $1 - \rho$ in the denominator. This is an important observation. As utilization at a station increases from 90% of capacity to 99%, waiting times [and so also loads, by (49)] typically increase by a factor of 10.

5.3. Deleterious Effects of Variability

In the Pollaczek–Khintchine formula, increasing the SCV of service causes the mean waiting time to increase also. This illustrates the general principle that increasing variability reduces performance. The same principle is illustrated more fully by the approximation (51) for the steady-state expected waiting time in a $G/G/1$ queue in heavy traffic. There we see that the SCVs of the interarrival and service times contribute equally to the approximate expected waiting time.

In the $G/G/1$ queue, it is not true in complete generality that increasing the *variance* of service times, say, will cause average waiting time to increase. To formalize this intuitive idea, we need a sufficiently stringent definition of increased variability. See Ross (1996) for a discussion of the stochastic ordering that makes the intuition precise.

5.4. Rate of Convergence to Steady State

An important example of the usefulness of the mathematics of stochastic models arises when simulating queues with fairly high server utilizations. It is not unusual to find that the mean waiting time,

say, is highly variable. Here is a fairly common experience. We carry out a simulation run on a model of a manufacturing system, involving the processing of $n = 100{,}000$ jobs. We compute the mean waiting time $\overline{W}_n$ over the run. Now we repeat the experiment, with a different seed for the random number generator, and compute another mean waiting time $\overline{W}'_n$. $\overline{W}_n$ and $\overline{W}'_n$ may well differ by on the order of 20%. The source of this extreme variability may not be clear from the model being simulated, and yet such variability in a real system would be indicative of poor design. To explain this phenomenon mathematically, suppose we are simulating a very simple system, say a $G/G/1$ queue. It may be shown that the asymptotic distribution of the mean $\overline{W}_n$ of the first n waiting times, for n large and ρ near 100%, is normal with expected value given by (51) and CV

$$\frac{1}{(1-\rho)}\sqrt{\frac{2(c_a^2 + c_s^2)}{n}} \tag{52}$$

(See Whitt 1989 and Asmussen 1992 for more on these limit results.) Because we must choose the simulation run-length n large enough to make this small, a substantial multiple of $(1-\rho)^{-2}$ waiting times is needed to get a reliable estimate of $\overline{W}$ from simulation. If $\rho = 0.95$, then $(1-\rho)^{-2} = 400$, and for an $M/M/1$ queue, for which $c_a^2 = c_s^2 = 1$ (see Subsection 1.3), the indications are that about 160,000 waiting times are needed to estimate $\overline{W}$ to about 20% accuracy with 95% probability. One interpretation of this result is that the queue converges to steady state very slowly for high traffic intensities, resulting in persistent correlations between the successive waiting times and slow attenuation of the variance of the mean waiting time as run-length n increases. This capability that the mathematical analysis of stochastic models provides to explain qualitatively and thereby validate the behavior of simulations is perhaps one of its most important uses in engineering.

5.5. ASTA and PASTA

Consider an $M/G/1$ queue with batch arrivals, the average batch size being 10 jobs. Suppose that the traffic intensity is low, say $\rho = 0.1$. Then arriving jobs see the queue in atypical conditions because 90% of them see other jobs ahead of them in the queue, whereas, since the traffic intensity is 0.1, in fact the queue is empty 90% of the time by (50). So jobs may tend to arrive when the station is busy, as in the example just given, or they may tend to arrive when it is not busy. The latter occurs in the $D/D/1$ queue, in which arrival and service times are constant. Suppose that initially the queue is empty and each interarrival time is 1 unit while each service time is 0.9 units. Then, although the utilization is 90%, no job ever has to wait. Incidentally, this illustrates the remark made earlier that waiting can be eliminated without increasing server capacity if variability can be eliminated.

What of the $M/M/1$ queue? Again, it illustrates something interesting—a perfect balance between the two extreme examples of the previous paragraph. It illustrates the property that *Poisson arrivals see time averages* (PASTA). More informally, Poisson arrivals see typical conditions. This property means that if we were to make observations on the queue at the arrival times, the distribution of these observations would be the time-average distribution of the system. In particular, the average number of jobs in the system just before arrival times is the same as the long-run average number of jobs in the system. Similarly, the proportion of arrivals that find the queue empty is precisely $1 - \rho$, the long-run proportion of time that the queue is empty.

This property extends to some more complex situations. For example, in the *open product-form queueing networks* to be discussed in the next section, the arrivals to the individual queues see the entire network in time-average (or steady-state) conditions. These arrivals are not necessarily Poisson, and so the acronym ASTA (arrivals see time averages) has been coined to describe this situation.

6. QUEUEING NETWORKS

A queueing network is a collection of stations among which jobs move and compete for service. Each station is a queueing system in its own right. Queueing networks are commonly used as models for manufacturing, telecommunication, and transportation systems. These models are usually analyzed by simulation. The level of complexity of queueing network models, from the viewpoint of mathematical analysis, is far beyond that of the individual stations. This is because the process of going from a single queue to a queueing network is the process of increasing the dimensionality of the model—going from a single dimension to many. As in all areas of applied mathematics, this brings with it a qualitative increase in difficulty. This is Bellman's "curse of dimensionality." Because of this, queueing networks must be approached with modest expectations as to what may be accomplished.

To understand what is known about queueing networks, one must recognize first that some networks have truly complex behavior and that a general and detailed theoretical understanding of them is probably unattainable. On the other hand, there is a remarkable class of networks, the *product-form networks,* for which a great deal is known. To a certain extent, these networks behave as if they

consisted of collections of independent stations, and to that extent the stations may be analyzed separately. Thus, a high-dimensional problem is replaced by several low-dimensional problems. In Subsections 6.1 and 6.2, we treat product-form networks. Then, to highlight the special nature of these networks, in Subsection 6.3 we discuss some networks whose behavior is complex and difficult to analyze. In particular, these networks may allow queues to grow without bound even when there is sufficient service capacity to process all arriving work. In between these extremes, there appear to be many queueing networks which, although not product form, are fairly amenable to simple *decomposition approximations.* This is the topic of Section 7.

It is difficult to describe the family of product-form networks qualitatively. One attempt is to say that they are a family of networks in which jobs behave in a highly random but nonconspiratorial manner. This is to say, the jobs do not interfere with one another in complex ways: they do not tend to batch together in their movements, and when a job arrives at a station it tends to see that station, and the larger network, in a typical condition, in the sense of the ASTA property discussed in Subsection 5.5. In particular, jobs are neither more nor less likely to arrive when a station is heavily loaded.

6.1. Jackson Networks

We describe the famous *Jackson networks* and discuss their remarkably simple steady-state distributions. Consider a network of M FIFO stations. Let s_m denote the number of servers at station m, $m = 1, 2, \ldots, M$. *Exogenous* arrivals, that is, arrivals from outside the network, enter station m in a Poisson process of rate λ_m^*. Jobs at station m require exponential service with rate μ_m. When a job completes service at a station, it either visits another station or leaves the network. The probability that a job that has just completed service at station m next goes to station n is written as p_{mn}, the choice of next station being independent of everything that has happened up to the time that choice is made. These routing probabilities are collected into an $M \times M$ routing matrix $P = (p_{mn})$. The technical condition that $I - P$ be invertible is needed to ensure that all jobs eventually leave the network.

This is quite a complicated process. Jackson's (1957) remarkable discovery was that the steady-state distribution is very simple. To identify it, we first find the overall arrival rate λ_n at each station n—this is the total of the exogenous arrival rate and the arrival rate of jobs from within the network. The exogenous arrival rate is λ_n^*. The exogenous arrival stream must be combined with the streams of jobs routed to station m after completing a service. A proportion p_{mn} of the jobs completing service at station m is routed to station n, for each $m = 1, 2, \ldots, M$. But the departure rate from station m is the same as its arrival rate, λ_m ("what goes in must come out"—see Section 5.1), and so we have

$$\lambda_n = \lambda_n^* + \sum_{m=1}^{M} \lambda_m p_{mn} \tag{53}$$

These equations are called the traffic equations. Invertibility of $I - P$ implies that these equations have a unique solution in the λ_ms. Suppose now that $\rho_m < s_m$, $\lambda_m > 0$ and $\mu_m > 0$ for each $m = 1, 2, \ldots, M$. These conditions ensure that the network is an irreducible, positive recurrent Markov chain. Jackson proved the following result: The steady-state distribution of the number of jobs at each station in the Jackson network is the same as that of M independent stations, the mth being an $M/M/s_m$ queue with arrival rate λ_m and service rate μ_m.

Here is a simple consequence. If we take each station to be a single-server queue, and denote by ρ_m the traffic intensity λ_m/μ_m of the mth station, then the steady-state expected flow time (of an exogenous arrival), written $E(T)$, of a job through the network is

$$E(T) = \frac{1}{\sum_{m=1}^{M} \lambda_m^*} \sum_{m=1}^{M} \frac{\rho_m}{1 - \rho_m} \tag{54}$$

To explain, the rightmost sum is the expected total number in the system by (39). This is divided by the overall exogenous arrival rate to get the average time-in-system, using Little's law (49).

Example 7.1: Consider the simple network depicted in Figure 2. There are two stations in tandem, processing an exogenous stream of rate $\lambda_1^* = 1$ arriving at the first station. There are no exogenous arrivals at the second station, so $\lambda_2^* = 0$. The service rates are $\mu_1 = 5$ and $\mu_2 = 4$. For any job completing service at the second station, there is a probability $p_{21} = 0.5$ that it will be sent back through the two stations again. Otherwise, it departs the network. By solving the traffic equations (53), we find the total arrival rates at the stations to be $\lambda_1 = \lambda_2 = 2$. Therefore the traffic intensities are $\rho_1 = \lambda_1/\mu_1 = 2/4 = .5$ and $\rho_2 = \lambda_2/\mu_2 = 2/5 = 0.4$, which are both less than 1 and so the

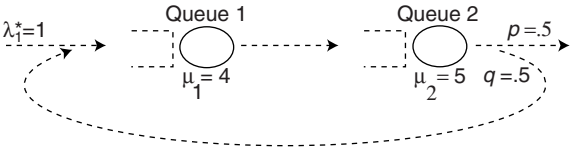

Figure 2 A Simple Queueing Network.

network is positive recurrent. Now from (54), the steady-state expected flow time of an exogenous arrival through the network is

$$E(T) = \frac{1}{\lambda_1^*}\left(\frac{\rho_1}{1-\rho_1} + \frac{\rho_2}{1-\rho_2}\right) = 1 + \frac{2}{3} = 1.666$$

The mean waiting times per arrival (rather than per exogenous arrival) at the two stations are given by

$$E(W_Q^{-1}) = \frac{0.5}{(4)\ (1-0.5)} = 0.25 \text{ and } E(W_Q^2) = \frac{0.4}{(5)\ (1-0.4)} = 0.133$$

6.2. General Product-Form Networks

In the Jackson network, the jobs at a station are indistinguishable in that they all have the same service requirements and all follow the same routing rules. This is a feature possessed by few real-world systems. Jobs in a queue often differ in urgency, routing, and service requirements. In this subsection we discuss *multiclass product-form networks,* in which jobs are distinguishable into classes, each class having its own distinctive routing pattern. In the networks considered, jobs behave in the same highly random but nonconspiratorial manner we observed in Jackson networks. We also consider some variations involving nonexponential service distributions and priority disciplines.

The first step in defining multiclass networks is to introduce a framework for describing a variety of routing rules in a simple, unified way. In this framework, each job in the network has a class. This class characterizes which station the job is presently at and the rule whereby it chooses its next class. Each class is associated with one and only one station, and so, when a job chooses its next class, this also determines its next station. Suppose our network is composed of M stations serving a total of K classes of jobs. Let $P = (p_{k\ell})$ denote a $K \times K$ *routing matrix,* which is to say $p_{k\ell}$ is the probability that a class-k job becomes a class-ℓ job after completing service. We suppose that $I - P$ is invertible, which is to say each job eventually leaves the network. One important special case allowed under this model is that of several different *types* of job, each type making transitions from one station to another according to its own $M \times M$ routing matrix. In this special case, job class is determined by both current station and type, and the type of a job never changes.

Once we have define the routing rules, the traffic equations for our multiclass network may be written down, using the same logic as in (53). These are

$$\lambda_\ell = \lambda_\ell^* + \sum_{k=1}^{n} \lambda_k p_{k\ell},\ \ell = 1, 2, \ldots, K \tag{55}$$

where the exogenous arrival rates λ_ℓ^* and the total arrival rates λ_ℓ are now specified for each class $\ell = 1, 2, \ldots, K$ rather than for each station as in (53). Note that the service distributions do not enter into this equation. Once we specify the service rates μ_ℓ for each class, the class traffic intensities $\rho_\ell = \lambda_\ell/\mu_\ell$ are determined. The traffic intensity at a *station* is the sum of the traffic intensities of its classes:

$$\rho^{(m)} = \sum_{\substack{\text{all classes } \ell \text{ served} \\ \text{at station } m}} \rho_\ell,\ m = 1, 2, \ldots, M \tag{56}$$

To complete the description of a family of multiclass queueing networks, we suppose that all exogenous arrival processes are independent Poisson processes, that the queues are FIFO, and that the service distributions at each station are exponential. We write s_m for the number of servers at station m, $m = 1, 2, \ldots, M$. This network is not a product-form network, in general. However, if

we further suppose that all classes ℓ served at a given station m have the same service rate $\mu^{(m)}$, so that $\mu_\ell = \mu^{(m)}$ for each such ℓ and m, then the network is product form. We refer to this network as the *standard multiclass product-form network*. We assume that the traffic intensity $\rho^{(m)}$ at each station m is less than the number of servers:

$$\rho^{(m)} < s_m,\ m = 1, 2, \ldots, M \tag{57}$$

This condition is known as the *capacity condition*. It ensures that sufficient service capacity is available to handle the arriving work. Special cases of this condition have arisen at several earlier points in this chapter. If the station service rates $\mu^{(m)}$ and the class total arrival rates λ_k are all positive, then (57) implies that the standard multiclass product-form network is an irreducible, positive recurrent Markov chain. Remarkably, an explicit formula for the steady-state distribution of this network is known (Kelly 1979). While the formula is complicated, it has a simple description in words.

1. The configurations (i.e., the classes and positions in queue of all the jobs) of the different stations at a fixed time in steady state are independent.
2. The number of jobs at station m has the same steady-state distribution as the $M/M/s_m$ queue with traffic intensity $\rho^{(m)}$.
3. Given that there are n jobs present at a particular station m, the number of jobs of each class has the multinomial distribution (Ross 1997) with n trials and with outcome probabilities $\rho_\ell/\rho^{(m)}$ for classes ℓ served at station m.

The distribution of the overall numbers of jobs at the stations described in (1) and (2) is exactly as in the Jackson network. Formulas for steady-state waiting and flow times in this multiclass network may be written down just as we did in the case of Jackson networks—see, for example, (54).

We can generalize the standard multiclass product-form network in several ways and still get the same simple steady-state distribution. Instead of the FIFO discipline, we can use any queueing discipline that depends only on the position of the jobs in the queue (and not, for example, on a job's class or service time) and the same steady-state distribution will apply. Under certain queue disciplines, nonexponential service distributions may be allowed, and the service distribution may be allowed to depend on class. These disciplines include SIRO, PS, and preemptive LIFO, which were discussed in the introduction to Section 4. The $M/M/s$ queue under any of these disciplines becomes what is known as a *symmetric queue* (Kelly 1979), and this property underlies the possibility of relaxing the exponentiality assumption while maintaining the product-form steady-state distribution.

All of these networks have very special structure, however, either having exponential service with a rate that does not depend on class or a somewhat exotic service discipline. And yet the product-form networks constitute a broad family having a simple steady-state behavior. It seems reasonable to view this steady-state behavior as in some sense typical of a well-behaved queueing network and to use the product-form solution as a first approximation to any reasonable network.

6.3. General Networks: Stability and Instability

A simple example of an unstable queue is an $M/M/1$ queue in which the arrival rate λ exceeds the service rate μ. For this queue, the number in the system grows without bound. In fact, the number of jobs in the system at time t, $L(t)$, satisfies

$$\lim_{t\to\infty} \frac{L(t)}{t} = \lambda - \mu > 0 \tag{58}$$

so the amount of work in the system grows roughly linearly over time. This kind of behavior cannot persist for very long in real systems, as waiting jobs will ultimately overwhelm any finite storage capacity. This is a strong form of instability. In contrast, if $\lambda < \mu$ then the limit of (58) is zero and, moreover, the expected queue size at time t converges to the value given in (39) as $t \to \infty$. This is typical of a stable queue. The critical case, in which $\lambda = \mu$, is more subtle; here the expected queue size at time t grows like $\sqrt{t}$. This we classify as unstable also.

For Markovian networks (with a discrete state space), there is a convenient definition of stability: a stable network is one that is a positive recurrent Markov chain. This definition may be extended to more general networks, but doing this formally would require a mathematical digression. For a detailed discussion of stability, see Meyn and Tweedie (1993).

The $M/M/1$ queue with $\lambda > \mu$ fails to be stable for a very simple reason: there is insufficient service capacity to handle the load. A feature of this situation is that the traffic equations (53) actually fail. The arrival and departure rates are *not* equal, the former being λ and the latter being the smaller value μ. In the case of a multiclass queueing network, we refer to the quantities λ_ℓ and ρ_ℓ determined by the traffic equations (53) as the nominal arrival rate and traffic intensity for class ℓ. Similarly, $\rho^{(m)}$

in (57) is the nominal traffic intensity for station m. A simple necessary condition for a queueing network to be stable, then, is that there be sufficient capacity to handle the load, which is condition (57) above. We have referred to this as the capacity condition for stability. This condition is sufficient to guarantee stability of product-form networks. However, as indicated earlier, the relative tractability of product-form networks conveys a false sense of how complex the behavior of general networks can be. Only in the late 1980s did researchers focus on the serious complications that may arise with non-product-form queueing networks. The Rybko–Stolyar (1992) network is an early example of a network exhibiting a certain key behavior, *subcritical instability*. This network is unstable in the sense that the amount of work in the system grows linearly with time, even though the capacity condition (57) is satisfied. The network is somewhat contrived in that it follows a discipline in which priority is given to slow jobs over fast jobs, contrary to the advice of Subsection 4.4 above. More recently, Bramson (1994) showed that the phenomenon of subcritical instability arises even under the FIFO discipline. While Bramson's network is again somewhat contrived, it clearly points to a need for a deeper understanding of instability. General necessary and sufficient conditions for stability of multiclass networks are not known at the present time and do not appear to be in the offing.

On the other hand, several results guaranteeing the stability of a queueing network are known. One approach to the question of stability is to initialize the network with a very large number of jobs in it and then to study its behavior over a proportionately long period of time. With this perspective, the jobs have so small an individual impact that they behave collectively like a fluid, and the network approaches a *fluid limit*, which is described by a *fluid model* reflecting the original network behavior. It has been proved in substantial generality that if a unit of fluid is emptied out of the fluid network within a fixed time, however it may be distributed among the stations, then the original network is stable. See Dai (1995) for details.

A *reentrant line* is a network in which all jobs follow the same route. The same station may be visited several times along the route—-hence the name ''reentrant.'' These are natural models of certain semiconductor manufacturing systems. A feature of these networks is that the different classes served at a station have a natural ordering, from the earliest stage in the route (''first'') to the latest stage in the route (''last''). Two common disciplines, first-buffer-first-served (FBFS) and last-buffer-first-served (LBFS), in which the buffers at a station receive priority according to how advanced they are along the common route, are known to be stable under subcritical nominal loads. See Dai and Weiss (1995) for details.

7. TWO-MOMENT APPROXIMATIONS AND DECOMPOSITION METHODS

Consider a queueing network, perhaps the Jackson network of Subsection 6.1 or the standard multiclass FIFO network described in Subsection 6.2. Suppose now we relax the assumption that service and external interarrival times are exponential. We may wish to do this, for example, because there are automated workstations in the system being modeled and service times at these stations are much less variable than the exponential distribution. Without exponential distributions, the explicit formulas for expected flow times and numbers-in-system of Section 6 fail, and, moreover, it is a formidable problem to devise a direct algorithm to compute these quantities. Simulation may be an effective answer to the problem. For this approach, see Subsection 1.2 and the chapters of the Handbook dealing with simulation referenced there. Here we address the question, What can be said about these more general networks, using a basic knowledge of stochastic models? In answer to this question, we present an approach to developing sensible and intuitive approximations. These approximations are built around two themes: (1) they are two-moment methods, requiring only means and variances (equivalently, SCVs) of service times and external interarrival times, and (2) they are decomposition methods, treating different stations as independent in steady state.

In support of this approach to queueing networks, there are the following points. In many situations, rough information on the mean and variability of service times and exogenous interarrival times is all we have to work with, even if the method of analysis is simulation. In a given context, it may also be intuitively clear that these quantities largely determine performance. Mathematics supports the two-moment approach to some degree. For example, the heavy-traffic mean of the single-server queue (51) is determined by the first two moments of the interarrival and service distributions. This phenomenon extends to single-class networks, whose heavy-traffic behavior depends only on two moments. See Reiman (1981) for an early result along these lines and Williams (1996) for a more recent survey. In support of decomposition as a theme for developing approximations, we note that a product-form network is a network for which decomposition is not merely an approximation but an exact mathematical property. It is natural in approximating more general networks to suppose that this decomposition property continues to hold.

On the other hand, there are many multiclass networks, for example the Rybko–Stolyar network discussed in Subsection 6.2, whose behavior is clearly not consistent with decomposition approximations, and so we must be modest in our expectations as to how far decomposition methods will take us in understanding queueing networks.

7.1. Introduction to Decomposition

Decomposition methods give quick, rough approximations for queueing networks using two-moment information. The effectiveness of these methods depends heavily on the nature of the network being approximated. It is not hard to find examples where any particular decomposition method will perform badly.

Decomposition is the process of approximating a system by breaking it up into parts, analyzing the parts, and then putting them back together. This general approximation strategy may be used in many diverse settings, offering fast approximate solutions to intractable computational problems. Typically, a decomposition method for queueing networks is based on two things: a method for approximating the behavior of individual stations and a method for approximating the flows of jobs between stations. The entire network is analyzed by characterizing the behavior of the individual stations in a manner that is consistent with the flows between the stations. Not only are decomposition methods fast, but they often also provide explicit approximate formulas that give insight into how variability affects performance in fairly complex systems. See Subsection 7.3 for an example. Decomposition methods are a central theme of two books on manufacturing systems, Buzacott and Shanthikumar (1993) and Gershwin (1994), and also feature in Hopp and Spearman (1996) and Compton (1997). They may be viewed as analogous to the analysis of variance (ANOVA) in statistics: a sensible elementary analysis, of great value as a benchmark, despite concerns about validity of approximations or assumptions. Just as ANOVA is valid under strict normality assumptions, the decomposition approach is exact for product-form networks.

In the next subsection we present a simple two-moment decomposition approximation scheme for queueing networks, based on the literature up to the time of publication of Whitt's 1983 paper describing the Queueing Network Analyzer (QNA). The underlying methodology is elegant and simple and makes small computational demands both in terms of CPU cycles and lines of computer code. The basic methodology is a part of many software packages for analyzing production systems, for example MPX (Suri and de Treville 1991).

7.2. A Simple Decomposition Method

We generally follow Whitt (1983), which contains both an elegant synthesis of early decomposition work and significant innovations. See also Nelson (1995, Subsection 8.10.2) for another simple analyzer. The network for which we develop the methodology is the *generalized Jackson network*, which is like the Jackson network of Subsection 6.1 with regard to routing, but its service times and external interarrival times are allowed to have general distributions. This network is stable under the capacity condition (57), and so we know that its behavior is not as erratic as, say, the Rybko–Stolyar network. This gives us some assurance that it is a reasonable network to attempt to approximate. The only change in the parameterization used in Subsection 6.1 is that we now must define an SCV of external interarrivals, c_{am}^{*2}, and of service times, c_{sm}^2, for each station m, $m = 1, 2, \ldots, M$.

We describe the behavior of a queueing network in terms of a collection of interacting point processes, or streams. These streams are the job flows of the network. All streams will be approximated by renewal processes. In dealing with these approximating renewal processes, we suppose that the only information we have about them is the mean m and variance σ^2 of the interarrival times. Knowing m and σ^2 is, of course, equivalent to knowing the rate $\lambda = 1/m$ and SCV c^2. All streams are treated as independent even if they are not.

In approximating a given stream N by a renewal process, we require the approximation to have the same rate λ as N. Here are the two main strategies for choosing the SCV $\tilde{c}^2$ of the approximating renewal process.

- *The stationary-interval method:* Here we choose the interarrival time SCV $\tilde{c}^2$ of the approximating renewal process to be the same as the SCV of the steady-state distribution of the interarrival times of N.
- *The asymptotic method:* Here we choose the interarrival-time SCV of the renewal process so that its asymptotic variance [defined in (18)] agrees with that of N. This means we choose $\tilde{c}^2$ so that

$$\lim_{t \to \infty} \frac{\mathrm{Var}(N(t))}{t} = \lambda \tilde{c}^2 \tag{59}$$

These two approaches typically lead to different approximations to the SCV, unless N itself is renewal, because the variance of $N(t)$ is affected by the correlations between the interarrival times.

Having decided how to deal with streams, we turn to the network. The dynamics of the network are described in terms of three key operations on streams: (1) splitting, (2) superposition, and (3) queueing. Splitting happens when a stream is divided into two or more streams that are directed to

different destinations. Superposition happens when two or more streams combine to form a single stream. Queueing is the process of going through a queue—viewed as an operation that transforms the arrival stream into the departure stream. We treat each of these operations on streams through simple approximations, and this leads to a natural approximation for the entire network.

The arrival rates of all streams are determined exactly through the traffic equations (53), and so we need only explain how the SCVs are handled.

7.2.1. Approximation for Splitting

First consider a renewal process N with rate λ and interarrival time SCV c^2, and suppose a proportion p of this stream is to be routed to a certain station. The routing model described in Section 6 has the following effect. For each arrival of N we toss a coin with probability of heads p, independently of everything. We reject the points for which the coin comes up tails and keep those for which the coin comes up heads. Now the split stream is again a true renewal process—no approximation here—and its interarrival time SCV $\tilde{c}^2$ is given by

$$\tilde{c}^2 = pc^2 + 1 - p \tag{60}$$

This may be used as an approximation for the splitting operation in the case that N is not renewal. The approximation is linear (more precisely, affine) in the SCV of the input stream. Even when the original stream is not renewal, as $p \to 0$ the split stream approaches a Poisson process and so its SCV approaches 1. This behavior is mimicked by the approximate SCV $\tilde{c}^2$, which also approaches 1 as $p \to 0$.

7.2.2. Approximation for Superposition

Suppose we have two independent streams, N_1 and N_2, to be superposed. Denote their rates and SCVs by λ_1, c_1^2, λ_2, and c_2^2. Then, as the variance of the sum of independent things is the sum of the variances by (16), it follows that the asymptotic variance (59) of the superposition is the sum of the asymptotic variances of the individual streams. Using the asymptotic method, this leads to approximating the superposition by a renewal process with SCV $\tilde{c}^2$ determined by

$$\lambda\tilde{c}^2 = \lambda_1 c_1^2 + \lambda_2 c_2^2 \tag{61}$$

where $\lambda = \lambda_1 + \lambda_2$ is the rate of the superposition. Again, $\tilde{c}^2$ is linear in the input SCVs c_1^2 and c_2^2. This formula, extended to nonrenewal and nonindependent streams, is the approximation for superposition.

7.2.3. Approximation for Queueing

A queue is viewed as transforming its arrival stream into its departure stream. A natural approximation is

$$\tilde{c}^2 = \rho^2 c_s^2 + (1 - \rho^2)c_a^2 \tag{62}$$

relating the approximation for the SCV of the departure stream, $\tilde{c}^2$, to those of the arrival stream and service time, c_a^2 and c_s^2. See Whitt (1983) for justification. Again, the approximation is linear in the input SCVs. It has the intuitively natural behavior that, as $\rho \to 1$, the departure SCV approaches the service SCV, whereas as $\rho \to 0$, the departure SCV approaches the interarrival SCV.

Rather than giving general equations to complete the specification of the analyzer, we illustrate the process for a simple example.

Example 7.2: We choose the network of Figure 2, treated in Example 7.1, making a single modification. We suppose that the service distribution at station 1 has SCV $c_{s1}^2 = 2$. All other distributions and parameters are as before. Writing c_{am}^2 and c_{dm}^2 for the arrival and departure SCVs at stations $m = 1$ and 2, upon applying (62) to the first station we have

$$c_{d1}^2 = \rho_1^2 c_{s1}^2 + (1 - \rho_1^2)c_{a1}^2 = 0.5 + 0.75c_{a1}^2$$

Clearly $c_{a2}^2 = c_{d1}^2$, as the arrivals to the second station are the departures from the first. and so upon applying (62) to the second station we get

$$c_{d2}^2 = \rho_2^2 c_{s2}^2 + (1 - \rho_2^2)c_{a2}^2 = 0.16 + 0.84c_{a2}^2$$

Using (60) and writing c_{21}^2 for the SCV of the feedback stream from station 2 to station 1, we have

$$c_{21}^2 = p_{21}c_{d2}^2 + (1 - p_{21}) = 0.5c_{d2}^2 + 0.5$$

An equation for c_{a1}^2 may now be written down, using (61). The result is

$$2c_{a1}^2 = (1)c_{a1}^2 + (1)c_{21}^2 = 1 + c_{21}^2$$

These equations may be solved to give $c_{a1}^2 = 1.06$ and $c_{a2}^2 = 1.30$. Substituting these values into the approximation (5.6), we find the approximate waiting times per arrival at the stations to be

$$E(W_Q^{(1)}) = \frac{0.5(1.06 + 2)}{2(4)(1 - 0.5)} = 0.38 \text{ and } E(W_Q^{(2)}) = \frac{0.4(1.30 + 1)}{2(5)(1 - 0.4)} = 0.15$$

The first of these is substantially inflated over the result of Example 7.1, mostly because of the increase in c_{s1}^2 itself but also partly because of the increase in c_{a1}^2 due to the extra variability manifesting in the feedback stream.

7.3. Insights from the Decomposition Approach

An excellent use of the decomposition approach is in devising simple insights into practical questions. We follow Buzacott (1996) in treating the following question using decomposition approximations. *When several tasks must be performed on each of a stream of jobs, should these tasks be carried out by separate servers in a flow-line arrangement, or should they all be carried out by parallel single-server stations?* We invoke two models to draw a conclusion. The first model consists of a flow line of n buffered stations, that is, a tandem network. Each task is performed by a different server. In the second model we have N parallel single-server stations where each server can process a job from start to finish. The question is to quantify the trade-offs. A difference is to be expected in the work-in-process levels, and we focus on quantifying this. Since the capacity of the flow line is constrained by its slowest station, a feature that does not arise in the parallel system, we begin by assuming that the service times for the different tasks are exactly balanced in the sense that their distributions are all the same. We suppose that, in the parallel system, arrivals are allocated at random, each job being assigned independently to one of the stations with equal probability. We may now analyze this model in a variety of ways. We can consider heavy-traffic theory, product-form network theory, and approximations, to make the comparison. Using the heavy-traffic approximation (51) and the splitting approximation (60) in conjunction with the asymptotic method of Subsection 7.1 yields the following approximations for the steady-state expected work-in-process when ρ is close to 1. We have

$$\overline{L}_{\text{series}} \approx \frac{c_a^2 + (2m - 1)c_s^2}{2(1 - \rho)} \tag{63}$$

for the tandem system, whereas for the parallel system we have

$$\overline{L}_{\text{parallel}} \approx \frac{m - 1 + c_a^2 + mc_s^2}{2(1 - \rho)} \tag{64}$$

In the case of Poisson arrivals and exponential service, (7.5) is exact because in this case the network is product-form. In the case of Poisson arrivals but general service, (7.6) is exact as each station becomes an $M/G/1$ queue, for which the Pollaczek–Khintchine formula (43) holds. We see by comparing (63) and (64) that the flow line has a smaller approximate expected number-in-system if and only if $c_s^2 \leq 1/2$. This leads us to conclude that low variability favors the flow line. Thus, repetitive tasks are suited to the flow-line arrangement, whereas tasks demanding cognitive skills may be better grouped.

Had arrivals to the parallel system been assigned to stations *cyclically*, so that the first arrival goes to the first queue, the second to the second, and so forth, the conclusion would have been that the parallel system is always better. This is because of the reduced variability in the arrival processes. Buzacott (1996) gives much more on this and related issues.

CHAPTER 84
Decision-Making Models

MARK R. LEHTO
Purdue University

1. INTRODUCTION

This chapter focuses on the broad topic of human decision making. Decision making is often viewed as a stage of human information processing because people must gather, organize, and combine information from different sources to make decisions. However, as decisions grow more complex, information processing actually becomes part of decision making and methods of decision support that help decision makers process information become of growing importance. Decision making also overlaps with problem solving. The point where decision making becomes problem solving is fuzzy, but many decisions require problem solving, and the opposite is true as well. Cognitive models of problem solving are consequently relevant for describing many aspects of human decision making. They become especially relevant for describing steps taken in the early stages of a decision where choices are formulated and alternatives are identified.

A complete treatment of human decision making is well beyond the scope of a single book chapter.* The topic has its roots in economics and is currently a focus of operations research and management science, psychology, sociology, and cognitive engineering. These fields have produced numerous models and a substantial body of research on human decision making. At least three objectives have motivated this work: to develop normative prescriptions that can guide decision makers, to describe how people make decisions and compare the results to normative prescriptions, and to determine how to help people apply their ''natural'' decision-making methods more successfully. The goals of this chapter are to synthesize the elements of this work into a single picture and to provide some depth of coverage in particularly important areas. The integrative model presented in Section 1.3 focuses on the first goal. The remaining sections address the second goal.

1.1. Role and Utility of Chapter

This chapter is intended to provide an overall perspective on human decision making to human factors practitioners, developers of decision tools (such as expert systems), product designers, researchers in

*No single book covers all of the topics addressed here. More detailed sources of information are references throughout the chapter. Sources such as von Neuman and Morgenstern (1947), Friedman (1990), Savage (1954), Luce and Raiffa (1957), and Shafer (1976), are useful texts for people desiring an introduction to normative decision theory. Raiffa (1968), Keeney and Raiffa (1976), Saaty (1988), Buck (1989), and Clemen (1996) provide applied texts on decision analysis. Kahneman et al. (1982), Winterfeldt and Edwards (1986), Sevenson and Maule (1993), Payne et al. (1993), Yates (1994), and Heath et al. (1994), among numerous others, provide recent texts addressing elements of behavioral decision theory. Klein et al. (1993) and Klein (1998) provide introductions to naturalistic decision making.

related areas, and others who are interested in both how people make decisions and how decision making might be improved. The chapter consequently presents a broad set of prescriptive and descriptive approaches. Numerous applications are presented and strengths and weaknesses of particular approaches are noted. Emphasis is also placed on providing useful references containing additional information on topics the reader may find of special interest.

Section 2 addresses topics grouped under the somewhat arbitrary heading of classical decision theory. The presented material provides a normative and prescriptive framework for making decisions. Section 3 summarizes decision analysis, or the application of normative decision theory to improve decisions. The discussion considers the advantages of the various approaches, how they can be applied, and what problems might arise during their application. Section 4 addresses topics grouped under the heading of behavioral decision theory. The material in the latter section compares human decision making to the normative models discussed earlier. Several descriptive models of human judgment, preference, and choice are also discussed. Section 5 explores topics falling under the heading of dynamic and naturalistic decision theory. This material should be of interest to practitioners interested in the process followed when many real-world decisions are made, the quality of these decisions, and why people use particular methods to make decisions. The discussion provides insight into how people perform diagnostic tasks, make decisions to take risks when using products, and develop expertise. Section 6 introduces the topic of group decision making. The discussion addresses conflict resolution both within and between groups, group performance and biases, and methods of group decision making.

1.2. Elements of Decision Making

Decision making requires that the decision maker make a choice between two or more alternatives (note that doing nothing can be viewed as making a choice). The selected alternative then results in some real or imaginary consequences to the decision maker. Judgment is a closely related process where a person rates or assigns values to attributes of the considered alternatives. For example, a person might judge both the safety and attractiveness of a car being considered for purchase. Obtaining an attractive car is a desirable consequence of the decision, while obtaining an unsafe car is an undesirable consequence. A rational decision maker seeks desirable consequences and attempts to avoid undesirable consequences.

The nature of decision making can vary greatly, depending on the decision context. Certain decisions, such as deciding where and what to eat for lunch, are routine and repeated often. Other choices, such as purchasing a house, choosing a spouse, or selecting a form of medical treatment for a serious disease, occur seldom, may involve much deliberation, and take place over a longer time period. Decisions may also be required under severe time pressure and involve potentially catastrophic consequences, such as when a fire chief decides whether to send fire fighters into a burning building. Previous choices may constrain or otherwise influence subsequent choices (for example, a decision to enter graduate school might constrain a future employment-related decision to particular job types and locations). The outcomes of choices may be uncertain and in certain instances are determined by the actions of potentially adverse parties, such as competing manufacturers of a similar product. Decisions may be made by a single individual or by a group. Within a group, there may be conflicting opinions and differing degrees of power between individuals or factions. Decision makers may also vary greatly in their knowledge and degree of aversion to risk.

Conflict occurs when a single decision maker is not sure which choice should be selected or when there is lack of consensus within a group regarding the choice. Both for groups and single decision makers, conflict occurs, at the most fundamental level, because of uncertainty or conflicting objectives. Uncertainty can take many forms and is one of the primary reasons decisions can be difficult. In ill-structured decisions, decision makers may not have identified the current condition, alternatives to choose between, or their consequences. Decision makers also may be unsure what their aspirations or objectives are, or how to choose between alternatives. After a decision has been structured, at least four reasons for conflict may exist. First, when alternatives have both undesirable and desirable consequences, decision makers may experience conflict due to conflicting objectives. For example, a decision maker considering the purchase of an air bag-equipped car may experience conflict because an air bag increases cost as well as safety. Second, decision makers may be unsure of their reaction to a consequence. For example, people considering whether to enter a raffle where the prize is a sailboat may be unsure how much they want a sailboat. Third, decision makers may not know whether a consequence will happen for sure. Even worse, they may be unsure what the probability of the consequences is, or may not have enough time to evaluate the situation carefully. They also may be uncertain about the reliability of information they have. For example, it may be difficult to determine the truth of a sale person's claim regarding the probability of their product breaking down immediately after the warranty expires.

To resolve conflicts, decision makers must deal appropriately with uncertainty, conflicting objectives, or a lack of consensus. Conflict resolution, therefore, becomes a primary focus of decision theory. The following section presents an integrative model of decision making that relates conflict resolution to the above-discussed elements of decision making. This model specifically considers how decision making changes when different sources of conflict are present. It also matches methods of conflict resolution to particular sources of conflict and decision rules.

1.3. Integrative Model of Decision Making

Human decision making can be viewed as a stage of information processing that falls between perception and response execution (Welford 1976). The integrative model of human decision making, presented in Figure 1, shows how the elements of decision making discussed above fit into this perspective. From this view, decision making is the process followed when a response to a perceived

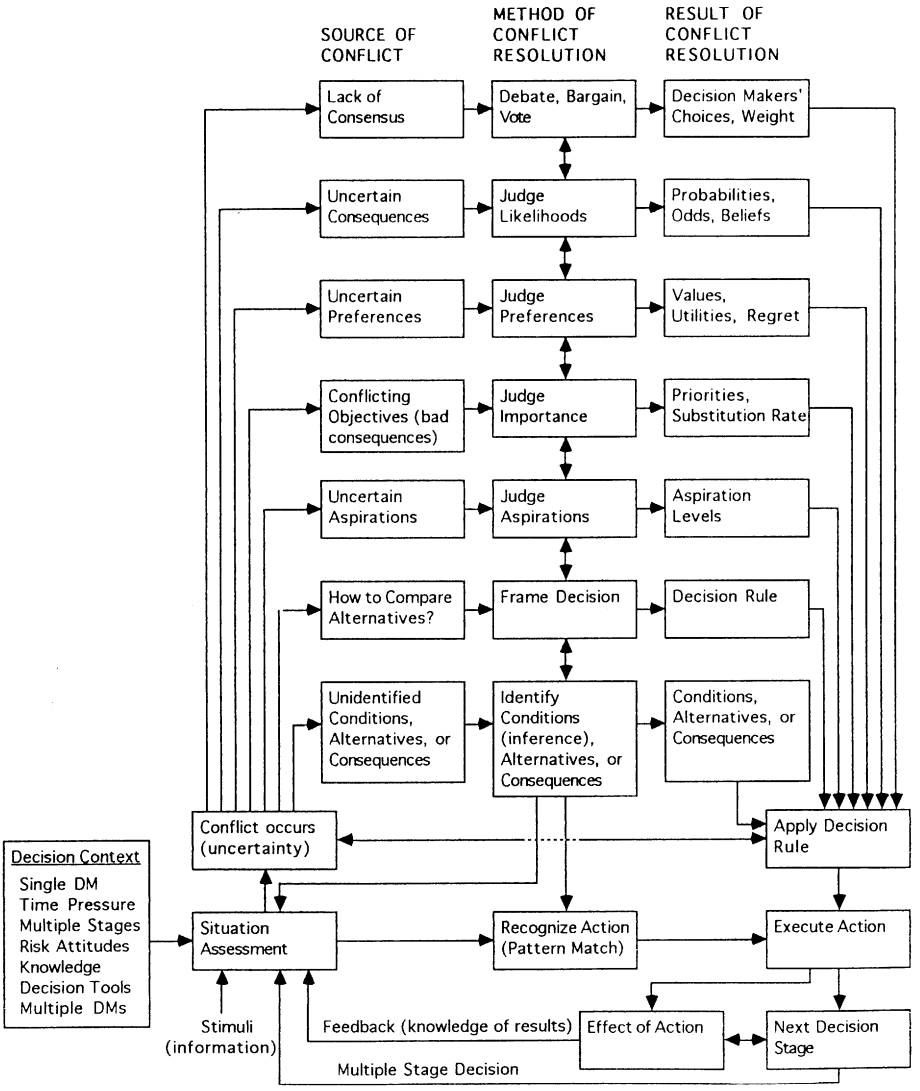

Figure 1 Integrative Model of Human Decision Making.

stimulus is chosen. The process followed depends on what decision strategy is applied and can vary greatly between decision contexts.* Decision strategies, in Figure 1, correspond to different paths between situation assessment and executing an action. The particular decision strategy followed depends upon both the decision context and whether or not the decision maker experiences conflict.†

At least four, sometimes overlapping, categories of decision making can be distinguished. *Group decision making* occurs when multiple decision makers interact and is represented at the highest level of the model as a source of conflict that might be resolved through debate, bargaining, or voting. For example, members of a university faculty committee might debate and bargain before voting between candidates for a job opening.

Dynamic decision making occurs in a changing environment, in which the results of earlier decisions impact future decisions. The decisions made in such settings often make use of feedback and are multistage in nature. For example, a decision to take a medical test almost always requires a subsequent decision regarding what to do after receiving the test results. Dynamic decision making is represented at the lowest level of the model by the presence of two feedback loops, which show how the action taken and its effects can feedforward to the assessment of a new decision or feedback to the reassessment of the current decision.

Routine decision making occurs when decision makers use knowledge and past experience to decide quickly what to do and is especially prevalent in dynamic decision making contexts. Routine decision making is represented in Figure 1 as a single pattern-matching step or associative leap between situation assessment and executing an action. For example, a driver after perceiving a stop sign decides to stop, or the user of a word-processing system after perceiving a misspelled word decides to activate the spell checker. Since routine decisions are often made in dynamic task environments, routine decision making is discussed in this chapter as a subtopic of dynamic decision making.

Conflict-driven decision making occurs when various forms of conflict must be resolved before an alternative action can chosen and often involves a complicated path between situation assessment and executing an action.‡ Before executing an action, the decision maker experiences conflict, somehow resolves it, and then either recognizes the best action (conflict resolution might transform the decision to a routine one) or applies a decision rule. Applying the decision rule ideally leads to a choice that is then executed. Attempting to apply the decision rule may, however, cause additional conflicts, leading to more conflict resolution. For example, decision makers may realize they need more information to apply a particular decision rule. In response, they might decide to use a different decision rule that requires less information. Along these lines, when choosing a home, a decision maker might decide to use a satisficing decision rule after seeing that hundreds of homes are listed in the classified ads of the local newspaper.

Potential sources of conflict, methods of conflict resolution, and the results of conflict resolution are listed at the top of Figure 1. Each source of conflict maps to a particular method of conflict resolution, which then provides a result necessary to apply a decision rule, as schematically illustrated in the figure.§ Table 1 presents a set of decision rules, briefly describes their procedural nature and their required inputs, and also lists the sections of this chapter where they are covered. The required inputs of particular decision rules can be easily mapped to sources of conflict. As shown in the table, each decision rule requires that alternatives and their consequences be identified. Other decision rules require measures of aspiration, importance, preference, and uncertainty for each consequence or consequence dimension. For example, to compare alternatives using expected value, the probability and value of each consequence must also be known. Certain decision rules also accept inputs describing the degree of consensus between decision makers.

Accordingly, conflict occurs at the most fundamental level when the current condition, alternative actions, or their consequences have not been identified. At the next most fundamental level, conflict occurs when the decision maker is unsure how to compare the alternatives. In other words, the

*The notion that the best decision strategy varies between decision contexts is a fundamental assumption of the theory of contigent decision making (Payne et al. 1993), cognitive continuum theory (Hammond 1980), and other approaches discussed later in this chapter.

†Conflict has been recognized as an important determinant of what people will do in risky decision-making contexts (Janis and Mann 1977). Janis and Mann focus on the stressful nature of conflict and on how affective reactions in stressful situations can impact the decision strategies followed.

‡The distinction between routine and conflict-driven decision making made here is similar to Rasmussen's (1983) distinction between (a) routine skill or rule-based levels of control and (b) nonroutine knowledge-based levels of control in information-processing tasks.

§Note that multiple sources of conflict are possible for a given decision context. An attempt to resolve one source of conflict may also make the decision maker aware of other conflicts that must first be resolved. For example, decision makers may realize they need to know what the alternatives are before they can determine their aspiration levels.

TABLE 1 Decision Rules, Required Inputs, and Procedure Applied by the Rules

Decision Rule	Required Inputs	Procedure Applied	Section Covered
Dominance	All alternatives, value of each consequence.	Select alternative best on all consequences.	2.1.2
EBA	All alternatives, value of each consequence.	Select first alternative found to be best on a consequence dimension. Random order of consequences.	2.1.3
Lexicographic	All alternatives, value of each consequence, priorities.	Order consequences by priority. Select first alternative found to be best on a consequence dimension.	2.1.3
Satisficing	At least one and up to all alternatives, aspiration level and value of each consequence	Sequentially evaluate each alternative. Stop if each consequence of an alternative equals or exceeds the aspiration level.	2.1.4
Minimax Cost	All alternatives, value of each consequence.	Compare the worst consequence values of each alternative	2.1.5
Minimax Regret	All alternatives, regret for each consequence.	Compare largest regrets of each alternative	2.1.5
EV	All alternatives, probability and value of each consequence.	Weight value of each consequence by its probability, for each alternative.	2.1.6
Laplace	All alternatives, value or utility of each consequence.	Weight value or utility of each consequence equally, for each alternative.	2.1.7
SEU	All alternatives, probability and utility of each consequence.	Weight utility of each consequence by its probability, for each alternative.	2.1.7
MAUT	All alternatives, value or utility of each consequence, priorities.	Weight value or utility of each consequence by priority, for each alternative.	2.1.8
Holistic	All alternatives and consequences.	Holistically compare the consequences of each alternative	2.1.9

decision maker has not yet selected a decision rule. Given that the decision maker has a decision rule, conflict can still occur if the needed inputs are not available. These sources of conflict and associated methods of conflict resolution are briefly addressed below in relation to the remainder of this chapter.

Identifying the current condition, alternative actions, and their consequences is an important part of decision making. This topic is emphasized in both naturalistic decision theory (Klein et al. 1993) and decision analysis* (Raiffa 1968; Clemen 1996). Decision trees, influence diagrams, and other tools for structuring decisions are covered in Section 3. Normative methods of identifying the current condition falling under the topic of inference (or diagnosis) are presented in Section 2.2. Section 4.1 describes several descriptive models of human inference and discusses their limitations. Section 6 includes discussion group decision-making methods that may be useful at this decision-making stage.

When decision makers are unsure how to compare alternatives, they must consider what information is available and then frame the decision appropriately. The way the decision is framed then determines (1) which decision rules are appropriate, (2) what information is needed to make the decision using the given rules (as discussed earlier in reference to Table 1), and (3) the choices selected. As discussed in Section 5.1, there is reason to believe that people apply different decision-making strategies in different decision contexts. Section 2.1 discusses the appropriateness of decision

*Clemen (1996) includes a chapter on creativity and decision structuring. Some practitioners claim that structuring the decision is the greatest contribution of the decision analysis process.

rules and how the particular rule used can impact choices. When the specific inputs needed by a decision rule are not available, the resulting conflict might be resolved by judging aspirations, importance, preference, or likelihood. It also might be resolved by choosing a different decision rule or strategy. As noted in Section 5.1, there is a prevalent tendency among decision makers in naturalistic settings to minimize analysis and its required cognitive effort. In group situations, conflict due to a lack of consensus between multiple decision makers might be resolved through debate, bargaining, or voting (Section 6).

2. CLASSICAL DECISION THEORY

Classical decision theory began with the development of normative models in economics and statistics that specified optimal decisions (von Neumann and Morgenstern 1947; Savage 1954). Classical decision theory focuses heavily on the notion of rationality (Winterfeldt and Edwards 1986; Savage 1954). Emphasis is placed on the quality of the process followed when making a decision rather than on the ultimate outcome. Accordingly, a rational decision maker must think logically about the decision. To do this, the decision maker must first formally describe what is known about the decision. The decision is then made by applying principles of logic and Bayesian probability theory (Savage 1954). This approach is therefore quantitative, and also normative or prescriptive if the numerical inputs needed are available.

The classical approach has been applied to two related problems: (1) preference and choice, and (2) statistical inference.

2.1. Choice Procedures

Classical decision theory represents preference and choice problems in terms of four basic elements: (1) a set of potential actions (A_i) to choose between, (2) a set of events or world states (E_j), (3) a set of consequences (C_{ij}) obtained for each combination of action and event, and (4) a set of probabilities (P_{ij}) for each combination of action and event. For example, a decision maker might be deciding whether to wear a seatbelt when traveling in an automobile. Wearing or not wearing a seat belt corresponds to two actions A_1 and A_2. The expected consequence of either action depends upon whether an accident occurs. Having or not having an accident corresponds to two events E_1 and E_2. Wearing a seatbelt reduces the expected consequences C_{11} having an accident (E_1). As the probability of having an accident increases, use of a belt should therefore become more attractive.

Once a decision has been represented in terms of these basic elements, the choice is then made by applying decision rules. Numerous decision rules have been developed. Decision rules are based upon basic axioms (or what are felt to be self-evident assumptions) of rational choice. Not all rules, however, make use of the same axioms. Different rules make different assumptions and can provide different preference orderings for the same basic decision. The following discussion will first present some of the most basic axioms. Then several well-known decision rules will be briefly covered.

2.1.1. Axioms of Rational Choice

Numerous axioms have been proposed that are essential either for a particular model of choice or for the method of eliciting numbers used for a particular model (Winterfeldt and Edwards 1986). The best-known set of axioms (Table 2) establishes the normative principle of subjective expected utility (SEU) as a basis for making decisions (see Savage 1954; Luce and Raiffa 1957 for a more rigorous description of the axioms). On an individual basis, these axioms are intuitively appealing (Stukey and Zeckhauser 1978), but, as discussed in Section 4, people's preferences can deviate significantly from the SEU model in ways that conflict with certain axioms. Consequently, there has been a movement toward developing other, less restrictive standards of normative decision making (Frisch and Clemen 1994; Zey 1992).

Frisch and Clemen propose that "a good decision should (a) be based on the relevant consequences of the different options (*consequentialism*), (b) be based on an accurate assessment of the world and a consideration of all relevant consequences (*thorough structuring*), and (c) make tradeoffs of some form (*compensatory decision rule*)." Consequentialism and the need for thorough structuring are both assumed by all normative decision rules. Most normative rules are also compensatory. However, when people make routine habitual decisions, they often don't consider the consequences of their choices, as discussed in Section 5. Also, because of cognitive limitations and the difficulty of obtaining information, it becomes unrealistic in many settings for the decision maker to consider all the options and possible consequences. To make a decision under such conditions, decision makers may limit the scope of the analysis by applying principles such as satisficing and other noncompensatory decision rules discussed below. They also may apply heuristics, based on their knowledge or experience, leading to performance that can approximate the results of applying compensatory decision rules (Section 4).

TABLE 2 Basic Axioms of Subjective Expected Utility Theory

A. Ordering/Quantification of Preference
Preferences of decision makers between alternatives can be quantified and ordered using the relations: $>$, where $A > B$ means that A is preferred to B $=$, where $A = B$ means that A and B are equivalent $\geq$, where $A \geq B$ means that B is not preferred to A
B. Transitivity of Preference
if $A_1 \geq A_2$ and $A_2 \geq A_3$, then $A_1 \geq A_3$
C. Quantification of Judgment
The relative likelihood of each possible consequence that might result from an alternative action can be specified.
D. Comparison of Alternatives
If two alternatives yield the same consequences, the alternative yielding the greater chance of the preferred consequence is preferred.
E. Substitution
If $A_1 > A_2 > A_3$, then the decision maker will be willing to accept a gamble [$p(A_1)$ and $(1 - p)(A_3)$] as a substitute for A_2 for some value of $p \geq 0$.
F. Sure Thing Principle
If $A_1 \geq A_2$, then for all p, the gamble [$p(A_1)$ and $(1 - p)(A_3)$] $\geq$ [$p(A_2)$ and $(1 - p)(A_3)$].

2.1.2. Dominance

Dominance is perhaps the most fundamental normative decision rule. Dominance is said to occur between two alternative actions A_i and A_j when A_i is at least as good as A_j for all events E, and for at least one event E_k, A_i is preferred to A_j. For example, one investment might yield a better return than another regardless of whether the stock market goes up or down. Dominance can also be described for the case where the consequences are multidimensional. This occurs when for all events E, the kth consequence associated with action i (C_{ik}) and action j (C_{jk}), satisfies the relation $C_{ik} \geq C_{jk}$ for all k, and for at least one consequence $C_{ik} > C_{jk}$. For example, a physician choosing between alternative treatments has an easy decision if one treatment is *both* cheaper and more effective for all patients.

Dominance is obviously a normative decision rule, since a dominated alternative can never be better than the alternative that dominates it. Dominance is also conceptually simple, but it can be difficult to detect when there are many alternatives to consider or many possible consequences. The use of tests for dominance by decision makers in naturalistic settings in discussed further in Section 5.1.5.

2.1.3. Lexicographic Ordering and EBA

The lexicographic ordering principle (see Fishburn 1974) considers the case where alternatives have multiple consequences. For example, a purchasing decision might be based on both the cost and performance of the considered product. The different consequences are first ordered in terms of their importance. Returning to the above example, performance might be considered more important than cost. The decision maker then sequentially compares each alternative beginning with the most important consequence. If an alternative is found that is better than the others on the first consequence, it is immediately selected. If no alternative is best on the first dimension, the alternatives are compared for the next-most important consequence. This process continues until an alternative is selected or all the consequences have been considered without making a choice. The latter situation can happen only if the alternatives have the same consequences.

The elimination by aspects (EBA) rule (Tversky 1972) is similar to the lexicographic decision rule. It differs in that the consequences used to compare the alternatives are selected in random order, where the probability of selecting a consequence dimension is proportional to its importance. Both EBA and lexicographic ordering are noncompensatory decision rules, since the decision is made

using a single consequence dimension. Returning to the above example, the lexicographic principle would result in selecting a product with slightly better performance, even if it costs much more. EBA would select either product depending on which of the consequences was first selected.

2.1.4. Minimum Aspiration Level and Satisficing

The minimum aspiration level or satisficing decision rule assumes that the decision maker sequentially screens the alternative actions until an action is found which is good enough. For example, a person considering the purchase of a car might stop looking once he or she found an attractive deal instead of comparing every model on the market. More formally, the comparison of alternatives stops once a choice is found that exceeds a minimum aspiration level S_{ik} for each of its consequences C_{ik} over the possible events E_k.

Satisficing can be a normative decision rule when (1) the expected benefit of exceeding the aspiration level is small, (2) the cost of evaluating alternatives is high, or (3) the cost of finding new alternatives is high. More often, however, it is viewed as an alternative to maximizing decision rules. From this view, people cope with incomplete or uncertain information and their limited rationality by satisficing in many settings instead of optimizing (Simon 1955, 1983).

2.1.5. Minimax (Cost and Regret) and the Value of Information

Minimax cost selects the best alternative (A_i) by first identifying the worst possible outcome for each alternative. The worst outcomes are then compared between alternatives. The alternative with the minimum worst-case cost is selected. Formally, the preferred action A_i is the action for which over the events k, $\text{MAX}_k(C_{ik}) = \text{MIN}_i[\text{MAX}_k(C_{ik})]$. For example, in Table 3, the maximum cost is 5 for alternative A_1, 7 for A_2, and 8 for A_3. A_1 would be chosen since it has the smallest maximum cost. Minimax cost corresponds to assuming the worst and therefore makes sense as a strategy where an adverse opponent is able to control the events (von Neumann and Morgenstern 1947). Along these lines, an airline executive considering whether to reduce fares might assume that a competitor will also cut prices, leading to a no-win situation.

Minimax regret involves a similar process, but the calculations are performed using regret instead of cost (Savage 1954). Regret is calculated by first identifying which alternative is best for each possible event. The regret R_{ik}, associated with each consequence (C_{ik}) for the combination of event E_k and alternative A_i then becomes: $R_{ik} = \text{MAX}_i(C_{ik}) - C_{ik}$. Returning to our earlier example, if E_1 occurs, alternative A_2 with a cost of 2 is best, resulting in a regret of 0 (2 − 2). A_1 has a cost of 5, resulting in a regret of 3 (5 − 2). A_3 has a cost of 6, resulting in a regret of 4 (6 − 2). These calculations are repeated for events E_2 and E_3, resulting in regret values for each combination of events and alternative actions. The preferred action A_i is the action for which over the events k, $\text{MAX}_k(R_{ik}) = \text{MIN}_i[\text{MAX}_k(R_{ik})]$. The maximum regrets for A_1 (a value of 3) and A_3 (a value of 4) are both found when event E_1 occurs. The maximum regret for A_2 (a value of 2) is found when event E_2 occurs. Alternative A_2 is then selected because it has the minimum maximum regret.

Note that the minimax cost and minimax regret principles do not always suggest the same choice (Table 3). Minimax cost is easily interpreted as a conservative strategy. Minimax regret is more difficult to judge from an objective or normative perspective (Savage 1954). As shown by the example, minimax regret can be less conservative than minimax cost. Alternatives that were not chosen can also impact choices made using minimax regret. For example, if alternative A_3 is removed from consideration, minimax regret and minimax cost will both select A_1. The interesting conclusion is that comparative and absolute measures of preference can result in different choices.

Bell (1982) argues persuasively that regret plays a very prominent role in decision making under uncertainty. For example, the purchaser of a new car might be happy, until finding out that a neighbor got the same car for $200 less from a different dealer. It is interesting to observe that regret is closely related to the value of information. This follows, since with hindsight, decision makers may regret their choice if they did not select the alternative giving the best result for the event (E_k) which actually took place. With perfect information, the decision maker would have chosen E_k. Conse-

TABLE 3 Example Comparison of Minimax Cost and Minimax Regret. Minimax cost selects A_1 and minimax regret selects A_2

	E_1	E_2	E_3	Max Cost	Max Regret
A_1	5	5	5	**5**	3
A_2	2	7	2	7	**2**
A_3	6	8	4	8	4

quently, the regret (R_{ik}) associated with having chosen alternative (A_i) is a measure of the value of having perfect information, or of knowing ahead of time that event E_k would occur. When each of the events (E_k) occur with probability P_k, it becomes possible to calculate the expected value of perfect information [EVPI(A_i)], given that the decision maker would chose action A_i before receiving this information with the following expression:

$$\text{EVPI}(A_i) = \sum_k P_k R_{ik} \tag{1}$$

The above approach can be extended to the case of imperfect information (Raiffa 1968) by replacing P_k in the above equation with the probability of event k (E_k) given the imperfect sample information (I). This results in an expression for the expected value of sample information [EVSI(A_i,I)], given that the decision maker would chose action A_i before receiving this information:

$$\text{EVSI}(A_i,I) = \sum_k (P_k|I)R_{ik} \tag{2}$$

The value of imperfect (or sample) information provides a normative rule for deciding whether to collect additional information. For example, a decision to perform a survey before introducing a product can be made by comparing the cost of the survey to the expected value of the information obtained. It is often assumed that decision makers are biased when they fail to seek out additional information. The above discussion shows that *not* obtaining information is justified when the information costs too much. From a practical perspective, the value of information can guide decisions to provide information to product users (Lehto and Papastavrou 1991).

2.1.6. Maximizing Expected Value

From elementary probability theory, return is maximized by selecting the alternative with the greatest expected value. The expected value of an action A_i is calculated by weighting its consequences C_{ik} over all events k, by the probability P_{ik} the event will occur. The expected value of a given action A_i is therefore:

$$\text{EV}[A_i] = \sum_k P_{ik}C_{ik} \tag{3}$$

More generally, the decision maker's preference for a given consequence C_{ik} might be defined by a value function $V(C_{ik})$, which transforms consequences into preference values. The preference values are then weighted using the same equation. The expected value of a given action A_i becomes:

$$\text{EV}[A_i] = \sum_k P_{ik}V(C_{ik}) \tag{4}$$

Monetary value is a common value function. For example, lives lost, units sold, or air quality might all be converted into monetary values. More generally, however, value reflects preference, as illustrated by ordinary concepts such as the value of money or the attractiveness of a work setting. Given that the decision maker has large resources and is given repeated opportunities to make the choice, choices made on the basis of expected monetary value are intuitively justifiable. A large company might make nearly all of its decisions on the basis of expected monetary value. Insurance buying and many other rational forms of behavior can not, however, be justified on the basis of expected monetary value. Many years ago, it was already recognized that rational decision makers made choices not easily explained by expected monetary value (Bernoulli 1738). Bernoulli cited the St. Petersburg paradox, in which the prize received in a lottery was 2^n and n was the number of times (n) a flipped coin turned up heads before a tails was observed. The probability of n flips before the first tail is observed is 0.5^n. The expected value of this lottery becomes:

$$\text{EV}[L] = \sum_k P_{ik}V(C_{ik}) = \sum_{n=0}^{\infty} 0.5^n 2^n = \sum_{n=1}^{\infty} 1 \Rightarrow \infty \tag{5}$$

The interesting twist is that the expected value of the above lottery is infinite. Bernoulli's conclusion was that preference cannot be a linear function of monetary value, since a rational decision maker would never pay more than a finite amount to play the lottery. Furthermore, the value of the lottery can vary between decision makers. According to utility theory, this variability reflects rational differences in preference between decision makers for uncertain consequences.

2.1.7. Subjective Expected Utility (SEU) Theory

Expected utility theory extended expected value theory to describe better how people make uncertain economic choices (von Neumann and Morgenstern 1947). In their approach, monetary values are first transformed into utilities, using a utility function $u(x)$. The utilities of each outcome are then weighted by their probability of occurrence to obtain an expected utility. Subjective utility theory (SEU) added the notion that uncertainty about outcomes could be represented with subjective probabilities (Savage 1954). It was postulated that these subjective estimates could be combined with evidence using Bayes' rule to infer the probabilities of outcomes* (see Section 2.2). This group of assumptions corresponds to the Bayesian approach to statistics. Following this approach, the SEU of an alternative (A_i), given subjective probabilities (S_{ik}) and consequences (C_{ik}) over the events E_k, becomes:

$$\text{SEU}[A_i] = \sum_k S_{ik} U(C_{ik}) \tag{6}$$

Note the similarity between the above formulation for SEU and the earlier equation for expected value. EV and SEU are equivalent if the value function equals the utility function. Methods for eliciting value and utility functions differ in nature (Section 3). Preferences elicited for uncertain outcomes measure utility.† Preferences elicited for certain outcomes measure value. It accordingly has often been assumed that value functions differ from utility functions, but there are reasons to treat value and utility functions as equivalent (Winterfeldt and Edwards 1986). The latter authors claim that the differences between elicited value and utility functions are small and that "severe limitations constrain those relationships, and only a few possibilities exist, one of which is that they are the same."

When people are presented choices that have uncertain outcomes, they react in different ways. In some situations, people find gambling to be pleasurable. In others, people will pay money to reduce uncertainty; for example, when people buy insurance. SEU theory distinguishes between risk neutral, risk averse, risk seeking, and mixed forms of behavior. These different types of behavior are described by the shape of the utility function (Figure 2).

A risk-neutral decision maker will find the expected utility of a gamble to be the same as the utility of the gamble's expected value. That is, expected u(gamble) = u(gamble's expected value). For a risk-averse decision maker, expected u(gamble) < u(gamble's expected value); for a risk-

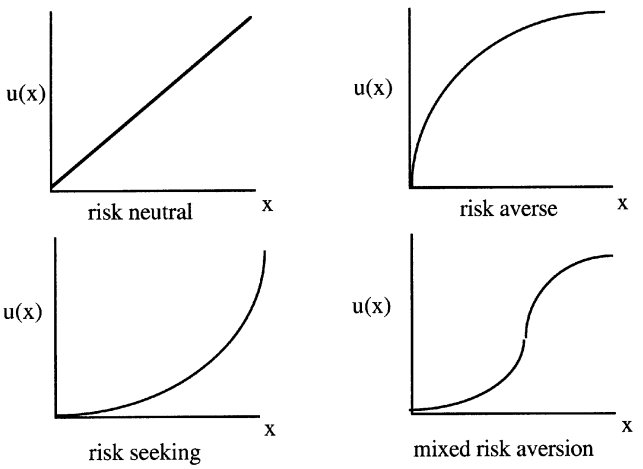

Figure 2 Utility Functions for Differing Risk Attitudes.

* When no evidence is available concerning the likelihood of different events, it was postulated that each consequence should be assumed to be equally likely. The Laplace decision rule makes this assumption and then compares alternatives on the basis of expected value or utility.

† Note that classical utility theory assumes that utilities are constant. Utilities may, of course, fluctuate. The random utility model (Bock and Jones 1968) allows such fluctuation.

seeking decision maker, expected u(gamble) > u(gamble's expected value). On any given point of a utility function, attitudes towards risk are described formally by the coefficient of risk aversion:

$$C_{RA} = \frac{u''(x)}{u'(x)} \tag{7}$$

where $u'(x)$ and $u''(x)$ are respectively the first and second derivatives of $u(x)$ taken with respect to x. Note that when $u(x)$ is a linear function of x, that is, $u(x) = ax + b$, then $C_{RA} = 0$. For any point of the utility function, if $C_{RA} < 0$, the utility function depicts risk-averse behavior, and if $C_{RA} > 0$, the utility function depicts risk-seeking behavior. The coefficient of risk aversion therefore describes attitudes toward risk at each point of the utility function, given that the utility function is continuous. SEU theory consequently provides a powerful tool for describing how people might react to uncertain or risky outcomes. However, some commonly observed preferences between risky alternatives can not be explained by SEU. Section 4.2 focuses on experimental findings showing deviations from the predictions of SEU.

A major contribution of SEU is that it represents differing attitudes towards risk and provides a normative model of decision making under uncertainty. The prescriptions of SEU are also clear and testable. Consequently, SEU has played a major role in fields other than economics, both as a tool for improving human decision making and as a stepping stone for developing models that describe how people make decisions when outcomes are uncertain. As discussed further in Section 4, much of this work has been done in psychology.

2.1.8. Multiattribute Utility Theory

Multiattribute tility theory (Keeney and Raiffa 1976) extends SEU to the case where the decision maker has multiple objectives. The approach is equally applicable for describing utility and value functions. Following this approach, the utility (or value) of an alternative A, with multiple attributes x, is described with the multiattribute utility (or value) function $u(x_1 \ldots x_n)$, where $u(x_1 \ldots x_n)$ is some function $f(x_1 \ldots x_n)$ of the attributes x. In the simplest case, multiattribute utility theory (MAUT) describes the utility of an alternative as an additive function of the single attribute utility functions $u_n(x_n)$. That is,

$$u(x_1 \ldots x_n) = \sum_n k_n u_n(x_n) \tag{8}$$

where the constants k_n are used to weight each single attribute utility function (u_n) in terms of its importance. Assuming an alternative has three attributes, x, y, and z, an additive utility function is $u(x,y,z) = k_x u_x(x) + k_y u_y(y) + k_z u_z(z)$. Along these lines, a community considering building a bridge across a river vs. building a tunnel or continuing to use the existing ferry system might consider the attractiveness of each option in terms of the attributes of economic benefits, social benefits, and environmental benefits.*

More complex multiattribute utility functions, include multiplicative forms and functions that combine utility functions for subsets of two or more attributes (Keeney and Raiffa 1976). An example of a simple multiplicative function would be $u(x,y) = u_x(x)*u_y(y)$. A function that combines utility functions for subsets, would be $u(x,y,z) = k_{xy}u_{xy}(x,y) + k_z u_z(z)$. This latter type of function becomes useful when utility independence is violated. Utility independence is violated when the utility function for one attribute depends on the value of another attribute. Along these lines, when assessing $u_{xy}(x,y)$, it might be found that $u_x(x)$ depends on the value of y. For example, peoples' reaction to the level of crime in their own neighborhood might depend on the level of crime in a nearby suburb. In the latter case, it is probably better to directly measure $u_{xy}(x$ = crime in own neighborhood, y = crime in nearby suburb) than to estimate it from the single-attribute functions. The assessment of utility and value functions is discussed later in Section 3.

MAUT has been applied to a wide variety of problems (Saaty 1988; Keeney and Raiffa 1976; Winterfeldt and Edwards 1986; Clemen 1996). An advantage of MAUT is that it helps structure complex decisions in a meaningful way. Alternative choices and their attributes often naturally divide into hierarchies. The MAUT approach encourages such divide-and-conquer strategies and, especially in its additive form, provides a straightforward means of recombining weights into a final ranking of alternatives. The MAUT approach is also a compensatory strategy that allows normative trade-offs between attributes in terms of their importance.

*To develop the multiattribute utility function, the single-attribute utility functions (u_n) and the importance weights (k_n) are determined by assessing preferences between alternatives. Methods of doing so are discussed in Section 3.4.

2.1.9. Holistic Comparison

Holistic comparison is a nonanalytical method of comparing alternatives. This process involves a holistic comparison of the consequences for each alternative instead of separately measuring and then recombining measures of probability, value, or utility (Sage 1981; Stanoulov 1994; Janis and Mann 1977). A preference ordering between alternatives is thus obtained. For example, the decision maker might rank in order of preference a set of automobiles that vary on objectively measureable attributes, such as color, size, and price. Mathematical tools can then be used to derive the relationship between observed ordering and attribute values and ultimately predict preferences for unevaluated alternatives, as discussed in Section 3.3.4.

One advantage of holistic comparison is that it requires no formal consideration of probability or utility. Consequently, decision makers unfamiliar with these concepts may find holistic comparison to be more intuitive, and potential violations of the axioms underlying SEU and MAUT, due to their lack of understanding, become of lesser concern. People seem to find the holistic approach helpful when they compare complex alternatives (Janis and Mann 1977). In fact, people may feel there is little additional benefit to be obtained from separately analyzing the probability and value attached to each attribute. This tendency becomes prevalent in naturalistic decision making, as addressed further in Section 5.

2.2. Statistical Inference

Inference is the procedure followed when a decision maker uses information to determine whether a hypothesis about the world is true. Hypotheses can specify past, present, or future states of the world, or causal relationships between variables. Diagnosis is concerned with determining past and present states of the world. Prediction is concerned with determining future states. Inference or diagnosis is required in many decision contexts. For example, before deciding on a treatment, a physician must first diagnose the illness.

From the classical perspective, the decision maker is concerned with determining the likelihood that a hypothesis (H_i) is true. Bayesian inference is the best-known technique, but signal detection theory, and fundamentally different approaches such as the Dempster–Schafer method, have seen application. Each of these approaches is discussed below.

2.2.1. Bayesian Inference

Bayesian inference is a well-defined procedure for inferring the probability (P_i) that a hypothesis (H_i) is true, from evidence (E_j) linking the hypothesis to other observed states of the world. The approach makes use of Bayes' rule to combine the various sources of evidence (Savage 1954). Bayes' rule states that the posterior probability of hypothesis H_i given that evidence E_j is present, or $P(H_i|E_j)$, is given by the equation:

$$P(H_i|E_j) = \frac{P(E_j|H_i)P(H_i)}{P(E_j)} \tag{9}$$

where $P(H_i)$ is the probability of the hypothesis being true prior to obtaining the evidence E_j and $P(E_j|H_i)$ is the probability of obtaining the evidence E_j given that the hypothesis H_i is true. For example, consider the case where a physician is attempting to determine whether a patient has a disease present in 10% of the general population. The physician has a test available that gives a positive result 90% of the time when administered to patients who actually have the disease. The test also gives a positive result 20% of the time when administered to patients who don't have the disease. If the test were to be administered to a member of the general population, Eq. (9) predicts that the probability of having the disease given a positive test result is:

$$P(\text{disease}|\text{positive test}) = \frac{P(\text{positive test}|\text{disease})P(\text{disease in general population})}{P(\text{positive test})}$$

Also,

$$\begin{aligned} P(\text{positive test}) = {} & P(\text{positive test}|\text{disease})P(\text{disease in general population}) \\ & + P(\text{positive test}|\text{no disease})P(\text{no disease in general population}) \end{aligned}$$

$$P(\text{disease}|\text{positive test}) = \frac{0.9*0.1}{0.9*0.1 + 0.2*0.9} = 0.33$$

As discussed further in Section 4.1, people often fail to combine evidence consistently with the above predictions of Bayes' rule. A common finding is that people fail to adequately consider the base rate of the hypothesis. In the above example, this would correspond to focusing on P(positive

test|disease) = 0.9 and not considering P(disease in general population) = 0.1. As a consequence, many people might be surprised that P(disease|positive test) = 0.33 rather than a number close to 0.9.

When the evidence E_j consists of multiple states $E_1, \ldots, E_n$, each of which is conditionally independent, Bayes' rule can be expanded into the expression:

$$P(H_i|E_j) = \frac{\prod_{j=1}^{n} P(E_j|H_i)P(H_i)}{P(E_j)} \tag{10}$$

Calculating $P(E_j)$ can be somewhat difficult, due to the fact that each piece of evidence must be dependent,* or else it would not be related to the hypothesis. The odds forms of Bayes' rule provides a convenient way of looking at the evidence for and against a hypothesis that doesn't require $P(E_j)$ to be calculated. This results in the expression:

$$\Phi(H_i|E_j) = \frac{P(H_i|E_j)}{P(\sim H_i|E_j)} = \frac{\prod_{j=1}^{n} P(E_j|H_i)P(H_i)}{\prod_{j=1}^{n} P(E_j)|\sim H_i)P(\sim H_i)} \tag{11}$$

where $\Phi(H_i|E_j)$ refers to the posterior odds for hypothesis H_i, $P(\sim H_i)$ is the prior probability that hypothesis H_i is not true, and $P(\sim H_i|E_j)$ is the posterior probability that hypothesis H_i is not true.

The two latter forms of Bayes' rule provide an analytically simple way of combining multiple sources of evidence. Bayesian inference becomes much more difficult when the evidence is not certain or when the conditional independence assumption is not met. When evidence is not certain, complex multistage forms of Bayesian analysis are required that consider the probability of the evidence being true (Winterfeldt and Edwards 1986). When conditional independence is not true, the expanded form of Bayes' rule must be modified. For example, consider the case where the evidence consists of three events (E_1, E_2, E_3), where E_1 and E_2 are conditionally dependent and E_3 is conditionally independent of the two other events. The posterior probability, $P(H_i|E_1,E_2,E_3)$, then becomes:

$$P(H_i|E_1,E_2,E_3) = \frac{P(E_1,E_2|H_i)P(E_3|H_i)P(H_i)}{P(E_1,E_2)P(E_3|E_1,E_2)} \tag{12}$$

where $P(E_1,E_2|H_i)$ is the conditional probability of obtaining E_1 and E_2 given the hypothesis H_i, $P(E_3|H_i)$ is the conditional probability of obtaining E_3 given H_i, and $P(E_1,E_2)P(E_3|E_1,E_2)$ is the probability of obtaining the evidence (E_1, E_2, E_3).

2.2.2. Signal-Detection Theory

Bayesian inference combined with SEU leads to signal-detection theory (Tanner and Swets 1954), which has been applied in a large variety of contexts to model human performance (Wickens 1992). In signal-detection theory, the human operator is assumed to use Bayes' rule to estimate the probability that a signal actually is present from a noisy observation of the system. For example, an operator might estimate the probability a machine is going out of tolerance from a warning signal. The responses of the operator and the true state of the system together determine a set of four outcomes (Table 4).

TABLE 4 Potential Outcomes Considered by Signal Detection Theory

		State of the World	
		Noise (N)	Signal (S)
Response	yes	false alarm (fa)	hit (h)
	no	correct rejection (cr)	miss (m)

*Note that conditional independence between E_1 and E_2 implies that $P(E_1/H_i,E_2) = P(E_1/H_i)$ and that $P(E_2/H_i,E_1) = P(E_2/H_i)$. This is very different from simple independence, which implies that $P(E_1) = P(E_1/E_2)$ and that $P(E_2) = P(E_2/E_1)$.

The signal-detection model assumes an operator receives evidence from the environment regarding the true state of the world. The relationship between the signal (S) and the evidence (E) is measured by the conditional probability [$P(E|S)$] of obtaining the observed evidence given the signal is there. The decision maker is assumed to select a criterion value (x_c) that the evidence must exceed before saying yes. It is assumed that the value chosen will maximize utility. If the evidence is represented with a variable x, the expected utility of the operator can be described in terms of x, x_c and the four outcomes in Table 4. The expected utility for a given probability cutoff x_c, and utility function u, is given by the expression:

$$\begin{aligned} \mathrm{SEU}[x_c] = {} & P(x \geq x_c|S)P(S)u(h) + P(x \geq x_c|N)P(N)u(fa) \\ & + P(x < x_c|S)P(S)u(m) + P(x < x_c|N)P(N)u(cr) \end{aligned} \tag{13}$$

where h is a hit, fa is a false alarm, m is a miss, and cr is a correct rejection. The above expression can be maximized by first substituting $1 - P(x \geq x_c|N)$ for $P(x < x_c|N)$ and also substituting $1 - P(x \geq x_c|S)$ for $P(x < x_c|S)$ into the equation for SEU[x_c], and then setting the derivative of SEU[x_c] with respect to x_c to zero. The result at the cutoff x_c is shown below:

$$\frac{P(x = x_c|S)}{P(x = x_c|N)} = \beta^* \geq \frac{P(N)(u(cr) - u(fa))}{P(S)(u(h) - u(m))} \tag{14}$$

where β^* is the optimal value of β. Substituting back the relation between $P(E|S)$ and the evidence x, the optimal decision rule is to say yes if

$$\frac{P(E|S)}{P(E|N)} \geq \beta^* \tag{15}$$

Equation (15) can be extended to multiple operators or multiple sources of evidence (Lehto and Papastavrou 1991). The resulting expression takes into account the probability of a false alarm and the probability of detection for the other source of information. Lehto and Papastavrou use this approach to analyze situations where the other source of information is a warning signal. The extent to which human judgments correspond to the predictions of Bayes' rule is further discussed in Section 4.1.

2.2.3. Dempster–Schafer Method

The Dempster–Schafer method (Schafer 1976; Fedrizzi et al. 1994) is an alternative to Bayesian inference for accumulating evidence for or against a hypothesis that has been proposed for use in decision analysis (Strat 1994). In this approach, the relation of hypotheses (H) to evidence (e) is described by a basic probability assignment (bpa) function, p. Given evidence (e), this function $p_e(n)$ assigns a value between 0 and 1 to each subset of H, such that the sum of the values assigned is 1. For example, consider the case where there are three hypotheses (A,B,C). When no evidence is available, the vacuous bpa assigns a value of 1 to the set of hypotheses $H = (A,B,C)$ and a 0 to all subsets. That is, the subsets (A), (B), (C), (A,B), and (A,C) are each assigned a value of 0. The Bayesian approach would instead assign a probability of 0.33 to A, B, and C respectively.

Also, given that evidence $p_e(A) = x$ supporting a specific hypothesis A is found, the Dempster–Schafer approach assigns $(1 - p_e(A))$ to H. The Bayesian approach, of course, assigns $(1 - p_e(A))$ to the complement of A. Returning to the above example, suppose the evidence supports hypothesis A to the degree $p_e(A) = 0.6$. Using the Dempster–Schafer approach, $p_e(A,B,C) = 0.4$. This, of course, is very different from the Bayes' interpretation, where $P(A) = 0.6$ and $P(\text{not } A) = 0.4$. The Dempster–Schafer method uses a belief function $B(n)$ to assign a total belief to n, where n is a subset of the set of possible hypotheses (H), as the sum of the beliefs assigned to m, where m is the set of possible subsets of n. In the above example, the belief in (A,B,C) after receiving evidence (e) is as given below:

$$\begin{aligned} B(A,B,C) &= p_e(A,B,C) + p_e(A,B) + \mathrm{p}_e(A,C) + p_e(B,C) + p_e(A) + p_e(B) + p_e(C) \\ &= 0.4 + 0 + 0 + 0 + 0.6 + 0 + 0 \\ &= 1.0 \end{aligned} \tag{16}$$

Similarly, the belief in (A,B) after receiving the evidence (e) is:

TABLE 5 Tableau for Dempster–Shafer Method of Combining Evidence

	Y = [(A,B), (A,B,C)]	
X = [(A), (A,B,C)]	$p_f(A,B) = 0.4$	$p_f(A,B,C) = 0.6$
$p_e(A) = 0.6$	A ; $p_e p_f = 0.24$	A ; $p_e p_f = 0.36$
$p_e(A,B,C) = 0.4$	A,B ; $p_e p_f = 0.16$	A,B,C ; $p_e p_f = 0.24$

$$\begin{aligned} B(A,B) &= p_e(A,B) + p_e(A) + p_e(B) \\ &= 0 + 0.6 + 0 \\ &= 0.6 \\ &= B(A) \end{aligned} \tag{17}$$

To combine evidence from multiple sources e and f, Dempster–Schafer theory uses the combining function $c(p_e(X),p_f(Y))$, where X and Y are both sets of subsets of H. For example, we might have $X = [(A), (A,B,C)]$ and $Y = [(A,B), (A,B,C)]$. The combining function then assigns a value to each subset n of H. The value assigned is determined by first describing the set of subsets n' within n defined by the intersection of subsets within X and subsets within Y. A value of 0 is assigned to all subsets of n not within n'. The products $p_e(X)*p_f(Y)$ are then summed and assigned to each subset within n'. Returning to the above example, we can calculate $c(n')$ using the values given in Table 5. First note that the set of subsets n' for the example is defined by the inner elements of the table. Specifically, $n' = [(A), (A,B), (A,B,C)]$. The values used by the combining function $c(n')$ are also shown. Using these numbers, the values of $c(n')$ become: $c(A) = 0.24 + 0.36 = 0.6$; $c(A,B) = 0.16$; $c(A,B,C) = 0.24$. All remaining subsets for this evidence are assigned a value of 0.

It has been argued that the Dempster–Schafer method of assigning evidence is better suited for diagnosing medical problems than the Bayesian method (Gordon and Shortliffe 1984). The latter researchers particularly criticize the Bayesian assumption that evidence partially supporting a hypothesis should also support its negation. Gordon and Shortliffe note that the Dempster–Schafer method shows promise as a means of accumulating belief in expert diagnostic systems used in medicine.

3. DECISION ANALYSIS

The application of classical decision theory to improve human decision making is the goal of decision analysis (Raiffa 1968; Howard 1968; 1988; Keeney and Raiffa 1976). Decision analysis requires inputs from decision makers, such as goals, preference and importance measures, and subjective probabilities. Elicitation techniques have consequently been developed that help decision makers provide these inputs. Particular focus has been placed on methods of quantifying preferences, trade-offs between conflicting objectives, and uncertainty (Keeney and Raiffa 1976; Raiffa 1968). As a first step in decision analysis, it is necessary to do some preliminary structuring of the decision, which then guides the elicitation process. The following discussion first presents methods of structuring decisions and then covers techniques for assessing subjective probabilities, utility functions, and preferences.

3.1. Structuring Decisions

The field of decision analysis has developed many useful frameworks for representing what is known about a decision (Howard 1968; Winterfelt and Edwards 1986; Clemen 1996). In fact, the above authors and others have stated that the process of structuring decisions is often the greatest contribution of going through the process of decision analysis. Among the many tools used, decision matrices and trees provide a convenient framework for comparing decisions on the basis of expected value or utility. Value trees provide a helpful method of structuring the sometimes complex relationships among objectives, attributes, goals, and values and are used extensively in multiattribute decision-making problems. Event trees, fault trees, inference trees, and influence diagrams are useful for describing probabilistic relationships between events and decisions. Each of these approaches is briefly discussed below.

3.1.1. Decision Matrices and Trees

Decision matrices are often used to represent single-stage decisions (Figure 3). The simplicity of decision matrices is their primary advantage. They also provide a very convenient format for applying

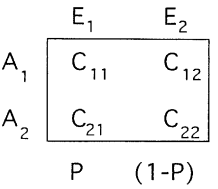

Figure 3 Decision Matrix Representation of a Single-Stage Decision.

the decision rules discussed in the previous section. Decision trees are also commonly used to represent single-stage decisions (Figure 4) and are particularly useful for describing multistage decisions (Raiffa 1968). Note that in a multistage decision tree, the probabilities of later events are conditioned on the result of earlier events. This leads to the important insight that the results of earlier events provide information regarding future events.* Following this approach, decisions may be stated in conditional form. An optimal decision, for example, might be to first do a market survey, and then market the product only if the survey to is positive.

Analysis of a single or multistage decision tree involves two basic steps referred to as averaging out and folding back (Raiffa 1968). These steps, respectively, occur at chance and decision nodes.† Averaging out occurs when the expected value (or utility) at each chance node is calculated. In Figure 4, this corresponds to calculating the expected value of A_1 and A_2, respectively. Folding back refers to choosing the action with the greatest expected value at each decision node.

Decision trees consequently provide a straightforward way of comparing alternatives in terms of expected value or SEU. However, their development requires significant simplification of most decisions and the provision of numbers, such as measures of preference and subjective probabilities, that decision makers may have difficulty determining. In certain contexts, decision makers struggling with this issue may find it helpful to develop value trees, event trees, or influence diagrams, as expanded upon below.

3.1.2. Value Trees

Value trees hierarchically organize objectives, attributes, goals, and values (Figure 5). From this perspective, an objective corresponds to satisficing or maximizing a goal or set of goals. When there is more than one goal, the decision maker will have multiple objectives, which may differ in importance. Objectives and goals are both measured on a set of attributes. Attributes may provide (1) objective measures of an goal, such as when fatalities and injuries are used as a measure of highway safety, (2) subjective measures of an goal, such as when people are asked to rate the quality of life in the suburbs vs. the city, or (3) proxy or indirect measures of a goal, such as when the quality of ambulance service is measured in terms of response time.

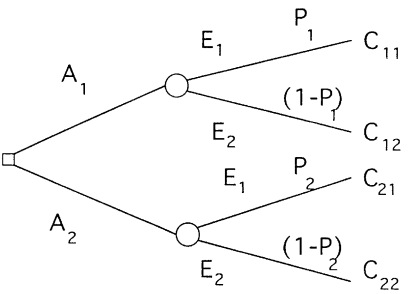

Figure 4 Decision Tree Representation of a Single-Stage Decision.

*For example, the first event in a decision tree might be the result of a test. The test result then provides information useful in making the final decision.

†Note that standard convention uses circles to denote chance nodes and squares to denote decision nodes (Raiffa 1968).

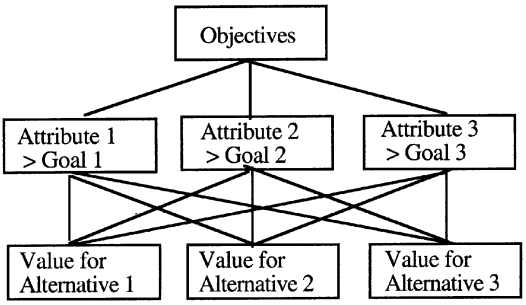

Figure 5 Generic Value Tree.

In generating objectives and attributes, it becomes important to consider their relevance, completeness, and independence. Desirable properties of attributes (Keeney and Raiffa 1976) include:

1. *Completeness:* The extent to which the attributes measure whether an objective is met.
2. *Operationality:* The degree to which the attributes are meaningful and feasible to measure.
3. *Decomposability:* Whether the whole is described by its parts.
4. *Nonredundancy:* Correlated attributes give misleading results.
5. *Minimum size:* Considering irrelevant attributes is expensive and may be misleading.

Once a value tree has been generated, various methods can be used to assess preferences directly between the alternatives.

3.1.3. Event Trees or Networks

Event trees or networks show how a sequence of events can lead from primary events to one or more outcomes. Human reliability analysis (HRA) event trees are a classic example of this approach (Figure 6). If probabilities are attached to the primary events, it becomes possible to calculate the probability of outcomes, as illustrated in Section 3.2.4. This approach has been used in the field of risk assessment to estimate the reliability of human operators and other elements of complex systems (Gertman and Blackman 1994). Chapter 32 provides additional information on human reliability analysis and other methods of risk assessment.

Fault trees work backwards from a single undesired event to its causes (Figure 7). Fault trees are commonly used in risk assessment to help infer the chance of an accident occurring (Hammer 1993; Gertman and Blackman 1994). Inference trees relate a set of hypotheses at the top level of the tree to evidence depicted at the lower levels. This latter approach has been used by expert systems, such as PROSPECTOR (Duda et al. 1979). PROSPECTOR applies a Bayesian approach to infer the presence of a mineral deposit from uncertain evidence.

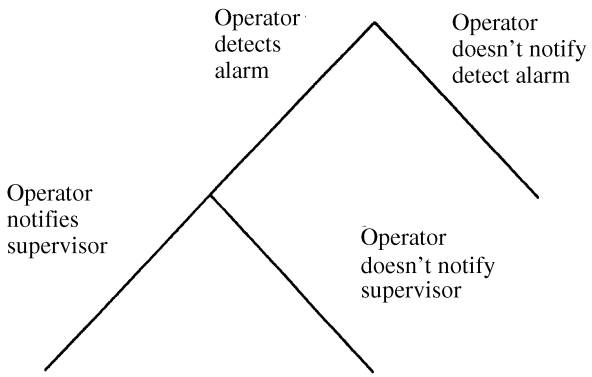

Figure 6 HRA Event Tree. (Adapted from Gertman and Blackman 1994)

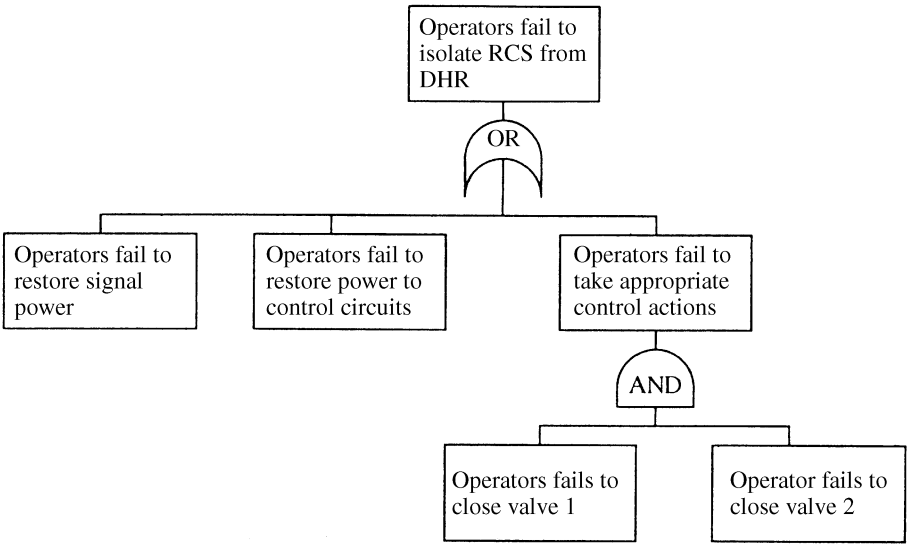

Figure 7 Fault Tree for Operators. (Adapted from Gertman and Blackman 1994).

3.1.4. Influence Diagrams and Cognitive Mapping

Influence diagrams are often used in the early stages of a decision to show how events and actions are related. Their use in the early stages of a decision is referred to as knowledge (or cognitive) mapping (Howard 1988). Links in an inference diagram depict causal and temporal relations between events and decision stages.* A link leading from an event *A* to an event *B* implies that the probability of obtaining event *B* depends on whether event *A* has occurred. A link leading from a decision to a event implies that the probability of the event depends on the choice made at that decision stage. A link leading from an event to a decision implies that the decision maker knows the outcome of the event at the time the decision is made.

One advantage of influence diagrams in comparison to decision trees is that influence diagrams show the relationships between events more explicitly. Consequently, influence diagrams are often used to represent complicated decisions where events interactively influence the outcomes. For example, the influence diagram in Figure 8 shows that the true state of the machine affects both the

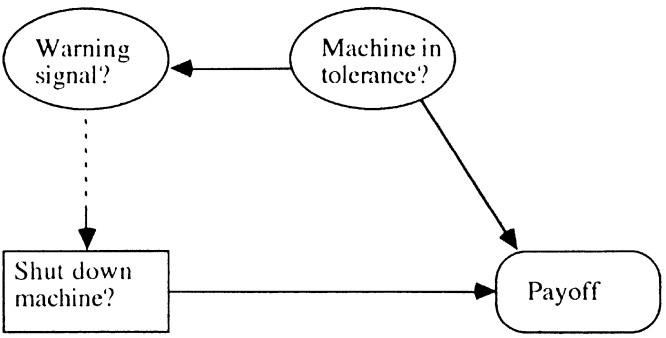

Figure 8 Influence Diagram Representation of a Single-Stage Decision.

*As for decision trees, the convention for influence diagrams is to depict events with circles and decisions with squares.

probability of the warning signal and the consequence of the operator's decision. This linkage would be hidden within a decision tree.* Influence diagrams have been used to structure medical decision-making problems (Holtzman 1989) and are emphasized in modern texts on decision analysis (Clemen 1996). Howard (1988) states that influence diagrams are the greatest advance he has seen in the communication, elicitation, and detailed representation of human knowledge. Part of the issue is that influence diagrams allow people who do not have deep knowledge of probability to describe complex conditional relationships with simple linkages between events. Once these linkages are defined, the decision becomes well defined and can be formally analyzed.

3.2. Probability Assessment

Several approaches have been used in decision analysis to assess subjective probabilities. In this section several of the more well-known techniques will be summarized. These techniques include: (1) direct numerical assessment, (2) fitting subjective belief forms, (3) the bisection method, (4) conditioning arguments, (5) preferences between reference gambles, and (6) scaling methods. Techniques proposed for improving the accuracy of assessed probabilities, including scoring rules, calibration, and group assessment, will then be presented.

3.2.1. Direct Numerical Assessment

In direct numerical estimation, decision makers are asked to give a numerical estimate of how likely they think the event is to happen. These estimates can be probabilities, odds, log odds, or words (Winterfeldt and Edwards 1986). Winterfeldt and Edwards argue that log odds have certain advantages over the other measures. Gertman and Blackman (1994) note that log odds are normally used in risk assessment for nuclear power applications because human error probabilities (HEPs) vary greatly in value. HEPs between 1 and 0.00001 are typical.

3.2.2. Fitting a Subjective Belief Form

Fitting a subjective belief form requires that the questions be posed in terms of statistical parameters. That is, decision makers could be asked to first consider their uncertainty regarding the true value of a given probability and then estimate their mean, mode, or median belief. This approach can be further extended by asking decision makers to describe how certain they are of their estimate. For example, a worker might subjectively estimate the mean and variance of the proportion of defective circuit boards before inspecting a small sample of circuit boards. If the best estimate corresponds to a mean, mode, or median, and the estimate of certainty to a confidence interval or standard deviation, a functional form such as the Beta-1 probability density function (pdf) can then be used to fit a subjective probability distribution (Clemen 1996; Buck 1989).

In other words, a distribution is specified that describes the subject's belief that the true probability equals particular values. This type of distribution can be said to express uncertainty about uncertainty (Raiffa 1968). Given that the subject's belief can be described with a Beta-1 pdf, Bayesian methods can be used to combine binomially distributed evidence easily with the subject's prior belief (Clemen 1996; Buck 1989). Returning to the above example, the worker's prior subjective belief can be combined with the results of inspecting the small sample of circuit boards, using Bayes' rule. As more evidence is collected, the weight given to the subject's initial belief becomes smaller compared to the evidence collected. The use of prior belief forms also reduces the amount of sample information that must be collected to show that a proportion, such as the percentage of defective items, has changed (Buck 1989).

3.2.3. Bisection Method

The bisection method (Raiffa 1968) is another direct technique for attempting to estimate a subjective probability density function (pdf). This technique is somewhat more general than fitting the subject's belief with a functional form, such as the beta-1, since it makes no parametric assumptions. The bisection method involves two steps which are repeated until the subject's belief is adequately described. Following this approach, the first step is to determine the median ($P_{0.5}$) of the subjective pdf. This question is posed to the decision maker in a form such as "For what value of p do you feel it is equally likely the true value p† is greater than or less than p?" This step is then repeated for subintervals to obtain the desired level of detail.

*The conditional probabilities in a decision tree would reflect this linkage, but the structure of the tree itself does not show the linkage directly. Also, the decision tree would use the flipped probability tree using P(warning) at the first stage and P(machine down|warning) at the second stage. It seems more natural for operators to think about the problem in terms of P(machine down) and P(warning|machine down), which is the way the influence diagram in Figure 7 depicts the relationship.

†Note that it has been shown that people viewing fault trees can be insensitive to missing information (Fischhoff et al. 1978).

3.2.4. Conditioning Arguments

Statistical conditioning arguments are based on the idea that the probability of a complicated event, such as the chance of having an accident, can be determined by estimating the probability of simpler events (or subsets). From a more formal perspective, a conditioning argument determines the probability of an event A by considering the possible conditions (C_i) under which A might happen, the associated conditional probabilities [$P(A|C_i)$], and the probability of each condition [$P(C_i)$]. The probability of A can then be represented as:

$$P(A) = \sum_i P(A|C_i)P(C_i) \tag{18}$$

This approach is illustrated by the development of event trees and fault tree analysis. In fault tree analysis, the probability of an accident is estimated by considering the probability of human errors, component failures, and other events. This approach has been extensively applied in the field of risk analysis (Gertman and Blackman 1994).* THERP (Swain and Guttman 1983) extends the conditioning approach to the evaluation of human reliability in complex systems.

SLIM-MAUD (Embrey 1984) implements a related approach in which expert ratings are used to estimate human error probabilities (HEPs) in various environments. The experts first rate a set of tasks in terms of performance-shaping factors (PSFs) that are present. Tasks with known HEPs are used as upper and lower anchor values. The experts also judge the importance of individual PSFs. A subjective likelihood index (SLI) is then calculated for each task in terms of the PSFs. A logarithmic relationship is assumed between the HEP and SLI, allowing calculation of the human error probability for task j (HEP_j) from the subjective likelihood index assigned to task j (SLI_j). More specifically:

$$\text{Log}(1 - \text{HEP}_j) = a\text{SLI}_j + b \tag{19}$$

$$\text{where } \text{SLI}_j = \sum_i \text{PSF}_{ij} * I(\text{PSF}_i) \tag{20}$$

$I(\text{PSF}_i)$ is the importance of PSF_i, and PSF_{ij} is the rating given to PSF_i for task j. Gertman and Blackman (1994) provide guidelines regarding the use of this method and have generally positive conclusions. SLIM-MAUD is interesting in that it uses multiattribute utility theory as a basis for generating probability estimates.

3.2.5. Reference Lotteries

Reference lottery methods take a less direct approach to obtaining point estimates of the decision maker's subjective probabilities. When the objective is to measure how likely event A is to occur, the approach asks decision makers to consider a lottery where they will receive a prize x if event A occurs, and a prize y if it does not. They are then asked how much they would be willing to pay for the lottery. The amount they are willing to pay z is then equated to the lottery, using the relation $z = P(A)x + [1 - P(A)]y$. From this expression it becomes possible to estimate the decision maker's subjective estimate of $P(A)$. Specifically, $P(A) = (z - y)/(x - y)$. A variant of this approach that asks decision makers to compare two lotteries over the same range of preferences might be preferable because it removes the potential effect of risk aversion (Winterfelt and Edwards 1986).

3.2.6. Scaling Methods

Scaling methods ask subjects to rate or rank the probabilities to be assessed. Likert scales with verbal anchors have been used to obtain estimates of how likely people feel certain risks are (Kraus and Slovic 1988). Another approach has been to ask subjects to do pair-wise comparisons of the likelihoods of alternative events (Saaty 1988). Pairwise comparisons of probabilities on a ratio scale correspond to relative odds and consequently have high construct validity. In fact, much of the risk assessment focuses on determining order of magnitude differences in probability. Saaty (1988), however, argues that the psychometric literature indicates that people's ability to distinguish items on the same scale is limited to 7 ± 2 categories. He consequently proposes use of a relative scale to measure differences in importance, preference, and probability that uses verbal anchors corresponding to equal, weak, strong, very strong, and absolute differences between rated items. In perhaps the most controversial aspect of his approach, these five verbal anchors are assigned the numbers 1, 3, 5, 7, and 9. Using these numbers, subjective probabilities can then be calculated from pair-wise ratings on his verbal scale.

3.2.7. Scoring Rules, Calibration, and Group Assessment

A number of approaches have been developed for improving the accuracy of assessed probabilities (Winterfelt and Edwards 1986; Lichtenstein et al. 1982). Two desirable properties of elicited prob-

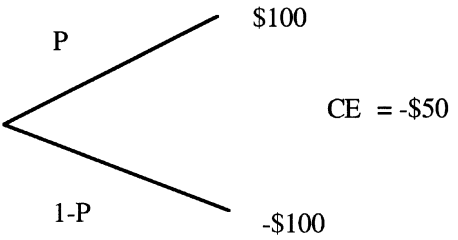

Figure 9 The Standard Gamble Used in the Variable Probability Method of Eliciting Utility Functions.

abilities include extremeness and calibration. More extreme probabilities (for example, P(good sales) = 0.9 vs. P(good sales) = 0.5) make decisions easier since the decision maker can be more sure of what is really going to happen. Well-calibrated probability estimates match the actual frequencies of observed events. Scoring rules provide a means of evaluating assessed probabilities in terms of both extremeness and calibration. If decision makers assess probabilities on a routine basis, feedback can be provided using scoring rules. Such feedback seems to be associated with the highly calibrated subjective probabilities provided by weather forecasters (Murphy and Winkler 1974).

Group assessment of subjective probabilities is another often-followed approach, as alluded to earlier in reference to SLIM-MAUD. There is evidence that group judgments are usually more accurate than individual judgments and that groups tend to be more confident in their estimates (Sniezek and Henry 1989; Sniezek 1992; also see Section 6.2). Assuming that individuals within a group independently provide estimates, which are then averaged, the benefit of group judgment is easily shown to have a mathematical basis. Simply put, a mean should be more reliable than an individual observation. Group dynamics, however, can lead to a tendency towards conformity (Janis 1972). Winterfeldt and Edwards (1986) therefore recommend that members of a group be polled independently.

3.3. Utility Function Assessment

Standard methods for assessing utility functions (Raiffa 1968) include (1) the variable probability method and (2) the certainty equivalent method. In the variable probability method, the decision maker is asked to give the value for the probability of winning at which they are indifferent between a gamble and a certain outcome (Figure 9). A utility function is then mapped out when the value of the certainty equivalent (CE) is changed over the range of outcomes. Returning to Figure 9, the value of P at which the decision maker is indifferent between the gamble and the certain loss of $50 gives the value for $u(-\$50)$. In the utility function in Figure 10, the decision maker gave a value of about 0.5 in response to this question.

The certainty equivalent method uses lotteries in a similar way. The major change is that the probability of winning or losing the lottery is held constant, while the amount won or lost is changed. In most cases, the lottery provides an equal chance of winning and losing. The method begins by

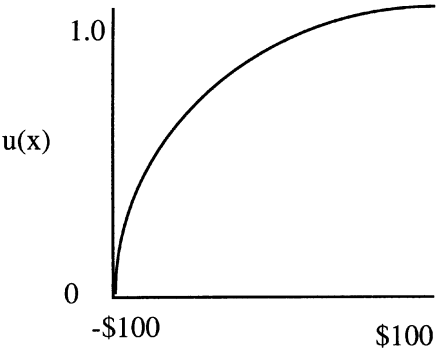

Figure 10 A Typical Utility Function.

asking the decision maker to give a certainty equivalent for the original lottery (CE_1). The value chosen has a utility of 0.5. This follows since the utility of the best outcome is assigned a value of 1 and the worst is given a utility of 0. The utility of the original gamble is therefore:

$$u(CE_1) = pu(\text{best}) + (1 - p)u(\text{worst}) = p(1) + (1 - p)(0) = p = 0.5 \quad (21)$$

The decision maker is then asked to give certainty equivalents for two new lotteries. Each uses the CE from the previous lottery as one of the potential prizes. The other prizes used in the two lotteries are the best and worst outcomes from the original lottery, respectively. The utility of the certainty equivalent (CE_2) for the lottery using the best outcome and CE_1 is given by the expression below:

$$u(CE_2) = pu(\text{best}) + (1 - p)u(CE_1) = p(1) + (1 - p)(0.5) = 0.75 \quad (22)$$

The utility of the certainty equivalent (CE_3) given for the lottery using the worst outcome and CE_1 is given by:

$$u(CE_3) = pu(CE_1) + (1 - p)u(\text{worst}) = p(0.5) + (1 - p)(0) = 0.25 \quad (23)$$

This process is continued until the utility function is specified in sufficient detail. A problem with the certainty equivalent method is that errors are compounded as the analysis proceeds. This follows since the utility assigned in the first preference assessment (i.e., $u(CE_1)$) is used throughout the subsequent preference assessments. A second issue is that the CE method uses different ranges in the indifference lotteries, meaning that the CEs are compared against different reference values. This might create inconsistencies since, as discussed later in Section 4, attitudes toward risk usually change depending upon whether outcomes are viewed as gains or losses. The use of different reference points may, of course, cause the same outcome to be viewed as either a loss or a gain. Utilities may also vary over time. Section 4.2 discusses some of these issues further.

3.4. Preference Assessment

Methods for measuring strength of preference include indifference methods, direct assessment, and indirect measurement (Keeney and Raiffa 1976; Winterfeldt and Edwards 1986). Indifference methods modify one of two sets of stimuli until subjects feel they are indifferent between the two. Direct-assessment methods ask subjects to rate or otherwise assign numerical values to attributes, which are then used to obtain preferences for alternatives. Indirect-measurement techniques avoid decomposition and simply ask for preference orderings between alternatives. Recently there has been some movement towards evaluating the effectiveness of particular methods for measuring preferences (Huber et al. 1993; Birnbaum et al. 1992).

3.4.1. Indifference Methods

Indifference methods are illustrated by the variable probability and certainty equivalent methods of eliciting utility functions presented in the previous section. There, indifference points were obtained by varying either probabilities or values of outcomes. Similar approaches have been applied to develop multiattribute utility or value functions. This approach involves four steps: (1) develop the single attribute utility or value functions, (2) assume a functional form for the multiattribute function, (3) assess the indifference point between various multiattribute alternatives, and (4) calculate the substitution rate or relative importance of one attribute compared to the other. The single-attribute functions might be developed by indifference methods (i.e., the variable probability or certainty equivalent methods) or direct-assessment methods, as discussed later. Indifference points between multiattribute outcomes are obtained through an interactive process in which the values of attributes are systematically increased or decreased. Substitution rates are then obtained from the indifference points.

For example, consider the case for two alternative traffic safety policies, A_1 and A_2. Each policy has two attributes, x = lives lost and y = money spent. Assume the decision maker is indifferent between A_1 and A_2, meaning the decision maker feels that $v(x_1,y_1) = v(20{,}000 \text{ deaths; } \$1 \text{ trillion})$ is equivalent to $v(x_2,y_2) = v(10{,}000 \text{ deaths; } \$1.5 \text{ T})$. For the sake of simplicity, assume an additive value function, where $v(x,y) = (1 - k)v_x(x) + kv_y(y)$. Given this functional form, the indifference point $A_1 = A_2$ is used to derive the relation:

$$(1 - k)v_x(20{,}000 \text{ deaths}) + kv_y(\$1 \text{ T}) = (1 - k)v_x(10{,}000 \text{ deaths}) + kv_y(\$1.5 \text{ T}) \quad (24)$$

This results in the substitution rate as shown below:

$$\frac{k}{1-k} = \frac{v_x(20{,}000 \text{ deaths}) - v_x(10{,}000 \text{ deaths})}{v_y(\$1.5 \text{ T}) - v_y(\$1 \text{ T})} \tag{25}$$

If $v_x = -x$, and $v_y = -y$, a value of approximately 2^{-5} is obtained for k. The procedure becomes somewhat more complex when nonadditive forms are assumed for the multiattribute function (Keeney and Raiffa 1976).

3.4.2. Direct-Assessment Methods

Direct-assessment methods include curve fitting and various numerical rating methods (Winterfeldt and Edwards 1986). Curve fitting is perhaps the simplest approach. Here, the decision maker first orders the various attributes and then simply draws a curve assigning values to them. For example, an expert might draw a curve relating levels of traffic noise (measured in decibels) to their level of annoyance (on a scale of 0 to 1). Rating methods, as discussed earlier in reference to subjective probability assessment, include direct numerical measures on rating scales and relative ratings.

The analytic hierarchy process (AHP) provides one of the more implementable methods of this type (Saaty 1988). In this approach, the decision is first structured as a value tree (Figure 5). Then each of the attributes is compared in terms of importance in a pair-wise rating process. When entering the ratings, decision makers can enter numerical ratios (for example, an attribute might be twice as important as another) or use the subjective verbal anchors mentioned earlier in reference to subjective probability assessment. The AHP program uses the ratings to calculate a normalized eigenvector assigning importance or preference weights to each attribute. Each alternative is then compared on the separate attributes. For example, two houses might first be compared in terms of cost and then be compared in terms of attractiveness. This results in another eigenvector describing how well each alternative satisfies each attribute. These two sets of eigenvectors are then combined into a single vector that orders alternatives in terms of preference. The subjective multiattribute rating technique (SMART) developed by Edwards (see Winterfeldt and Edwards 1986) provides a similar, easily implemented approach. Both techniques are computerized, making the assessment process relatively painless.

3.4.3. Indirect Measurement

Indirect-measurement techniques avoid asking people to rate or rank directly the importance of factors that impact their preferences. Instead, subjects simply state or order their preferences for different alternatives. A variety of approaches can then be used to determine how individual factors influence preference. Conjoint measurement theory provides one such approach for separating the effects of multiple factors when only their joint effects are known. Application of the approach entails asking subjects to develop an ordered set of preferences for a set of alternatives that systematically vary attributes felt to be related to preference. The relationship between preferences and values of the attributes is then assumed to follow some functional form. The most common functional form assumed is a simple additive-weighting model. Preference orderings obtained using the model are then compared to the original rankings. Example applications of conjoint measurement theory to describe preferences between multiattribute alternatives are discussed in Winterfeldt and Edwards (1986). Related applications include the dichotomy-cut method, used to obtain decision rules for individuals and groups from ordinal rankings of multiattribute alternatives (Stanoulov 1994).

The policy capturing approach used in social judgment theory (Hammond et al. 1975; Hammond 1993) is another indirect approach for describing human judgments of both preferences and probability. The policy-capturing approach uses multivariate regression or other similar techniques to relate preferences to attributes for one or more decision makers. The obtained equations correspond to policies followed by particular decision makers. An example equation might relate medical symptoms to a physician's diagnosis. It has been argued that the policy-capturing approach measures the influence of factors on human judgments more accurately than decomposition methods. Captured weights might be more accurate because decision makers may have little insight into the factors that impact their judgments (Valenzi and Andrews 1973). People may also weigh certain factors in ways that reflect social desirability rather than influence on their judgments (Brookhouse et al. 1986). For example, people comparing jobs might rate pay as being lower in importance than intellectual challenge, while their preferences between jobs might be predicted entirely by pay. Caution must also be taken when interpreting regression weights as indicating importance, since regression coefficients are influenced by correlations between factors, their variability, and their validity (Stevenson et al. 1993).

4. BEHAVIORAL DECISION THEORY

As a normative ideal, classical decision theory has influenced the study of decision making in a major way. Much of the earlier work in behavioral decision theory compared human behavior to the

prescriptions of classical decision theory (Edwards 1954; Slovic et al. 1977; Einhorn and Hogarth 1981). Numerous departures were found, including the influential finding that people use heuristics during judgment tasks (Tversky and Kahneman 1974). On the basis of such research, pyschologists have concluded that other approaches are needed to describe the process of human decision making. Descriptive models that relax assumptions of the normative models, but still retain much of their essence, are now being evaluated in the field of judgment and decision theory (Stevenson et al. 1993).

The following discussion summarizes findings from this broad body of literature. The discussion begins by considering research on statistical estimation and inference. Attention then shifts to the topic of decision making under uncertainty and risk.

4.1. Statistical Estimation and Inference

The ability of people to perceive, learn, and draw inferences accurately from uncertain sources of information has been a topic of much research. The following discussion first briefly considers human abilities and limitations on such tasks. The next section introduces several heuristics people seem to use to cope with their limitations and considers how their use can cause certain biases. Attention then shifts to probabilistic information-processing models and policy capturing models. These modeling approaches provide a mathematically oriented view of how people judge probabilities, the biases that might occur, and how people learn to perform probability judgment tasks. The final section briefly summarizes findings on debiasing human judgments.

4.1.1. Human Abilities/Limitations

Research conducted in the early 1960s tested the notion that people behave as ''intuitive statisticians'' who gather evidence and apply it in accordance with the Bayesian model of inference (Peterson and Beach 1967). Several studies evaluated how good people are at estimating statistical parameters, such as means, variances, and proportions. Other studies have compared human inferences obtained from probabilistic evidence to the prescriptions of Bayes' rule.

A number of interesting results were obtained (Table 6). The research first shows that people can be fairly good at estimating means, variances, or proportions from sample data. However, this ability drops greatly when the judged events occur either rarely or very often. In particular, when people are asked to estimate the risk associated with the use of consumer products (Dorris and Tabrizi 1978; Rethans 1980) or various technologies (Lichtenstein et al. 1978), estimates can be weakly related to accident data. Weather forecasters are one of the few groups of people that have been documented as being able to estimate high and low probabilities accurately (Winkler and Murphy 1973).

Part of the issue is that risk estimates are related to factors other than likelihood, such as catastrophic potential, degree of control, or familiarity (Lichtenstein et al. 1978; Slovic 1978; 1987; Lehto et al. 1994). Weber (1994) provides additional evidence that subjective probabilities are related to factors other than uncertainty and argues that people will overestimate the chance of highly positive outcome because of their desire to obtain it. Weber also argues that people will overestimate the chance of a highly undesirable outcome because of their fear of receiving it. Traditional methods of decision analysis separately elicit and then recombine subjective probabilities with utilities, as discussed earlier, and assume that subjective probabilities are independent of consequences. A finding of dependency therefore casts serious doubt upon the normative validity of this commonly accepted approach.

When studies of human inference are considered, several other trends become apparent (Table 6). In particular, several significant deviations from the Bayesian model have been found. These include:

1. Decision makers tend to be conservative in that they don't give as much weight to probabilistic evidence as Bayes' rule (Edwards 1968).
2. They don't consider base rates or prior probabilities adequately (Tversky and Kahneman 1974).
3. They tend to ignore the reliability of the evidence (Tversky and Kahneman 1974).
4. They tend to overestimate the probability of conjunctive events and underestimate the probability of disjunctive events (Bar-Hillel 1973).
5. They tend to seek out confirming evidence rather than disconfirming evidence and place more emphasis on confirming evidence when it is available (Einhorn and Hogarth 1978; Baron 1985).
6. They are overconfident in their predictions (Fischhoff et al. 1977), especially in hindsight (Fischhoff 1982; Christensen-Szalanski 1991).
7. They show a tendency to infer illusionary causal relations (Tversky and Kahneman 1973).

A lively literature has developed regarding these deviations and their significance (Evans 1989; Wickens 1992; Caverni et al. 1990; Klein et al. 1993). From one perspective, these deviations demonstrate inadequacies of human reason and are a source of societal problems (Hammond 1974). From the opposite perspective, it has been held that the above findings are more or less experimental

TABLE 6 Sample Findings on the Ability of People to Estimate and Infer Statistical Quantities

Statistical Estimation	
Accurate estimation of sample means	Peterson and Beach 1968
Variance estimates correlated with mean	Lathrop 1967
Variance biases not found	Levin 1975
Variance estimates based on range	Pitz 1980
Accurate estimates of sample proportions between 0.75 and 0.25	Edwards 1954
Severe overestimates of high probabilities; severe underestimates of low proportions	Fischhoff et al. 1977; Lichtenstein et al. 1982
Reluctance to report extreme events	
Weather forecasters provided accurate probabilities	Winkler and Murphy 1973
Poor estimates of expected severity	Dorris and Tabrizi 1977
Correlation of 0.72 between subjective and objective measures of injury frequency	Rethans 1980
Risk estimates lower for self than for others	Weinstein 1980, 1987
Risk estimates related to catastrophic potential, degree of control, familiarity	Lichtenstein et al. 1978
Evaluations of outcomes and probabilities are dependent	Weber 1994
Statistical Inference	
Conservative aggregation of evidence	Edwards 1966
Nearly optimal aggregation of evidence in naturalistic setting	Lehto et al. 2000
Failure to consider base rates	Tversky and Kahneman 1974
Base rates considered	Birnbaum and Mellers 1983 Koehler 1996
Overestimation of conjunctive events	Bar-Hillel 1973
Underestimation of disjunctive events	
Tendency to seek confirming evidence	Einhorn and Hogarth 1978; Baron 1985
Tendency to discount disconfirming evidence	
Tendency to ignore reliability of the evidence	Kahneman and Tversky 1973
Subjects considered variability of data when judging probabilities	Evans and Pollard 1985
People insensitive to information missing from fault trees	Fischhoff et al. 1978
Overconfidence in estimates	Fischhoff et al. 1977
Hindsight bias	Fishhoff 1982 Christensen-Szalanski and Willham 1991
Illusionary correlations	Tversky and Kahneman 1974
Gambler's fallacy	
Misestimation of covariance between items	Arkes 1981
Misinterpretation of regression to the mean	Tversky and Kahneman 1974

artifacts that do not reflect the true complexity of the world (Cohen 1993). From one such perspective, people deviate from Bayes' rule because it makes unrealistic assumptions about what is known or knowable. Simon (1955, 1983) makes a particularly compelling argument for the latter point of view. It also has been noted that researchers overreport findings of bias (Evans 1989; Cohen 1993).

There is an emerging body of literature that, on one hand, shows that deviations from Bayes' rule can in fact be justified in certain cases from a normative view and, on the other hand, shows that these deviations may disappear when people are provided richer information or problems in more natural contexts. For example, drivers performing a simulated passing task combined their own observations of the driving environment with imperfect information provided by a collision-warning

system, as predicted by a distributed signal detection theoretic model of optimal team decision making (Lehto et al. 2000). Other researchers have pointed out that:

1. A tendency towards conservatism can be justified when evidence is not conditionally independence (Navon 1979).
2. Subjects do use base rate information and consider the reliability of evidence, in slightly modified experimental settings (Birnbaum and Mellers 1983; Koehler 1996).
3. A tendency to seek out confirming evidence can offer practical advantages (Cohen 1993) and may reflect cognitive failures, due to a lack of understanding of how to falsify hypotheses, rather than entirely a motivational basis (Klayman and Ha 1987; Evans 1989).
4. Subjects prefer stating subjective probabilities with vague verbal expressions rather than precise numerical values (Wallsten et al. 1993), demonstrating that they are not necessarily overconfident in their predictions.*
5. There is evidence that the hindsight bias can be moderated by familiarity with both the task and the type of outcome information provided (Christensen-Szalanski and Willham 1991).

Koehler (1996) provides a particularly compelling reexamination of the base rate fallacy. He concludes that the literature does not support the conventional wisdom that people routinely ignore base rates. To the contrary, he states that base rates are almost always used and that their degree of use depends on task structure and representation as well as their reliability compared to other sources of information. Because such conflicting conclusions can be obtained, depending upon the setting in which human decision making is observed, Koehler and researchers in the field of naturalistic decision making (Klein 1998; Klein et al. 1993) strongly emphasize the need to conduct ecologically valid research in rich realistic decision environments.

4.1.2. Heuristics and Biases

Tversky and Kahneman (1973, 1974) made a key contribution to the field when they showed that many of the above-mentioned discrepancies between human estimates of probability and Bayes' rule could be explained by the use of three heuristics.† The three heuristics they proposed were those of representativeness, availability, and anchoring and adjustment.

The *representativeness* heuristic holds that the probability of an item *A* belonging to some category *B* is judged by considering how representative *A* is of *B*. For example, a person is typically judged more likely to be a librarian than a farmer when described as "A meek and tidy soul, who has a desire for order and structure and a passion for detail." Application of this heuristic will often lead to good probability estimates but can lead to systematic biases. Tversky and Kahneman (1974) give several examples of such biases. In each case, representativeness influenced estimates more than other, more statistically oriented information. In the first study, subjects ignored base rate information (given by the experimenter) about how likely a person was to be either a lawyer or an engineer. Their judgments seemed to be based entirely on how representative the description seemed to be of either occupation. Tversky and Kahneman (1983) found people overestimated conjunctive probabilities in a similar experiment. Here, after being told that "Linda is 31 years old, single, outspoken, and very bright," most subjects said it was more likely she was both a bank teller and active as a feminist than simply a bank teller. In a third study, most subjects felt that the probability of more than 60% male births on a given day was about the same for both large and small hospitals (Tversky and Kahneman 1974). Apparently, the subjects felt large and small hospitals were equally representative of the population.

Other behaviors explained in terms of representativeness by Tversky and Kahneman included gambler's fallacy, insensitivity to predictability, illusions of validity, and misconceptions of statistical regression to the mean. With regard to gambler's fallacy, they note that people may feel long sequences of heads or tails when flipping coins are unrepresentative of normal behavior. After a sequence of heads, a tail therefore seems more representative. Insensitivity to predictability refers to a tendency for people to predict future performance without considering the reliability of the information they base the prediction upon. For example, a person might expect an investment to be profitable solely on the basis of a favorable description without considering whether the description has any predictive value. In other words, a good description is believed to be representative of high profits, even if it states nothing about profitability. The illusion of validity occurs when people use highly correlated evidence to make a conclusion. Despite the fact that the evidence is redundant, the

*It is interesting to note that Dawes and Mulford (1996) claim that the empirical support for the overconfidence effect is inadequate and logically flawed.

†It is important to point out that heuristic reasoning can lead to excellent results.

presence of many representative pieces of evidence increases confidence greatly. Misconception of regression to the mean occurs when people react to unusual events and then infer a causal linkage when the process returns to normality on its own. For example, a manager might incorrectly conclude that punishment works after seeing that unusually poor performance improves to normal levels following punishment. The same manager might also conclude that rewards don't work after seeing that unusually good performance drops after receiving a reward.

The availability heuristic holds that the probability of an event is determined by how easy it is to remember the event happening. Tversky and Kahneman state that perceived probabilities will, therefore, depend on familiarity, salience, effectiveness of memory search, and imaginability. The implication is that people will judge events as more likely when the events are familiar, highly salient (such as an airplane crash), or easily imaginable. Events also will be judged more likely if there is a simple way to search memory. For example, it is much easier to search for words in memory by the first letter rather than the third letter. It is easy to see how each of the above items impacting the availability of information can influence judgments. Biases should increase when people lack experience or when their experiences are too focused.

Anchoring and adjustment holds that people start from some initial estimate and then adjust it to reach some final value. The point initially chosen has a major impact on the final value selected when adjustments are insufficient. Tversky and Kahneman refer to this source of bias as an anchoring effect. They show how this effect can explain under- and overestimates of disjunctive and conjunctive events. This happens if the subject starts with a probability estimate of a single event. The probability of a single event is of course less than that for the disjunctive event and greater than that for the conjunctive event. If adjustment is too small, then under- and overestimates respectively occur for the disjunctive and conjunctive events. Tversky and Kahneman also discuss how anchoring and adjustment may cause biases in subjective probability distributions. Hogarth and Einhorn (1992) present an anchoring and adjustment model of how people update beliefs that explains a number of ordering effects, such as the primacy and recency effects. This latter model holds that the degree of belief in a hypothesis after collecting k pieces of evidence can be described as follows:

$$S_k = S_{k-1} + w_k[s(x_k) - R] \tag{26}$$

where S_k is the degree of belief after collecting k pieces of evidence, S_{k-1} is the anchor or prior belief, w_k is the adjustment weight for the kth piece of evidence, $s(x_k)$ is the subjective evaluation of the kth piece of evidence, and R is the reference point against which the kth piece of evidence is compared. In evaluation tasks, $R = 0$. This corresponds to the case where evidence is either for or against a hypothesis.* For estimation tasks, $R \neq 0$. The different values of R result in an additive model for evaluation tasks and an averaging model for estimation tasks. Also, if the quantity, $s(x_k) - R$, is evaluated for several pieces of evidence at a time, the model predicts primacy effects. If single pieces of evidence are individually evaluated in a step-by-step sequence, recency effects become more likely.

The notion of heuristics and biases has had a particularly formative influence on decision theory. A substantial recent body of work has emerged that focuses on applying research on heuristics and biases (Kahneman et al. 1982; Heath et al. 1994). Applications include medical judgment and decision making, affirmative action, education, personality assessment, legal decision making, mediation, and policy making. It seems clear that this approach is excellent for describing many general aspects of decision making in the real world. However, research on heuristics and biases has been criticized as being pretheoretical (Slovic et al. 1977). Koehler (1996) also points out that efforts to confirm the representativeness heuristic has contributed to overselling of the "base rate" bias. Other views of human judgment are expanded upon below.

4.1.3. Selective Processing of Information

Evans (1989) argues that factors which cause people to process information in a selective manner or attend to irrelevant information are the major cause of biases in human judgment. Factors assumed to influence selective processing include the availability, vividness, and relevance of information, and working memory limitations. The notion of availability refers to the information actually attended to by a person while performing a task. Evans's model assumes that relevant information elements are determined during a heuristic, preattentional stage. This stage is assumed to involve unconscious processes and is influenced by stimulus salience (or vividness) and the effects of prior knowledge.

In the next stage of his model, inferences are drawn from the selected information. This is done using rules for reasoning and action developed for particular types of problems. Working memory

*It is easy to see that Eq. (26) approximates the log-odds form of Bayes' rule where evidence for or against the hypothesis is additively combined.

influences performance at this stage by limiting the amount of information that can be consciously attended to while performing a task. The knowledge used during the inference process might be organized in schemas that are retrieved from memory and fit to specific problems (Cheng and Holyoak 1985). Support for this latter conclusion is provided by studies showing that people are able to develop skills in inference tasks but may fail to transfer these skills (inference related) from one setting to another. Evans also provides evidence that prior knowledge can cause biases when it is inconsistent with provided information and that improving knowledge can reduce or eliminate biases.

Evans's model of selective processing of information is consistent with other explanations of biases. Among such explanations, information overload has been cited as a reason for impaired decision making by consumers (Jacoby 1977). The tendency of highly salient stimuli to capture attention during inference tasks has also been noted by several researchers (Nisbett and Ross 1980; Payne 1980). Nisbett and Ross suggest that vividness of information is determined by its emotional content, concreteness and imagability, and temporal and spatial proximity. As noted by Evans, these factors have also been shown to affect the memorability of information. This provides a plausible explanation of both the availability heuristic and the experimental results mentioned earlier regarding biases in risk perceptions.

4.1.4. Models of Human Judgment

A number of approaches have been developed for mathematically describing human judgments. These approaches include social judgment theory, policy capturing, multiple-cue probability learning models, information integration theory, and conjoint measurement approaches.

Social judgment theory (SJT) implements an ecological approach for explaining how environmental cues are related to psychological responses (Hammond et al. 1975; Hammond 1993; Brehmer and Joyce 1988). The approach can be traced back to the Brunswick lens model (Brunwick 1952), which describes human judgments in terms of perceived environmental cues. Emphasis is placed on performing experiments where information cues reflect the statistical characteristics of the real world. Policy-capturing models are also derived from the lens model and have been applied to a wide number of real-world applications to describe expert judgments (Brehmer and Joyce 1988). For example, policy-capturing models have been applied to describe software selection by management information system managers (Martocchio et al. 1993), medical decisions (Brehmer and Joyce 1988), and highway safety (Hammond 1993). As mentioned earlier with regard to preference assessment, linear or nonlinear forms of regression are used in this approach to relate judgments to environment cues. These equations provide surprisingly good fits to expert judgments. In fact, there is evidence, and consequently much debate, over whether the models can actually do better than experts on many judgment tasks (Slovic et al. 1977; Brehmer 1981; Kleinmuntz 1984).

Cognitive continuum theory (Hammond 1980) builds upon Brunswick's earlier work by distinguishing judgments on a cognitive continuum varying from highly intuitive decisions to highly analytical decisions. Hammond (1993) summarizes earlier research showing that task characteristics cause decision makers to vary on this continuum. A tendency towards analysis increases, and reliance on intuition decreases, when (1) the number of cues increases, (2) cues are measured objectively instead of subjectively, (3) cues are of low redundancy, (4) decomposition of the task is high, (5) certainty is high, (6) cues are weighted unequally in the environmental model, (7) relations are nonlinear, (8) an organizing principle is available, (9) cues are displayed sequentially instead of simultaneously, and (10) the time period for evaluation is long. Intuitive methods can be better than analytical methods in some situations (Hammond et al. 1987).

Multiple cue probability learning models extend the lens model to the psychology of learning (Brehmer and Joyce 1988). Research on multiple-cue probability learning has provided valuable insight into factors affecting learning of inference tasks. One major finding is that providing cognitive feedback about cues and their relationship to the inferred effects leads to quicker learning than feedback about outcomes (Balzer et al. 1989). Stevenson et al. (1993) summarize a number of other findings, including that (1) subjects can learn to use valid cues, even when they are unreliable, (2) subjects are better able to learn linear relationships than nonlinear or inverse relationships, (3) subjects do not consider redundancy when using multiple cues, (4) source credibility and cue validity are considered, and (5) the relative effectiveness of cognitive and outcome feedback depends on the formal, substantive, and contextual characteristics of the task.

Information integration theory (Anderson 1981) takes a somewhat different approach than SJT or the lens model to describe how cue information is used when making judgments. A major deviation is that information-integration theory emphasizes the use of factorial experimental designs where cues are systematically manipulated. The goal of this approach is to determine first how people scale cues when determining their subjective values, and second how these scaled values are combined to form overall judgments. Various functional forms of how information is integrated are considered, including additive and averaging functions. A substantial body of research follows this approach to test various ways people might combine probabilistic information. A primary conclusion is that people tend to

integrate information using simple averaging, adding, subtracting, and multiplying models. Conjoint measurement approaches (Wallsten 1972, 1976), in particular, provide a convenient way of both scaling subjective values assigned to cues and testing different functional forms describing how these values are combined to develop global judgments. By applying this approach, Wallsten (1976) was able to model primacy and recency effects.

4.1.5. Debiasing Human Judgments

The notion that many biases (or deviations from normative models) in statistical estimation and inference can be explained has led researchers to consider the possibility of debiasing human judgments (Keren 1990). Part of the issue is that heuristics often work very well. It seems logical that biases based on both the availability and representativeness heuristics might be reduced if people were provided more information. As discussed earlier in Section 4.1.1, there is evidence that biases can be moderated by familiarity with both the task and the type of outcome information provided. However, debiasing research has provided mixed results. Many biases, such as optimistic beliefs regarding health risks, have been difficult to modify (Weinstein and Klein 1995). People show a tendency to seek out information that supports their personal views (Weinstein 1979) and are quite resistant to information that contradicts strongly held beliefs (Nisbett and Ross 1980; McGuire 1966). Evans (1989) concludes that ''pre-conceived notions are likely to prejudice the construction and evaluation of arguments.''

Other evidence shows that experts may have difficulty providing accurate estimates of subjective probabilities even when they receive feedback. For example, many efforts to reduce both overconfidence in probability estimates and the hindsight bias have been unsuccessful (Fischhoff 1982). One problem is that people may not pay attention to feedback (Fischhoff and MacGregor 1982). They also may only attend to feedback that supports their hypothesis, leading to poorer performance and at the same time greater confidence (Einhorn and Hogarth 1978). Efforts to reduce confirmation biases through training have also in general been unsuccessful (Evans 1989).

On the positive side, there is evidence that providing feedback on the accuracy of weather forecasts may help weather forecasters (Winkler and Murphy 1973). There is also some evidence that people can learn to perform statistical reasoning more accurately after training in statistics (Fong et al. 1986). Failure to consider sample size was significantly reduced after training. Another study showed that asking people to write down reasons for and against their estimates of probabilities improved calibration and reduced overconfidence (Koriat et al. 1980). There is evidence that overconfidence is reduced when decision makers represent subjective probabilities verbally (Zimmer 1983; Wallsten et al. 1993). Conservatism, or the failure to modify probabilities adequately after obtaining evidence, was also reduced in Zimmer's study.

The conclusion is that debiasing human judgments is difficult but not impossible. Some perspective can be obtained by considering that most studies showing biases have focused on statistical inference and generally involved people not particularly knowledgeable about statistics, who are not using decision aids such as computers or calculators. It naturally may be expected that people will perform poorly on such tasks, given their lack of training and forced reliance on mental calculations (Winterfeldt and Edwards 1986). The finding that people can improve their abilities on such tasks after training in statistics is particularly telling, but also encouraging. Another encouraging finding is that biases are occasionally reduced when people process information verbally instead of numerically. This result might be expected, given that most people are more comfortable with words than numbers.

4.2. Preference and Choice

Much of the research on human preference and choice has focused on comparing observed preferences to the predictions of subjective utility theory (SEU) (Goldstein and Hogarth 1997). Early work, examining SEU as a descriptive theory, drew generally positive conclusions. However, it soon became apparent that people's preferences for risky or uncertain alternatives often violated basic axioms of SEU theory. The finding that people's preferences change when the outcomes are framed in terms of costs, as opposed to benefits, has been particularly influential. Several other common deviations from SEU have been observed. One potentially serious deviation is that preferences can be influenced by sunk costs or prior commitment to a particular alternative. Preferences change over time and may depend upon which alternatives are being compared, or even the order in which they are compared. The regret associated with making the ''wrong'' choice seems to play a major role when people compare alternatives. Accordingly, the satisfaction people derive from obtaining particular outcomes after making a decision is influenced by positive and negative expectations prior to making the decision. Other research on human preference and choice has shown that people choose between and apply different decision strategies, depending upon the cognitive effort required to apply a decision strategy successfully, the needed level of accuracy, and time pressure. Certain strategies are more likely than others to lead to choices consistent with those prescribed by SEU theory.

Alternative models, such as prospect theory and random utility theory, were consequently developed in order to explain human preferences under risk or uncertainty.* The following discussion will first summarize some common violations of the axioms underlying SEU theory before moving on to framing effects and preference reversals. Attention will then shift to models of choice and preference. The latter discussion will begin with prospect theory before addressing other models of labile or conditional preferences. Decision-making strategies, and how people choose between them, will be covered in Section 6.

4.2.1. Violation of Rationality Axioms

Several studies have shown that people's preferences between uncertain alternatives can be inconsistent with the axioms underlying subjective expected utility (SEU) theory. One fundamental violation of the assumptions is that preferences can be intransitive (Tversky 1969; Budescu and Weiss 1987). Also, as mentioned in the previous section, subjective probabilities may depend upon the values of consequences (violating the independence axiom) and, as discussed in the next section, the framing of a choice can impact preference. Another violation is given by the Myers effect (Myers et al. 1965), where preference reversals between high (H) and low (L) variance gambles can occur when the gambles are compared to a certain outcome, depending upon whether the certain outcome is positive (H preferred to L) or negative (L preferred to H). This latter effect violates the assumption of independence because the ordering of the two gambles depends on the certain outcome.

Another commonly cited violation of SEU theory is that people show a tendency towards uncertainty avoidance which can lead to behavior inconsistent with the ''sure-thing'' axiom. The Ellsburg and Allais paradoxes (Ellsburg 1961; Allais 1953) both involve violations of the sure-thing axiom (see Table 2) and seem to be caused by people's desire to avoid uncertainty. The Allais paradox is illustrated by the following set of gambles. In the first gamble, a person is asked to choose between gambles $A1$ and $B1$, where:

> Gamble $A1$ results in \$1 million for sure. Gamble $B1$ results in \$2.5 million with a probability of 0.1, \$1 million with a probability of 0.89, and \$0 with a probability of 0.01.
>
> In the second gamble, the person is asked to choose between gambles *A2 and B*2, where: $A2$ results in \$1 million with a probability of 0.11 and \$0 with a probability of 0.89. Gamble $B2$ results in \$2.5 million with a probability of 0.1 and \$0 with a probability of 0.9.

Most people prefer gamble $A1$ to $B1$ and gamble $B2$ to $A2$. It is easy to see that this set of preferences violates expected utility theory. First, if $A1 > B1$, then $u(A1) > u(B1)$, meaning that: $u(\$1 \text{ million}) > 0.1u(\$2.5 \text{ million}) + 0.89u(\$1 \text{ million}) + 0.01u(\$0)$. If a utility of 0 is assigned to receiving \$0 and a utility of 1 to receiving \$2.5 million, then $u(\$1 \text{ million}) > 1/11$. However, from the preference $A2 > B2$, it follows that $u(\$1 \text{ million}) < 1/11$. Obviously, no utility function can satisfy this requirement of assigning a value both greater than and less than $1/11$ to \$1 million.

As noted by Savage (1954), the above set of gambles can be reframed in a way that shows that these preferences violate the sure-thing principle. After doing so, Savage found that his initial tendency towards choosing $A1$ over $B1$ and $A2$ over $B2$ disappeared. As noted by Stevenson et al. (1993), this example is one of the first cited cases of a preference reversal caused by reframing a decision, the topic discussed below.

4.2.2. Framing of Decisions and Preference Reversals

A substantial body of research has shown that people's preferences can shift dramatically depending upon the way a decision is represented. The best-known work on this topic was conducted by Tversky and Kahneman (1981), who showed that preferences between medical intervention strategies changed dramatically depending upon whether the outcomes were posed as losses or gains. The following question, worded in terms of benefits, was presented to one set of subjects:

> Imagine that the U.S. is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimate of the consequences of the programs are as follows:
>
> If Program A is adopted, 200 people will be saved.
>
> If Program B is adopted, there is a $1/3$ probability that 600 people will be saved, and a $2/3$ probability that no people will be saved.
>
> Which of the two programs would you favor?

* Yates (1992) and Singleton and Hovden (1987) are useful sources for the reader interested in additional details on risk perception, risk acceptability, and risk-taking behavior. Section 5.1.1 is also relevant to this topic.

The results showed that 72% of subjects preferred program A. The second set of subjects was given the same cover story, but worded in terms of costs, as given below:

> If Program C is adopted, 400 people will die.
> If Program D is adopted, there is a 1/3 probability that nobody will die, and a 2/3 probability that 600 people will die.
> Which of the two programs would you favor?

The results now showed that 78% of subjects preferred program D. Since program D is equivalent to B and Program A is equivalent to C, the preferences for the two groups of subjects were strongly reversed. Tversky and Kahneman concluded that this reversal illustrated a common pattern in which choices involving gains are risk averse and choices involving losses are risk seeking. The interesting result was that the way the outcomes were worded caused a shift in preference for identical alternatives. Tversky and Kahneman called this tendency the *reflection effect*. A body of literature has since developed showing that the framing of decisions can have practical effects for both individual decision makers (Kahneman et al. 1982; Heath et al. 1994) and group decisions (Paese et al. 1993). On the other hand, recent research shows that the reflection effects can be reversed by certain outcome wordings (Kuhberger 1995); more importantly, Kuhberger provides evidence that the reflection effect observed in the classic experiments can be eliminated by fully describing the outcomes (i.e., referring to the above paragraph, a more complete description would state, ''If Program C is adopted, 400 people will die AND 200 WILL LIVE'').

Other recent research has explored the theory that perceived risk and perceived attractiveness of risky outcomes are psychologically distinct constructs (Weber et al. 1992). In the latter study, it was concluded that perceived risk and attractiveness are ''closely related, but distinct phenomena.'' Related research has shown weak negative correlations between the perceived risk and value of indulging in alcohol-related behavior for adolescent subjects (Lehto et al. 1994). This latter study also showed that the rated propensity to indulge in alcohol-related behavior was strongly correlated with perceived value ($R = 0.8$), but weakly correlated with perceived risk ($R = -0.15$). Both findings are consistent with the theory that perceived risk and attractiveness are distinct constructs, but the latter finding indicates that perceived attractiveness may be the better predictor of behavior. Lehto et al. conclude that intervention methods attempting to lower preferences for alcohol-related behavior should focus on lowering perceived value rather than on increasing perceived risk.

4.2.3. Prospect Theory

Prospect theory (Kahneman and Tversky 1979) attempts to account for behavior not consistent with the SEU model by including the framing of decisions as a step in the judgment of preference between risky alternatives. Prospect theory assumes that decision makers tend to be risk averse with regard to gains and risk seeking with regard to losses. This leads to a value function that disproportionately weights losses. As such, the model is still equivalent to SEU, assuming a utility function expressing mixed risk aversion and risk seeking. Prospect theory, however, assumes that the decision maker's reference point can change. With shifts in the reference point, the same returns can be viewed as either gains or losses.* This latter feature of prospect theory, of course, is an attempt to account for the framing effect discussed above. Prospect theory also deviates significantly from SEU theory in the way probabilities are addressed. To describe human preferences more closely, perceived values are weighted by a function $\pi(p)$, instead of the true probability, p. Compared to the untransformed form of p, $\pi(p)$ overweights very low probabilities and underweights moderate and high probabilities. The function $\pi(p)$ is also generally assumed to be discontinuous and poorly defined for probability values close to 0 or 1.

Prospect theory assumes that the choice process involves an editing phase and an evaluation phase. The editing phase involves reformulation of the options to simplify subsequent evaluation and choice. Much of this editing process is concerned with determining an appropriate reference point in a step called coding. Other steps that may occur include the segregation of riskless components of the decision, combining probabilities for events with identical outcomes, simplification by rounding off probabilities and outcome measures, and search for dominance. In the evaluation phase, the perceived values are then weighed by the function $\pi(p)$. The alternative with the greatest weighed value is then selected. Several other modeling approaches that differentially weigh utilities in risky decision making

*The notion of a reference point against which outcomes are compared has similarities to the notion of making decisions on the basis of regret (Bell 1982). Regret, however, assumes comparsion to the best outcome. The notion of different reference points also is related to the well-known trend that buying and selling price of assets often differ for a decision maker (Raiffa 1968).

have been proposed (Goldstein and Hogarth 1998). As in prospect theory, such models often assume that the subjective probabilities, or decision weights, are a function of outcome sign (i.e. positive, neutral, or negative), rank (i.e., 1st, 2nd, etc), or magnitude. Other models focus on display effects (i.e., single-stage vs. multistage arrangements) and distribution effects (i.e., two outcome lotteries vs multiple-outcome lotteries). Prospect theory and other approaches also address how the value or utility of particular outcomes can change between decision contexts, as discussed below.

4.2.4. Labile Preferences

There is no doubt that human preferences often change after receiving some outcome. After losing money, an investor may become risk averse. In other cases, an investor may escalate her commitment to an alternative after an initial loss, even if better alternatives are available. From the most general perspective, any biological organism becomes satiated after satisfying a basic need, such as hunger. Preferences also change over time or between decision contexts. For example, a 30-year-old decision maker considering whether to put money into a retirement fund may currently have a very different utility function than at retirement. The latter case is consistent with SEU theory but obviously complicates analysis.

Economists and behavioral researchers have both focused on mathematically modeling choice processes to explain intransitive or inconsistent preference orderings of alternatives (Goldstein and Hogarth 1997). Game theory provides interesting insight into this issue. From this perspective, preferences of the human decision maker are modeled as the collective decisions obtained by a group of internal agents, or selves, each of which is assumed to have distinct preferences (see Elster 1986). Intransitive preferences and other violations of rationality on the part of the human decision maker then arise from interactions between competing selves.* Along these lines, Ainslie (1975) proposed that impulsive preference switches (often resulting in risky or unhealthy choices) arise as the outcome of a struggle between selves representing conflicting short-term and long-term interests, respectively.

Another area of active research has focused on how experiencing outcomes can cause shifts in preference. One robust finding is that people tend to be more satisfied if an outcome exceeds their expectations and less satisfied if it does not (i.e., Feather 1966; Connolly et al. 1997). Expectations therefore provide a reference point against which obtained outcomes are compared. Numerous studies have also shown that people in a wide variety of settings often consider sunk costs when deciding whether to escalate their commitment to an alternative by investing additional resources (Arkes and Blumer 1985). From the perspective of prospect theory, sunk costs cause people to frame their choice in terms of losses instead of gains, resulting in risk-taking behavior and consequently escalating commitment. Other plausible explanations for escalating commitment include a desire to avoid waste or to avoid blame for an initially bad decision to invest in the first place. Interestingly, some recent evidence suggests that people may deescalate commitment in response to sunk costs (Heath 1995). The latter effect is also contrary to classical economic theory, which holds that decisions should be based solely on marginal costs and benefits. Heath explains such effects in terms of mental accounting. Escalation is held to occur when a mental budget is not set or expenses are difficult to track. Deescalation is held to occur when people exceed their mental budget, even if the marginal benefits exceed the marginal costs.

Other approaches include value or utility as random variables within models of choice to explain intransitive or inconsistent preference orderings of alternatives. Random utility models (Iverson and Luce 1998) describe the probability $P_{a,A}$ of choosing a given alternative a from a set of options A as

$$P_{a,A} = \text{Prob}(U_a \geq U_b, \text{ for all } b \text{ in } A) \tag{27}$$

where U_a is the uncertain utility of alternative a and U_b is the uncertain utility of alternative b. The most basic random utility models assign a utility to each alternative by sampling a single value from some known distribution. The sampled utility of each alternative then remains constant throughout the choice process. Basic random utility models can predict a variety of preference reversals and intransitive preferences for single and multiple attribute comparisons of alternatives (i.e., Tverski 1972).

Sequential sampling models extend this approach by assuming preferences can be based on more than one observation. Preferences for particular alternatives are accumulated over time, by integrating

*As discussed further in Section 6, group decisions, even though they are made by rational members, are subject to numerous violations of rationality. For example, consider the case where the decision maker has three selves that are, respectively, risk averse, risk neutral, and risk seeking. Assume that the decision maker is choosing between alternatives A, B, and C. Suppose the risk-averse self rates the alternatives in the order A, B, C; the risk-neutral self rates them in the order B, C, A; and the risk-seeking self rates them in the order C, A, B. Also, assume the selves are equally powerful. Then two of the three agents always agree that $A > B$, $B > C$, and $C > A$. This ordering is, of course, nontransitive.

or otherwise summing the sampled utilities. The utility of an alternative, at a particular time, is proportional to the latter sum. A choice is made when the summed preferences for a particular alternative exceed some threshold, which itself may vary over time or depend on situational factors (Wallsten 1995; Busemeyer and Townsend 1993). It is interesting to observe that sequential sampling models can explain speed accuracy trade-offs in signal-detection tasks (Stone 1960), as well as shifts in preferences due to time pressure (Wallsten 1995; Busemeyer and Townsend 1993), if it is assumed that people adjust their threshold downwards under time pressure. That is, under time pressure, people sample less information before making a choice. The following section will further explore how and why decision strategies might change over time and between decision contexts.

5. DYNAMIC AND NATURALISTIC DECISION MAKING

In dynamic decision making, actions taken by a decision maker are made sequentially in time. Taking actions can change the environment, resulting in a new set of decisions. The decisions might be made under time pressure and stress, by groups or by single decision makers. This process might be performed on a routine basis or might involve severe conflict. For example, either a group of soldiers or an individual officer might routinely identify marked vehicles as friends or foes. When a vehicle has unknown or ambiguous marking, the decision changes to a conflict driven process. Naturalistic decision theory has emerged as a new field that focuses on such decisions in real-world environments (Klein et al. 1993; Klein 1998). The notion that most decisions are made in a routine, nonanalytical way is the driving force of this approach.* Areas where such behavior seems prominent include juror decision making, troubleshooting of complex systems, medical diagnosis, management decisions, and numerous other examples.

The following discussion will first address models of dynamic and naturalistic decision making. These models both illustrate naturalistic decision-making strategies and explain their relation to experience and task familiarity. A brief discussion will also be provided on teams and team leadership, in naturalistic settings. Attention will then shift to the issue of time pressure and stress and how this factor influences performance in naturalistic decision making.

5.1. Naturalistic Decision Making

In recent years, it has been recognized that decision making in natural environments often differs greatly between decision contexts (Beach 1993; Hammmond 1993). In addressing this topic, the involved researchers often question the relevance and validity of both classical decision theory and behavioral research not conducted in real-world settings (Cohen 1993). Numerous naturalistic models have been proposed (Klein et al. 1993). These models assume that people rarely weigh alternatives and compare them in terms of expected value or utility. Each model is also descriptive rather than prescriptive. Perhaps the most general conclusion that can be drawn from this work is that people use different decision strategies, depending upon their experience, the task and the decision context. Several of the models also postulate that people choose between decision strategies by trading off effectiveness against the effort required.

The following discussion will briefly review seven modeling perspectives that fit into this framework: (1) levels of task performance (Rasmussen 1983), (2) recognition-primed decisions (Klein 1989), (3) image theory (Beach 1990), (4) contingent decision making (Payne et al. 1993), (5) dominance structuring (Montgomery 1989), (6) explanation-based decision making (Pennington and Hastie 1988), and (7) shared mental models and awareness. Attention will then shift to leadership and its impact on team performance in naturalistic settings.

5.1.1. Levels of Task Performance

There is growing recognition that most decisions are made on a routine basis in which people simply follow past behavior patterns (Rasmussen 1983; Beach 1993; Svenson 1990). Rasmussen (1983) follows this approach to distinguish among skill-based, rule-based, and knowledge-based levels of task performance. Lehto (1991) further considers judgment-based behavior as a fourth level of performance.

Performance is said to be at either a skill-based or a rule-based level when tasks are routine in nature. Skill-based performance involves the smooth, automatic flow of actions without conscious decision points. As such, skill-based performance describes the decisions made by highly trained operators performing familiar tasks. Rule-based performance involves the conscious perception of environmental cues, which trigger the application of rules learned on the basis of experience. As such, rule-based performance corresponds closely to recognition-primed decisions (Klein 1989). The

*Drucker (1985), in discussing ways of improving the effectiveness of executive decision makers, emphasizes the importance of establishing a generic principle or policy that can be applied to specific cases in a routine way. This recommendation is interesting because it prescribes a naturalistic form of behavior.

knowledge-based level of performance is said to occur during learning or problem-solving activity during which people cognitively simulate the influence of various actions and develop plans for what to do. The judgment-based level of performance occurs when affective reactions of a decision maker cause a change in goals or priorities between goals (Janis and Mann 1977; Etzioni 1988; Lehto 1991). Distinctive types of errors in decision making occur at each of the four levels (Reason 1989; Lehto 1991).

At the skill-based level, errors occur due to perceptual variability and when people fail to shift up to rule-based or higher levels of performance. At the rule-based level, errors occur when people apply faulty rules or fail to shift up to a knowledge-based level in unusual situations where the rules they normally use are no longer appropriate. The use of faulty rules leads to an important distinction between running and taking risks. Along these lines, Wagenaar (1992) discusses several case studies in which people following risky forms of behavior do not seem to be consciously evaluating the risk. Drivers, in particular, seem to habitually take risks. Wagenaar explains such behavior in terms of faulty rules derived on the basis of benign experience. In other words, drivers get away with providing small safety margins most of the time and consequently learn to run risks on a routine basis. Drucker (1985) points out several cases where organizational decision makers have failed to recognize that the generic principles they used to apply were no longer appropriate, resulting in catastrophic consequences.

At the knowledge-based level, errors occur because of cognitive limitations or faulty mental models or when the testing of hypotheses cause unforeseen changes to systems. At the judgment-based levels, errors (or violations) occur because of inappropriate affective reactions, such as anger or fear (Lehto 1991). As noted by Isen (1993), there also is growing recognition that positive affect can influence decision making. For example, positive affect can promote the efficiency and thoroughness of decision making, but may cause people to avoid negative materials. Positive affect also seems to encourage risk-averse preferences. Decision making itself can be anxiety provoking, resulting in violations of rationality (Janis and Mann 1977).

A recent study involving drivers arrested for drinking and driving (McKnight et al. 1995) provides an interesting perspective on how the sequential nature of naturalistic decisions can lead people into traps. The study also shows how errors can occur at multiple levels of performance. In this example, decisions made well in advance of the final decision to drive while impaired played a major role in creating situations where drivers were almost certain to drive impaired. For instance, the driver may have chosen to bring along friends and therefore have felt pressured to drive home because the friends were dependent upon him or her. This initial failure by drivers to predict the future situation could be described as a failure to shift up from a rule-based level to a knowledge-based level of performance. In other words, the driver never stopped to think about what might happen if he or she drank too much. The final decision to drive, however, would correspond to an error (or violation) at the judgment-based level if the driver's choice was influenced by an affective reaction (perceived pressure) to the presence of friends wanting a ride.

5.1.2. Recognition-Primed Decision Making

Klein (1989, 1998) developed the theory of recognition-primed decision making on the basis of observations of firefighters and other professionals in their naturalistic environments. He found that up to 80% of the decisions made by firefighters involved some sort of situation recognition, where the decision makers simply followed a past behavior pattern once they recognized the situation.

The model he developed distinguishes between three basic conditions. In the simplest case, the decision maker recognizes the situation and takes the obvious action. A second case occurs when the decision maker consciously simulates the action to check whether it should work before taking it. In the third and most complex case, the action is found to be deficient during the mental simulation and is consequently rejected. An important point of the model is that decision makers don't begin by comparing all the options. Instead, they begin with options that seem feasible based upon their experience. This tendency, of course, differs from the SEU approach but is comparable to applying the satisficing decision rule (Simon 1955) discussed earlier.

Situation assessment is well recognized as an important element of decision making in naturalistic environments (Klein et al. 1993). Recent research by Klein and his colleagues has examined the possibility of enhancing situation awareness through training (Klein and Wolf 1995). Klein and his colleagues have also applied methods of cognitive task analysis to naturalistic decision-making problems. In these efforts, they have focused on identifying (1) critical decisions, (2) the elements of situation awareness, (3) critical cues indicating changes in situations, and (4) alternative courses of action (Klein 1995). Accordingly, practitioners of naturalistic decision making tend to focus on process-tracing methods and behavioral protocols (Ericsson and Simon 1984) to document the processes people follow when they make decisions.*

*Goldstein and Hogarth (1998) describe a similar trend in judgment and decision-making research.

5.1.3. Image Theory

Image theory (Beach 1990) is a descriptive theory of decision making. Beach theorizes that knowledge used to make decisions falls into three categories: value images, trajectory images, and strategic images. The value image describes the decision maker's values, and principles; the trajectory image describes goals; the strategic image describes plans to attain the goals. He also theorizes that there are two types of decisions: adoption decisions and progress decisions. Adoption decisions first involve a screening process where alternatives are eliminated from consideration. The most promising alternative is then selected from the screened set. Progress decisions involve a comparison between goals and the expected result of choosing the alternative.

Two means of evaluating decisions are applied. One test compares the compatibility of the generated alternatives to value images, trajectory images, and strategic images. The profitability test is used to evaluate screened options further in adoption decisions when more than one option survives the initial screening. Beach (1993) argues strongly for the primacy of screening as a characteristic of most real-world decision-making activity.

5.1.4. Contingent Decision Making

The theory of contingent decision making (Beach and Mitchell 1978; Payne et al. 1993) is similar to image theory and cognitive continuum theory (see Section 4.1.4) in that it holds that people use different decision strategies, depending upon the characteristics of the task and the decision context. Payne et al. limit their modeling approach to tasks that require choices to be made (simple memory tasks are excluded from consideration). They also add the assumption that people make choices about how to make choices.*

Choices between decision strategies are assumed to be made rationally by comparing their cost (in terms of cognitive effort) against their benefits (in terms of accuracy). Cognitive effort and accuracy (of a decision strategy) are both assumed to depend upon task characteristics, such as task complexity, response mode, and method of information display. Cognitive effort and accuracy also are assumed to depend upon contextual characteristics, such as the similarity of the compared alternatives, attribute ranges and correlations, the quality of the considered options, reference points, and decision frames. Payne et al. place much emphasis on measuring the cognitive effort of different decision strategies in terms of the number of elemental information elements that must be processed for different tasks and contexts. They relate the accuracy of different decision strategies to task characteristics and contexts and also present research showing that people will shift decision strategies to reduce cognitive effort, increase accuracy, or in response to time pressure.

5.1.5. Dominance Structuring

Dominance structuring (Montgomery 1989) holds that decision making in real contexts involves a sequence of four steps. The process begins with a preediting stage in which alternatives are screened from further analysis. The next step involves selecting a promising alternative from the set of alternatives that survive the initial screening. A test is then made to check whether the promising alternative dominates the other surviving alternations. If dominance is not found, then the information regarding the alternatives is restructured in an attempt to force dominance. This process involves both the bolstering and deemphasizing of information in a way that eliminates disadvantages of the promising alternative.

5.1.6. Explanation-Based Decision Making

Explanation-based decision making (Pennington and Hastie 1986, 1988) assumes that people begin their decision-making process by constructing a mental model that explains the facts they have received. While constructing this explanatory model, people are also assumed to be generating potential alternatives to choose between. The alternatives are then compared to the explanatory model, rather than to the facts from which it was constructed.

Pennington and Hastie have applied this model to juror decision making and obtained experimental evidence that many of its assumptions seem to hold. They note that juror decision making requires consideration of a massive amount of data that is often presented in haphazard order over a long time period. Jurors seem to organize this information in terms of stories describing causation and intent. As part of this process, jurors are assumed to evaluate stories in terms of their uniqueness, plausibility, completeness, or consistency. To determine a verdict, jurors then judge the fit between choices provided by the trial judge and the various stories they use to organize the information.

*As such, the theory of contingent decision making directly addresses a potential source of conflict shown in the integrative model of decision making presented earlier (Figure 1). That is, it states that decision makers must choose between decision strategies when they are uncertain how to compare alternatives."

Jurors' certainty about their verdict is assumed to be influenced by both evaluation of stories and the perceived goodness of fit between the stories and the verdict.

5.1.7. Shared Mental Models and Awareness

Orasanu and Salas (1993) discuss two closely related frameworks for describing the knowledge used by teams in naturalistic settings. These are referred to as *shared mental models* and the *team mind*. The common element of these two frameworks is that the members of teams hold knowledge in common and organize it in the same way. Orasanu and Salas claim that this improves and minimizes the need for communication between team members, enables team members to carry out their functions in a coordinated way, and minimizes negotiation over who should do what at what time. Under emergency conditions, Orasanu and Salas claim there is a critical need for members to develop a shared situation model. As evidence for the notion of shared mental models and the team mind, the authors cite research in which firefighting teams and individual firefighters developed the same solution strategies for situations typical of their jobs.

This notion of shared mental models and the team mind can be related to the notion discussed earlier of schemas containing problem-specific rules and facts (Cheng and Holyoak 1985). It also might be reasonable to consider other team members as a form of external memory (Newell and Simon 1972). This approach would have similarities to Wegner's (1987) concept of transactive memory where people in a group know who has specialized information of one kind or another. Klein (1998) provides an interesting discussion of how this metaphor of the team mind corresponds to thinking by individuals. Teams, like people, have a working memory that contains information for a limited time, a long-term or permanent memory, and limited attention. Like people, they also filter out and process information and learn in many ways.

5.1.8. Team Leadership

Torrance (1953) describes retrospective accounts of military survivors lost behind enemy lines indicating that survival depended upon the leader's leadership skills. Important elements of leadership skills included keeping the members of the group focused on a common goal, making sure they knew what needed to be done, and keeping them informed of the current status. Related conclusions concerning the value of keeping people informed have been obtained in retrospective accounts of survivors of mining accidents (Mallet et al. 1993). Orasanu and Salas (1993) cite research in which captains of high-performing air crews explicitly stated more plans, strategies, and intentions to the other members of the crew. They also gave more warnings and predictions to the crew members. Orasanu and Salas cite other work showing that crews performed better with captains who were task oriented and had good personal skills. Performance dropped when captains had negative expressive styles and low task orientation.

A complementary literature has been developed on leadership theory (Chemers and Ayman 1993). Most of this research is based on leaders in organizational contexts. A sampling of factors which have been shown to be related to the effectiveness of leadership include legitimacy, charisma, individualized attention to group members, and clear definitions of goals. These results seem quite compatible with the above findings for leadership in naturalistic, dynamic contexts.

5.2. Time Pressure and Stress

Time pressure and stress are a defining characteristic of naturalistic decision making. Jobs requiring high levels of skill or expertise, such as firefighting, nursing, emergency care, and flying an airplane, are especially likely to involve high stakes, extreme time pressure, uncertainty, or risk to life. The effect of stressors, such as those mentioned above, on performance has traditionally been defined in terms of physiological arousal.* The Yerkes–Dodson law (Yerkes and Dodson 1908) states that the relation between performance and arousal is an inverted U. Either too much or too little arousal causes performance to drop. Too little arousal makes it difficult for people to maintain focused attention. Too much arousal results in errors, more focused attention (and filtering of low-priority information), reduced working memory capacity, and shifts in decision strategies.† One explanation of why performance drops when arousal levels are too high is that arousal consumes cognitive resources that could be allocated to task performance (Mandler 1979).

Time pressure is a commonly studied stressor assumed to impact decision making. Maule and Hockey (1993) note that people tend to filter out low-priority types of information, omit processing

* The general adaptation syndrome (Selye 1936, 1979) describes three stages of the human response to stressors. In simplified form, this sequence corresponds to (1) arousal, (2) resistance, and (3) exhaustion.

† The literature on stress and its effects on decision making will not be surveyed here. Books edited by Hamilton and Warburton (1979), Svenson and Maule (1993), Driskell and Salas (1996), and Flin et al. (1997) provide a good introduction to the area.

information, and accelerate mental activity when they are under time pressure. Variable state activation theory (VSAT) provides a potential explanation of the above effects in terms of a control model of stress regulation (Maule and Hockey 1993). Sequential sampling models provide a compatible perspective on how time pressure can cause changes in performance, such as speed–accuracy trade-offs (see Section 4.2.4). The two approaches are compatible, because VSAT provides a means of modeling how the decision thresholds used within a sequential sampling model might change as a function of time pressure. VSAT also proposes that disequilibriums between control processes and the demands of particular situations can lead to strong affective reactions or feelings of time pressure. Such reactions could, of course, lead to attentional narrowing or reduced working memory capacity and therefore result in poorer task performance. Alternatively, performance might change when decision thresholds are adjusted.

Time pressure also can cause shifts between the cognitive strategies used in judgment and decision-making situations (Payne et al. 1993; Maule and Hockey 1993; Edland and Svenson 1993). People show a strong tendency to shift to noncompensatory decision rules when they are under time pressure. This finding is consistent with contingency theories of strategy selection (Section 5.1.4). In other words, this shift may be justified when little time is available, because a noncompensatory rule can be applied more quickly. Compensatory decision rules also require more analysis and cognitive effort. Intuitive decision strategies require much less effort because people can rely on their experience or knowledge, and can lead to better decisions in some situations (Hammond et al. 1987). As Klein (1998) points out, stress should impact performance if people use analytical choice procedures.

Novices and experts in novel, unexpected, situations will lack domain experience and knowledge and therefore will have to rely on analytical choice procedures. Consequently, it is not surprising that time pressure and stress have a major negative impact on novice decision makers performing unfamiliar tasks. Interestingly, there is little evidence that stress or time pressure causes experienced personnel to make decision errors in real-world tasks (Klein 1996; Orasanu 1997). The latter finding is consistent with research indicating that experts rely on their experience and intuition when they are under stress and time pressure (Klein 1998). The obvious implication is that training and experience are essential if people are to make good decisions under time pressure and stress.

6. GROUP DECISION MAKING

Much research has been done over the past 25 years or so on decision making by groups and teams. Most of this work has focused on groups, as opposed to teams. In a team, it is assumed that the members are working toward a common goal and have some degree of inderdependence, defined roles and responsibilities, and task-specific knowledge (Orasanu and Salas 1993). Team performance is a major area of interest in the field of naturalistic decision theory (Klein et al. 1993; Klein 1998), as discussed earlier. Group performance has traditionally been an area of study in the fields of organizational behavior and industrial psychology. Traditional decision theory has also devoted some attention to group decision making (Raiffa 1968; Keeney and Raiffa 1976). The following discussion will first briefly discuss some of the ways that group decisions differ from those made by isolated decision makers who need to consider only their own preferences. That is, ethics and social norms play a much more prominent role when decisions are made by or within groups. Attention will then shift to group processes and how they affect group decisions. The last section will address methods of supporting or improving group decision making.

6.1. Ethics and Social Norms

When decisions are made by or within groups, a number of issues arise that have not been touched upon in the earlier portions of this chapter. To start, there is the complication that preferences may vary between members of a group. It often is impossible to maximize the preferences of all members of the group, meaning that trade-offs must be made and issues such as fairness must be addressed to obtain acceptable group decisions. Another complication is that the return to individual decision makers can depend on the actions of others. Game theory* distinguishes two common variations of this situation. In competitive games, individuals are likely to take ''self-centered'' actions that maximize their own return but reduce returns to other members of the group. Behavior of group members in this situation may be well described by the minimax decision rule discussed in Section 2.1.5. In cooperative games, the members of the group take actions that maximize returns to the group as a whole.

Members of groups may choose cooperative solutions that are better for the group as a whole for many different reasons (Dawes et al. 1988). Groups may apply numerous forms of coercion to punish members who deviate from the cooperative solutions. Group members may apply decision strategies such as reciprocal altruism. They also might conform because of their social conscience, a need for

*Friedman (1990) provides an excellent introduction to game theory.

self esteem, or feelings of group identity. Fairness considerations can in some case explain preferences and choices that seem to be in conflict with economic self-interest (Bazerman 1998). Changes in the status quo, such as increasing the price of bottled water immediately after a hurricane, may be viewed as unfair even if they are economically justifiable based on supply and demand. People are often willing to incur substantial costs to punish ''unfair'' opponents and reward their friends or allies. The notion that costs and benefits should be shared equally is one fairness-related heuristic people use (Messick 1991). Consistent results were found by Guth et al. (1982) in a simple bargaining game where player 1 proposes a split of a fixed amount of cash and player 2 either accepts the offer or rejects it. If player 2 rejects the offer, both players receive nothing. Classical economics predicts that player 2 will accept any positive amount (that is, player 2 should always prefer something to nothing). Consequently, player 1 should offer player 2 a very small amount greater than zero. The results showed that, contrary to predictions of classical economics, subjects tended to offer a substantial proportion of the cash (the average offer was 30%). Some of the subjects rejected positive offers. Others accepted offers of zero. Further research, as summarized by Bolton and Chatterjee (1996), confirms these findings that people seem to care about whether they receive their fair share.

Ethics clearly plays an important role in decision making. Some choices are viewed by nearly everyone as being immoral or wrong (i.e., violations of the law, dishonesty, and numerous other behaviors that conflict with basic societal values or behavioral norms). Many corporations and other institutions formally specify codes of ethics prescribing values such as honesty, fairness, compliance with the law, reliability, considerance or sensitivity to cultural differences, courtesy, loyalty, respect for the environment, and avoiding waste. It is easy to visualize scenarios, where it is in the best interest of a decision maker to choose economically undesirable options (at least in the short term) to comply with ethical codes. According to Kidder (1995), the ''really tough choices . . . don't center on right versus wrong. They involve right versus right.'' Kidder refers to four dilemmas of right vs. right he feels qualify as paradigms: (1) truth vs. loyalty (i.e., whether to divulge information provided in confidence), (2) individual vs. community, (3) short term vs. long term, and (4) justice vs. mercy. At least three principles, which in some cases provide conflicting solutions, have been proposed for resolving ethical dilemmas. These include (1) utilitarianism, or selecting the option with the best overall consequences, (2) rule-based, or following a rule regardless of its current consequences (i.e., waiting for a stop light to turn green, even if no cars are coming), and (3) fairness, or doing what you would want others to do for you.

Numerous social dilemmas also occur in which the payoffs to each participant result in individual decision strategies harmful to the group as a whole. The tragedy of the commons (Hardin 1968) is illustrative of social dilemmas in general. For a recent example, discussed in detail by Baron (1998), consider the recent crash of the East Coast commercial fishing industry, brought about by overfishing. Here, the fishing industry as a whole is damaged by overfishing, but individual fishers gain a short-term advantage by catching as many fish as possible. Individual fishers may reason that if they don't catch the fish, someone else will. Each fisher attempts to catch as many fish as possible, even if this will cause the fish stocks to crash. Despite the fact that cooperative solutions, such as regulating the catch, are obviously better than the current situation, individual fishers continue to resist such solutions. Regulations are claimed to infringe on personal autonomy, to be unfair, or to based on inadequate knowledge.

Other similar examples include littering, wasteful use of natural resources, pollution, or social free riding. These behaviors can all be explained, in terms of the choices faced by the offending individual decision maker (Schelling 1978). Simply put, the individual decision maker enjoys the benefits of the offensive behavior, as small as they may be, but the costs are incurred by the entire group.

6.2. Group Processes

A large amount of research has focused on groups and their behavior. Accordingly, many models have been developed that describe how groups make decisions. A common observation is that groups tend to move through several phases as they go through the decision-making process (Ellis and Fisher 1994). One of the more classic models (Tuckman 1965) describes this process with four words: forming, storming, norming, and performing. Forming corresponds to initial orientation, storming to conflict, norming to developing group cohesion and expressing opinions, and performing to obtaining solutions. As implied by Tuckman's choice of terms, there is a continual interplay between socio-emotive factors and rational, task-oriented behavior throughout the group decision-making process. Conflict, despite its negative connotations, is a normal, expected aspect of the group decision process and can in fact serve a positive role (Ellis and Fisher 1994). The following discussion will first address causes and effects of group conflict. Attention will then shift to conflict resolution.

6.2.1. Conflict

Whenever people or groups have different preferences, conflict can occur. As pointed out by Zander (1994), conflict between groups becomes more likely when groups have fuzzy or potentially antag-

onistic roles, or when one group is disadvantaged (or perceives it is not being treated fairly). A lack of conflict-settling procedures and separation or lack of contact between groups can also contribute to conflict. Conflict becomes especially likely during a crisis and often escalates when the issues are perceived to be important, or after resistance or retaliation occurs. Polarization, loyalty to one's own group, lack of trust, and cultural and socioeconomic factors are often contributing factors to conflict and conflict escalation.

Ellis and Fisher (1994) distinguish between affective and substantive forms of conflict. Affective conflict corresponds to emotional clashes between individuals or groups, while substantive conflict involves opposition at the intellectual level. Substantive conflict is especially likely to have positive effects on group decisions by promoting better understanding of the issues involved. Affective conflict can also improve group decisions by increasing interest, involvement, and motivation among group members and, in some cases, cohesiveness. On the other hand, affective conflict may cause significant ill will, reduced cohesiveness, and withdrawal by some members from the group process. Baron (1998) provides an interesting discussion of violent conflict, and how it is related to polarized beliefs, group loyalty, and other biases.

Defection and the formation of coalitions is a commonly observed effect of conflict, or power struggles, within groups. Coalitions often form when certain members of the group can gain by following a common course of action at the expense of the long-run objectives of the group as a whole. Rapidly changing coalitions between politicians and political parties are obviously a fact of life. Another typical example is when a subgroup of technical employees leave a corporation to form their own small company producing a product similar to one they had been working on. Coalitions, and their formation, have been examined from decision-analytic and game theory perspectives (Bolton and Chatterjee 1996; Raiffa 1982). These approaches make predictions regarding what coalitions will form, depending on whether the parties are cooperating or competing, which have been tested in a variety of experiments (Bolton and Chatterjee 1996). These experiments have revealed that the formation of coalitions is influenced by expected payoffs, equity issues, and the ease of communication. However, Bazerman (1998) notes that the availability heuristic, overconfidence, and sunk cost effects are likely to explain how coalitions actually form in the real world.

6.2.2. Conflict Resolution

Groups resolve conflict in many different ways. Discussion and argument, voting, negotiation, arbitration, and other forms of third-party intervention are all methods of resolving disputes. Discussion and argument is clearly the most common method followed within groups to resolve conflict. Other methods of conflict resolution normally play a complementary, rather than primary, role in the decision process. That is, the latter methods are relied upon when groups fail to reach consensus after discussion and argument, or they simply serve as the final step in the process.

Group discussion and argument is often viewed as being a less than rational process. Along these lines, Brashers et al. (1994) state that the literature suggests "that argument in groups is a social activity, constructed and maintained in interaction, and guided perhaps by different rules and norms than those that govern the practice of ideal or rational argument. Subgroups speaking with a single voice appear to be a significant force. . . . Displays of support, repetitive agreement, and persistence all appear to function as influence mechanisms in consort with, or perhaps in place of, the quality or rationality of the arguments offered." Brashers et al. also suggest that members of groups appear uncritical because their arguments tend to be consistent with social norms rather than the rules of logic: "[S]ocial rules such as: (a) submission to higher status individuals, (b) experts' opinions are accepted as facts on all matters, (c) the majority should be allowed to rule, (d) conflict and confrontation are to be avoided whenever possible."

A number of approaches for conflict management have been suggested that attempt to address many of the issues raised by Brashers et al. These approaches include seeking consensus rather than allowing decisions to be posed as win–lose propositions, encouraging and training group members to be supportive listeners, deemphasizing status, depersonalizing decision making, and using facilitators (Likert and Likert 1976). Other approaches that have been proposed include directing discussion toward clarifying the issues, promoting an open and positive climate for discussion, facilitating face-saving communications, and promoting the development of common goals (Ellis and Fisher 1994).

Conflicts can also be resolved through voting and negotiation, as discussed further in Section 6.3. Negotiation becomes especially appropriate when the involved people have competing goals and some form of compromise is required. A typical example would be a dispute over pay between a labor union and management. Strategic concerns play a major role in negotiation and bargaining (Schelling 1960). Self-interest on the part of the involved parties is the driving force throughout a process involving threats and promises, proposals and counterproposals, and attempts to discern how the opposing party will respond. Threats and promises are a means of signaling what the response will be to actions taken by an opponent and consequently become rational elements of a decision strategy

(Raiffa 1982). Establishing the credibility of signals sent to an opponent becomes important because if they are not believed, they will not have any influence.

Methods of attaining credibility include establishing a reputation, the use of contracts, cutting off communication, burning bridges, leaving an outcome beyond control, moving in small steps, and using negotiating agents (Dixit and Nalebuff 1991). Given the fundamentally adversarial nature of negotiation, conflict may move from a substantive basis to an affective, highly emotional state. At this stage, arbitration and other forms of third-party intervention may become appropriate due to a corresponding tendency for the negotiating parties to take extreme, inflexible positions.

6.3. Group Performance and Biases

The quality of the decisions made by groups in a variety of different settings has been seriously questioned. Part of the issue here is the phenomenon of so-called group think, which has been blamed for several disastrous public policy decisions (Hart et al. 1997; Janus 1972). Eight symptoms of groupthink cited by Janis and Mann (1977) are the illusion of invulnerability; rationalization (discounting of warnings and negative feedback); belief in the inherent morality of the group; stereotyping of outsiders; pressure on dissenters within the group; self-censorship; illusion of unanimity; and the presence of mindguards who shield the group from negative information. Janis and Mann proposed that the results of groupthink include failure to consider all the objectives and alternatives, failure to reexamine choices and rejected alternatives, incomplete or poor search for information, failure to adequately consider negative information, and failure to develop contingency plans. Groupthink is one of the most cited characteristics of how group decision processes can go wrong. Given the prominence of groupthink as an explanation of group behavior, it is somewhat surprising that only a few studies have empirically evaluated this theory. Empirical evaluation of the groupthink effect and the development of alternative modeling approaches continue to be an active area of research (Hart et al. 1997).

Other research has attempted to measure the quality of group decisions in the real world against rational, or normative, standards. Viscusi (1991) cites several examples of apparent regulatory complacency and regulatory excess in government safety standards in the United States. He also discusses a variety of inconsistencies in the amounts awarded in product liability cases. Baron (1998) provides a long list of what he views as errors in public decision making and their very serious effects on society. These examples include collective decisions resulting in the destruction of natural resources and overpopulation, strong opposition to useful products such as vaccines, violent conflict between groups, and overzealous regulations, such as the Delaney clause. He attributes these problems to commonly held, and at first glance innocuous, intuitions such as Do no harm, Nature knows best, and Be loyal to your own group, the need for retribution (an eye for an eye), and a desire for fairness.

A significant amount of laboratory research also is available that compares the performance of groups to that of individual decision makers (Davis 1992; Kerr et al. 1996). Much of the early work showed that groups were better than individuals on some tasks. Later research indicated that group performance is less than the sum of its parts. Groups tend to be better than individuals on tasks where the solution is obvious once it is advocated by a single member of the group (Davis 1992; Kerr et al. 1996). Another commonly cited finding is that groups tend to be more willing to select risky alternatives than individuals, but in some cases the opposite is true. One explanation is that group interactions cause people within the group to adopt more polarized opinions (Moscovici 1976). Large groups seem especially likely to reach polarized, or extreme, conclusions (Isenberg 1986). Groups also tend to overemphasize the common knowledge of members, at the expense of underemphasizing the unique knowledge certain members have (Gruenfeld et al. 1996; Stasser and Titus, 1985). A more recent finding indicates that groups were more rational than individuals when playing the ultimatum game (Bornstein and Yaniv 1998).

Duffy (1993) notes that teams can be viewed as information processes and cites team biases and errors that can be related to information-processing limitations and the use of heuristics, such as framing. Topics such as mediation and negotiation, jury decision making, and public policy are now being evaluated from the latter perspective (Heath et al. 1994). Much of this research has focused on whether groups use the same types of heuristics and are subject to the same biases of individuals. This research has shown: (1) framing effects and preference reversals (Paese et al. 1993), (2) overconfidence (Sniezek 1992), (3) use of heuristics in negotiation (Bazerman and Neale 1983), and (4) increased performance with cognitive feedback (Harmon and Rohrbaugh 1990). One study indicated that biasing effects of the representativeness heuristic were greater for groups than for individuals (Argote et al. 1986). The conclusion is that group decisions may be better than those of individuals in some situations but are subject to many of the same problems.

6.4. Prescriptive Approaches

A wide variety of prescriptive approaches have been proposed for improving group decision making. The approaches address some of the above issues, including the use of agendas and rules of order, idea-generating techniques such as brainstorming, nominal group and Delphi techniques, decision

structuring, and methods of computer-mediated decision making. As noted by Ellis and Fisher (1994), there is conflicting evidence regarding the effectiveness of such approaches. On the negative side, prescriptive approaches might stifle creativity in some situations and can be sabotaged by dissenting members of groups. On the positive side, prescriptive approaches make the decision process more orderly and efficient, promote rational analysis and participation by all members of the group, and help ensure implementation of group decisions. The following discussion briefly reviews some of these tools for improving group decision making.

6.4.1. Agendas and Rules of Order

Agendas and rules of order are often essential to the orderly functioning of groups. As noted by Welch (1994), an agenda "conveys information about the structure of a meeting: time, place, persons involved, topics to be addressed, perhaps suggestions about background material or preparatory work." Agendas are especially important when the members of a group are loosely coupled or do not have common expectations. Without an agenda, group meetings are likely to dissolve into chaos (Welch 1994). Rules of order, such as *Robert's Rules of Order* (Robert 1990), play a similarly important role, by regulating the conduct of groups to ensure fair participation, by all group members, including absentees. Rules of order also specify voting rules and means of determining consensus. Decision rules may require unanimity, plurality, or majority vote for an alternative.

Attaining consensus poses an advantage over voting, because voting encourages the development of coalitions, by posing the decision as a win–lose proposition (Ellis and Fisher 1994). Members of the group who voted against an alternative are often unlikely to support it. Voting procedures can also play an important role (Davis 1992).

6.4.2. Idea-Generation Techniques

A variety of approaches have been developed for improving the creativity of groups in the early stages of decision making. Brainstorming is a popular technique for quickly generating ideas (Osborn 1937). In this approach, a small group (of no more than 10 individuals) is given a problem to solve. The members are asked to generate as many ideas as possible. Members are told that no idea is too wild and encouraged to build upon the ideas submitted by others. No evaluation or criticism of the ideas is allowed until after the brainstorming session is finished. Buzz group analysis is a similar approach, more appropriate for large groups (Elliss and Fisher 1994). Here, a large group is first divided into small groups of four to six members. Each small group goes through a brainstorming-like process to generate ideas. They then present their best ideas to the entire group for discussion. Other commonly applied idea-generating techniques include focus group analysis and group exercises intended to inspire creative thinking through role playing (Elliss and Fisher 1994; Clemen 1996).

The use of brainstorming and the other idea-generating methods mentioned above will normally provide a substantial amount of, in some cases, creative suggestions, especially when participants build upon each other's ideas. However, personality factors and group dynamics can also lead to undesirable results. Simply put, some people are much more willing than others to participate in such exercises. Group discussions consequently tend to center around the ideas put forth by certain more forceful individuals. Group norms, such as deferring to participants with higher status and power, may also lead to undue emphasis on the opinions of certain members.

6.4.3. Nominal Group and Delphi Technique

Nominal group technique (NGT) and the Delphi technique attempt to alleviate some of the disadvantages of working in groups (Delbecq et al. 1975). The nominal group technique consists of asking each member of a group to write down and think about his or her ideas independently. A group moderator then asks each member to present one or more of his or her ideas. Once all of the ideas have been posted, the moderator allows discussion to begin. After the discussion is finished, each participant rates or ranks the presented ideas. The subject ratings are then used to develop a score for each idea. Nominal group technique is intended to increase participation by group members and is based on the idea that people will be more comfortable presenting their ideas if they have a chance to think about them first (Delbecq et al. 1975).

The Delphi technique allows participants to comment anonymously, at their leisure, on proposals made by other group members. Normally, the participants do not know who proposed the ideas they are commenting on. The first step is to send an open-ended questionnaire to members of the group. The results are then used to generate a series of follow-up questionnaires in which more specific questions are asked. The anonymous nature of the Delphi process theoretically reduces the effect of participant status and power. Separating the participants also increases the chance that members will provide opinions "uncontaminated" by the opinions of others.

6.4.4. Structuring Group Decisions

As discussed earlier in this chapter, the field of decision analysis has devised several methods for organizing or structuring the decision-making process. The rational reflection model (Siebold 1992)

is a less formal, six-step procedure that serves a similar function. Group members are asked first to define and limit the problem by identifying goals, available resources, and procedural constraints. After defining and limiting the problem, the group is asked to analyze the problem, collect relevant information, and establish the criteria a solution must meet. Potential solutions are then discussed in terms of the agreed-upon decision criteria. After further discussion, the group selects a solution and determines how it should be implemented. The focus of this approach is on forcing the group to confine its discussion to the issues that arise at each step in the decision making process. As such, this method is similar to specifying an agenda.

Raiffa (1982) provides a somewhat more formal decision-analytic approach for structuring negotiations. The approach begins by assessing (1) the alternatives to a negotiated settlement, (2) the interests of the involved parties, and (3) the relative importance of each issue. This assessment allows the negotiators to think analytically about mutually acceptable solutions. In certain cases, a bargaining zone is available. For example, an employer may be willing to pay more than the minimum salary acceptable to a potential employee. In this case, the bargaining zone is the difference between the maximum salary the employer is willing to pay and the minimum salary a potential employee is willing to accept. The negotiator may also think about means of expanding the available resources to be divided, potential trading issues, or new options that satisfy the interests of the concerned parties.

Other methods for structuring group preferences are discussed in Keeny and Raiffa (1976). The development of group utility functions is one such approach. A variety of computer-mediated methods for structuring group decisions are also available, as discussed below.

6.4.5. Computer-Mediated Group Decision Making

Computer tools for helping groups make decisions are now available that implement all of the approaches discussed above to varying degrees. The spectrum of available tools ranges from traditional tools used in decision analysis, such as the analytic hierarchy process (Basak and Saaty 1993; Saaty 1988), to electronic meeting places (Mockler and Dologite 1991; Nunamaker et al. 1991) and group decision support systems (GDSS) (Sage 1997). Some of the many functions provided by GDSS (Johansen 1988; Sage 1997) include computer-supported presentations, project and calendar management, group authoring, electronic meeting places, audio and visual conferencing, screen sharing, group e-mail services, text-filtering services, conversational structuring, group and organizational memory management, and comprehensive work team support.

Computer-mediated group decision making has several potential benefits (Brasher et al. 1994), including (1) enabling all participants to work simultaneously (they don't have to wait their turn to speak), (2) providing a more equal and potentially anonymous opportunity to be heard, (3) providing a more structured environment (that is, a more linear process and control of the agenda). Computer-mediated group decision making also might make it easier to control and manage conflict, through the use of facilitators and convenient voting procedures. As noted by Sage (1997), the purpose of GDSS is to (1) remove communication barriers, (2) provide techniques for the formulation, analysis, and interpretation of decisions, and (3) systematically direct the decision-making process. Successfully attaining these objectives means that a GDSS must provide the right information to decision makers, at an appropriate level of detail, at the time it is needed, in a form that is conveniently applied. Simply put, to be useful, a GDSS must not make group decision making more difficult than it already is.

7. SUMMARY CONCLUSIONS

Beach (1993) discusses four revolutions in behavioral decision theory. The first took place when it was recognized that the evaluation of alternatives is seldom extensive. It is illustrated by use of the satisficing rule (Simon 1955) and heuristics (Tversky and Kahneman 1974) rather than optimizing. The second occurred when it was recognized that people choose between strategies to make decisions. It is marked by the development of contingency theory (Beach 1990) and cognitive continuum theory (Hammond 1980). The third is currently occurring. It involves the realization that people rarely make choices and instead rely on prelearned procedures. This perspective is illustrated by the levels-of-processing approach (Rasmussen 1983) and recognition-primed decisions (Klein 1989). The fourth is just beginning. It involves recognization that decision-making research must abandon a single-minded focus on the economic view of decision making and include approaches drawn from relevant developments and research in cognitive psychology, organizational behavior, and systems theory.

The discussion within this chapter parallels this view of decision making. The integrative model presented at the beginning of the chapter shows how these various approaches fit together as a whole. Each path through the model is distinguished by specific sources of conflict, the methods of conflict resolution followed, and the types of decision rules used to analyze the results of conflict-resolution processes. The different paths through the model correspond to fundamentally different ways of making decisions, ranging from routine situation assessment-driven decisions to satisficing, analysis

of single- and multiattribute expected utility, and even obtaining consensus of multiple decision makers in group contexts. Numerous other strategies discussed in this chapter are also described by particular paths through the model.

This chapter goes beyond simply describing methods of decision making by pointing out reasons people and groups may have difficulty making good decisions. These include cognitive limitations, inadequacies of various heuristics used, biases and inadequate knowledge of decision makers, and task-related factors, such as risk, time pressure, and stress. The discussion also provides insight into the effectiveness of approaches for improving human decision making. The models of selective attention point to the value of providing only truly relevant information to decision makers. Irrelevant information might be considered simply because it is there, especially if it is highly salient. Methods of highlighting or emphasizing relevant information, therefore, clearly seem to be warranted. The models of selective information also indicate that methods of helping decision makers cope with working memory limitations will be of value. There also is reason to believe that providing feedback to decision makers in dynamic decision-making situations will be useful. Cognitive, rather than outcome, feedback is indicated as being particularly helpful when decision makers are learning. Training decision makers also seems to offer potentially large benefits. One reason for this conclusion is that the studies of naturalistic decision making revealed that most decisions are made on a routine, nonanalytical basis.

The studies of debiasing also partially support the potential benefits of training and feedback. On the other hand, the many failures to debias expert decision makers imply that decision aids, methods of persuasion, and other approaches intended to improve decision making are no panacea. Part of the problem is that people tend to start with preconceived notions about what they should do and show a tendency to seek out and bolster confirming evidence. Consequently, people show a tendency to develop overconfidence with experience, and strongly held beliefs become difficult to modify, even if they are hard to defend rationally.

CHAPTER 85
Design of Experiments

H. SAMUEL WANG
Chung Yuan Christian University

CHUNG-PU CHANG
Eureka Consulting Co.

1. INTRODUCTION

1.1. Perspective

Experimentation is common in every aspect of life. As part of a problem-solving program, experiments are carried out in order to observe the effects of changes under a controlled framework. Through one or more iterations of experiments, adequate knowledge is acquired or confirmed. Know-how, sometimes coupled with know-why, is gathered and used for decision making. Experiments are indispensable to the learning process.

The need for learning through experiments is particularly obvious in industry, whether in manufacturing or the service sector. Consider the development and marketing of a new drug. After a new drug is found to be effective for treating a certain kind of cancer, a series of experiments is usually conducted before the drug is formally marketed. For instance, a laboratory scientist performs experiments to identify other supportive constituents. With the aid of these experimental results, he or she picks the most effective composition. A manufacturing engineer uses experiments to determine process conditions such as pressure, temperature, flow rate, the catalyst quantity, and so forth. Thus the goal of fabricating quality medicine at the lowest possible cost is achieved. A marketing staff relies on computer simulation, which in fact is a form of numerical experimentation, to pick the most profitable marketing strategy. An FDA officer carries out experiments to detect potential adverse effects on different consumers determined by age, sex, and ethnicity. Experimentation is also important to the consumer organization. It is relied upon to compare the effectiveness of this new drug against others existing in the market.

Other examples illustrating when and where experiments are performed are numerous (Diamond 1989, 1997; John 1998).

1.2. Statistical Experiments (Box et al. 1978; Du Pont Co. 1988)

An experiment is often confused with a trial or a test, which in practice takes no account of experimental errors due to inherent variations. In fact, variations occur in every component and stage of experimentation, including variation in experiment parameters, due to inaccurate setting of machines and instruments, in methods and handling, in measurements, and due to analysis.

Moreover, experiments are often run by intuition with factors varied one at a time. This is not only ineffective costwise, it also causes the risk of reaching incorrect conclusions due to negligence of the potential interactions among factors

In the following, we are concerned with the design and analysis of experiments based on statistical considerations. These are often referred to as statistical experiments.

A statistical experiment serves as a means to compare and choose the most effective treatment, identify significant factors, reveal cause-and-effect mechanisms, and determine optimal process conditions. It therefore plays an important role in quality improvement, productivity increases, cost saving, and management decisions.

In essence, a statistical experiment implies a systematic varying of process, observation of change in response, collection and analysis of data, and extraction of information to arrive at a conclusion. Experiments are designed so that the appropriate decision can be arrived at in the shortest time and within cost constraints.

1.3. Basic Definitions (Anderson and McLean 1974; Du Pont Co. 1988; Hunter 1998; Montgomery 1996)

An experimental design is a formal plan for execution of the experiment. It includes the choice of response, factors, designation of levels, and assignment of blocks as well as application of treatment on experimental units.

These commonly used terms are defined and explained below:

- *Response:* A response is the dependent variable that corresponds to the outcome or resulting effects of interest in the experiment. One or more response variables may be studied simultaneously.
- *Factors:* A factor is a variable contribute to the response. A factor can be controllable or uncontrollable. It may be quantitative, such as pressure in psi or duration time in minutes. It may be qualitative, such as different methods, different operators, or different suppliers.
- *Levels:* The levels are the chosen conditions of the factor under study. They may be quantitative values such as 5%, 8%, and 10% alcohol concentration. They also take categorical forms such as supplier A, B, C, and D.
- *Blocks:* A block is a homogenous portion of the experimental environment or materials that bears certain variation effects on the response(s). A block may be a batch of material supplied

by a vendor or products manufactured in a shift on a production floor. The term *block* is sometimes associated with *factor* and called *block variable*.

- *Treatments:* A treatment is the condition or a factor associated with a specific level in a specific experiment.
- *Experimental units:* Experimental units are the objects or entities that are used for application of treatments and measurements of resulting effects.

2. PLANNING FOR EXPERIMENTS (Du Pont Co. 1988; Hunter 1998)

A complete experimental process involves five stages: including (1) design, (2) data collection, (3) data analysis, (4) interpretation of results, and (5) communication of results. In order to achieve an effective and efficient experimentation, it is of utmost importance to take effort to work out a comprehensive experimental plan.

In the planning stage of the experiment, the design of the experiment implies the careful and thorough consideration of the following issues:

- Global environment of the problem
- Objectives of the study
- Properties to be studied
- Variables to be controlled
- The environment of concern
- Size of experimental units
- Number of experimental runs
- Conduct of the experiments
- Approach for data analysis

Each of the technical, statistical, and administrative aspects of experiments are to be taken into consideration.

2.1. Program and Activities: Steps and Checkpoints (Du Pont Co. 1988; Hunter 1998)

2.1.1. Stage 1: PLAN

1. *Problem Recognition*
  (a) Formation of task force
  (b) Evaluation of strengths, weaknesses, opportunities, and threats
  (c) Identification of problem area(s)

2. *Statement of problem and objective:*
  (a) Determination of ultimate goal(s)
  (b) Determination of en route objectives
  (c) Determination of immediate objectives
  (d) Identification of the cost and time constraints

3. *Design of experiment:*
  (a) Definition of experimental units
  (b) Determination of response variable(s)
  (c) Selection of factors
  (d) Determination of factor levels
  (e) Appraisal of possible interaction
  (f) Choice of design
  (g) Definitions of data and effect models
  (h) Decision of number of replicates
  (i) Setup of execution plan (timetable, sequence schedule, facilities allocation)
  (j) Setup of data-collection plan

2.1.2. Stage 2: DO

1. *Mission orientation:*
  (a) Explanation of objectives and tasks to be achieved
  (b) Attention to precautions in execution and data recording

2. *Physical preparations:*
   (a) Preparation of experimental units
   (b) Development of methods and facilities needed
3. *Execution of experiments:*
   (a) Execution in accordance with prescribed conditions
   (b) Control of schedules
   (c) Varying and control of treatments in terms of randomization
4. *Observation and measurement:*
   (a) Surveillance of condition of facilities
   (b) Control of measurement procedures
5. *Recording:*
   (a) Recording of program by date, run numbers, etc.
   (b) Recording of abnormal situations
   (c) Recording of change of designs
   (d) Recording of measured data
   (e) Recording of data from extra or missing experiments

2.1.3 Stage 3: STUDY

1. *Analysis of data:*
   (a) Diagnosis of data
   (b) Application of appropriate statistical methods
   (c) Graphical analysis
   (d) Checking of model adequacy
2. *Interpretation of results:*
   (a) Identification of substantial factors
   (b) Selection of desired levels
   (c) Estimation of factor effects
   (d) Account for limitations in data acquisition or analysis
   (e) Interpretation in terms of statistical, technical, and economical significance

2.1.4. Stage 4: ACT

1. *Confirmation of conclusion*
2. *Presentation of results:*
   (a) Preparation of report
   (b) Use of graphical and tabular forms
   (c) Indication of implications for potential applications
3. *Recommendations:*
   (a) For process change
   (b) For further experiments
   (c) For modification in strategies of experiment
4. *Process change and standardization*
5. *New situation appraisal*
6. *Preparation for further experiments*

2.2. Size of Experiments

Each experimenter should be concerned with the size of the experiment. A large enough experiment enables the detection of the significant effects of the factors in the response and thus ensures obtaining some know-how from the study. Yet it must be small enough to ensure that the cost of the experimentation is within the allocated budget and can be completed within the assigned time frame.

The number of experimental runs or experimental units is to be determined beforehand. Its precise determination involves statistical computation that requires prestated probability of committing type I and II errors, the desired accuracy in detecting the difference between the means of the responses resulting from different treatments. Besides, other statistical parameters are also required. As a rule of thumb, the appropriate size for an experiment is between 8 and 60. For more elaborate evaluation, consult statistical handbooks (Box et al. 1978; Daniel 1976; Wadsworth 1990; Winer et al. 1991).

3. GOOD EXPERIMENTAL PRACTICES (Hicks 1982; Montgomery 1996)

In the process of experimentation, there exist two types of errors: random errors and bias errors. Random error is experimental error for which the numerical values change from one run to another without a consistent pattern. It can be thought of as inherent noise in measured responses. Bias error is experimental error for which the numerical values tend to follow a consistent pattern over a number of experimental runs. It is attributed to an assignable cause. To reduce the effects of both types of errors, it is strongly adviced that the following good experimental practices be taken into consideration.

Replication, randomization, and blocking, the three measures for ensuring a successful experiment as presented below, are called the three Fisherean principles of experimental designs. They are attributed to R. A. Fisher, the forerunner of the modern design of experiments.

3.1. Randomization

Randomization is the procedure of assigning the experimental units to various treatments in a purely chance manner. It is also used for arrangement of the experiments in random order. It is intended to balance out the effect of uncontrollable variables. Because bias errors are not confused with the effect of the factors, the quality of data is improved and statistical inferences are made possible.

To achieve randomization, the order of experiment is scrambled so that any bias present will be mixed up and become a part of the random variation. One of the following options can be taken

The trial numbers can be written on small slips of paper and selected at random.

A table of random numbers can be employed to assign a run order and the trials.

3.2. Blocking

The source of bias error in an experiment may accompany differences among blocks, namely batches of raw materials, production machine, hours within a day, or seasons of the year. It is necessary to reduce their influence by proper design of the experiment. Blocking means running the experiment in a specially chosen subgroup that allows removal of the effect of bias errors that are confounded with the main factors.

To achieve blocking, the run order is broken up into smaller units so that the bias is negligible within the block. Note that under these circumstances a separate randomization is needed in each block.

3.3. Replication

Replication involves the repetition of experimental runs so that more than one observation for each treatment combination is available for statistical analysis.

The benefit of replication is that the average of several observations comes closer to the true value than a single observation. Replication helps balance out the bias due to the effect of nuisance factors. It also helps to detect gross errors in the measurements. It therefore improves the precision of the statistical inferences.

Different randomization applies to different replications of the experiment.

4. PRECAUTIONS FOR EXPERIMENTAL DESIGNS

4.1. Ten Commandments for Experimental Designs (Gryna and Juran 1993; Montgomery 1996)

1. *Don't set out without a clear problem definition and objective statement:* An unplanned experiment often ends up in total loss of time and money.
2. *Do keep the design and analysis of experiment as simple as possible:* A comprehensive but complicated design of experiment may cost much more and end nowhere.
3. *Don't rely solely on statistical experts:* Interaction with subject matter specialists makes professional insight invaluable.
4. *Don't underestimate the importance of randomization:* The adverse effect of systematic errors can be of vital importance.
5. *Don't start statistical analysis without first challenging the validity of the data:* What can you expect out of garbage input?
6. *Don't throw away outliers without solid reasoning:* Every piece of data stores a hidden story waiting to be opened.
7. *Do make full use of graphical presentations:* A picture can be worth more than hundreds of words.

TABLE 1 A Balanced Design

DIET	D_1	D_2	D_3
	y_{11}	y_{21}	y_{31}
	y_{12}	y_{22}	y_{32}
	y_{13}	y_{23}	y_{33}

8. *Do avoid statistical jargon in conclusion and report writing:* Problem language is the only thing that is universal in a corporation.
9. *Don't blindly follow statistical conclusions without taking into account their practical significance and economic considerations:* Negligence of the nonstatistical aspects of the experimental design can prove to be vital.
10. *Don't think that one iteration of a time experiment can solve the problem once and for all:* The outcome of one experiment often provides a direction for further iterations of exploration.

5. FUNDAMENTAL DESIGNS AND CONCEPTS (Anderson and McLean 1974; Box and Draper 1987; Gryna and Juran 1993; Hunter 1998; Montgomery 1996)

Statistical experiments can have various objectives and constraints. Identifying the most influential factor(s) or independent variables and their respective effect on the response or dependent variable(s) is one of the most common objectives. The nature and number of factors of interest, the number of levels a factor can vary, the limitation in time span and budget, and so forth are some of the common constraints. Depending on its specific objective and constraints, an experiment can have various designs. In the following we take a weight-watch program as an example to illustrate various alternative designs and their underlying principles.

5.1. A Case: Weight-Watch Program

One response variable of concern is the weight loss (WTLOSS) in kilograms measured in the first month. The main factor DIET has three levels, that is, options, D_1, D_2, and D_3. Suppose nine persons volunteer to participate in this experiment program. One natural arrangement is to assign three persons to each of the three DIETs, as shown in Table 1. Note that this is a balanced design in the sense that the same number of persons received the same treatment. For a simple design like this, balancing is not a must but is desired. However, in other cases it is almost a requirement for easy analysis and guarantees the same degree of precision in estimation of different treatments.

Under this arrangement, one diet is assigned to three volunteers, that is, each has three replications. Replication is used to estimate the experimental error. It also helps to increase the precision.

5.2. Fixed-Effect and Random-Effect Models

In this experiment, the three DIETs may be the only ones of concern to the experimenter. In this case it is called a fixed-effect model, and the conclusion drawn is applicable only to these specific three options. However, situations may arise in which the experimenter is seeking for a conclusion applicable to all possible DIET options and yet he or she can only handle three options. Then, three of the available options should be drawn from all possible at random. This is called a random-effect model. In addition to the difference in the scope of conclusion, different types of effect models also imply a somewhat different approach of data analysis. In what is to follow, only the fixed-effect model is considered.

An advertent error can easily occur at this point. Very often, experimental units are assigned to treatments by convenience. For example, the WTLOSS may vary from one ethnic group to another. Yet persons of the same ethnic group (ETHNIC) are assigned the same diet. One extreme case could appear like the one shown in Table 2, where all Caucasians (C) are assigned to D_1, all Africans (A)

TABLE 2 Confounding of Factors

DIET	D_1	D_2	D_3
	C	A	O
	C	A	O
	C	A	O

to D_2, and all Orientals (O) to D_3. One problem arises: Whenever one of the DIETs is found to be more effective than the others, we cannot separate the confounding of the two factors and thus can hardly claim which is the truly dominant one.

5.3. Completely Randomized Designs (CRD)

To overcome this problem, the experimental units are usually assigned to treatments by randomization, that is, in a purely chance manner. This way of completely randomized allocation of DIETs to volunteers, as shown in Table 3, is called completely randomized design (CRD).

5.4. Randomized Complete Block Design (RCBD)

Another way to guard against any possible bias due to the effect of ETHNIC is to carry out the experiment by the randomized complete block design (RCBD), as shown in Table 4. Here, each of the three ethnic groups constitutes a block and receives all of the three treatments in random order.

A RCBD has the advantage of eliminating the contamination of the block factor on the main factor. It permits the removal of the block effect from the experimental error and thus provides a more decisive conclusion. Moreover, the effect of the block factor can usually be tested and evaluated.

5.5. Latin Square Designs and Interactions

At this point one may suspect that different amount of EXERCISE, say light (L), medium (M), and heavy (H), may have different degrees of effect on WTLOSS and should be treated as another block factor. Under these circumstances, the experiment is often carried out according to the Latin square design, as shown in Table 5. Note that each DIET is assigned only once to each ETHNIC and only once to each EXERCISE. It enables the evaluation of three factors with only nine observations. However, it requires that no interaction exist between the factors.

Two factors are said to have interaction when the effect of one factor varies under the different levels of another factor. The concept of interaction is illustrated in Figure 1.

5.6. Factorial Designs

Whenever interaction exists between factors, the experiment must be run according to the factorial design (FD) shown in Table 6 to ensure accurate and precise conclusion. Note that this experiment covers each of the 27 combinations of the levels of the three factors.

One may note that the factorial design differs from the conventional one-factor-at-a-time approach. In the latter the experiment is run in several iterations, and in each iteration only one factor is varied while the others are held constant. As a result, the factorial design allows the test and evaluation of

TABLE 3 Completely Randomized Design (CRD)

the effects of all three factors at one iteration. It is therefore more effective in the sense that it requires a shorter time to reach a complete conclusion. It also guards against the risk of missing the optimum of a surface, as is often seen in other approaches.

The FD also has disadvantages. The number of observations increases exponentially with the number of factors and also with their number of levels.

5.7. 2^k and 3^k Factorial Designs

As long as the experiment is still in its exploratory stage and one is mainly interested in screening out the less effective factors, the preceding problem can be partially solved by reducing the number of levels of each factor to two or three. Under such arrangement, the k-factor FD is then denoted as 2^k or 3^k FD, respectively. Although the two-level FD (see Table 7) requires a lower number of observations than its three-level counterpart, it is applicable only when it is believed that none of the factors has a nonlinear effect on the response.

5.8. Fractional Factorial Designs (FFD)

Further reduction of the number of observations can be achieved by employing the fractional factorial design (FFD). The notation 2^{k-p} is used to denote a 2^p fraction of a 2^k fractional design. See Table 8 for the one-half fraction of the 2^3 FD of the weight-watch experiment.

8	2	2	1	2	1	1	2

5.9. Orthogonal Arrays (OA) (Taguchi 1986)

For each FD there exist several alternative FFDs. One specific class of FFDs is called an orthogonal array (OA), often referred to as the Taguchi method. Reduced to its simplest level in allocating factor-level combinations, it has become increasingly popular.

Depending on the number of levels and the number of rows, a cluster of different OAs is available from which to choose.

Shown in Table 9 is one typical two-level OA with eight rows and seven columns, denoted as $L_8(2^7)$. The subscript denotes the number of rows or the number of factor-level combinations this OA provides. The lower number between the parentheses stands for the number of factors it should have, while its superscript stands for the number of columns this OA has or the maximum number of factors the experimenter is allowed to allocate.

Inside the array, numbers 1 and 2 label the low and high levels of the factors. However, each of the rows indicates the factor-level combination to be applied to the specific experimental unit. Note that in each column, both levels 1 and 2 appear an equal number of times. It is also true for all combinations (1,1), (1,2), (2,1) (2,2) appearing in any two columns. Hence the name ''orthogonal array.''

The OA is a balanced design in nature. As a form of fractional factorial design, it has an economic advantage, and it allows evaluation of main effects and the interactions between factors as well.

Attached to the bottom of the table is the component row, which tells how the main effects and interaction effects are associated with columns. In other words, if factors A, B, and C are assigned to columns, 1, 2, and 4, the component row points out that the interactions A X B, A X C, B X C, and A X B X C, are associated with columns 3, 5, 6, and 7. It can therefore be used as an aid to allocate factors to the array.

Besides $L_8(2^7)$, other OAs of the two-level family include $L_4(2^3)$, $L_{16}(2^{15})$, and $L_{32}(2^{31})$. Their counterparts in the three-level family include $L_9(3^4)$ and $L_{27}(1^3)$.

A set of linear graphs is available for each of the OAs to facilitate allocation of factors and interactions to columns of the arrays.

6. ANALYSIS OF A BASIC DESIGN (Box et al. 1978; Hicks 1982; Montgomery 1996)

6.1. Hypotheses and Models

In the weight-watch experiment we are concerned with the problem of comparing the effects of three diets. The hypotheses under test are therefore

H_0: $\mu_1 = \mu_2 = \mu_3$.
H_1: At least one of the three is different from the others.

The true mean of any one treatment can, in fact, be looked upon as the sum of a grand mean μ and the specific effect of the ith treatment α_i, that is, $\mu_i = \mu + \alpha_i$.
The hypotheses under test hence become (Box et al. 1978):

H_0: $\alpha_1 = \alpha_2 = \alpha_3 = 0$.
H_1: At least one of α_i's is unequal to zero.

Realizing the existence of variation due to environment, experimental units, execution process, and also measurement errors, any measured WTLOSS taken from the ith DIET group is unlikely equal to its treatment mean, and is usually decomposed as (Bhote 1991):

$$\begin{aligned} Y_{ij} &= \mu_i + \varepsilon_{ij} \\ &= \mu + \alpha_i + \varepsilon_{ij} \end{aligned}$$

This equation is usually referred to as the data model. The data model of the measured WTLOSS data acquired under the CRD setup shown in Table 3 can be represented as

$$\begin{matrix} \text{Observation} \end{matrix}$$

$$\begin{bmatrix} 6.53 & 3.23 & -0.11 \\ 6.72 & 2.19 & 0.35 \\ 3.91 & 4.72 & 2.61 \end{bmatrix} = \begin{bmatrix} 4 & 4 & 4 \\ 4 & 4 & 4 \\ 4 & 4 & 4 \end{bmatrix} + \begin{bmatrix} 1 & 0 & -1 \\ 1 & 0 & -1 \\ 1 & 0 & -1 \end{bmatrix} + \begin{bmatrix} 1.53 & -0.77 & -3.11 \\ 1.72 & -1.81 & -2.65 \\ -1.09 & 0.72 & -0.039 \end{bmatrix}$$

Mean Effect Error

To enable valid statistical analysis, the error component ε_{ij} is required to follow independent identical normal distribution of the mean zero and common variance, or iid $N(0, \sigma^2)$.

6.2. ANOVA: Analysis of Variance

The test of the hypotheses uses the analysis of variance (ANOVA) approach, which is based on the decomposition principle of sum of squares. In other words, the variation of the observations from the grand average can be decomposed into two components: the variation around their group average, or the within-group variation, and the variation between the group average, or the between-group variation.

If the between-group variation is larger than what is expected from the variation that occurs within the groups, we would suspect that group means μ_1, μ_2, μ_3 are not the same. The F distribution is used for checking this point.

The F statistic is computed from

$$F = \frac{\text{SSB}/(k-1)}{\text{SSW}/(N-k)}$$

where SSB = sum of squares due to between-group variation.

$$= \sum_{i=1}^{k} \sum_{j=1}^{n} (\overline{Y}_{ij} - \overline{Y})^2$$

where SSW = sum of squares due to within-group variation.
= SSTO − SSB

$$\text{SSTO} = \sum_{i=1}^{k} \sum_{j=1}^{n} (\overline{Y}_{ij} - \overline{Y})^2$$

where k = number of groups
n = number of observations in each group
$N = kn$

The whole computation procedure is usually summarized in an ANOVA table, as shown in Table 10.

The ANOVA table is provided by almost every statistical software.

TABLE 10 ANOVA Table for WTLOSS Data in CRD

Source	SS	*df*	MS	F_s
Between DIETs	34.13	2	17.07	8.25
Within DIETs	12.41	6	2.07	
Total	46.54	8		

The computed F statistic F_s is now compared to its corresponding critical value at the specified significance level $\alpha = 0.05$, that is, $F_{0.05}(2,6) = 5.14$. Since $F_s > 5.14$, we accept H_1 and conclude that at least one of the DIETs is unequal to the others.

6.3. Marginal Averages

By comparing the marginal averages (see Figure 2) of the three DIETs, those of DIET D_1 have an average 5.72, which is significantly larger than DIETs D_2 and D_3. We are therefore assured that D_1 is the most effective program for a keen weight watcher.

6.4. Rationale of ANOVA Analysis

According to the statistical theory, the mean squares SSB/(k − 1) and SSB/(N − k) have their respective expected mean squares (EMS) as (Box et al. 1978):

$$\text{E(MSB)} = \sigma^2 + n\sigma_A^2$$

$$\text{E(MSE)} = \sigma^2$$

where

$$\sigma_A^2 = \sum_{i=1}^{k} \alpha_i^2/(\text{k} - 1) \text{ for the fixed-effect model}$$

The test of the hypotheses can also be understood by viewing F approximately, as the ratio of $\sigma^2 + \sigma_A^2$ to σ^2. If all α_i's are the same and equal to zero, the ratio E(MSB)/E(MSW) is likely to be close to 1 and therefore leads us to accept H_0. On the other hand, if one of the α_i's is not equal to the others, the same ratio is likely to take a quantity much greater than 1 and therefore leads us to accept H_1.

For the applicable occasions and the analysis of some basic designs, please refer to the summary that follows.

Whenever there are more than one source or variation to be compared to, the EMS can be used as a quick decision aid. As a principle, a designate is always compared with a shorter row having common elements but one.

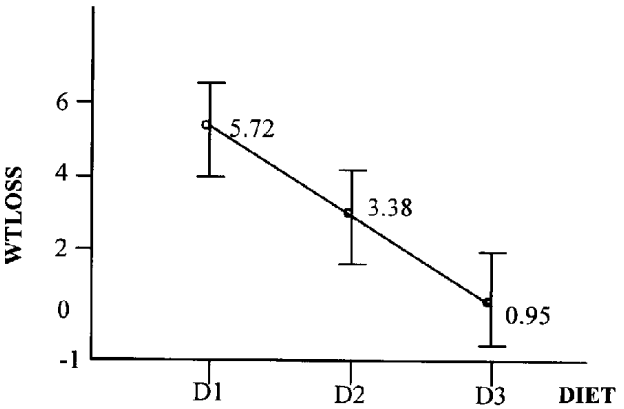

Figure 2 Marginal Average Chart with 95% Confidence Interval.

7. SCREENING DESIGNS (Barker 1990; Box et al. 1978; Dean and Voss 1999)

7.1. Strategy of Screening Design (Du Pont Co. 1988)

Many of the factors initially considered in the early stage of an experimental project may have little or no effect on response. The purpose of a screening experiment is to reduce experimental time and cost by identifying the factors that deserve thorough investigation in the subsequent stages. Therefore, in designing an experiment with many factors, it is useful to start with a screening experiment before going on to the more in-depth studies described in the preceding section.

7.2. Weight-Watch Experiment Using $L_8(2^7)$

Let us return to the weight-watch experiment to illustrate how an OA such as $L_8(2^7)$ is used to assign the factor levels. Suppose the factors and their levels of concern at this stage are as listed here.

Factor	Level 1	Level 2
DIET	DIET 1(D_1)	DIET 2(D_2)
EXERCISE	Medium (M)	High (H)
SEX	Female (F)	Male (M)
ETHNIC	White (W)	Black (B)

Suppose it is anticipated that interaction between DIET and EXERCISE and between DIET and SEX may exist. With the aid of the component row of the $L_8(2^7)$, we choose to assign the factors DIET, EXERCISE, SEX, and ETHNIC to columns 1, 2, 4, and 6. The treatment conditions can then be readily read from the array and are shown in Table 11.

Taking the randomization principle into account, the treatment condition D_1LFW, which is decoded as DIET 1, low exercise on a white female, and so on should be assigned in a random manner.

7.3. ANOVA

Table 11 also serves as a worksheet for data analysis. Recorded in the far-right column of Table 11 are the WTLOSS data resulting from the assigned treatment combinations. The T_1 of any column stands for the total of all observed data that are associated with level 1. Likewise, T_2 stands for the same types of data for level 2. For example, the T_1 for the DIET column is obtained by adding the four observations corresponding to the l's in column 1. Hence,

$$T_1 \text{ (DIET)} = 6.21 + 8.82 + 2.23 + 4.85 = 22.11$$

The task of subsequent analysis is to test the null hypotheses that different levels of the factors DIET, EXERCISE, SEX, and ETHNIC do not have any effect on WTLOSS. It is the same as in analyzing the CRD data; the ANOVA is used to test the previously mentioned hypotheses. The

TABLE 11 Orthogonal Array for Weight-Watch Experiment

Factor Interaction	DIET	EXR	$D \times E$	SEX	$D \times S$	ETH

SS	4.946	0.008	32.602	22.545	1.103	2.916	2.892		

TABLE 12A ANOVA for Weight-Watch Experiment

Source	SS	DOF	MS	F_c
DIET	4.95	1	4.95	1.71
EXERCISE	0.01	1	0.01	0.00
SEX	22.54	1	22.54	7.80
ETHNIC	2.92	1	2.92	1.01
Interaction				
DIET × EXR	32.60	1	32.60	11.27
DIET × SEX	1.1	1	1.10	0.38
ERROR	2.87	1	2.87	
TOTAL	67.01	7		

$F_{0.05}(1,1) = 161$

variation due to the effect of a specific factor is compared to the variation due to random error. The sum-of-squares for the ith column and the corresponding F statistic are computed by

$$\mathrm{SS}_i = \frac{(T_1 - T_2)^2}{8}$$

$$F = \frac{SS_i/df_i}{SSE/df_E}$$

where SSE, the sum-of-squares due to errors, is found by summing up the SS's of the undesignated columns. For the weight-watch experiment, SSE = SS_7. The ANOVA table obtained through this method is shown in Table 12A.

The computed F statistics are now compared to their common critical value at the specified significance level, say, $\alpha = 0.05$, that is, $F_{0.05}(1,1) = 161$. Since none of these is greater than 161,we do not have sufficient evidence to conclude that any of the main effects and interactions are significant at $\alpha = 0.05$. However, the computed F statistics do reveal that while the interaction DIET × EXR is relatively larger than the others, the factor SEX and another interaction DIET × SEX are negligible and thus can be merged with the error term. The resulting ANOVA table is listed in Table 12B.

As the computed F statistics of the interaction DIET × EXR, that is $F_c = 14.15 > 10.128 = F_{0.05}(1,3)$, we do have sufficient evidence to claim that two DIETs do affect WTLOSS differently at the two different levels of EXERCISE amount. It also suggests that SEX may have different WTLOSS. Further examination of the marginal average chart (see Figure 3) reveals that the male under this experimental setup attains greater WTLOSS than the female. It is noted that DIET 1 has effect on WTLOSS when it is used with a medium amount of EXERCISE. However, DIET 2 also produces a sizable WTLOSS when it is used with a higher amount of EXERCISE.

7.4. Recommendations

As mentioned earlier, the OA mainly serves the purpose of screening the vital few from the trivial many. In order to reach a solid and meaningful conclusion, more thorough confirmatory experiments are required. Take the weight-watch experiment as an example. It is recommended that the focus be

TABLE 12B ANOVA for Weight Watch Experiment

TOTAL	67.01	7		

$F_{0.05}(1,3) = 10.128$

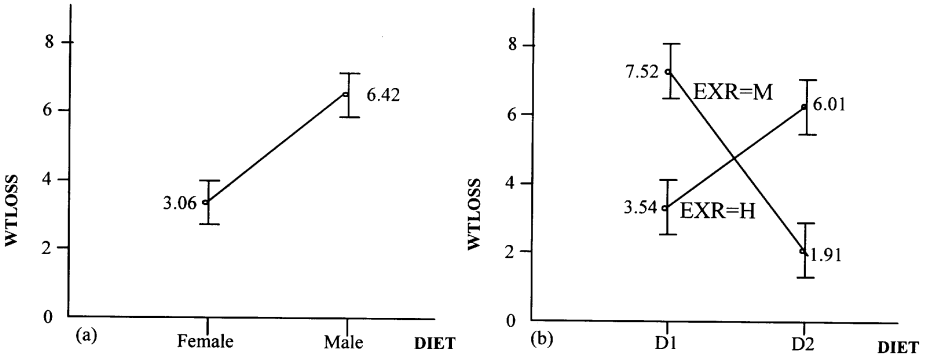

Figure 3 Marginal Average Chart with 95% Confidence Level.

placed at this point on only DIET and EXERCISE as the two main factors. Adding a few more levels may be worthwhile. A replicated two-way factorial design run on both sexes may be the experimenter's best choice. Some statistical tools, such as multiple comparison, confidence interval estimation, residual analysis, normality check, and response surface methodologies, are commonly used.

8. PARAMETER DESIGN (Peace 1989; Phadke 1989; Taguchi and Wu 1980; Taguchi 1986, 1987)

8.1. Strategy of Parameter Design

Traditionally, when performing an experimental design, the experimenter places his or her focus on finding the product or process condition that yields the best mean performance. However, this approach may not satisfy the demands of modern marketing strategies. This strategy requires a robust product or process that satisfies a wide range of customer interests.

For example, the combination of DIET I and the medium exercise amount in the preceding weight-watch experiment may, in fact, yield the greatest amount of WTLOSS, though this conclusion is valid for only some combinations of SEX and ETHNIC. However, a weight-watch service salesperson is more interested in a program that is robust or resistant to noise factors such as SEX and ETHNIC, that is, a program that is suitable for all possible combinations of SEX and ETHNIC.

The same is true for a production engineer. In designing a product or process, in addition to the major parameter settings, noise factors such as manufacturing variation, component tolerance, customer use conditions, and product deterioration need to be taken care of. A good product or process is one that is robust to variations due to these noise factors.

It is this requirement for robustness that prompted Taguchi to develop the concept of parameter design and produced a great impact on the world of experimental design.

8.2. Concepts of Parameter Designs (Barker 1990; Taguchi and Wu 1980; Taguchi 1986)

In the context of parameter design, the simple response is no longer of major interest. Rather, a composite performance measure that integrates both the mean and variance of the response plays the role of a dependent variable. Depending on the nature of the problem under study, various performance measures are developed for situations including "the larger the better," "the smaller the better," and "the specified target value is the best."

The objective of the parameter design is a matter of choosing a product or process condition that yields the best performance measure. In other words reducing the variation of response from the target while controlling the mean response toward the target is the ultimate goal of the parameter design.

These settings are determined by (1) systematically varying the settings of design parameters in the experiment and (2) comparing the effect of noise factors for each test run.

The parameter design achieves this goal by setting up an inner array and an outer array that constitute an orthogonal array such as $L_8(2^7)$ or $L_9(3^4)$. This array is assigned with control factor parameters, while the outer array is also an orthogonal array. This latter array is assigned with noise factor parameters.

TABLE 13 Parameter Design for Weight Watch Experiments

Outer Array			Row		1	2	3	4	
			Column						
			1	SEX	1	1	2	2	
			2	ETH	1	2	1	2	
			3		1	2	2	1	
Column	Inner Array 1	2			Observed WTLOSS				Performance Statistics
Row	DIET	EXR	3	4					Z_i
1	1	1	1	1	y_{11}	y_{12}	y_{13}	y_{14}	Z_1
2	1	2	2	2	y_{21}	y_{22}	y_{23}	y_{24}	Z_2
3	1	3	3	3	y_{31}	y_{32}	y_{33}	y_{34}	Z_3
4	2	1	2	3	y_{41}	y_{42}	y_{43}	y_{44}	Z_4
5	2	2	3	1	y_{51}	y_{52}	y_{53}	y_{54}	Z_5
6	2	3	1	2	y_{61}	y_{62}	y_{63}	y_{64}	Z_6
7	3	1	3	2	y_{71}	y_{72}	y_{73}	y_{74}	Z_7
8	3	2	1	1	y_{81}	y_{82}	y_{83}	y_{84}	Z_8
9	3	3	2	1	y_{91}	y_{92}	y_{93}	y_{94}	Z_9

8.3. Weight-Watch Experiments

Table 13 illustrates how the parameter design is set up for the weight-watch experiment.

Placed in the lower left corner is a $L_9(3^4)$. Columns 1 and 2 are assigned as DIET and EXERCISE, respectively, both having three levels. Placed in the upper right corner is a transposed outer array $L_4(2^3)$. In this outer array the transposed column 1 is assigned the noise factor SEX while column 2 is assigned another noise factor ETHNIC. The two arrays are arranged in such a manner that each of the nine control factor parameter combinations cross all of the four noise factor parameter combinations. Thus, a total of 36 observed WTLOSS pieces of date data are obtained and displayed as shown.

The subsequent analysis of data consists of computing performance statistics based on a formula such as

$$Z_i = (-10)\log\ 1/n \sum_{i=1}^{n} (1/y_i^2)$$

for a ''greater-the-better'' case like this.

The next steps follow the same flow of analysis using an ANOVA table as seen in the preceding sections.

9. THE STRATEGIES OF EXPERIMENTS (Du Pont Co. 1988)

The practice of experimentation is a matter of problem solving. It is also a learning process rendered through step-by-step development of know-how as well as know-why. However, it takes sound and smart strategies to reach this goal effectively and efficiently.

A complete set of strategies consists of three major components: strategy for screening designs, strategy for parameter designs, and strategy of response surface designs.

The main purpose of the strategy of screening designs is to screen out the significant factors from various possible factors selected for experiment.

However, in order to keep the cost of experimentation from being too high, two levels for each factor are used in general. Consequently, 2^k orthogonal arrays are most oftenly used in the screening designs.

The strategy of parameter designs is practiced after the strategy of screening designs. At this stage, only the factors that are found to be significant are included in the experiments. As the number of factors is reduced, the experiment is now focused at the finding and determination of the optimal condition. The 3^k orthogonal arrays are commonly used in this stage.

The strategy of response surface designs takes place after the parameter design strategy. All of the data collected in the repeatability experiments are then utilized in the database used in conjunction with the response surface designs.

The elaboration of response surface designs is beyond the scope of this article. For more treatment of the subject, see Cornell (1990), Khuri and Cornell (1987), and Montgomery (1991).

10. CONCLUSION

The success of experimentation relies on the following issues:

1. Thorough consideration of all technical, statistical, and administrative aspects
2. Sound planning of the experimentation
3. Effective implementation
4. Proper observation of good experimental practices
5. Smart adoption of strategies of experimentation

CHAPTER 86

Statistical Inference and Hypothesis Testing

Don T. Phillips
Alberto Garcia-Diaz
Texas A&M University

1. INTRODUCTION

One might define the function of applied statistics as the art and science of collecting and processing data in order to make inferences about the parameters of one or more populations associated with random phenomena. These inferences are made in such a way that the conclusions reached are consistent and unbiased. When properly applied and executed, statistical procedures depend entirely on specific methodologies, definitions, and parameters required by the statistical test chosen.

The science of statistics is purely mathematical with probability theory as the cornerstone. Because all statistical methods are based on probability concepts, it is necessary for one to understand the

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

basic concept of probability measure before undertaking statistical analysis. In order to proceed with the development of procedures for hypothesis testing and estimation, a fundamental knowledge of statistical measures, random variables, probability density functions, and statistical sampling procedures will be assumed.

2. STATISTICAL INFERENCE

Each (and every) random variable has a unique probability distribution. For the most part statisticians deal with the theory of these distributions. Engineers, on the other hand, are mostly interested in finding factual knowledge about certain random phenomena, by way of probability distributions of the variables directly involved, or other related variables.

In basic statistics we learn that probability density functions can be defined by certain constants called *distribution parameters.* These parameters in turn can be used to characterize random variables through measures of location, shape, and variability of random phenomena. The most important parameters are the mean μ and the variance σ^2. The parameter μ is a measure of the center of the distribution (an analogy is the center of gravity of a mass) while σ^2 is a measure of its spread or range (an analogy being the moment of inertia of a mass). Hence, when we speak of the mean and the variance of a random variable, we refer to two statistical parameters (constants) that greatly characterize or influence the probabilistic behavior of the random variable. The mean or expected value of a random variable x is defined as

$$\mu = \sum_x xp(x) \quad \text{or} \quad \mu = \int_x xf(x)dx$$

where $p(x)$ represents probabilities of a *discrete* random variable and $f(x)$ represents the probability density function of a *continuous* random variable. The parameters of interest are embedded in the form of the probability density functions. As an illustration, the variance of a random variable is defined as

$$\sigma^2 = \sum_x (x - \mu)^2 p(x) \quad \text{or} \quad \sigma^2 = \int_x (x - \mu)^2 f(x)dx$$

In mathematical statistics we can show that many random variables that occur in nature follow the same general form of distribution with differences only in the parameters and the statistical quantities μ and σ^2 Some of these recurring distributions have been given special names, such as:

Binomial	Beta	Uniform
Hypergeometric	Normal	Cauchy
Poisson	Chi-square	Rayleigh
Geometric	Student's-*t*	Maxwell
Negative binomial	*F* distribution	Weibull
Gamma	Exponential	Erlang

Thus, it is not difficult to see why the field of ''probability and statistics'' is a discipline within itself, nor is it difficult to see why almost every discipline in existence needs a working knowledge of statistics. Random phenomena (variables) exist in all phases of activity.

When one is interested in certain random phenomena, the first requirement seems to be that one develop some means of measuring it. Upon doing so, one often collects a number of observations of the random phenomena. Statistics deals with developing tools and techniques for choosing those observations (a sample) and manipulating them in such a way that useful information is gained about the underlying random variable(s). This information is generally derived from studying probability distributions of the random variables or functions of the random variables. The average (or mean) and/or the variance (or spread) of the probability distribution of the random variable obviously yield useful information.

While the parameters of a statistical distribution are constant, any computation based on the numerical values of the random observations in a sample may yield different quantities from sample to sample. These quantities are known as ''statistics.'' The two most widely used statistics are the mean of a sample of n observations

$$\bar{x} = \sum_{i=1}^{n} x_i/n$$

and the variance of the sample

$$S^2 = \sum_{i=1}^{n} \frac{(x_i - \bar{x})^2}{n - 1}$$

Note that these descriptors are not theoretical in nature but are calculated from a set of n data points.

Mathematical developments have proven that $\bar{x}$ is usually the best single (point) estimate of μ, and S^2 is usually the best single (point) estimate of σ^2. Normally, the nature of these parameters is totally unknown, and statistics is used to draw inferences about their true values.

Since knowledge of the mean and variance is of utmost importance, statistics deals extensively with developing tools and techniques for studying their behavior. Two basic objectives will be dealt with in the remainder of this chapter:

1. Ways of testing to see whether or not some assumed value of μ or σ^2 is "reasonable" under normal operating or assumed conditions.
2. Ways of using observed values of $\bar{x}$ and S^2 so that one may state with a given measure of confidence that the population parameters of these estimates fall within a given interval. For example, we can be 95% confident that the interval from I_1 to I_2 includes the true value of μ.

   The first objective is dealt with using statistical *hypothesis testing,* while the second one gives rise to *confidence interval estimation.*

Statistical tools also exist for estimating the difference between, or testing an assumption about, the means or variances of two or more probability distributions. These tools are natural extensions of the tools developed for estimating and testing hypotheses about single populations.

All statistical methods have, as a basis, a sample of n observations on the random phenomena of interest. Such methods require that the random sample (of size n) be "representative" of the outcomes that could occur. Because of this, much is said about making sure that the sample is a random sample. Many statistical calculations become invalid when the data used are not representative.

3. STATISTICAL HYPOTHESIS TESTING

Working with a representative (random) sample of n observations, statisticians have shown that the function $Z = \sqrt{n}(\bar{x} - \mu)/\sigma$ for sufficiently large values of n is a random variable that follows (or has) a normal probability distribution with $\mu = 0$ and $\sigma^2 = 1$. This fact is the result of the well-known central limit theorem, which can be stated as follows (Bowker and Lieberman 1972; Devore 1987; Dougherty 1990; Hogg and Craig 1978):

If $\bar{x}$ is the mean of a random sample of size n taken from a population having a mean μ and a finite variance σ^2, then

$$Z = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}}$$

is a random variable whose probability distribution approaches that of the standard normal distribution ($\mu = 0$, $\sigma^2 = 1$) as n approaches infinity.

This is undoubtedly the most amazing theorem in statistics for it does not require that one know anything about the shape of the probability distribution of the individual observations. It only requires that the distribution of those random observations have a finite mean, μ, and variance, σ^2. The standard normal density function is defined as

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-1/2z^2} \quad \text{for} \quad -\infty < z < \infty$$

This distribution is graphically represented in Figure 1.

If we use the notation $Z_{\alpha/2}(-Z_{\alpha/2})$ to indicate the value of Z corresponding to an area $\alpha/2$ under the distribution falling to the right (left) of $Z_{\alpha/2}$ ($-Z_{\alpha/2}$), then we can associate the cross-hatched area shown in Figure 2 with the region in which $100(1 - \alpha)\%$ of all random variables, characterized by the standard normal density function $f(Z)$ with mean $\mu_z = 0$ and variance $\sigma_z^2 = 1$, are expected to lie. Within the context of a hypothesis test, this area will be called the *acceptance region* and the

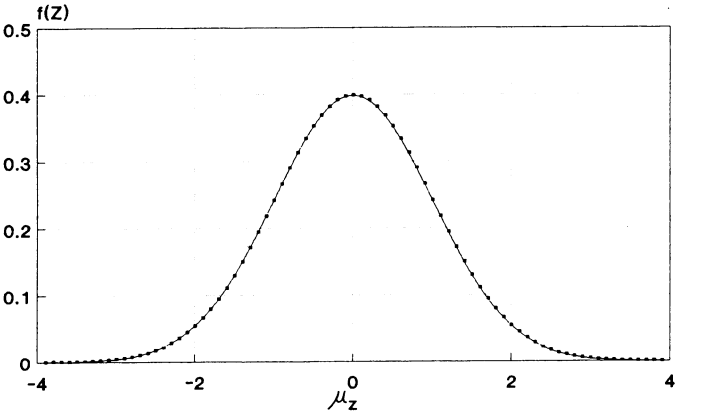

Figure 1 Standardized Normal Distribution.

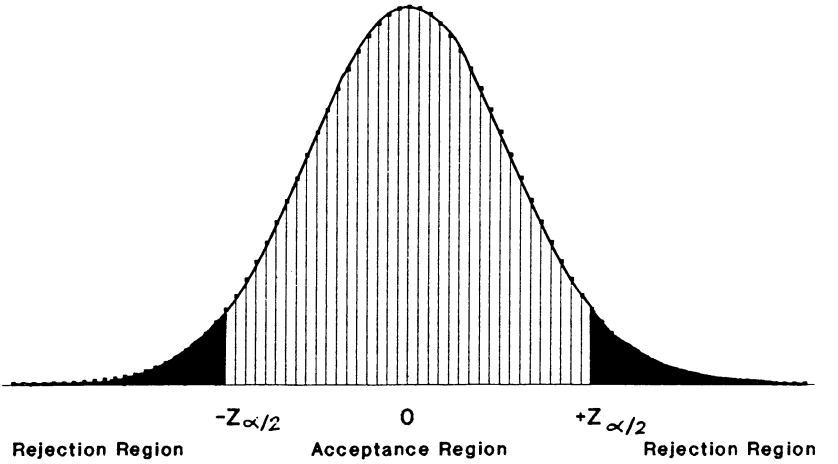

Figure 2 Acceptance and Rejection Regions.

tail areas called the *rejection region.* The points $-Z_{\alpha/2}$ and $Z_{\alpha/2}$ will be called the *rejection points* for reasons which will shortly become evident. Although the underlying probability density function $f(Z)$ might change, these concepts will remain the same. The procedure of statistical hypothesis testing will now be described.

4. TESTING A MEAN VALUE (μ) WITH σ^2 KNOWN

Given a value of $\bar{x}$ computed using a sample of size n from an infinite population with known mean (μ) and variance (σ^2), the probability that the random variable

$$Z = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}}$$

falls between the points $-Z_{\alpha/2}$ and $Z_{\alpha/2}$ is $1 - \alpha$. Note that α is a value between zero and one and represents the probability that a random variable $\bar{x}$, which approximates the mean μ, will naturally fall outside the points $-Z_{\alpha/2}$ and $Z_{\alpha/2}$. This interpretation of the natural behavior of the random variable $\bar{x}$, along with the distribution of the (transformed) variable Z, allows one to structure a

hypothesis test concerning the true mean, μ. Assume that the value of $\alpha = 0.05$, and that the following statement is to be tested:

$$H_0: \quad \mu = \mu_0$$
$$H_1: \quad \mu \neq \mu_0$$

The value μ_0 is the numerical value of μ which is assumed known or is hypothesized. H_0 is called the *null* or *primary* hypothesis and H_1 is called the *alternative* or *secondary* hypothesis. If a random sample of size n is extracted from the population under study, then

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n}$$

can be calculated. Since $\bar{x}$ is the best point estimator of μ, and μ is assumed to be equal to μ_0 one would expect the random variable

$$Z = \frac{\bar{x} - \mu_0}{\sigma/\sqrt{n}}$$

to fall between the points $-Z_{\alpha/2} = -Z_{0.025}$ and $Z_{\alpha/2} = Z_{0.025}$ 95% of the time. The values $-Z_{0.025}$ and $Z_{0.025}$ can be determined by using a standard normal table. We can see that they are equal to ± 1.96. These values are called *critical values* and obviously depend upon α. Hence, calculation of Z yields a statistic that will cause H_0 to be believed 95% of the time and H_1 to be believed only 5% of the time, when H_0 is actually *true.* Therefore, α can be interpreted as the magnitude of the error of *rejecting* the *null hypothesis* when in fact it is true. This error is often referred to as an error of type I. Additionally, if the null hypothesis is *false,* there is still a chance that the calculated value of Z will lie between ± 1.96 (when $\alpha = 0.05$). This result will cause the decision analyst to *accept* the null hypothesis when in fact it is *false.* The magnitude (likelihood) of this error is commonly denoted by β, and this error is called an error of type II. Table 1 characterizes the decision process.

In order to illustrate the basic procedures of statistical hypothesis testing, consider the following example:

An oil investment cartel is considering the purchase of an oil well from Blow Hard, Inc. in Texas. Current owners claim that the well produces on the average 100 barrels of oil per day, with a standard deviation of 10 barrels per day. In order to test this claim, the cartel chooses $\alpha = 0.05$ and observes daily production for 16 days. Total production over this period of time is 1690 barrels of oil. Can the owner's claim be disputed?

Assumptions: $\mu = 100$
$\sigma^2 = 100$
Infinite population
$\alpha = 0.05$

Hypothesis test: H_0: $\mu = 100$
H_1: $\mu \neq 100$

Test statistic: $Z - \dfrac{\bar{x} - \mu}{\sigma/\sqrt{n}}$

Critical values: $\pm Z_{0.025} = \pm 1.96$

Calculated Z statistic: $Z = \dfrac{\bar{x} - \mu}{\sigma/\sqrt{n}} = \dfrac{105.63 - 100}{10/4} = 2.252$

Since the value of $Z = 2.252$ is greater than $Z_{\alpha/2} = 1.96$, one would choose to reject H_0 in favor of

TABLE 1 Decision Based upon Sampling Evidence

True State or Nature	H_0 True	H_0 False
Hypothesis H_0 True	No Error	Type I Error
Hypothesis H_0 False	Type II Error	No Error

H_1. In other words, if H_0 is true, it is highly unlikely that a sample of size $n = 16$ would yield a value of $\bar{x}$ equal to 105.63, resulting in a value of Z as large as $Z = 2.252$. What value of $\bar{x}$ would cause the decision maker to accept H_0?

Since $\pm Z_{\alpha/2} = = \pm 1.96$ one can define the following relationship to find the limits of the acceptance region:

$$\pm 1.96 = \frac{\bar{x}_c - 100}{2.5}$$

It can be verified that the solution for $\bar{x}_c$ is given by $\bar{x}_c = 95.1$ and $\bar{x}_c = 104.9$. Therefore, any sample average between these two values will result in the acceptance of H_0.

Next, let us assume that the true population mean (daily production rate) is equal to $\mu_1 = 110$ and not 100. What is the probability that the null hypothesis will be erroneously accepted? Assuming that the variance remains constant, consider the two distributions shown in Figure 3.

Note that the probability that the null hypothesis will be accepted (erroneously) is given by the area marked β in Figure 3. This area can be calculated as follows:

Test statistic: $Z = \dfrac{\bar{x} - \mu}{\sigma/\sqrt{n}}$

Critical value: $Z_1 = \dfrac{104.9 - 110}{2.5} = -2.04$

Type II error: $\beta = P(Z \leq -2.04)$

Using a standard normal table, the probability corresponding to the β area is given by $\beta = 0.0217$. Note, however, that the β error should not include that area to the *left* of $\bar{x}_c = 95.1$. The probability that $\bar{x}$ will be less than this value given that $\mu = 110$ is determined by $P(Z \leq Z_2)$, where

$$Z_2 = \frac{95.1 - 110}{2.5} = -5.96$$

This probability is almost 0. Therefore, $\beta = 0.0217$ is the correct value to four significant digits. In other words the probability of accepting the null hypothesis when μ is actually $\mu_1 = 110$ is only 0.0217. Note that this probability is actually based on the values $\bar{x}_c = 95.1$ and $\bar{x} = 104.9$, which were uniquely determined by the chosen value of α. Clearly, one would never know what the true population mean (μ) actually is in any meaningful application. Hence, the value of β cannot be calculated except in reference to values of μ different from that specified in the null hypothesis. For this example several values of β were calculated for the alternative values of μ_1 indicated in Table 2.

For clarity, one should note that *in the limit* as μ approaches 100, the probability of a type II error approaches $\beta = 1 - \alpha$. At the exact point $\mu_0 = 100$, the null hypothesis is true and a type II error does not exist; hence, $\beta = 0$ at that single point. Figure 4 graphically depicts the behavior of the β error as a function of the true (unknown) population mean, under the original rejection criterion specified by the null hypothesis and the chosen α error. This curve is called an *operating characteristic curve,* or simply an *OC curve.*[1]

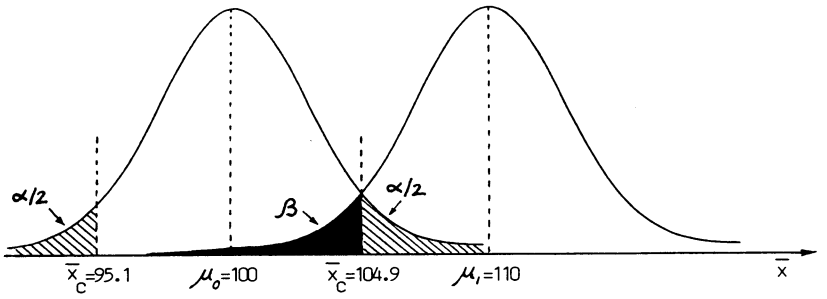

Figure 3 Probabilities of Type I and Type II Errors.

TABLE 2 Probability of Type II Error

					Population Mean Values								
91	93	95	96	97	98	99	101	102	103	104	105	107	109
0.025	0.200	0.484	0.641	0.776	0.874	0.932	0.932	0.874	0.776	0.641	0.484	0.200	0.025

The calculations shown in Table 2 were performed relative to an alternative hypothesis that included two rejection points ($-Z_{\alpha/2}$, $Z_{\alpha/2}$). Such a hypothesis test is called a *two-tailed hypothesis test.*

Consider once again our numerical example. Note that the null hypothesis states that well production is *exactly* 100 barrels per day. In reality, the purchase of the well would be desirable if the daily production met or exceeded 100 barrels per day. In that case the null and alternative hypotheses would be

Case I:
$$H_0: \quad \mu \geq 100$$
$$H_1: \quad \mu < 100$$

or

Case II:
$$H_0: \quad \mu \leq 100$$
$$H_1: \quad \mu > 100$$

Both hypothesis statements reflect the same objective, but there are significant differences in the decision criterion utilized in each hypothesis. The null hypothesis of case I assumes that the well is producing 100 or more barrels per day unless statistical evidence proves otherwise, resulting in rejection of H_0. The null hypothesis of case II assumes that the well production is inferior unless production records indicate that daily output is more than 100 barrels per day, which will result in rejection of H_0. Both tests are valid and are called *one-tailed* hypothesis tests under a given type I error. Consider again the original data with $\alpha = 0.05$. Table 3 summarizes the calculations for the significance tests associated with cases I and II.

Both test statistics in Table 3 use the value of 100 in calculating a Z value, for it is at this single point that the type I error and the type II errors are the greatest. It should also be noted that the type II error now exists in only one direction, and hence the operating characteristic curve will be one sided. For completeness, one should note that the null hypothesis is an a priori state of nature that one chooses to believe, unless statistical evidence indicates otherwise. In statistics, one does not "prove" the null hypothesis but rather "fail to reject" the hypothesis. These concepts are consistent

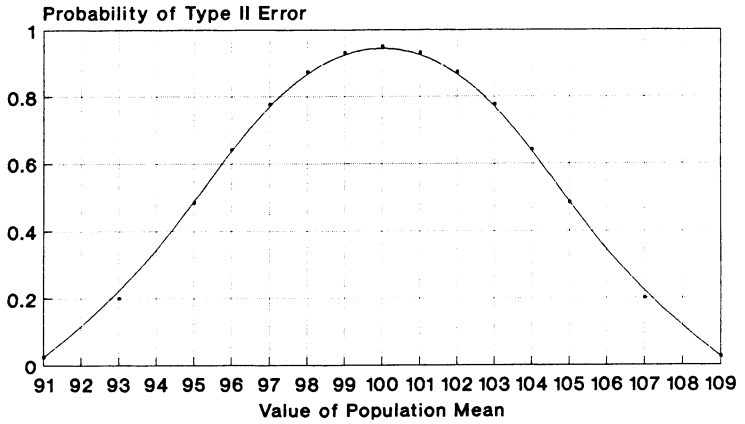

Figure 4 Operating Characteristic Curve. Level of significance = 0.05.

TABLE 3 One-Tail Hypothesis Tests for Means

Procedure	Case I	Case II
Assumptions	$\mu \geq 100$ $\sigma^2 = 100$ Normal population $\alpha = .05$	$\mu \leq 100$ $\sigma^2 = 100$ Normal population $\alpha = .05$
Hypothesis test	H_0: $\mu \geq 100$ H_1: $\mu < 100$	H_0: $\mu \leq 100$ H_1: $\mu > 100$
Test statistic	$Z = (\bar{x} - \mu)/(\sigma/\sqrt{n})$	$Z = (\bar{x} - \mu)/(\sigma/\sqrt{n})$
Critical value	$-Z_\alpha = -1.645$	$Z_\alpha = 1.645$
Calculated value	$Z = 2.252$	$Z = 2.252$
Conclusion	Accept H_0 Buy the well	Reject H_0 Buy the well

with the underlying uncertain (stochastic) nature under which hypothesis testing is conducted. One can never be absolutely certain of statistical inference. Along these same lines of thought, it is critical that the hypothesis test be chosen *before* statistical sampling and not after. Selection of the test (one or two tailed) and the associated a error should never be chosen a posteriori to "statistically confirm" any belief. Such statistical inference is obviously improper.

In summary, a decision maker can apply either a one-tailed or two-tailed hypothesis test with a chosen type I error probability equal to α. The true probability of type II error (β) is always unknown since the actual population mean is unknown. However, the β risk can be characterized by the construction of an OC curve.

5. TESTING A MEAN VALUE (μ) WITH σ^2 UNKNOWN

Consider again the oil well example. After detailed examination, it was discovered that the theoretical variance (σ^2) was really not known but had been "guessed at" by the seller. In order to estimate σ^2, the sample of 16 days was used to calculate S^2 in the following manner:

$$S^2 = \frac{\sum_{i-1}^{n} (x_i - \bar{x})^2}{n - 1}$$

Using $n = 16$, a value of $S^2 = 225$ was calculated. Under the assumption that σ^2 is unknown, the Z statistic is no longer a valid test statistic. It can be shown that the following test statistic should be used in this case (Bowker and Lieberman 1972; Devore 1987; Hogg and Craig 1978).

$$t = \frac{\bar{x} - \mu}{S/\sqrt{n}}$$

This is called simply the student t test statistic. The rejection points $t_{\alpha/2}$ and $-t_{\alpha/2}$ for a two-tailed test can be determined from an appropriate t table, but they now depend on a parameter called the "degrees of freedom," which is defined by $df = n - 1$. Consider the original two-tailed hypothesis test under the new assumption (σ^2 unknown):

Assumptions: σ^2 unknown
$\mu = 100$
Infinite population
Population is normal
$\alpha = 0.05$

Hypothesis test: H_0: $\mu = 100$
H_1: $\mu \neq 100$

Test statistic: $t = \dfrac{\bar{x} - \mu}{S/\sqrt{n}}$

Critical values: $t_{\alpha/2,df} = t_{0.025,15} = 2.131$
$-t_{\alpha/2,df} = -t_{0.025,15} = -2.131$

Calculated t statistic: $t = \dfrac{105.63 - 100}{15/4} = 1.501$

Therefore, the null hypothesis cannot be rejected and one is led to believe that the true well production is actually 100 barrels per day.

This example illustrates the use of the t statistic for testing a hypothesis related to a population mean value (μ) when the variance (σ^2) is *unknown.* As before, both two-tailed and one-tailed tests are possible, whichever the problem situation demands. Rejection limits are set based on a chosen type I (α) error, and operating characteristic curves (OC curves) can be constructed to reflect the associated type II (β) error risk. Finally, one should note that the t test was necessitated due to the fact that σ^2 was being estimated by S^2 from a sample of size n. If n is large enough, then one would expect S^2 to closely approximate σ^2 and the Z test can be used anyway. For $n \geq 30$ this is generally an acceptable procedure.

6. HYPOTHESIS TESTING: SINGLE VARIANCE

Continuing with the example about oil well production, the potential buyer was quite perplexed at the result obtained from the two-tailed t test, since it differed from that previously obtained via the original two-tailed Z test. An engineer explained that the difference was probably a result of lack of knowledge concerning the population variance, σ^2. Since σ^2 was unknown, the induced uncertainty caused failure to reject the null hypothesis (note that the rejection points were wider).

Reflecting upon this logic, management requested a statistical examination of the sample variance to determine if the original (specified) σ^2 had indeed changed, since the estimated value of σ^2 (S^2) was greater than the original specified value. The proper statistical test is a chi-square test. The chi-square test is described as follows:

Assumptions: $\sigma^2 = 100$
Infinite population
Population is normal
$\alpha = .05$

Hypothesis test: H_0: $\sigma^2 = 100$
H_1: $\sigma^2 \neq 100$

Test statistic: $\chi^2 = \dfrac{(n-1)S^2}{\sigma^2}$

Critical values: $\chi^2_{df,1-\alpha/2}$; $\chi^2_{df,\alpha/2}$

Degrees of freedom: $df = n - 1$

As in previous tests, the χ^2 rejection values are both functions of the chosen type 1 error (α) and the sample size ($df = n - 1$). Critical values are easily obtained from χ^2 tables. For the numerical example the procedure is as follows:

Hypothesis test: H_0 $\sigma^2 = 100$
H_1 $\sigma^2 \neq 100$

Test statistic: $\chi^2 = \dfrac{(n-1)S^2}{\sigma^2} = \dfrac{(15)(225)}{100} = 33.75$

Critical values: $\chi^2_{15,0.975} = 6.262$, $\chi^2_{15,0.025} = 27.488$

Since $\chi^2 = 33.75$ is greater than the critical value $\chi^2_{15,0.025} = 27.488$, one is led to believe that the underlying statistical variance of well production has changed from 100 to something else. Of course, based on the value of S^2, one might conclude that it has increased to somewhere around 225. Although further investigation would be up to decision maker (buyer), it appears that a good course of action could be to obtain more sample data and reexamine the entire situation.

7. HYPOTHESIS TESTING: TWO POPULATION MEANS WITH VARIANCES KNOWN

After a rather lengthy discussion, company management reached the decision that the well should be purchased. Due to optimistic market projections, it was decided that a second well should also be purchased if one could be found that produced 100 more barrels per day on the average than the

single established well. Further testing led management to believe that, for comparison purposes, the first well did indeed produce at a rate of 100 barrels per day. At this point Blow Hard, Inc. presented a new well that it claimed produced at a rate of 100 barrels per day more than the first well. Management again insisted on statistical investigation and in order to provide new, current data, a separate independent evaluation was undertaken. Samples from both wells were obtained to compare daily production rates. Blow Hard, Inc. assured the purchasing cartel that the variance in daily production for the first well was actually 240 and for the second well 276.

Additionally, a sample of production records for $n_1 = 12$ days from well 1 and $n_2 = 18$ days from well 2 provided average daily production of $\bar{x}_1 = 102$ and $\bar{x}_2 = 212$ barrels per day, respectively.

Since the variances of production, $\sigma_1^2 = 240$ and $\sigma_2^2 = 276$, are both assumed known, the proper test statistic is a Z test for the difference in the means of populations. The procedure is as follows:

Assumptions: σ_1^2 and σ_2^2 known
Infinite populations
Normal populations
$\alpha = 0.05$

Hypothesis test: H_0: $\mu_2 - \mu_1 = \delta$
H_1: $\mu_2 - \mu_1 \neq \delta$
$\delta = 100$

Test statistic: $$Z = \frac{(\bar{x}_2 - \bar{x}_1) - (\mu_2 - \mu_1)}{\sqrt{\dfrac{\sigma_1^2}{n_1} + \dfrac{\sigma_2^2}{n_2}}}$$

Critical values: $-Z_{\alpha/2}, Z_{\alpha/2}$

The numerical calculations are as follows:

$$H_0: \quad \mu_2 - \mu_1 = 100$$

$$H_1: \quad \mu_2 - \mu_1 \neq 100$$

$$Z = \frac{(\bar{x}_2 - \bar{x}_1) - (\mu_2 - \mu_1)}{\sqrt{\dfrac{\sigma_1^2}{n_1} + \dfrac{\sigma_2^2}{n_2}}} = \frac{(212 - 102) - 100}{\sqrt{\dfrac{240}{12} + \dfrac{276}{18}}}$$

$$Z = \frac{10}{5.94} = 1.684$$

The critical value for this test is given by $\pm Z_{\alpha/2} = \pm Z_{0.025} = \pm 1.96$. Hence, there is no statistical evidence to support the rejection of the null hypothesis, and the proper decision would be to purchase both wells under the management interpretation of these results. However, the same clever engineer who questioned the first test results again questioned the validity of using σ_1^2 and σ_2^2 in the calculations. The question was then posed, ''Can we perform a similar test without knowing the population variances?'' The statistician responded yes as the same example used to calculate $\bar{x}_1$ and $\bar{x}_2$ could be used to estimate σ_1^2 and σ_2^2 with S_1^2 and S_2^2, respectively.

8. HYPOTHESIS TESTING WITH TWO MEANS: POPULATION VARIANCES UNKNOWN BUT ASSUMED EQUAL

The test statistic, assumptions, and hypothesis test are as follows:

Assumptions: σ_1^2 and σ_2^2 (both are unknown)
Infinite populations
Normal populations
$\alpha = .05$

Hypothesis test: H_0: $\mu_2 - \mu_1 = \delta$
H_1: $\mu_2 - \mu_1 \neq \delta$

Test statistic: $$t = \frac{(\bar{x}_2 - \bar{x}_1) - (\mu_2 - \mu_1)}{\sqrt{(n_1 - 1)\,S_1^2 + (n_2 - 1)\,S_2^2}} \sqrt{\frac{n_1 n_2 (n_1 + n_2 - 2)}{n_1 + n_2}}$$

Critical values: $-t_{\alpha/2,df}, t_{\alpha/2,df}$

Degrees of freedom: $df = n_1 + n_2 - 2$

Using the same set of data, it was found that $S_1^2 = 165$ and $S_2^2 = 453$. The calculations related to this example are as follows:

Hypothesis test: H_0: $\mu_2 - \mu_1 = 100$
H_1: $\mu_2 - \mu_1 \neq 100$

The calculated value of the test statistic is given by

$$t = \frac{(212 - 102) - (100)}{\sqrt{11(165) + 17(453)}} \sqrt{\frac{(12)(18)(28)}{30}} = 1.454$$

The critical values (rejection points) for this test are $t_{0.025,28} = 2.048$ and $-t_{0.025,28} = -2.048$. Since the calculated value of $t = 1.454$ is less than the upper rejection value, there is insufficient evidence to reject the null hypothesis. Finally, one should note that under the assumption that $\sigma_1^2 = \sigma_2^2$, a pooled estimate of the variance is used from a total sample of $N = n_1 + n_2$. As in the single parameter t test, if n_1 and n_2 are both greater than 30, one can simply use the two parameter Z test directly.

Our same clever engineer now observes that these results can be reached only if it can be assumed that the two population variances are equal. At this point, the manager asks our statistician, ''Can we test this assumption?'' The answer is yes, using an F test for equality of variances.

9. HYPOTHESIS TESTING FOR EQUALITY OF TWO POPULATION VARIANCES

The following assumptions, hypothesis test, and test statistic should be observed when conducting an F test:

Assumptions: Normal populations
Infinite populations
Hypothesis test: H_0: $\sigma_1^2 = \sigma_2^2$
H_1: $\sigma_2^2 \neq \sigma_2^2$
Test statistic: $F = S_1^2/S_2^2$
Critical values: $F_{1-\alpha/2,v_1,v_2}$, $F_{\alpha/2,v_1,v_2}$
v_1 = degrees of freedom in numerator
$= n_1 - 1$
v_2 = degrees of freedom in denominator
$= n_2 - 1$

The critical values $F_{\alpha/2,v_1,v_2}$ for commonly used values of α are easily found in statistical tables. Once these values are obtained, the values of $F_{1-\alpha/2,v_1,v_2}$ are easily calculated for the left-hand rejection point according to the following formula

$$F_{1-\alpha/2,v_1,v_2} = (F_{\alpha/2,v_2,v_1})^{-1}$$

For example, if S^2 was calculated using a sample of size $n_1 = 13$ and S_2^2 was calculated using a sample of size $n_2 = 21$; the rejection points for the quantity $F = S_1^2/S^2$ for $\alpha = .10$ would be given by

$$F_{\alpha/2,v_1,v_2} = F_{.05,12,20} = 2.28$$

and

$$F_{1-\alpha/2,v_1,v_2} = (F_{0.05,20,12})^{-1} = (2.54)^{-1} = 0.394$$

In order to illustrate the F test, consider the previous example. Recall that $S_1^2 = 165$, $n_1 = 12$, $S_2^2 = 453$, and $n_2 = 18$.

Assumptions: $\alpha = 0.10$
Normal populations
Hypothesis test: H_0: $\sigma_1^2 = \sigma_2^2$
H_1: $\sigma_1^2 \neq \sigma_2^2$
Test statistic: $F = S_1^2/S_2^2$

Critical values: Using $\alpha = 0.10$, $n_1 = 12$, $n_2 = 18$, we obtain the critical values shown:
$F_{0.05,11,17} = 2.41$
$F_{0.95,11,17} = (F_{0.05,17,11})^{-1} = 0.372$

Calculated F statistic: $F = S_1^2/S_2^2 = 165/453 = 0.364$

Hence, the null hypothesis would be rejected and one is led to assume that $\sigma_1^2 \neq \sigma_2^2$. Our astute manager, still seeking statistical evidence, now inquires as to the availability of a statistical test when $\sigma_1^2 \neq \sigma_2^2$. Fortunately, such a test is available, and is called the t' test.

10. EQUALITY OF TWO MEANS WITH VARIANCES UNKNOWN AND NOT EQUAL

The proper statistical test for this procedure is the t' test and is based on the following:

Assumptions: $\sigma_1^2 \neq \sigma_2^2$
Normal populations
Infinite populations

Hypothesis test: H_0: $\mu_1 - \mu_2 = \delta$
H_1: $\mu_1 - \mu_2 \neq \delta$

Test statistic: $$t' = \frac{(\bar{x}_2 - \bar{x}_1) - \delta}{\sqrt{\dfrac{S_1^2}{n_1} + \dfrac{S_2^2}{n_2}}}$$

Critical values: $t_{\alpha/2,df}$, $t_{1-\alpha/2,df}$

Degrees of freedom: $$df = \left[\frac{\left(\dfrac{S_1^2}{n_1} + \dfrac{S_2^2}{n_2} \right)^2}{\dfrac{\left(\dfrac{S_1^2}{n_1} \right)^2}{n_1 - 1} + \dfrac{\left(\dfrac{S_2^2}{n_2} \right)^2}{n_2 - 1}} \right]$$

For the oil well example, the following calculations illustrate the procedure:

Assumptions: $\sigma_1^2 \neq \sigma_2^2$
Normal populations
Infinite populations
$\alpha = 0.05$

Hypothesis test: H_0: $\mu_2 - \mu_1 = 100$
H_1: $\mu_2 - \mu_1 \neq 100$

Critical values: $t_{\alpha/2,df}$, $-t_{\alpha/2,df}$

Degrees of freedom: $$df = \left[\frac{\left(\dfrac{165}{12} + \dfrac{453}{18} \right)^2}{\dfrac{\left(\dfrac{165}{12} \right)^2}{11} + \dfrac{\left(\dfrac{453}{18} \right)^2}{17}} \right]$$
$$= [27.82] = 27$$

Critical values: $t_{0.025,27} = 2.052$
$-t_{0.025,27} = -2.052$

Calculated t statistic: $$t' = \frac{(212 - 102) - 100}{\sqrt{\dfrac{165}{12} + \dfrac{453}{18}}} = \frac{10}{\sqrt{38.92}}$$
$$t' = 1.603$$

Since $t' = 1.603$ is less than the critical value of $t = 2.052$, statistical evidence does not support rejection of the null hypothesis.

11. CONFIDENCE INTERVAL ESTIMATION

A subject closely related to hypothesis testing is that of confidence intervals. The basic concepts are best understood by considering once again the test statistic:

$$Z = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}}$$

If, as before, we use the notation $Z_{\alpha/2}$ and $-Z_{\alpha/2}$ to indicate the values of the random variable Z where $\alpha/2$ of the area lies to the right of $Z_{\alpha/2}$ and $\alpha/2$ to the left of $-Z_{\alpha/2}$, then the following probability statement must be true:

$$P\left\{-Z_{\alpha/2} \leq \frac{\bar{x} - \mu}{\sigma/\sqrt{n}} \leq Z_{\alpha/2}\right\} = 1 - \alpha$$

If we rearrange the inequality in brackets and solve for the true population parameter μ, then we obtain

$$\bar{x} - Z_{\alpha/2}\,\sigma/\sqrt{n} \leq \mu \leq \bar{x} + Z_{\alpha/2}\,\sigma/\sqrt{n}$$

This last expression says that if we take a random sample of n observation on the random phenomenon of interest and calculate the interval,

$$\bar{x} - Z_{\alpha/2}\,\sigma/\sqrt{n} \quad \text{to} \quad \bar{x} + Z_{\alpha/2}\,\sigma/\sqrt{n}$$

we can be $100(1 - \alpha)\%$ confident that the interval will include the true mean, μ. In other words, if we repeatedly took samples of size n and calculated the interval from each sample, in the long run $100(1 - \alpha)\%$ of the intervals will include μ. The interval is obviously calculated only once, and the resulting values of the endpoints constitute a $100(1 - \alpha)\%$ confidence interval estimate of μ. For a numerical illustration consider once again the first example given in this chapter, that is, the single oil well production problem:

Assumptions: $\alpha = 0.05$
$\sigma^2 = 100$
Critical values: $\pm Z_{\alpha/2} = \pm Z_{0.025} = \pm 1.96$
Input data: $\bar{x} = 105.63$, $n = 16$

The 95% confidence interval for the true (unknown) population mean (μ) is given by

$$105.63 - (1.96)(5/2) \leq \mu \leq 105.63 + (1.96)(5/2)$$

or

$$100.73 \leq \mu \leq 110.53$$

Note that this interval assumes that one knows σ^2, the variance of the random variable. Usually this is not the case, and we have to estimate σ^2 with S^2. If we change the expression for Z accordingly, we get a different distribution. As already mentioned in this chapter,

$$t = \frac{\bar{x} - \mu}{S/\sqrt{n}}$$

is a random variable that follows a t distribution.

Now, utilizing the knowledge that we have provided about the t distribution, we write a probability statement similar to the one for the previous case:

$$P\left\{-t_{\alpha/2} \leq \frac{\bar{x} - \mu}{S/\sqrt{n}} \leq t_{\alpha/2}\right\} = 1 - \alpha$$

and upon rearranging the inequality in the brackets, we obtain

$$\bar{x} - t_{\alpha/2}\, S/\sqrt{n} \le \mu \le \bar{x} + t_{\alpha/2}\, S/\sqrt{n}$$

which is a $100(1 - \alpha)\%$ confidence interval estimate of μ when σ is not known.

It should be pointed out that when the sample size from which S is calculated exceeds 30, it makes little difference whether one uses the normal distribution with $\sigma = S$ or the more precise distribution. The probability distributions of t and Z become the same at $n = \infty$.

If one is interested in calculating a $100(1 - \alpha)\%$ confidence interval for the quantity $\mu_1 - \mu_2$, the difference between the means of two different distributions, one would take a random sample from each distribution, n_1 from the first and n_2 from the second. From these samples one would calculate $\bar{x}_1$ and S_1^2 as well as $\bar{x}_2$ and S_2^2. In a manner identical to that used earlier, the following $100(1 - \alpha)\%$ confidence interval could be constructed:

$$P\left\{(\bar{x}_1 - \bar{x}_2) - Z_{\alpha/2}\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}} \le \mu_1 - \mu_2 \le (\bar{x}_1 - \bar{x}_2) + Z_{\alpha/2}\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}\right\} = 1 - \alpha$$

Clearly, this procedure could be repeated for *any* test statistic previously discussed in this section. The reader is referred to any of a number of engineering statistics texts for developments of χ^2, F, and t' confidence intervals.

12. MAXIMUM-LIKELIHOOD ESTIMATORS

A well-known procedure for finding estimators of unknown parameters is the method of maximum likelihood (Devore 1987; Dougherty 1990; Hogg and Craig 1978). Maximum-likelihood estimators are consistent and have minimum variance but are not always unbiased. A summary of the procedure follows.

Let X be a random variable with density function $f(x,\theta)$, where the parameter θ is unknown. Given a random sample of independent observations $x_1, x_2, \ldots, x_n$, the likelihood function is defined as

$$L(x_1, x_2, \ldots, x_n; \theta) = f(x_1, \theta) f(x_2, \theta), \ldots, f(x_n, \theta)$$

The likelihood function is actually the joint probability density function (for continuous variables) or the joint mass probability function (for discrete variables) of the n random variables. Therefore, the value of θ for which the observed sample would have the highest probability of being extracted, can be found by maximizing the likelihood function over all possible values of the parameter θ. As shown in elementary calculus, this can be achieved by setting the first derivative of the likelihood function with respect to the parameter equal to zero, and then solving for θ:

$$dL/d\theta = 0$$

The solution to this equation can be more efficiently found by considering the logarithm (base e) of the likelihood function, instead of the function itself:

$$d \ln L/d\theta = 0$$

To illustrate the fundamental steps of the procedure followed to obtain a maximum-likelihood estimator, we will consider a random variable X having the exponential density function:

$$f(x; \theta) = \theta e^{-\theta x}$$

where x is nonnegative. For a sample size n the likelihood function for this example is given by

$$L(x_1, x_2, \ldots, x_n) = \Pi_i \theta e^{-\theta x_i}$$

where the index i takes on the values $i = 1, 2, \ldots, n$. Taking the natural logarithm of the preceding likelihood function, we obtain

$$\ln L(x_1, x_2, \ldots, x_n) = n \ln \theta - \theta \sum_i x_i$$

After differentiating $\ln L$ with respect to θ, setting the derivative equal to zero, and solving for θ we obtain the final result shown:

$$\hat{\theta} = n/\sum_i x_i$$

which is equal to the inverse of the sample mean. Now let us assume that the random sample consists of the following values for $n = 5$: 0.9, 1.7, 0.4, 0.3, 2.4. In this case the maximum-likelihood estimator would be equal to $\hat{\theta} = 5/5.7 = 0.88$. It can be verified that $\bar{x}$ and $S^2 = \Sigma_i(x_i - \bar{x})^2/n$ are maximum-likelihood estimators for the mean and variance, respectively, of a normal distribution (Bowker and Lieberman 1972).

13. TESTING FOR EQUALITY OF MEANS AND VARIANCES FOR *K* POPULATIONS

13.1. Testing Means

In the case where there are k populations under consideration, and the test of hypothesis is equality of population means, a different type of procedure is necessitated. This area of statistics is called *experimental design* or *analysis of variance.* This topic is covered in Chapter 85 of this Handbook.

13.2. Testing the Homogeneity of Variances

A problem frequently encountered in applied statistics is that of testing the equality of variances of several normal populations. Let us assume that we have collected a random sample of size n_i from a normal population with mean μ_i and variance σ_i^2, repeating this basic procedure for $i = 1, 2, \ldots, k$. The hypothesis to be tested in this case can be formulated as

$$H_0: \quad \sigma_1^2 = \sigma_2^2 = \ldots = \sigma_k^2$$

As already explained earlier in this chapter, an F test can be used for $k = 2$. However, a different procedure is required for larger values of k.

Among several methodologies for testing this hypothesis, the following three are perhaps the best known (Snedecor and Cochran 1980): (a) Cochran's test, (b) Barlett's test, and (c) Levene's test. Each of these methods is described below.

13.3. Cochran's Test

In the case where there are k populations and the test of equality of population variances is required, the most commonly applied test is the Cochran's test for homogeneity of variances.

Assumptions: Samples are independent
Populations are normal

Test statistic: $$R = \frac{\max\{S_1^2, S_2^2, \ldots, S_k^2\}}{\sum_{i=1}^{k} S_i^2}$$

In the relationship defined for the test statistic R, S_i^2 is the unbiased point estimator of σ_i^2 for $i = 1, 2, \ldots, k$. Each S_i^2 is calculated from a sample of size n. The corresponding test of significance is conducted according to the following rule:

Test rule: Accept the null hypothesis that $\sigma_1^2 = \sigma_2^2 = \ldots = \sigma_k^2$ if $R \leq RC_{\alpha,n,k}$, where $RC_{\alpha,n,k}$ is a critical value for chosen values of the type I error (α), the sample size (n), and the number of populations (k). Tables of critical values for $\alpha = 0.05$ and 0.01, for values of k up to 120 and n up to 145, are given in Bowker and Lieberman (1972).

13.4. Barlett's Test

Barlett developed in 1937 a testing procedure that can be used when all sample sizes n_i for $i = 1, 2, \ldots, k$, are not equal. The procedure is described as follows, where N indicates the total number of observations collected from the k populations:

Assumptions: Samples are independent
Populations are normal

Test statistic: $$M = -\frac{1}{c}\Sigma_i(n_i - 1)\ln\frac{S_i^2}{S^2}$$
$$S^2 = \Sigma_i(n_i - 1)S_i^2/(N - k)$$
$$c = (\Sigma_i\, 1/f_i - 1/f)/3(k - 1) + 1$$

TABLE 4 Sample Calculations for Goodness of Fit Testing

Sample	O_i	e_i	$(O_i - e_i)^2/e_i$
1	18	19.4	0.101
2	17	19.4	0.297
3	19	19.4	0.008
4	17	19.4	0.297
5	18	19.4	0.101
6	20	19.4	0.019
Total	—	—	0.823

Test rule: The statistic M has approximately a χ^2 distribution with $k - 1$ degrees of freedom. This approximation is more appropriate for sample sizes larger than 3. If the observed value of M exceeds the critical value of the chi-square statistic for a level of significance α and $k - 1$ degrees of freedom, the hypothesis is rejected.

13.5. Levene's Test

An approximate test, which is less sensitive to the lack of normality in the data than Barlett's test, was developed by H. Levene in 1960. The procedure assumes that all sample sizes are equal to n. This testing method is described as follows:

Assumptions: Samples are independent
Populations are normal (or approximately normal)

Test statistic: F

Test rule: For Levene's test we conduct an analysis of variance (ANOVA) of the absolute deviations from each sample average. Details on the ANOVA procedure are given in another chapter of this handbook. If the observed mean square ratio exceeds the appropriate critical value of the F statistic, we reject the hypothesis that all variances are equal.

14. OTHER USES OF HYPOTHESIS TESTING

Finally, it should be noted that the concepts of type 1(α) error, type II (β) error, critical values, OC curves, and one/two-tailed hypothesis tests are common to all hypothesis testing. This chapter has illustrated only tests concerning means and variances since they are most common to industrial engineering. One might also find occasions to test hypotheses in quality control applications, proportions, percentages, and in goodness-of-fit testing. These applications, and others, are well documented in a host of applied engineering textbooks.

14.1. Nonparametric Tests

One should note that for most of the hypothesis tests we have discussed, the assumption of normally distributed random variables is required. In actual practice this may not be justified. One has two choices by which this assumption can be ignored. First, one can obtain enough samples to use a Z test (normal tables) rather than a t test (t tables). If the sample is large enough, then the assumption of normality is not required. However, in the case where larger samples cannot be obtained or cost prohibits larger samples, the use of *nonparametric statistical tests* is necessitated (Hollander and Wolfe 1973; Lehmann 1975; Marascuilo and McSweeney 1977).

A nonparametric test is one that requires no assumptions regarding the form or shape of the underlying random variables. Usually, all that is required is knowledge of the scale of measurement used in the experiment and whether the random variable is discrete or continuous. The treatment of nonparametric statistics is well beyond the scope of this introductory section. However, the reader should be aware of its role in hypothesis testing. A test frequently used in industrial organizations is the goodness of fit test, which is described in the next section.

14.2. Goodness of Fit Test

The assumption of normality is not an unusual one in problems dealing with hypothesis testing about means. However, it becomes an important one when testing hypotheses about variances. For this reason, before testing the hypotheses, one should verify if there is sufficient statistical evidence indicating that the population is normal. A statistical method used for this purpose is known as ''test

of goodness of fit.'' Actually, this test can be used to verify if a random sample comes from a specified theoretical distribution (such as the binomical, Poisson, uniform, and normal distributions). The procedure can be described as follows:

1. A theoretical distribution is specified in the null hypothesis H_0.
2. A level of significance α is assumed.
3. An empirical distribution with m frequency classes is formed with the observations in a random sample of size n. In this distribution 0_i is the observed frequency (number of observations) in class i, for $i = 1, 2, \ldots, m$.
4. The test statistic used is defined as

$$G = \sum_{i=1}^{m} (O_i - e_i)^2 / e_i$$

where e_i is the expected frequency for class i according to the theoretical distribution specified in the null hypothesis H_0.

It is shown that this test statistic approximately follows a chi-square distribution, with $m - 1 - r$ degrees of freedom, where r is the number of population parameters estimated by sample statistics.

5. The decision rule is simply stated as follows:

H_0 is rejected if the calculated value of G exceeds the critical value $\chi^2_{m-1-r,\alpha}$

The following numerical example illustrates these steps of the goodness of fit procedure. In a test of industrial welding robots 6 samples of 20 robots each were taken at random. Each robot in the sample operated continuously until it either failed or reached 1000 hr of operation. It is desired to verify if the true proportion of the entire population of robots that can operate over 1000 hr is 0.97.

In other words, we want to test the hypothesis that the number of robots satisfying the specified requirements follows a binomial distribution with parameter equal to 0.97.

The computations for the appropriate chi-square test with $\alpha = 0.05$, $m = 6$, and $r = 0$ are summarized in Table 4, where O_i is the observed number of robots in each sample of 20 operating over 1000 hr, and $e_i = (20)\ (0.97) = 19.4$. Since $G = 0.823$ is significantly smaller than $\chi^2_{5,.05} = 11.1$, we accept the null hypothesis that the true proportion of robots operating continuously over 1000 hr is indeed 0.97.

Other non-parametric techniques frequently used are:

1. The sign test to compare two treatments. We assume that there are several independent pairs of observations on the two treatments. The hypothesis to be tested states that each difference has a probability distribution having mean equal to zero. For each difference the algebraic sign is noted and then the number of times the less frequent sign is considered as the test statistic. There are specialized tables for the critical value of this quantity once a level of significance is chosen.
2. The Wilcox signed-rank test is used to test the hypothesis that observations come from symmetrical populations having a specified common median. For each observation the hypothesized median is substracted and then all differences are ranked from lowest to highest in order of magnitude, omitting the algebraic sign. The test statistic is the sum of ranks for all differences originally having positive signs. The significance test is performed by means of a statistic known as the signed-rank statistic.
3. Run tests to test the hypothesis that observations have been randomly collected from a single population. In this procedure, positive signs are assigned to observations above the median, and negative signs to those below. If the number of runs associated with plus and minus signs is larger or smaller than expected by chance, the hypothesis is rejected. The critical values for the number of runs comes from specialized tables.

There are entire books devoted to nonparametric statistical testing. We have only tried to alert the reader to several common examples.

15. HYPOTHESIS TESTING IN THE ANALYSIS OF DESIGNED EXPERIMENTS

15.1. One-Factor Experiments

The simplest experiment corresponds to one factor and no restrictions on randomization. The statistical model of the experiment response is formulated as

$$Y_{if} = \mu + \tau_j + \varepsilon_{ij}, \qquad j = 1, 2, \ldots, k; \qquad i = 1, 2, \ldots, n_j$$

where μ = common effect, μ_j = population mean for jth treatment, and τ_j = effect of jth treatment, defined as $\mu_j - \mu$. There are two types of completely randomized one-factor models:

Fixed-effect model, H_0: $\tau_j = 0$, for all j
Random-effect model, H_0: $\sigma_\tau^2 = 0$, τ_j distributed as $N(0, \sigma_\tau^2)$

The hypothesis testing is carried out in each case by means of an F-test.

Other one-factor experiments can include one or more restrictions on randomization. Examples of these designs are the randomized block design, the Latin square design, the Graeco-Latin square design, and the Youden square design. In all these design the effect of the restrictions on randomization can be tested using F-tests.

15.2. After-ANOVA Range Tests

The purpose of the range test is to investigate which *pairs* of treatments are significantly different to cause H_0 to be rejected. Consider the sample averages $\overline{Y}_1, \overline{Y}_2, \ldots, \overline{Y}_k$, computed from k random samples drawn from the k populations corresponding to the k levels of the factor. Furthermore, let us assume that $n_j = n$ for all j. These sample averages can be rearranged in increasing order of magnitude, from smallest to largest, as $\overline{Y}_{(1)}, \overline{Y}_{(2)}, \ldots, \overline{Y}_{(k)}$. The hypothesis to be tested is formulated as H_0: $\mu_{(j)} = \mu_{(i)}$, for any two values of i and j such that $j > i$.

The statistic to be used is the *studentized range statistic* as $Q_{rf} = \dfrac{\overline{Y}_{(j)} - \overline{Y}_{(i)}}{(MS_{\text{error}}/n)^{1/2}}$ where $r = j - i + 1$ is number of steps (on an ordered scale) associated with the range defined by the ith and the jth treatments, or more specifically, treatments (i) and (j). There are several versions of the range test, the following ones being the most popular. These tests use specialized tables of critical values of the studentized range statistic:

1. Newman-Keusl range test, $r = 2, \ldots, k$
2. Tukey's Range Procedure, $r = k$
3. Duncan's Multiple Range Test, $r = 2, \ldots, k$

15.3. Factorial Experiments

Instead of assuming that the experimental response can be affected by one factor, a factorial experiment assumes that it is affected by two or more factors, each having an arbitrary number of levels. In a factorial experiment a level combination (one level per factor) is known as an experimental condition. All experimental conditions are sampled, and all observations are collected at random. It is possible to test the significance of each main effect (due to a factor) or and interaction effect (due to a group of factors) by means of an F-test.

15.4. Hypothesis Testing in Regression Analysis

A regression model is a *fitting* relationship that allows the estimation of a dependent variable or experimental response for given settings of a specified group of independent variables or factors. The parameters of the model are known as regression coefficients. Typical tests include the following:

1. Testing the hypothesis that a regression coefficient is equal to zero. The test statistic is the t-statistic.
2. Testing for linearity of regression using an analysis-of-variance technique. The test statistic is the F-statistic.

CHAPTER 87
Regression and Correlation*

1. INTRODUCTION TO REGRESSION ANALYSIS

Regression analysis is:

A technique for measuring and explaining (reducing unexplained) variability in a system
An aid to understanding interrelationships in complex systems
A process for building a useful model of a system
A method for improving forecasting or prediction
A mechanism for focusing on important phenomena
A system for evaluating theories or beliefs
An aid in formulating new theory
A method for obtaining better control of variation
A technique for estimating equation parameters

Regression modeling involves practical problems, problems of judgment, and a good deal of art. This chapter is not intended to be a recipe book or a catalog of rules of thumb. It is intended to introduce the reader to some basic principles involved in statistical modeling while at once exposing the dangers. In this spirit, this chapter discusses many of the difficulties that may be encountered in attempting to model systems displaying statistical variation. It is intended to serve as a good blend of theoretical structure, philosophical outlook, and practical guidance.

1.1. General Linear Model

An equation of the form

$$Y_i = \sum_{j=0}^{P} b_j X_{ij} \tag{1}$$

is sometimes referred to as the general linear model. In this equation, Y is a variable whose behavior is of interest. It was once common to refer to Y as the dependent variable, taken from the mathematical concept of a function. In statistical modeling, most authors have come to call Y the response variable. This is the convention adopted here.

In Eq. (1), Y is a linear additive function of the X variables, which are P in number, $P \geq 1$. These X's were formerly often referred to as independent variables, again using the mathematical sense. They are now sometimes called regressors or explanatory variables but are more commonly called predictors (although prediction may not be the goal). The subscript j denotes which predictor. In this general form of Eq. (1), there is a dummy variable, $X_0 = 1$ (''dummy'' because it does not vary), which is not counted as a predictor but is included in the summation. Its coefficient, b_0 is the constant term or intercept. It is in units of Y. The other regression coefficients, b_j ($j = 1$ to P), are the slopes (multipliers of their respective predictors) and are expressed in units of Y/X_j. These b_j's are unknowns that are to be determined from the analysis. The values obtained are estimates of the ''true'' unknown coefficients, β_j. Geometrically, Eq. (1) represents a line, a plane, or a hyperplane in $P + 1$ dimensional space. This process is known as multiple linear regression (MLR) analysis. The subscript, i, denotes the series of observations in the sample going from 1 to n. Each observation provides a value for each of the variables—the predictors and the response—for each of the units or individuals in the sample. The unit of observation may be, for example, a day, a person, an automobile, a task, an event, or a batch.

The X's can, of course, represent quite complicated transformations of originally observed bits of information about each unit. Reciprocals, powers, and logs are examples, and so are ratios or products of two (or more) predictors. It is astounding to witness how often this linear additive equation form gives a very good representation of the underlying physics that relate the response to the predictors.* That the variability, that is, the behavior, of so many things in nature can be so well described (predicted) by this simple summation process is truly profound.

1.2. Utility and Dangers

Variation is the essence of statistical modeling. Variation is the problem. Information is contained in variation. In fact, without variation, there is no information. The activities of industrial engineers virtually always involve dealing with variation in multiple-variable systems. The goal may be to evaluate or explain previous events or to predict or control future events. Modeling a response variable in such systems is usually complex and difficult. Part of the difficulty arises in most cases because the data come from the existing system as it normally operates rather than being generated during a designed experiment. Such data might be called nonexperimental or clinical.

Some major difficulties found in dealing with nonexperimental data result from the interrelationships naturally present among the predictors. The unwanted intercorrelations are avoided in controlled experiments by keeping the predictors uncorrelated with (orthogonal to) each other. This difficulty in dealing with clinical data is shared with many other disciplines. In fact, the exception is the analyst who is able to operate with ''scientific'' laboratory technique.

The great power of MLR lies in its ability to relate simultaneously the many intercorrelated predictors to the response—to deal with nonexperimental data. Herein also lies the main source of danger. Successful modeling of nonexperimental data is a tricky business. But not all the dangers are associated with the natural intercorrelations of nonexperiments. The variety of ways in which the analyst can encounter trouble is nearly as great as the variety of problem situations. Perhaps no other technique suffers more misuse and abuse than regression analysis. Because of this, much criticism of the general technique is offered by those who apparently do not understand its power or proper use and who misrepresent it. The dangers can be avoided or treated if they are recognized and understood. Much of the balance of this chapter deals directly or indirectly with establishing appropriate safeguards.

1.3. Importance of Goals

Multiple linear regression should not be a process that follows a fixed, predetermined path or employs an established ritual for achieving a goal. That is because different goals require different analytic behavior. As illustrated by this chapter's opening list, regression goals are various. Before attempting to model a system, it is important to know what the model is supposed to do. What is the question the analysis is supposed to answer?
