The ability to create prototypes of properties conforming totally with the series properties quickly at low cost has become increasingly important because the engineering lead time dictated by the market has drastically diminished. Apart from the classical methods of generating prototypes, such as cutting and casting, generic manufacturing techniques are increasingly being used. In cutting or casting, tools, dies, or fixtures are required for fabricating the prototype, whereas prototyping by means of generic techniques is based on joining incremental solid elements. Thus, complex components can immediately be made from computerized data, such as from a CAD file, without comprehensive rework being necessary.

In contrast to cutting technologies, where the material is removed, in generic manufacturing techniques (rapid prototyping), the material is supplied layer by layer or is transformed from a liquid or powder into a solid state (state transition) by means of a laser beam. The most essential rapid prototyping techniques (also called solid freeform manufacturing or desktop manufacturing) are:

- Stereolithography (STL)
- Fused deposition modeling (FDM)
- Laminated object manufacturing (LOM)
- Selective laser sintering (SLS)

These techniques are able to process both metals and non metals. As a result of intensive research, disadvantages of these techniques, such as high fabrication time, insufficient accuracy, and high cost, have been widely eliminated. Today, maximum part dimension is limited to less than 1000 mm.

Near-net-shape processes for prototyping and small-batch production by means of rapid prototyping techniques can be characterised by the process chains listed in Figure 28.

In principle, prototypes or patterns that in turn enable the manufacture of prototypes and small batches in combination with casting processes can be produced directly by means of rapid prototyping techniques. Rapid prototyping can also be applied to manufacturing primary shaping and forming tools to be used for the fabrication of prototypes.

4. NEAR-NET-SHAPE PRODUCTION: DEVELOPMENT TRENDS

Near-net-shape production will continue to expand in the directions of application described in this chapter. An important question for decision making is how far the objectives of industrial production and common global interests in reduction of costs, shorter process chains and production cycles, and environment- and resource-protecting manufacturing can be made compatible one with each other and whether these objectives are feasible in an optimal manner. Besides chipless shaping, for near-net-shape process planning, the state of the art of both chipless shaping and cutting techniques has to be paid attention to because a reasonable interface between chipless and cutting manufacturing is highly significant. Thus, for instance, in the case of a nns strategy consisting of chipless shaping, heat treatment, and grinding, in future, grinding could be substituted for to a greater extent by

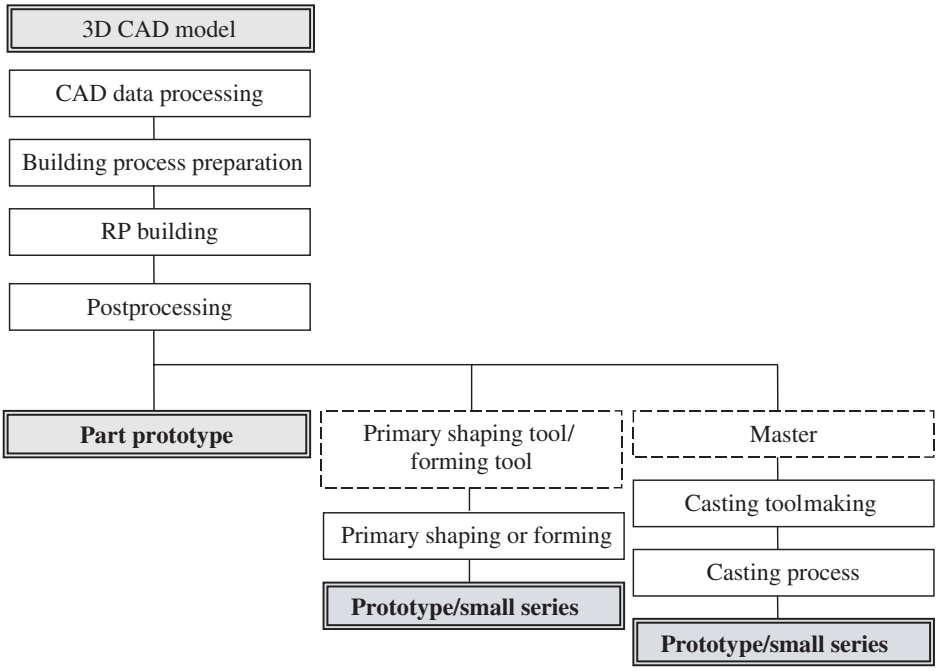

Figure 28 Near-Net-Shape Process Chain for Producing Prototypes and Small Series by Means of Generic Manufacturing Techniques (RP techniques).

machining of hard materials (turning, milling). As a result, reduced manufacturing times and lower energy consumption could be achievable and the requirements for chipless shaping could possibly be diminished. In cases where the final contours can be economically produced to the required accuracy using chipless shaping, the change to net-shape manufacturing is a useful development goal.

CHAPTER 19

Environmental Engineering: Regulation and Compliance

ROBERT B. JACKO
TIMOTHY M. C. LABRECHE
Purdue University

1. OVERVIEW

This chapter provides industrial, plant, and facilities engineers with a brief overview of some environmental engineering considerations in process and manufacturing operations. This information will be helpful to engineers who are designing or operating new industrial processes or involved in the modification of existing facilities.

2. ENVIRONMENTAL LAW

2.1. Overview

Regulations designed to protect and improve the environment play a substantial role in the design and management of industrial processes. These regulations should be incorporated into the initial

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

process design and not as an afterthought. This section provides a brief overview of some major environmental laws and organizations.

2.2. Environmental Protection Act

Prior to the Environmental Protection Act, environmental regulations were divided along media lines (air, water, earth). In 1970, President Nixon submitted to Congress a proposal to consolidate many of the environmental duties previously administered by agencies including the Federal Water Quality Administration, the National Air Pollution Control Administration, the Bureau of Solid Waste Management, the Bureau of Water Hygiene, the Bureau of Radiological Health; certain functions with respect to pesticides carried out by the Food and Drug Administration; certain functions of the Council on Environmental Quality; certain functions of the Atomic Energy Commission and the Federal Radiation Council; and certain functions of the Agricultural Research Service (Nixon 1970a).

President Nixon recognized that some pollutants exist in all forms of media and that successful administration of pollution-control measures required the cooperation of many of the federal bureaus and councils. A more effective management method would be to recognize pollutants, observe their transport and transformation through each medium, observe how they interact with other pollutants, note the total presence of the pollutant and its effect on living and nonliving entities, and determine the most efficient mitigation process. This multimedia approach required the creation of a new agency to assume the duties of many existing agencies, thus eliminating potential miscommunication and interdepartmental biases that could hinder environmental protection. Thus, the President recommended the establishment of an integrated federal agency that ultimately came to be called the Environmental Protection Agency (EPA).

The roles and functions of the EPA were to develop and enforce national standards for the protection of the environment; research the effects of pollutants, their concentrations in the environment, and ways of controlling them; provide funding for research and technical assistance to institutions for pollutant research, and propose new legislation to the President for protection of the environment (Nixon 1970b).

In the words of William D. Ruckelshaus, EPA's first administrator,

> EPA is an independent agency. It has no obligation to promote agriculture or commerce; only the critical obligation to protect and enhance the environment. It does not have a narrow charter to deal with only one aspect of a deteriorating environment; rather it has a broad responsibility for research, standard-setting, monitoring and enforcement with regard to five environmental hazards; air and water pollution, solid waste disposal, radiation, and pesticides. EPA represents a coordinated approach to each of these problems, guaranteeing that as we deal with one difficulty we do not aggravate others. (Ruckelshaus 1970)

The EPA has instituted numerous programs and made significant changes in the way businesses operate in the United States. A brief summary of the EPA's milestones (Table 1) shows the many ways the course of business and the environment have been altered since the agency's inception in 1970.

2.3. Clean Air Acts

2.3.1. Air Pollution Control Concept in the United States

Air pollution control in the United States is said to be a ''command and control'' regulatory approach to achieving clean air. That is, regulations are promulgated at the federal level and via state implementation plans (SIPs) at the state level and air pollution sources are required (''commanded'') to comply. These regulations have been set up to operate on the air we breathe as well as the sources that produce the air pollution. The regulations established to control the air we breathe are called National Ambient Air Quality Standards (NAAQSs). Their engineering units are concentration based, that is, micrograms-pollutant per cubic meter of air or parts per million by volume (ppm_v). These NAAQSs also have a time-averaging period associated with them such as a 24-hour or an annual averaging period. Additionally, the NAAQSs have primary standards and secondary standards associated with them. The primary standards are for the protection of human health and the secondary standards are for the protection of things. For example, the primary 24-hour average standard for sulfur dioxide is 365 $\mu g/m^3$ and the secondary standard is a 3-hour average standard of 1300 $\mu g/m^3$. The 365 $\mu g/m^3$ standard protects humans from a high-level short-term dose of sulfur dioxide, while the 1300 $\mu g/m^3$ standard could protect a melon crop from a high-level, short-term dose of sulfur dioxide. Table 2 contains the NAAQSs for the six EPA criteria pollutants.

The other thrust of the air pollution regulations applies to the sources of the pollutants. These regulations are emission standards called the New Source Performance Standards (NSPSs). These sources include stationary sources such as power plants and industrial manufacturing operations as well as mobile sources such as automobiles, trucks, and aircraft. These regulations are mass flow rate-based, that is, grams-pollutant/hr or lb-pollutant/10^6 Btu. Pollutant-specific emission limits were

TABLE 1 Timeline of Environmental Regulation

Year	Event
1970	Agency established December 2, 1970. Clean Air Act Amendments set national health-based standards.
1971	Bans use of lead-containing interior paints in residences built or renovated by the federal government.
1972	Bans the use of DDT. Commits to a national network of sewage-treatment plants to provide fishable and swimmable waterways. United States and Canada sign the International Great Lakes Water Quality Agreement.
1973	Phase-out of lead-containing gasoline begins. First industrial wastewater discharge permit issued.
1974	New Safe Water Drinking Act establishes health-based standards for water treatment. Standards limiting industrial water pollution established.
1975	Fuel economy standards allow consumers to include fuel efficiency in their purchasing considerations. EPA emission standards require catalytic convertors to be installed on automobiles.
1976	Resource Conservation and Recovery Act established to track hazardous waste from "cradle to grave." Toxic Substance Control Act developed to reduce public exposure to pollutants that pose an unreasonable threat of injury. Included in this act is a ban on polychlorinated biphenyls (PCBs).
1977	Air quality in pristine natural areas is addressed by Clean Air Act Amendments.
1978	Chlorofluorocarbons (CFCs) banned for use as a propellant in most aerosol cans. CFCs are implicated as ozone-depleting chemicals.
1979	Dioxin is indicated as a carcinogen. Two herbicides containing dioxins banned.
1980	Under the new Superfund law a nationwide program for the remediation of hazardous waste sites is established.
1984	Amendments to the RCRA Resource Conservation and Recovery Act enacted to prevent contamination from leaking underground storage tanks (USTs) and landfills and require treatment of hazardous wastes prior to land disposal.
1985	EPA joins international movement calling for worldwide ban on the use of Ozone-Depleting Chemicals (ODCs).
1986	A major toxic chemical release in Bhopal, India, stimulates the passage of the Community Right to Know Law, requiring that individuals in possession of chemicals maintain records of location, quantity, and use and any releases of chemicals. The EPA is charged with maintaining a public database of these records. The EPA begins assisting communities in the development of Emergency Response Plans.
1987	The United States and 23 other countries sign the Montreal Protocol to phase out the production of chloroflourocarbons (CFCs).
1989	The new Toxic Releases Inventory provides the public with the location and character of toxic releases in the United States.
1990	EPA assesses $15 billion fine to a single company for PCB contamination at 89 sites. New Clean Air Act Amendments require states to demonstrate continuing progress toward meeting national air quaility standards.
1992	EPA bans dumping of sewage sludge into oceans and coastal waters.
1993	EPA's Common Sense Initiative announces a shift from pollutant-by-pollutant regulation to industry-by-industry regulation.
1994	Grants initiated to revitalize inner-city brownfields. Clinton administration nearly doubles the list of toxic chemicals that must be reported under the Community Right to Know laws.
1995	Two thirds of metropolitan areas that did not meet air quality standards in 1990 now do meet them, including San Francisco and Detroit. EPA requires municipal incinerators to reduce toxic emissions by 90%.

From EPA OCEPA 1995.

assigned to both existing sources and proposed new sources under the 1970 Clean Air Act. The existing-source emission limits were less stringent than the new source limits because new sources had the opportunity to incorporate the latest technology into the process or manufacturing design.

To determine what emission standards apply to your new proposed operation, refer to the Code of Federal Regulations (CFR) part 60, which is also Title I under the 1990 Clean Air Act Amend-

TABLE 2 National Ambient Air Quality Standards

Criteria Pollutant	Averaging Period	Primary NAAQS $\mu g/m^3$	Secondary NAAQS $\mu g/m^3$
PM-10	Annual	50	50
	24 hour	150	150
Sulfur dioxide (SO_2)	Annual	80	
	24 hour	365	
	3 hour		1,300
Nitrogen dioxide (NO_2)	Annual	100	100
Ozone	1 hour	235	235
Carbon monoxide (CO)	8 hour	10,000	
Lead	Quarterly	1.5	1.5

ments. The NSPSs are shown for a large number of industrial classifications. Look for your type of industry and you will find the applicable new source emission standards.

2.3.2. The 1970 Clean Air Act

Control of outdoor air pollution in the United States certainly grew its regulatory roots prior to the 1970 Clean Air Act. However, for the practicing industrial engineer, the passage of the 1970 Clean Air Act is the real beginning of contemporary outdoor or ambient air pollution control. Therefore, this section will focus on those aspects of the Clean Air Act of 1970 and the subsequent amendments of 1977 and 1990 that will be most meaningful to the industrial engineer.

The 1970 Clean Air Act was the first piece of air pollution legislation in this country that had any real teeth. The establishment of an autonomous federal agency that ultimately came to be known as the EPA was a result of the 1970 Act. Prior to this time, matters relating to outdoor air pollution had their home in the United States Public Health Service. Furthermore, it is historically interesting to note that the EPA went through a number of name changes in the months following promulgation of the 1970 Clean Air Act before the current name was chosen.

2.3.3. The 1977 Clean Air Act Amendments

The 1970 Clean Air Act had a deadline of July 1, 1975, by which all counties in the United States were to comply with concentration-based standards (NAAQSs) for specified air pollutants. However, when July 1, 1975, arrived, very few counties in industrialized sections of the country met the standards. As a consequence, much debate took place in Congress and the result was the promulgation of the 1977 Clean Air Act Amendments. In some quarters, this amendment was viewed as the strongest piece of land use legislation the United States had ever seen. This legislation required each state to evaluate the air sheds in each of its counties and designate the counties as either attainment or non-attainment counties for specified air pollutants, according to whether the counties attained the National Ambient Air Quality Standards (NAAQS) for those pollutants. If the state had insufficient data, the county was designated unclassified. A company in a non-attainment county had to take certain steps to obtain an air permit. This ultimately added a significant increased cost to a manufactured product or the end result of a process.

Under this same amendment were provisions for ''protecting and enhancing'' the nation's air resources. These provisions, called the Prevention of Significant Deterioration (PSD) standards, prevented an industrial plant from locating in a pristine air shed and polluting that air shed up to the stated ambient air standard. They classified each state's counties as to their economic status and air polluting potential and established ceilings and increments more stringent than the ambient air standards promulgated under the 1970 Clean Air Act. No longer could a company relocate to a clean air region for the purpose of polluting up to the ambient air standard. In essence, the playing field was now level.

2.3.4. The 1990 Clean Air Act Amendments

Due to a number of shortcomings in the existing air pollution regulations at the end of the 1980s, the Clean Air Act was again amended in 1990. The 1990 Clean Air Amendments contain a number of provisions, or titles, as they are referred to. These titles, some of which carry over existing regulations from the 1970 and 1977 amendments, are listed below, along with a general statement of what they cover:

- Title I:
  - National Ambient Air Quality Standards (NAAQS), Clean Air Act sections 105–110 and 160–193; 40 CFR Parts 50–53, 55, 58, 65, 81, and 93. Establishes concentration-based ambient air standards.
  - New Source Performance Standards (NSPSs), Clean Air Act section 111; 40 CFR Part 60. Establishes emission limitations for specific categories of new or modified sources.
- Title II:
  Mobile Sources Program, Clean Air Act sections 202–250; 40 CFR Parts 80 and 85–88. Covers tailpipe emission standards for aircraft, autos, and trucks, including fuel and fuel additives, clean fuel vehicles, and Hazardous Air Pollutants (HAPS) research for mobile sources.
- Title III:
  National Emission Standards for Hazardous Air Pollutants (NESHAPS), Clean Air Act section 112; 40 CFR Parts 61, 63, and 68. Includes an accidental release program, list of HAPS and sources, residual risk standards, and maximum achievable control technology (MACT) standards.
- Title IV:
  Acid Rain Program, Clean Air Act sections 401–416; 40 CFR Parts 72–78. Acid deposition control via sulfur and nitrogen oxide controls on coal- and oil-burning electric utility boilers.
- Title V:
  Operating permit program, Clean Air Act sections 501–507; 40 CFR Parts 70–71. Requires operating permits on all sources covered under the Clean Air Act.
- Title VI:
  Stratospheric Ozone Protection Program, Clean Air Act sections 601–618; 40 CFR Part 82. Contains a list of ozone-depleting substances. Bans certain freons, requires freon recycling.
- Title VII:
  Enforcement Provisions, Clean Air Act sections 113, 114, 303, 304, 306, and 307. Compliance certification, enhanced monitoring, record keeping and reporting, $25,000/day fines, civil and criminal penalties, entry/inspector provisions, citizen lawsuits and awards up to $10,000, and public access to records.

2.4. Worker Right to Know

The Hazard Communication Standard of the Occupational Safety and Health Act requires that all employees be informed of the hazards associated with the chemicals they are exposed to or could be accidentally exposed to. In addition to chemical hazards, OSHA requires workers be trained to recognize many other types of hazards. Hazards may include chemical, explosion and fire, oxygen deficiency (confined spaces, for example), ionizing radiation, biological hazards, safety hazards, electrical hazards, heat stress, cold exposure, and noise. Compliance with Worker Right to Know laws general requires a written plan that explains how the Hazard Communication Standard will be executed. The only operations where a written Hazard Communication Plan is not required are handling facilities where workers contact only sealed chemical containers and laboratories. These facilities must still provide hazard training to employees, retain the original labeling on the shipping containers, and make material safety data sheets (MSDSs) available to all employees. In general, no employees should be working with any chemical or equipment that they are not familiar with. OSHA statistics indicate that failure to comply with the Hazard Communication Standard is its most cited area (OSHA 1999b).

The Hazard Communication Standard requires each facility to conduct a hazard assessment for each chemical in the workplace, maintain an inventory of chemicals in the workplace, retain MSDSs for each chemical in the workplace, properly label each chemical according to a uniform labeling policy, train each employee to understand the MSDSs, product labels, and Hazard Communication Standard, and develop a written program that explains how the Hazard Communication Standard is to be implemented at the facility.

2.5. Resource Conservation and Recovery Act

The Resource Conservation and Recovery Act (RCRA) of 1976, an amendment to the Solid Waste Disposal Act of 1965, and the Hazardous and Solid Waste Amendments of 1984, which expanded RCRA, were enacted to protect human health and environment, reduce waste and energy, and reduce or eliminate hazardous waste as rapidly as possible. Three programs addressing hazardous waste, solid waste, and underground storage tanks are included in RCRA.

Subtitle C requires the tracking of hazardous waste from ''cradle to grave,'' which refers to the requirement that hazardous waste be documented by a paper trail from the generator to final disposal,

whether it be incineration, treatment, landfill, or some combination of processes. Subtitle D establishes criteria for state solid waste management plans. Funding and technical assistance are also provided for adding recycling and source reduction implementation and research. Subtitle I presents rules for the control and reduction of pollution from underground storage tanks (USTs).

A RCRA hazardous waste is any substance that meets physical characteristics such as ignitibility, corrosivity, and reactivity or may be one of 500 specific hazardous wastes. They may be in any physical form: liquid, semisolid, or solid. Generators and transporters of hazardous waste must have federally assigned identification numbers and abide by the regulations pertinent to their wastes. Individuals treating and disposing of hazardous wastes must meet stringent operating guidelines and be permitted for treatment and disposal technologies employed. RCRA hazardous waste regulations apply to any commercial, federal, state, or local entity that creates, handles, or transports hazardous waste.

A RCRA solid waste is any sludge, garbage, or waste product from a water treatment plant, wastewater treatment plant, or air pollution control facility. It also includes any discarded material from industrial, mining, commercial, agricultural, and community activities in contained gaseous, liquid, sludge, or solid form. RCRA solid waste regulations pertain to owners and operators of municipal solid waste landfills (EPA OSW 1999a,b).

2.6. Hazardous Materials Transportation Act

The Hazardous Materials Transportation Act of 1975 (HMTA) and the 1990 Hazardous Materials Uniform Safety Act were promulgated to protect the public from risks associated with the movement of potentially dangerous materials on roads, in the air, and on waterways. They do not pertain to the movement of materials within a facility. Anyone who transports or causes to be transported a hazardous material is subject to these regulations, as is anyone associated with the production or modification of containers for hazardous materials. Enforcement of the HMTA is delegated to the Federal Highway Administration, Federal Railway Administration, Federal Aviation Administration, and Research and Special Programs Administration (for enforcement of packaging rules).

The regulations of the HMTA are divided into four general areas: procedures and policies, labeling and hazard communication, packaging requirements, and operational rules. Proper labeling and hazard communication requires the use of the standard hazard codes, labeling, shipping papers, and placarding. Hazardous materials must be packaged in containers compatible with the material being shipped and be of sufficient strength to prevent leaks and spills during normal transport (DOE OEPA 1996).

2.7. Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) and Superfund Amendments and Reauthorization Act (SARA)

The Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) was enacted in 1980 to provided a federal Superfund for the cleanup of abandoned hazardous waste sites. Funding for the Superfund was provided through fines levied or lawsuits won against potentially responsible parties (PRPs). PRPs are those individuals having operated at or been affiliated with the hazardous waste site. Affiliation is not limited to having physically been on the site operating a process intrinsic to the hazardous waste creation. Affiliation can include those parties that have provided transportation to the site or customers of the operation at the hazardous waste site that transferred raw materials to the site for processing (EPA OPA 1999a).

The Superfund Amendment Reauthorization Act (SARA) of 1986 continued cleanup authority under CERCLA and added enforcement authority to CERCLA (EPA OPA 1999b). Within SARA was the Emergency Planning and Community Right-to-Know Act (EPCRA) also know as SARA Title III. EPCRA established the framework for communities to be prepared for chemical emergencies that could occur at industrial sites in their neighborhoods. EPCRA required states to form State Emergency Response Commissions (SERCs). SERCs divided the states into Emergency Planning Districts and formed Local Emergency Planning Committees. These committees consist of a broad range of community leaders, emergency officials, and health professionals (EPA OPA 1999c). SERCs use information acquired through Section 313 of SARA, the Toxic Releases Inventory (TRI), to make emergency planning decisions. Chemical producers and consumers must annually report releases of chemicals during the year to the EPA. These releases may occur continuously throughout the year or in a single large burst and include releases that a company is legally permitted to make, such as through air permits. Included in these reports are the type and volume of chemical released, the media the chemical was released to, how much of the chemical was transported from the site for recycling or disposal, how the chemical was treated for disposal, the efficiency of treatment, and pollution prevention and recycling activities at the reporting company. Reporting is required if a facility employs 10 or more full-time employees and (EPA OPPT 1999):

Manufactures or processes over 25,000 lb (total) of approximately 600 designated chemicals or 28 chemical categories
OR
Manfactures or processes over 10,000 lb of an individual designated chemical or chemical category
OR
Is among facilities grouped into Standard Industrial Classification Codes 20–39
OR
Is a federal facility ordered to report by August 1995 President Clinton executive decree.

2.8. Clean Water Act (CWA)

The 1972 Water Pollution Control Act, the 1977 Clean Water Act amendments, and the 1987 reauthorization of the Clean Water Act provide the basis for regulation of discharges to receiving water bodies in the United States. Both point sources, discharges such as a pipe or channel, and nonpoint sources, such as runoff from fields or parking lots, are regulated by the Clean Water Act. Both direct dischargers and dischargers to a municipal treatment works must obtain National Pollution Discharge Elimination System (NPDES) permits that govern the character of pollutants in waste streams and mandatory control technologies (EPA OW 1998).

The objectives of the CWA were to achieve fishable and swimmable waters and to eliminate the discharge of pollutants into navigable waterways. To achieve these goals, industries were required to meet performance standards for pollutant emissions, states were charged with developing criteria for their waterways as well as programs to protect them, funding was provided for the construction of public wastewater treatment plants and other technologies to mitigate discharges, and development was regulated via a permit process to protect wetlands and minimize impacts on water resources.

In addition to the permit requirements of the 1977 amendments, the 1987 amendments permitted citizen suits that allowed any individual to bring a legal suit against any party believed to be in conflict with the provisions of the CWA. Citizen suits were also permitted against any party responsible for the enforcement and administration of the CWA that was believed derelict in its responsibilities. This expanded the responsibility of clean water enforcement to include the public as well as government bodies.

3. COMPLYING WITH ENVIRONMENTAL LAWS

3.1. Overview

In the early 1970s, compliance with environmental regulations by most industrial entities was not a top priority. Indeed, some major corporations brought lawsuits and attempted to lessen the impact of the regulations. However, in the intervening years, continued research on the human health effects of water and air pollution has resulted in a heightened awareness of their deleterious impact on the human system. As a result, compliance with environmental regulations is now the norm rather than the exception for the industrial sector. An example of this is the tightening of the ambient air quality standards for particulates over the years. In the early years, dustfall buckets (measured particulates >40 μm diameter) and total suspended particulates (measured particulates <40 μm diameter) were targeted by the NAAQS. Human health research indicated that finer particulates (10 μm and less), which penetrate deeper into the human respiratory system, are more harmful than the larger particulate matter. Fine particulate matter has a much greater surface area-to-volume ratio relative to larger particulate matter, which allows the fine particulate matter to adsorb and absorb hazardous volatile substances and carry them deep into the human lung. This ''piggyback'' effect of fine particulate matter with hazardous air pollutants has resulted in the diameter of the particulate standard being reduced over the years. The current NAAQS standard for fine particulate matter is PM-10, which means particles less than or equal to 10 μm. But a PM-2.5 NAAQS standard has been proposed by the EPA and awaits promulgation at the time of writing.

3.2. Permits

3.2.1. Air Permits

One of the provisions of the 1970 Clean Air Act initiated the requirement for air pollution sources to obtain a permit for construction of the source and a permit to operate it. The construction permit application must be completed prior to the initiation of construction of any air pollution source. Failure to do so could result in a $25,000 per day fine. In some states, initiation of construction was interpreted as issuance of a purchase order for a piece of equipment; in others, groundbreaking for the new construction. Therefore, to ensure compliance with the air permit requirement, this author suggests that completion of the air permit be given first priority in any project involving air emissions into the atmosphere. The best practice is to have the state-approved permit in hand before beginning construction. Most states have their permit forms on the Internet, and a hard copy can be downloaded. Alternatively, the permit forms can be filled out electronically and submitted.

Recently, many states have offered the option of allowing an air pollution source to begin construction prior to obtaining the approved construction permit. However, the required paperwork is not trivial, and it may still be easier to fill out the permit form unless extenuating circumstances demand that construction begin before the approved permit is in hand. The caveat is the state could disapprove the construction (which the company has already begun) if, after reviewing the permit application, the state disagrees with the engineering approach taken to control the air pollution.

3.2.2. Water Permits

Any person discharging a pollutant from a point source must have a National Pollution Discharge Elimination System (NPDES) permit. This applies to persons discharging both to a public treatment works or directly to a receiving water body. These permits will limit the type of pollutants that can be discharged and state the type of monitoring and reporting requirements and other provisions to prevent damage to the receiving body or treatment facility. In most states, the state department of environmental quality is responsible for issuing permits. In states that have not received approval to issue NPDES permits, you should contact the regional EPA office.

Wastewater permits that regulate the discharge of many pollutants can be broken down into the general categories of conventional, toxic, and nonconventional. Conventional pollutants are those contained in typical sanitary waste such as human waste, sink disposal waste, and bathwater. Conventional wastes include fecal coliform and oil and grease. Fecal coliform is present in the digestive tracts of mammals, and its presence is commonly used as a surrogate to detect the presence of pathogenic organisms. Oils and greases such as waxes and hydrocarbons can produce sludges that are difficult and thus costly to treat. Toxic pollutants are typically subdivided into organics and metals. Organic toxins include herbicides, pesticides, polychlorinated biphenyls, and dioxins. Nonconventional pollutants include nutrients such as phosphorus and nitrogen, both of which can contribute to algal blooms in receiving waters.

The EPA maintains many databases of environmental regulatory data. Among these is the Permit Compliance System (PCS) database http://www.epa.gov/enviro/html/ pcs/pcs_query_java.html. This database provides many of the details governing a facility's wastewater discharges. Specific limitations typically depend on the classification and flow of the stream to which a facility is discharging. Surface waters are classified as to their intended use (recreation, water supply, fishing, etc.), and then the relevant conditions to support those uses must be maintained. Discharge limitations are then set so that pollution will not exceed these criteria.

Total suspended solids, pH, temperature, flow, and oils and grease are typical measures that must be reported. In the case of a secondary sewage treatment, the minimum standards for BOD_5, suspended solids, and pH over a 30-day averaging period are 30 mg/L, 30 mg/L, and 6–9 pH, respectively. In practice, these limits will be more stringent, and in many cases there will be separate conditions for summer and winter conditions as well as case-by-case limitations.

4. ESTIMATING PLANT-WIDE EMISSIONS

4.1. Overview

A part of the overall air pollution requirements is an annual emissions inventory to be submitted to the state in which the source resides. This inventory identifies and quantifies all significant atmospheric discharges from the respective industrial plant. Most states now have this inventory in electronic form and require submission electronically. The Indiana Department of Environmental Management uses a commercial package called i-STEPS, which is an automated tool for storing, reporting, and managing air emissions data. i-STEPS facilitates data compilation for pollution management and reporting emissions data to government agencies.*

4.2. Estimating Methods

4.2.1. Mass Balance

From an engineering viewpoint, the most direct way to estimate pollution emissions from an industrial plant is by mass balance. The concept is ''mass in = mass out''—that is, everything the purchasing department buys and is delivered to the plant must somehow leave the plant, whether within the manufactured product; as solid waste to a landfill; as air emissions either through a stack or vent; or as liquid waste either to an on-site treatment plant or to the sewer and the municipal wastewater treatment plant.

*i-STEPs Environmental Software is available from Pacific Environmental Services, Inc., 5001 South Miami Boulevard; Suite 300, P.O. Box 12077, Research Triangle Park, NC 27709-2077, www.i-steps.com.

The mass balance approach, however, does not necessarily yield exceptional accuracy. Accuracy is a function of understanding the way in which a particular feed stock or raw material is used and how much of it is released to the atmosphere or perhaps transformed in the process. The mass balance approach would probably be used if measured parameters were not available, such as stack emission data and wastewater effluent data.

An example where a mass balance approach would yield inaccurate emissions to the atmosphere would be an industrial resin coating line. This process uses an organic carrier solvent, such as ethanol, which is volatized from the resin solids in a drying oven. The vapors (volatile organic compounds [VOCs]) are then incinerated. The ethanol can be transformed into other organic compounds in the incinerator. The total mass of applied carrier solvent (ethanol) would not be accounted for in the incinerator exhaust gas stream due to its transformation into other organic compounds.

4.2.2. Emission Factors

Emission factors are unique to the air pollution field. They are usually based on stack emission test data for a specific process and are presented as a ratio of two flow rates. The numerator is the mass flow rate of the air pollutant parameter and the denominator is the flow rate of the process or manufactured product. In the spraypainting of automobiles, for example, the carrier solvent in the paint (VOC) is released to the atmosphere as the paint is dried in an oven. A stack test quantifies the amount of paint VOC released during the painting of some quantity of autos. The resulting VOC emission factor would be lb-VOC/hr divided by # of autos/hr painted. Note that the hour (hr) unit cancels and the emission factor is expressed as lb-VOC/# autos.

The U.S. Environmental Protection Agency publishes AP-42, a well-known compilation of air pollutant emission factors that contains emission factors for many industrial process and manufacturing operations (EPA AP-42 1995).

To illustrate the use of an emission factor, let us turn to the fish-canning industry. From AP-42, section 9.13.1-7 and Table 3, entitled ''Uncontrolled Emission Factors for Fish Canning and Byproduct Manufacture,'' emission factors are shown for particulate emissions, trimethylamine (fish odor), and hydrogen sulfide (rotten egg odor). Emissions from the fish scrap cookers for both fresh fish and stale fish are shown. Notice that the particulate emissions are negligible for the cookers. Trimethylamine (fish odor) has an emission factor of 0.3 lb-trimethylamine/ton of fresh fish cooked. If we are cooking 5 tons of fresh fish/hr, then the uncontrolled fish odor emission to the atmosphere is 0.3 lb-trimethylamine/ton of fresh fish cooked $\times$ 5 tons of fresh fish/hr = 1.5 lb-trimethylamine/hr. Since the chemical responsible for typical fish odor is trimethylamine, 1.5 lb/hr will certainly be noticed by residents' noses downwind of the plant.

For hydrogen sulfide (H_2S, rotten egg odor), the uncontrolled atmospheric emission factor is 0.01 lb-H_2S/ton of fresh fish cooked. If we are cooking 5 tons of fresh fish/hr, then the uncontrolled H_2S odor to the atmosphere is 0.01 lb-H_2S/ton cooked fresh fish $\times$ 5 tons cooked fresh fish/hr = 0.05 lb-H_2S/hr. It is interesting to note that if the cooking fish is stale, not fresh, the trimethylamine emission is over 10 times higher. Similarly, for the hydrogen sulfide, if the fish is stale, the hydrogen sulfide emission is 20 times greater. With the concept of the emission factor, uncontrolled emissions

TABLE 3 Uncontrolled Emission Factors for Fish Canning and Byproduct Manufacture[a]

EMISSION FACTOR RATING: C						
	Particulate		Trimethylamine [$(CH_3)_3N$]		Hydrogen Sulfide (H_2S)	
Process	kg/Mg	lb/ton	kg/Mg	lb/ton	kg/Mg	lb/ton
Cookers, canning (SCC 3-02-012-04)	Neg	Neg	–[c]	–[c]	–[c]	–[c]
Cookers, scrap						
Fresh fish (SCC 3-02-012-01)	Neg	Neg	0.15[c]	0.3[c]	0.005[c]	0.01[c]
Stale fish (SCC 3-02-012-02)	Neg	Neg	1.75[c]	3.5[c]	0.10[c]	0.2[c]
Steam tube dryer (SCC 3-02-012-05)	2.5	5	–[b]	–[b]	–[b]	–[b]
Direct-fired dryer (SCC 3-02-012-06)	4	8	–[b]	–[b]	–[b]	–[b]

[a] From Prokop (1992). Factors are in terms of raw fish processed. SCC = Source Classification Code. Neg = negligible.
[b] Emissions suspected, but data are not available for quantification.
[c] Summer (1963).

from fish cookers can be estimated without costly measurements. The expected accuracy of the estimate is alluded to at the top of the table as having an emission factor rating of C. This means that on a scale of A to E, with A being the relative best estimate, the C rating is mediocre. It is important to refer to the references associated with each emission factor so a value judgment can be made when using the factor.

5. TOTAL-ENCLOSURE CONCEPT FOR FUGITIVE AIR EMISSIONS

Most if not all industrial operations result in the generation of air pollution emissions to the atmosphere. The emissions may be partially captured by a ventilation hood and be taken to an oven, incinerator, baghouse, or other air pollution control device. The air pollutants not captured by the ventilation hood escape into the workplace and are referred to as fugitive emissions. These fugitive emissions eventually reach the outdoor atmosphere either through roof ventilation fans, open windows, doors, or exfiltration through the walls of the building structure itself. Ultimately, all the air pollutants generated by the industrial process reach the outdoor atmosphere. For this reason, the EPA and state regulatory agencies require an industrial process that generates air pollutants to be mass-balance tested prior to approving an air pollution operating permit. In other words, either the fugitive emissions must be quantified and figured in the overall destruction and removal efficiency (DRE) of the air pollution controls or it must be demonstrated that the ventilation hood(s) form a 100% permanent total enclosure of the pollutants. With 100% permanent total enclosure demonstrated, it is known that all air pollutants generated by the process are captured by the hood(s) or enclosure and taken to the ''as-designed'' air pollution control device, whether it be an integral oven, external incinerator, baghouse filter, electrostatic precipitator, or some other tail gas cleanup device.

5.1. Criteria for 100% Permanent Total Enclosure of Air Pollutants

The United States Environmental Protection Agency has developed a criterion for determining 100% total enclosure for an industrial operation, EPA method 204 (EPA M204 2000). It requires that a series of criteria be met in order for a ventilation hooded industrial process to qualify as 100% permanent total enclosure. These criteria are:

1. The total area of all natural draft openings (NDOs) must be less than 5% of the total surface area of the enclosure.
2. The pollutant source must be at least four equivalent diameters away from any natural draft opening (NDO). The equivalent diameter is defined as $2(LW)/(L + W)$, where L is the length of the slot and W is the width.
3. The static pressure just inside each of the NDOs must be no less than a negative pressure of 0.007 in. of water.
4. The direction of flow must be into the enclosure as demonstrated by a device such as a smoke tube.

6. GREEN ENGINEERING

While many of the earlier legislative efforts were oriented toward ''end-of-pipe'' technologies, where pollution was captured and disposed of after being generated, the focus is now shifting to legislation that favors recycling, reuse, and reduction of waste generation. The problem with end-of-pipe technologies is that frequently the waste product, while no longer in the air, water, or earth, must still be disposed of in some manner. If a product is designed from its inception with the goal of reducing or eliminating waste not only during the production phase but also for its total life cycle, from product delivery to salvage, resources can be greatly conserved. This philosophy results in the design concept of ''cradle to reincarnation'' rather than ''cradle to grave'' because no well-designed product is ever disposed of—it is recycled (Graedel et al. 1995). Many phrases have been adopted into the expanding lexicon of green engineering. Total cost assessment (TCA), design for the environment (DFE), design for recycling (DFR), and life-cycle assessment are some of the many phrases that summarize efforts to look beyond the traditional design scope when designing and manufacturing a product.

6.1. Product Design

There is a threshold for the economic feasibility of recycling. If only a small portion of a product is recyclable or if great effort is required to extract the recyclable materials, then it may not be economically feasible to recycle a product. If, however, the product is designed to be largely recyclable and is designed in a manner that facilitates easy removal, then reuse and recycling will be economically reasonable. Consider the personal computer. The rapid rate at which computing power has expanded has resulted in a proportionate turnover in computers in the workplace. However, no such improvement in computer externals has accompanied that in computer internals, so last year's computer case could in theory hold this year's computer processor, motherboard, memory, and so on.

TABLE 4 Elements of Designing for Recycling

Element	Rationale
Minimize variety of materials	Multiple material types require more separation processes, thus increasing the cost of recycling.
Minimize use of toxics	Toxins must be removed prior to product reuse or recycling.
Do not plate plastics with metal.	Reduces the value of scrap plastic, may prevent recycling.
Place parts that are frequently improved and parts that frequently fail in accessible areas and make them easy to replace.	Designing a product that can be upgraded and easily repaired reduces the need for totally new products.
Use molded labels and details rather than adhesive labels or printed inks.	Adhesive labels and printed text must be removed prior to recycling.
Avoid polymeric materials with similar specific gravity to plastics used in product.	Gravimetric separation methods may be complicated or negated if incompatible materials with similar specific gravities are used.

The computer is an excellent example where design for recycling could be applied. While the elements in Table 4 are based on computer and electronic production, similar principles can be adopted for other processes.

6.2. Process Design

In many cases, recycling of process material streams is both environmentally and economically sound. While efforts to minimize the use of hazardous air pollutants (HAPs) such as toluene and xylene continue, some applications, such as cleanup solvents for spraypainting, still require the properties of HAP-containing solvents. However, HAP emissions can be minimized through the use of solvent-recovery systems. These systems reduce emissions to the atmosphere, thus reducing permitting costs, and they also reduce purchasing costs by reducing the total volume of virgin cleanup solvent necessary.

In other cases, waste minimization technologies can result in enhanced product quality. A continuous process data analysis system is one example. Rather than operator experience and intuition guiding when to cycle a process bath, computer analysis can be instituted to monitor key indicators of the process solution and automatically adjust the bath conditions. The result can be longer bath life, a more consistent product, and greater product engineer confidence (Dickinson 1995).

6.3. Total Cost Analysis

In some cases, an immediate benefit from a process change or recycling effort will not be evident. Any number of organizational, legal, or economic obstacles could distort the analysis of process options. Alternative budgeting and accounting methods are necessary to provide a more holistic perception of the process alternatives. Total cost analysis assesses the potential profitability of a green engineering proposal with several key differences from traditional methods. These differences are (White and Savage 1999):

1. Included in the inventory of costs, savings, and revenues are compliance training, testing, liability, and product and corporate image.
2. Rather than being lumped into overhead accounts, specific costs and savings are placed into process and product lines.
3. Longer time horizons are used to capture longer-term benefits.
4. Profitability indicators capable of incorporating the time value of money, long-term costs, and savings are used.

CHAPTER 20
Collaborative Manufacturing

JOSÉ A. CERONI
Catholic University of Valparaíso—Chile

SHIMON Y. NOF
Purdue University

1. INTRODUCTION

Manufacturing is a constantly evolving field that is strongly driven by optimization of the resources it employs. Manufacturing optimization is showing a shift from processes to businesses in a more systemic analysis of its nature and role in the whole picture. Current economic conditions throughout the world, characterized by the steady growth of local economies, have contributed a good deal to this trend.

This chapter briefly presents the economic principles that drive collaborative manufacturing and the conditions supporting what manufacturing has become nowadays. Later sections of this chapter examine the coordination feature that enables collaborative manufacturing within and between enterprises and discuss several cases that demonstrate the ideas of collaborative manufacturing.

2. MANUFACTURING IN THE CONTEXT OF THE GLOBAL ECONOMY: WHY COLLABORATE?

To understand collaborative manufacturing in its actual form, we must refer to the current world economic conditions that motivate collaborative manufacturing. Many scholars recognize that we are

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

living in the knowledge revolution. As Sahlman (1999) notes, the new economy markedly drives out inefficiency, forces intelligent business process reengineering, and gives knowledgeable customers more than they want. This new economy, based primarily on knowledge and strong entrepreneurship, is focused on productivity and is profoundly changing the role of distribution. Distribution and logistics must be more efficient, cheaper, and more responsive to the consumer. This trend of new, competitive, and open channels between businesses is geographically dispersed, involving highly technical and rational parties in allocating effort and resources to the most qualified suppliers (even if they are part of another company).

One of the key aspects leading the way in this new knowledge-based world economy is science. There is a well-documented link between science and economic growth (Adams 1990), with a very important intermediate step, technology. Science enables a country to grow stronger economically and become the ideal base for entrepreneurs to start new ventures that will ultimately raise productivity to unprecedented levels. This science–growth relationship could lead to the erroneous conclusion that this new economy model will prevail only in these geographic areas favoring high-level academic and applied R&D and, even more, only to those institutions performing leading research. However, as Stephan (1996) points out, there is a spillover effect that transfers the knowledge generated by the research, and this knowledge eventually reaches underdeveloped areas (in the form of new plants, shops, etc.). This observation is confirmed by Rodriguez-Clare (1996), who examined an early study of collaborative manufacturing, multinational companies and their link to economic development. According to the Rodriguez-Clare model, the multinational company can create a positive or negative linkage effect upon any local economy. A positive linkage effect, for example, is created by forcing local companies to attain higher standards in productivity and quality. An example is the electronics industry in Singapore (Lim and Fong 1982). A negative linkage effect is created by forcing local companies to lower their operational standards. An example is the Lockheed Aircraft plant in Marietta, Georgia (Jacobs 1985).

We are therefore facing a new world of business, business of increasing returns for knowledge-based industries (Arthur 1996). The behavior of increasing-returns products is contrary to the classical economic equilibrium, in which the larger the return of a product or service, the more companies will be encouraged to enter the business or start producing the product or service, diminishing the return. Increasing-returns products or services, on the other hand, present positive feedback behavior, creating instability in the market, business, or industry. Increasing returns put companies on the leading edge further ahead of the companies trailing behind in R&D of new products and technologies. A classical example of this new type of business is the DOS operating system developed by Microsoft, which had a lock-in with the distribution of the IBM PC as the most popular computer platform. This lock-in made it possible for Microsoft to spread its costs over a large number of users to obtain unforeseen margins. The world of new business is one of pure adaptation and limits the use of traditional optimization methods, for which the rules are not even defined.

Reality presents us with a highly complex scenario: manufacturing companies unable to perform R&D seem doomed to disappear. One of the few alternatives left to manufacturing companies is to go downstream (Wise and Baumgartner 1999). This forces companies to rethink their strategy on downstream services (customer support) and view them as a profitable activity instead of a trick to generate sales. Under this new strategy, companies must look at the value chain through the customer's eyes to detect opportunities downstream. This affects how performance is measured in the business. Product margin is becoming more restricted to the manufacturing operation, disregarding services related to the functioning and maintenance of the product throughout its life. A feature that is increasing over time in actual markets is for businesses to give products at a very low price or even for free and wait for compensation in service to the customer or during the maintenance stage of the product's life cycle (e.g., cellphones, cable television markets in the United States). According to Wise and Baumgartner (1999), manufacturing companies follow one of four downstream business models (Table 1).

The ability to respond quickly and effectively to satisfy customers is what is making the difference among manufacturing companies nowadays. Technological advances such as Internet are facilitating ways for companies to meet their customer needs. As DeVor et al. (1997) point out, agile manufacturing focuses on enhancing competitiveness through cooperation and use of information technology to form virtual enterprises. Virtual enterprises are constructed by partners from different companies collaborating with each other to design and manufacture high-quality, customized products (Chen et al. 1999). Agile manufacturing practices are based on five principles (Yusuf and Sarhadi 1999):

- Identifying and creating value
- Enabling the flow-of-value stream
- Allowing customers to pull value uninterrupted
- Responding to unpredictable change
- Forming tactical and virtual partnerships

TABLE 1 Downstream Business Models

Downstream Model	Characteristics	Example
Embedded services	Embedding of downstream services into the product, freeing the customer of the need to perform them.	Honeywell and its airplane information management system (AIMS)
Comprehensive services	Coverage of downstream services not possible to embed into the product, for example financial services.	General Electric in the locomotive market
Integrated solutions	Combination of products and services for addressing customer needs	Nokia's, array of products for mobile telephony
Distribution control	Moving forward over the value chain to gain control over distribution activities	Coca-Cola and its worldwide distribution network

Agile manufacturing can be considered as the integration of technologies, people, and business processes.

3. COORDINATION AND CONTROL REQUIREMENTS IN COLLABORATIVE MANUFACTURING

An increasing number of companies are basing their future on global markets. The globalization of resources and customers has shifted the focus of industrial companies from resource control to customer-focused control over time (Hirsch et al. 1995). Competitiveness among companies nowadays relies on an increasingly important aspect: time-to-market. Pursuing shorter time-to-market requires faster development cycles for the products and close attention to geographically distributed markets. To cope effectively in this demanding environment, companies frequently engage in collaborative partner relationships, which allow them to focus and coordinate their efforts and improve their position in the market. The collaboration results in an integrated, aligned enterprise composed of several independent companies. Partner companies combine their capabilities in generating new business opportunities to which they could not have access otherwise.

Manufacturing covers a wide range of activities, from early design stages to product recycling. Companies often need to use collaboration between designers, technicians, departments, and divisions, or with other companies, to attain the desired results in an efficient way. As the complexity of the problems in manufacturing increases, concurrent engineering teams have resulted the most effective manner in which to tackle them. Concurrent engineering teams are composed of individuals with a wide range of expertise in different areas. This diversity of knowledge and viewpoints provides the team with the view of the manufacturing process necessary for addressing the complexity of the problems. However, to make from concurrent engineering something more than never-ending meetings, support to coordinate and control the collaboration must be provided. Coordination allows the cooperative operation of two or more systems in the pursuit of complementary objectives, as well as the efficient utilization of resources and allocation of efforts in the organization(s). Much of the support for the collaboration effort required by concurrent engineering comes from the information technologies and the great advances they have experienced in the last decade. Computer-supported collaborative work (CSCW) has been implemented largely for engineering collaboration (Phillips 1998), along with more sophisticated techniques, such as conflict resolution in distributed design (Nof and Huang 1998). The advantages from using information technologies in collaborative manufacturing arise from two sources. First, more information can be acquired from teams having computer support. Second, information availability makes possible a more objective analysis of the problem in a system view. However, some drawbacks should be kept in mind: information overload, lack of knowledge integration, cooperation, and coordination among team members may render the utilization of CSCW tools completely counterproductive.

A key aspect that any CSCW tool must consider is reconfiguration. Adaptation to constantly changing conditions in the manufacturing industry must be attained through tools providing the enterprise with reconfiguration capabilities. Numerous methods for quick reconfiguration of collaborative engineering initiatives have been developed so far. Methods range from those based on integration requirements of the activities being performed (Khanna and Nof 1994; Witzerman and Nof

1995; and Kim and Nof 1997, among others) to those based on concepts taken from disciplines other than manufacturing (Khanna et al. 1998; Ceroni 1999; and Ceroni and Nof 1999, who extend the parallel computing problem to manufacturing modeling).

4. FRAMEWORK FOR COLLABORATIVE MANUFACTURING

The distributed environment presents new challenges for the design, management, and operational functions in organizations. Integrated approaches for designing and managing modern companies have become mandatory in the modern enterprise. Historically, management has relied on a well-established hierarchy, but, the need for collaboration in modern organizations overshadows the hierarchy and imposes networks of interaction among tasks, departments, companies, and so on. As a result of this interaction, three issues arise that make the integration problem critical: variability, culture, and conflicts. Variability represents all possible results and procedures for performing the tasks in the distributed organizations. Variability is inherently present in the processes, but distribution enhances its effects. Cultural aspects such as language, traditions, and working habits impose additional requirements for the integration process of distributed organizations. Lastly, conflicts may represent an important obstacle to the integration process. Conflicts here can be considered as the tendency to organize based on local optimizations in a dual local/global environment. Collaborative relationships, such as user–supplier, are likely to present conflicts when considered within a distributed environment. Communication of essential data and decisions plays a crucial role in allowing organizations to operate cooperatively. Communication must take place in a timely basis in order to be an effective integration facilitator and allow organizations to minimize their coordination efforts and costs.

The organizational distributed environment has the following characteristics (Hirsch et al. 1995):

- Cooperation of different (independent) enterprises
- Shifting of project responsibilities during the product life cycle
- Different conditions, heterogeneity, autonomy, and independence of the participants' hardware and software environments

With these characteristics, the following series of requirements for the integration of distributed organizations can be established as the guidelines for the integration process:

- Support of geographically distributed systems and applications in a multisite production environment and, in special cases, the support of site-oriented temporal manufacturing
- Consideration of heterogeneity of systems ontology, software, and hardware platforms and networks
- Integration of autonomous systems within different enterprises (or enterprise domains) with unique responsibilities at different sites
- Provision of mechanisms for business process management to coordinate the information flow within the entire integrated environment

Among further efforts to construct a framework for collaborative manufacturing is Nofs' taxonomy of integration (Figure 1 and Table 2), which classifies collaboration in four types: mandatory, optional, concurrent, and resource sharing. Each of these collaboration types is found along a human–machine integration level and an interaction level (interface, group decision support system, or computer-supported collaborative work).

5. FACILITATING AND IMPLEMENTING COLLABORATION IN MANUFACTURING

During the design stages of the product, *codesign* (Eberts and Nof 1995) refers to integrated systems implemented using both hardware and software components. Computer-supported collaborative work (CSCW) allows the integration and collaboration of specialists in an environment where work and codesigns in manufacturing are essential. The collaboration is accomplished by integrating CAD and database applications, providing alphanumeric and graphical representations for the system's users. Codesign protocols were established for concurrency control, error recovery, transaction management, and information exchange (Figure 2). The CSCW tool supports the following design steps:

- Conceptual discussion of the design project
- High-level conceptual design
- Testing and evaluation of models
- Documentation

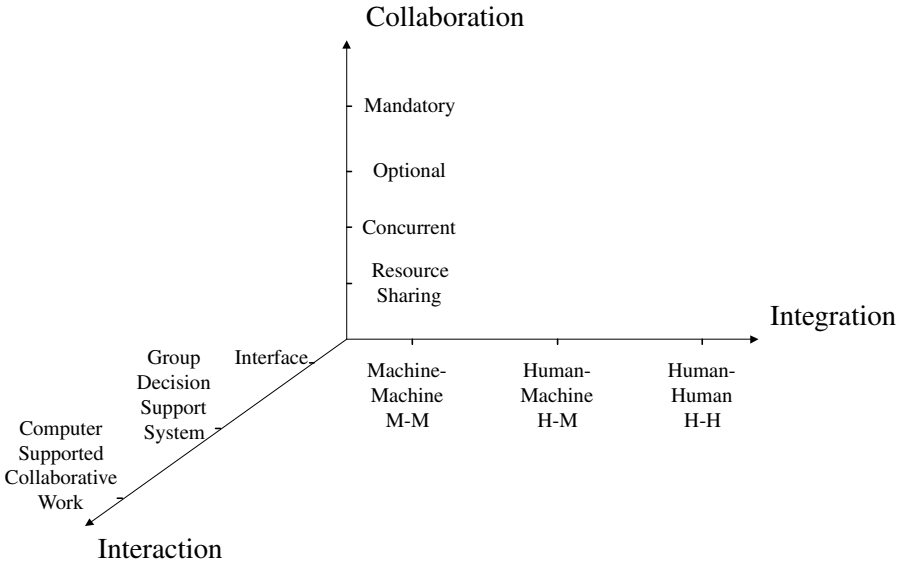

Figure 1 Integration Taxonomy. (From Nof 1994)

When deciding on its operation, every manufacturing enterprise accounts for the following transaction costs (Busalacchi 1999):

1. Searching for a supplier or consumer
2. Finding out about the nature of the product
3. Negotiating the terms for the product
4. Making a decision on suppliers and vendors
5. Policing the product to ensure quality, quantity, etc.
6. Enforcing compliance with the agreement

Traditionally, enterprises grew until they could afford to internalize the transaction costs of those products they were interested in. However, the transaction costs now have been greatly affected by

TABLE 2 Example of Collaboration Types for Integration Problems

	Integration Problem	Example		Collaboration Type
1	Processing of task without splitting and with sequential processing	Concept design followed by physical design	H-H	Mandatory, sequential
2	Processing of task with splitting and parallel processing	Multi-robot assembly	M-M	Mandatory, parallel
3	Processing of task without splitting. Very specific operation	Single human planner (particular)	H-M	Optional, similar processors
4	Processing of task without splitting. General task	Single human planner (out of a team)	H-M	Optional, different processors types
5	Processing of task can have splitting	Engineering team design	H-H	Concurrent
6	Resource allocation	Job-machine assignment	M-M	Competitive
7	Machine substitution	Database backups	M-M	Cooperative

From Nof 1994.

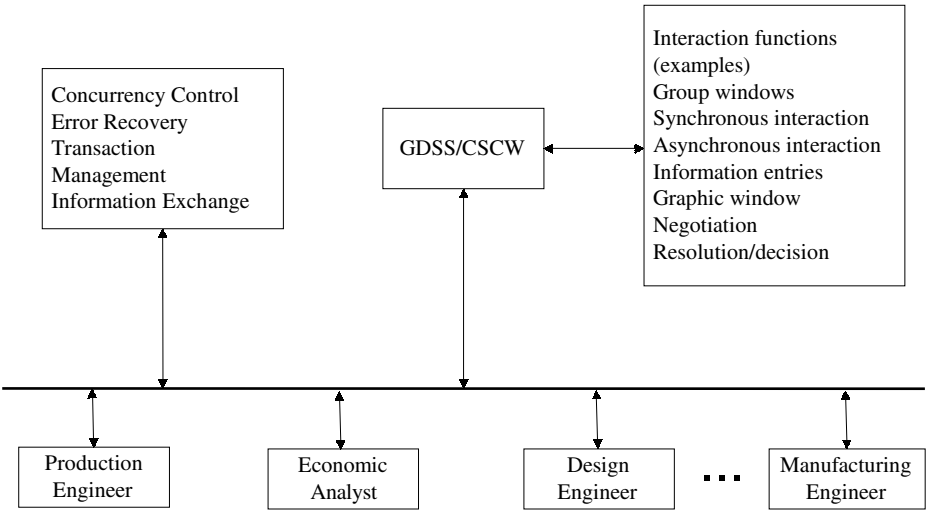

Figure 2 Codesign Computer-Supported Collaborative Work (CSCW) System.

technologies such electronic data interchange (EDI) and the Internet, which are shifting the way of doing business, moving the transaction costs to:

1. Coordination between potential suppliers or consumers
2. Rapid access to information about products
3. Means for rapid negotiation of terms between suppliers and consumers
4. Access to evaluative criteria for suppliers and consumers
5. Mechanisms for ensuring the quality and quantity of products
6. Mechanisms for enforcing compliance with the agreement

6. MOVING FROM FACILITATING TO ENABLING COLLABORATION: E-WORK IN THE MANUFACTURING ENVIRONMENT

We define e-work as collaborative, computer-supported activities and communication-supported operations in highly distributed organizations of humans and/or robots or autonomous systems, and we investigate fundamental design principles for their effectiveness (Nof 2000a,b). The premise is that without effective e-work, the potential of emerging and promising electronic work activities, such as virtual manufacturing and e-commerce, cannot be fully realized. Two major ingredients for future effectiveness are autonomous agents and active protocols. Their role is to enable efficient information exchanges at the application level and administer tasks to ensure smooth, efficient interaction, collaboration, and communication to augment the natural human abilities.

In an analogy to massively parallel computing and network computing, the teamwork integration evaluator (TIE) has been developed (Nof and Huang 1998). TIE is a parallel simulator of distributed, networked teams of operators (human, robots, agents). Three versions of TIE have been implemented with the message-passing interface (on Intel's Paragon, on a network of workstations, and currently on Silicon Graphics' Origin 2000):

1. TIE/design (Figure 3) to model integration of distributed designers or engineering systems (Khanna et al. 1998)
2. TIE/agent (Figure 4) to analyze the viability of distributed, agent-based manufacturing enterprises (Huang and Nof, 1999)
3. TIE/protocol (Figure 5) to model and evaluate the performance of different task administration active protocols, such as in integrated assembly-and-test networks (Williams and Nof 1995)

7. CASE EXAMPLES

Global markets are increasingly demanding that organizations collaborate and coordinate efforts for coping with distributed customers, operations, and suppliers. An important aspect of the collaboration

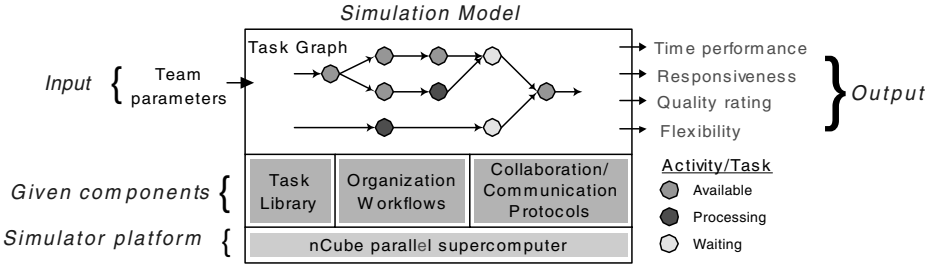

Figure 3 Integration of Distributed Designers with TIE/Design.

process of distributed, often remote organizations is the coordination cost. The coordination equipment and operating costs limit the benefit attainable from collaboration. In certain cases, this cost can render the interaction among distributed organizations nonprofitable. Previous research investigated a distributed manufacturing case, operating under a job-shop model with two distributed collaborating centers, one for sales and one for production. A new model incorporating the communication cost of coordination has been developed (Ceroni et al. 1999) yields the net reward of the total system, determining the profitability of the coordination. Two alternative coordination modes are examined: (1) distributed coordination by the two centers and (2) centralized coordination by a third party. The results indicate that distributed and centralized coordination modes are comparable up to a certain limit; over this limit, distributed coordination is always preferred.

7.1. Coordination Cost in Collaboration

In a modern CIM environment, collaboration among distributed organizations has gained importance as companies try to cope with distributed customers, operations, and suppliers (Papastavrou and Nof 1992; Wei and Zhongjun 1992). The distributed environment constrains companies from attaining operational efficiency (Nof 1994). Furthermore, coordination becomes critical as operations face real-time requirements (Kelling et al. 1995). The role of coordination is demonstrated by analyzing the coordination problem of sales and production centers under a job-shop operation (Matsui 1982, 1988). Optimality of the centers' cooperative operation and suboptimality of their noncooperative operation have been demonstrated for known demand, neglecting the coordination cost (Matsui et al. 1996). We introduce the coordination cost when the demand rate is unknown and present one model of the coordination with communication cost. The communication cost is modeled by a message-passing protocol with fixed data exchange, with cost depending on the number of negotiation iterations for reaching the system's optimal operating conditions. The model developed here is based on the research in Matsui et al. (1996) and the research developed on the integration of parallel distributed production systems by the Production Robotics and Integration Software for Manufacturing Group (PRISM) at Purdue University (Ceroni 1996; Ceroni and Nof 1999).

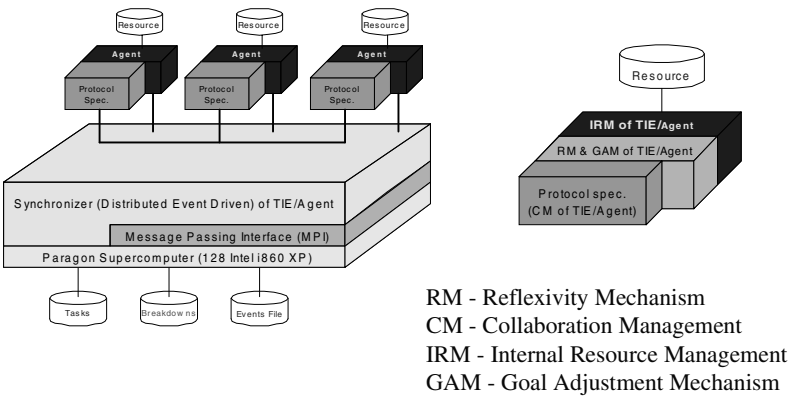

Figure 4 Viability Analysis of Distributed Agent-Based Enterprises with TIE/Agent.

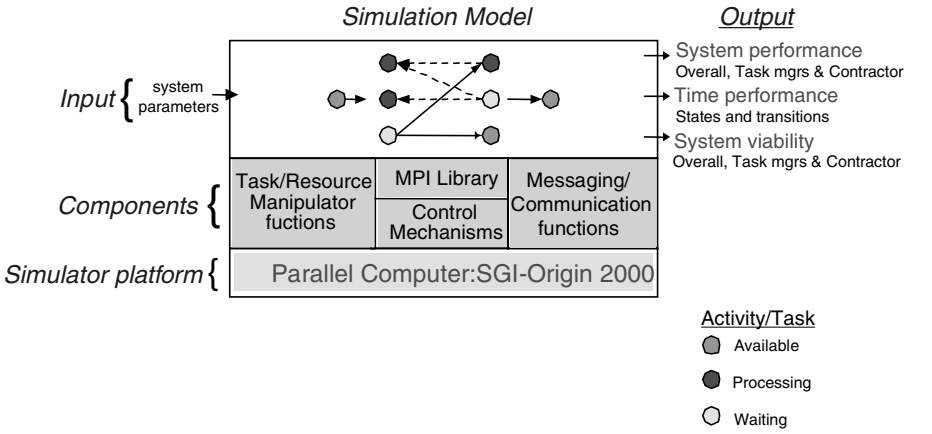

Figure 5 Modeling and Evaluation of Task Administration Protocols with TIE/Protocol.

7.1.1. Job-Shop Model

The job-shop model consists of two distributed centers (Figure 6). Job orders arrive at the sales center and are selected by their marginal profit (Matsui 1985). The production center processes the job orders, minimizing its operating cost (Tijms 1977).

7.1.2. Coordination Cost

Two basic coordination configurations are analyzed: (1) a distributed coordination model in which an optimization module at either of the two centers coordinates the optimization process (Figure 7) and (2) a centralized coordination model where a module apart from both centers optimizes all operational parameters (Figure 8).

The distributed model requires the centers to exchange data in parallel with the optimization module. The centralized model provides an independent optimization module.

Coordination cost is determined by evaluating (1) the communication overhead per data transmission and (2) the transmission frequency over the optimization period. This method follows the concepts for integration of parallel servers developed in Ceroni and Nof (1999). Communication overhead is evaluated based on the message-passing protocol for transmitting data from a sender to one or more receptors (Lin and Prassana 1995). The parameters of this model are exchange rate of messages from/to the communication channel (t_d), transmission startup time (t_s), data packing/unpacking time from/to the channel (t_l), and number of senders/receptors (p).

7.1.3. Results

The coordination of distributed sales and production centers is modeled for investigating the benefits of different coordination modes. Results show that the coordination cost and the number of negotiation iterations should be considered in the decision on how to operate the system. The numerical results indicate:

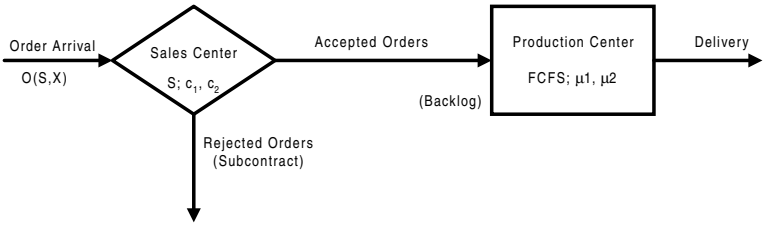

Figure 6 Distributed Job-shop Production System.

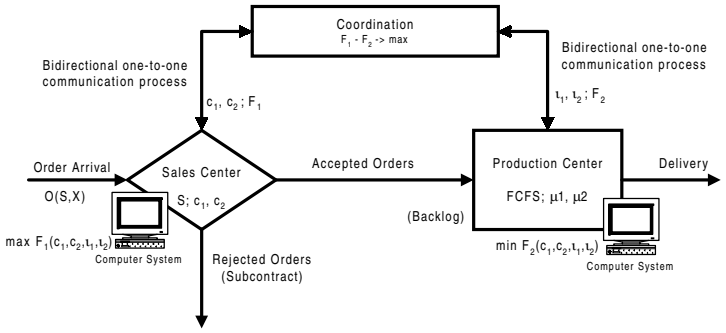

Figure 7 Distributed Configuration for the Coordination Model.

1. Same break-even point for the distributed and centralized modes at 400 iterations and $\lambda = 2$ jobs per time unit.
2. The lowest break-even point for the centralized mode at 90 iterations and $\lambda = 5$ jobs per time unit.
3. Consistently better profitability for the centralized mode. This effect is explained by lower communication requirements and competitive hardware investment in the centralized mode.
4. The distributed mode with consistently better profitability than the centralized mode at a higher hardware cost. This shows that distributed coordination should be preferred at a hardware cost less than half of that required by the centralized coordination mode.

From this analysis, the limiting factor in selecting the coordination mode is given by the hardware cost, with the distributed and centralized modes becoming comparable for a lower hardware investment in the centralized case. Coordination of distributed parties interacting for attaining a common goal is also demonstrated to be significant by Ceroni and Nof (1999) with the inclusion of parallel servers in the system. This model of collaborative manufacturing is discussed next.

7.2. Collaboration in Distributed Manufacturing

Manaco S.A. is a Bolivian subsidiary of Bata International, an Italian-based shoemaker company with subsidiaries in most South American countries as well as Canada and Spain. The company has several plants in Bolivia, and for this illustration the plants located in the cities of La Paz and Cochabamba (about 250 miles apart) are considered. The design process at Manaco is performed by developing prototypes of products for testing in the local market. The prototypes are developed at the La Paz plant and then the production is released to the Cochabamba plant. This case study analyzes the integration of the prototype production and the production-planning operations being performed at distributed locations by applying the distributed parallel integration evaluation model (Ceroni 1999).

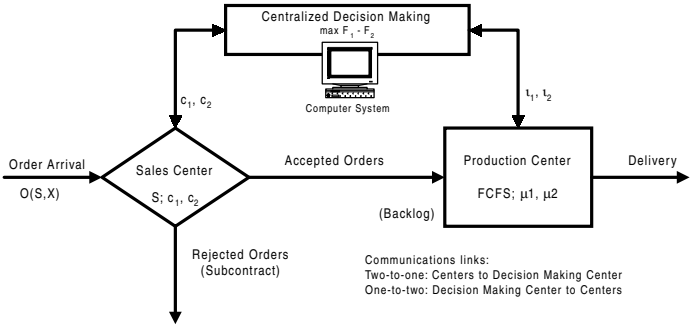

Figure 8 Centralized Configuration for the Coordination Model.

TABLE 3 Description of Tasks in the Distributed Manufacturing Case

Operation: Production Planning (La Paz plant)		Operation: Prototype Production (Cochabamba plant)	
Task	Description	Task	Description
1A	Market research	1B	CAD drawing
2A	Cutting planning	2B	Cutting
3A	Purchasing planning	3B	Sewing
4A	Capacity planning	4B	Assembly
5A	Assembly planning		
6A	Generation of production plan		

The production-planning operation (operation A) consists of six tasks, with some of them being executed in parallel. The prototype development operation (operation B) consists of four tasks, all of them sequential. Table 3 and Figure 9 show the description and organization of the tasks in each operation.

Means and standard deviations for the task duration are assumed. The time units of these values are work days (8 hours).

To contrast the situations with and without integration, two alternative solutions were developed. The first solution considers the sequential processing of the operations: the prototype was developed at La Paz and then the results were sent to Cochabamba for performance of the production planning. Parallelism is included at each operation for reducing the individual execution cycles. The second solution considers the integration and inclusion of parallelism in both operations simultaneously.

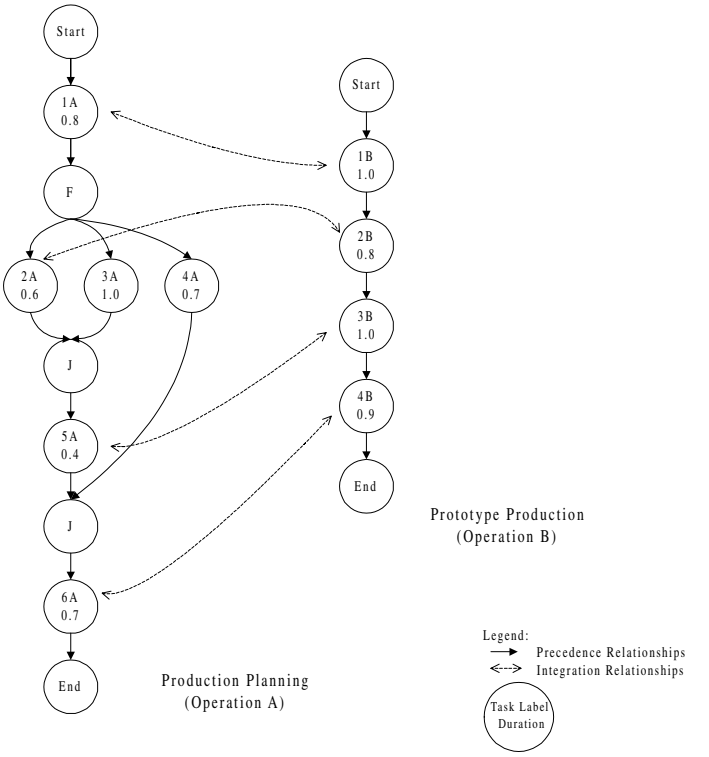

Figure 9 Tasks and Their Precedence Relationship in the Distributed Manufacturing Case.

Assumptions were made for generating an integration model for applying the parallelism optimization.

7.2.1. Integrated Optimization

The integration process in both operations is simplified by assuming relationships between tasks pertaining to different operations. A relationship denotes an association of the tasks based on the similarities observed in the utilization of information, resources, personnel, or the pursuing of similar objectives. Integration then is performed by considering the following relationships:

1A–1B
2A–2B
5A–3B
6A–4B

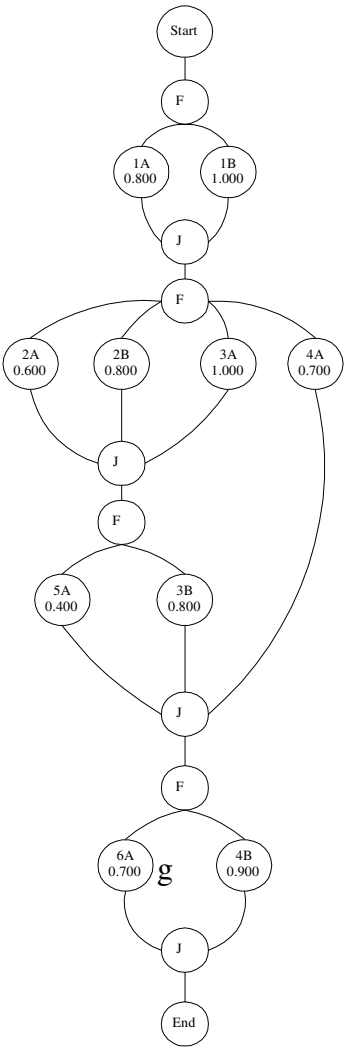

Figure 10 Integrated Model of the Distributed Manufacturing Tasks.

TABLE 4 Simulation Results for Operation A

Task	λ_I Average Communication Delay	$\sigma_{\lambda I}$ Standard Deviation	π Average Duration
1A	0.0008104	0.000129777	0.801865
2A	0.0004519	0.000154528	0.595181
4A	0.0003821	2.87767E-05	0.977848
3A	0.0003552	1.83533E-05	0.734888
5A	0.0277421	0.013688588	0.399918
6A	0.0561208	0.022934333	0.698058

The task relationships allow the construction of an integrated model of the operations. This integrated model preserves the execution order of the tasks as per their local model (Figure 9). Figure 10 shows the integrated model for operations A and B.

Once the integrated schema was generated, the parallelism analysis was performed. In order to evaluate the parallelism in the system, the time of communication and congestion delays needed to be estimated. The estimation of these delays was performed using the software TIE 1.4 (Khanna and Nof 1994; Huang and Nof 1998). TIE 1.4 allows the simulation of a network of distributed tasks with an Intel Paragon Supercomputer, up to a maximum of 132 parallel processors. TIE 1.4 uses a message-passing mechanism for communicating data among the computer nodes simulating the tasks. The data transmission can take place either synchronously or asynchronously. In synchronic data transmission the activity of the sending processor is stalled while waiting for confirmation from the receiver processor. In asynchronic data transmission, the sending processor does not wait for confirmation from receiving nodes and continue with their activity.

The simulation with TIE 1.4 is modeled based on two types of programs: a controller node and a task node. The controller assigns each of the programs to the available computer nodes and starts the execution of the first task in the execution sequence. The implementation in TIE 1.4 will require as many computer nodes as there are tasks in the operation plus the controller node. For example, operation A has 6 tasks, requiring a partition of 7 nodes for its execution on the parallel computer.

7.2.2. Simulation Results

Three models were simulated: operation A, operation B, and integrated operation. A total of 10 simulation runs were performed for each model, registering in each case the production (Π), interaction (T), and total (Φ) times, and the degree of parallelism (Ψ), which is a concurrency measurement for the system. The results obtained for each case are presented in Tables 4 to 6. The simulation of the individual operations allows us to generate an estimate of the delay times due to communication and congestion, both required to optimize the operations locally.

The results obtained from the simulation of the integrated operation were utilized for determining the parallelism of the tasks. The parallelism optimization assumes the tasks' duration and communication times as per those generated by the TIE 1.4 simulation (Table 5) and congestion time as $0.02e^{0.05*\Psi}$. The results obtained are presented in Table 7 and Figures 11 and 12.

The solution generated includes the number of parallel servers for the tasks shown in Figure 12.

7.2.3. Local Optimization

For generating the local optimal configurations of the tasks, the PIEM model was applied to both cases with the congestion delays computed according to the expression $0.02e^{0.05*\Psi}$. The results obtained for each operation are presented in Figures 13 and 14.

TABLE 5 Simulation Results for Operation B

6A	0.102065	0.015836	0.748419

7.2.4. Case Remarks

The numerical results obtained from the local and integrated scenarios are presented in Table 8.

The results in Table 8 show a slight difference in the total production time, which seems to contradict the hypothesis that the integrated scenario will benefit from a reduction of the cycle time. However, it must be noted that the number of subtasks required by the local scenario for achieving a comparable total production time is double that required by the integrated scenario. This situation is the result of no constraint being imposed on the maximum number of subtasks for each task in each scenario (infinite division of tasks). In particular for operation B, the number of subtasks in which each task is divided is nine, which can be considered excessive given the total number of four tasks in the operation.

For evaluating the comparative performance of the integrated and local scenarios, the local scenario for each operation was chosen according to the final number of subtasks in the integrated

TABLE 7 PIEM Model Result for the Integrated Operation

Iteration #	Task Modified	Ψ	Π	T	Φ

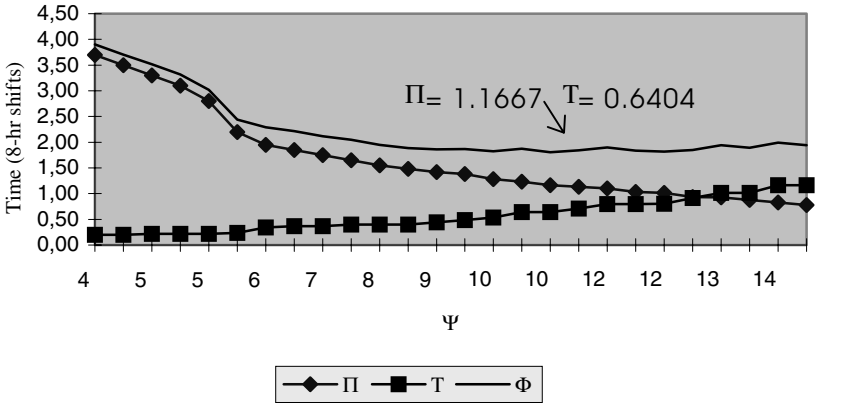

Figure 11 Changes in the Total Production Time per Unit (Π) and Congestion Time (T) for Different Values of the Degree of Parallelism (Ψ) at the Integrated Operation.

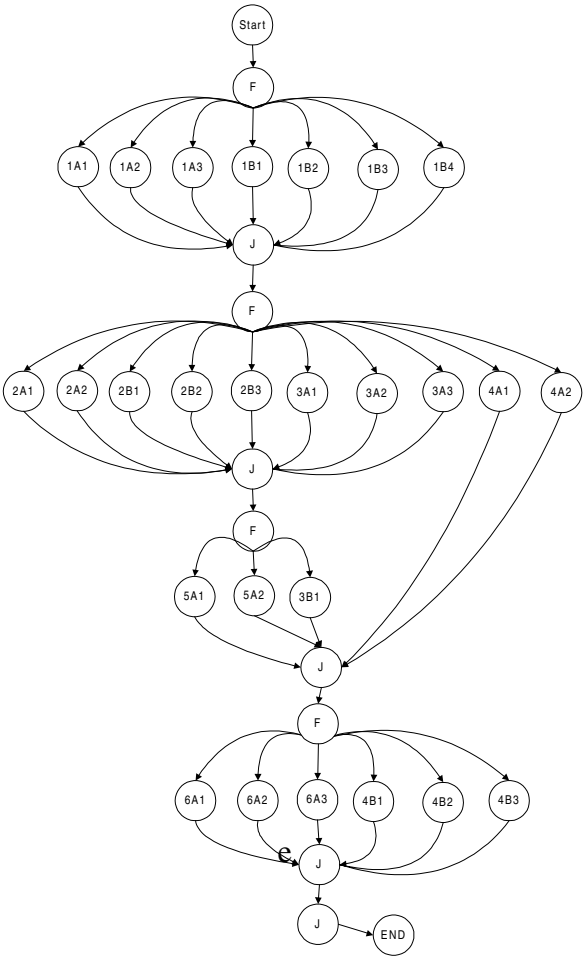

Figure 12 Configuration of Parallel Tasks for the Integrated Operation.

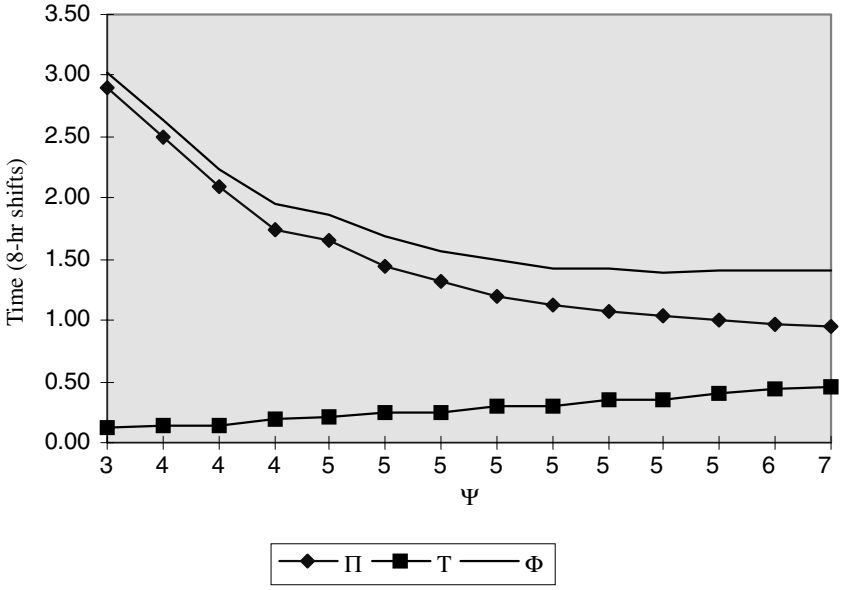

Figure 13 Total Production Time (Π) and Congestion Time (T) for Different Values of the Degree of Parallelism (Ψ) at Operation A.

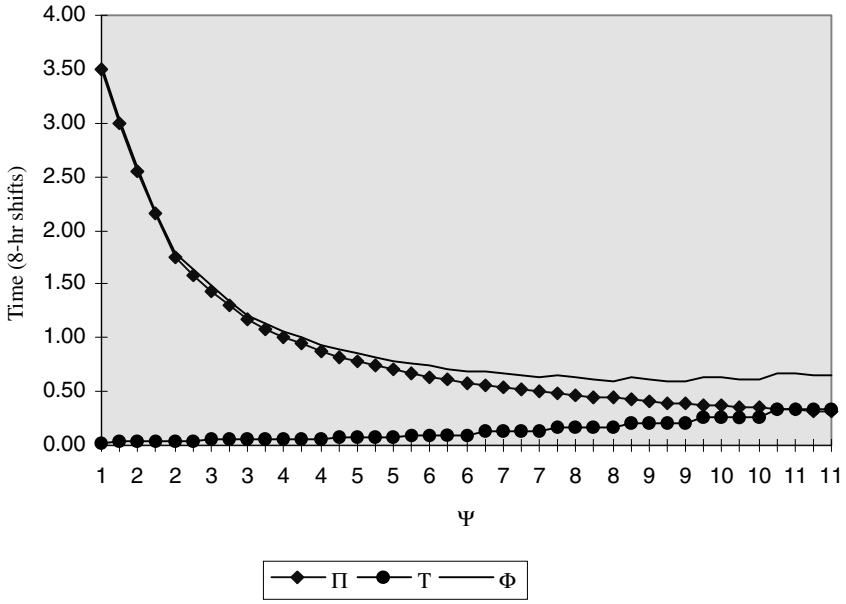

Figure 14 Total Production Time (Π) and Congestion Time (T) for Different Values of the Degree of Parallelism (Ψ) at Operation B.

TABLE 8 Summary of the Results for the Local and Integrated Scenarios

	Φ	Π	T	Number of Subtasks
Local Scenario	1.9846	1.4239	0.5607	52
Operation A	1.3908	1.0350	0.3558	16
Operation B	0.5938	0.3889	0.2049	36
Integrated Scenario	1.8071	1.1666	0.6404	26

scenario. Therefore, the number of subtasks was set at 15 for operation A and 11 for operation B. This makes a total of 26 subtasks in both local operations, which equals the number of subtasks for the integrated scenario. The values for the performance parameters show a total production time (Π + Φ) of 2.7769 shifts, direct-production time (Π) of 2.3750, and interaction time (Φ) of 0.4019 shifts. These values represent an increment of 54% for the total production time, an increment of 104% for the production time, and a decrement of 37% for the interaction time with respect to the integrated solution.

The results obtained from this case study reinforce the hypothesis that exploiting potential benefits is feasible when optimizing the parallelism of integrated distributed operations. Key issues in PIEM are the communication and congestion modeling. The modeling of time required by tasks for data transmission relates to the problem of coordination of cooperating servers. On the other hand, the congestion modeling relates to the delays resulting from the task granularity (number of activities being executed concurrently).

7.3. Variable Production Networks

The trend for companies to focus on core competencies has forced enterprises to collaborate closely with their suppliers as well as with their customers to improve business performance (Lutz et al. 1999). The next step in the supply chain concept is the production or supply networks (Figure 15), which are characterized by intensive communication between the partners. The aim of the system is to allocate among the collaborating partners the excess in production demand that could not be faced by one of them alone. This capability provides the entire network with the necessary flexibility to respond quickly to peaks in demand for the products. A tool developed at the Institute of Production Systems at Hanover University, the FAS/net, employs basic methods of production logistics to provide procedures for the efficient use of capacity redundancies in a production network. The tool satisfies the following requirements derived from the capacity subcontracting process:

- Monitoring of resource availability and order status throughout the network
- Monitoring should be internal and between partners

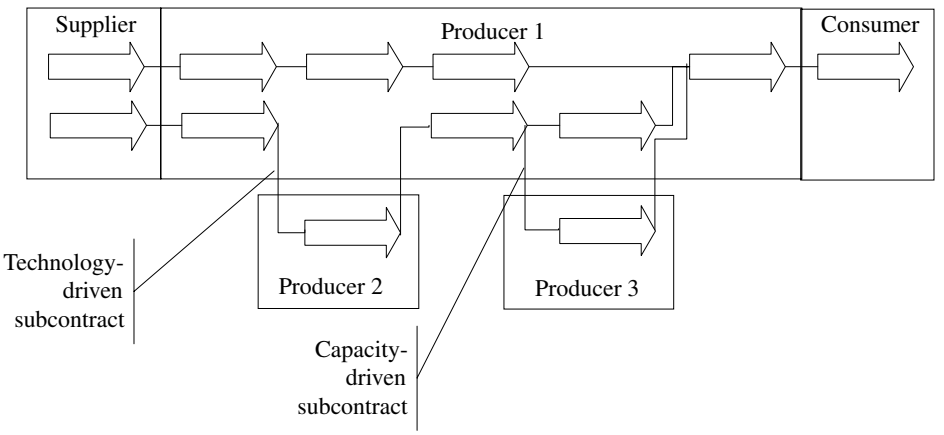

Figure 15 Capacity- and Technology-Driven Subcontracting in Production Networks. (Adapted from Lutz et al. 1999)

- Support of different network partner perspectives (supplier and producer) for data encapsulation
- Detection of the logistics bottlenecks and capacity problems

A key aspect of the system is the identification of orders the partner will not be able to produce. This is accomplished by detecting the bottlenecks through the concept of degree of demand (a comparison of the capacity needed and available in the future, expressed as the ratio between the planned input and the capacity). All the systems with potential to generate bottlenecks are identified by the FAS/net system and ranked by their degree of demand. The subcontracting of the orders can be performed by alternative criteria such as history, production costs, and throughput time.

The system relies on the confidence between partners and the availability of communication channels among them. Carefully planned agreements among the partners concerning the legal aspects, duties, responsibilities, and liability of the exchanged information are the main obstacles to implementing production networks.

8. EMERGING TRENDS AND CONCLUSIONS

The strongest emerging trend that we can observe in the collaborative manufacturing arena is partnership. In the past, the concept of the giant, self-sufficient corporation with presence in several continents prevailed. Emerging now and expected to increase in the years to come are agile enterprises willing to take advantage of and participate in partnerships. The times of winning everything or losing everything are behind us. What matters now is staying in business as competitively as possible. Collaborative efforts move beyond the manufacturing function downstream where significant opportunities exist. Manufacturing is integrating and aligning itself with the rest of the value chain, leaving behind concepts such as product marginal profit that controlled operations for so long. The future will be driven by adaptive channels (Narus and Anderson 1996) for acquiring supplies, producing, delivering, and providing after-sale service. Companies will continue to drive inefficiencies out and become agile systems, forcing companies around them to move in the same direction.

CHAPTER 21

Service Industry Systems and Service Quality

MARTIN WETZELS
KO DE RUYTER
Maastricht University

1. INTRODUCTION

Since the beginning of the 20th century, most economically advanced western societies have evolved from predominantly manufacturing-based to predominantly service-based economies (Bell 1973; Fitzsimmons and Fitzsimmons 1998; Heskett 1987; Mills 1986; Rust et al. 1996; Zeithaml and Bitner 2000). This transition has been especially dramatic in the United States (Ginsberg and Vojta 1981), where from 1948 to 1978 the service sector increased from 54% to 66% of GNP. A similar trend can be discerned in employment. From 1948 to 1977, employment in the service sector has risen from 27.2 million to 54.4 million, more than the total number of people employed in 1948. Currently, the services sector employs approximately 80% of the workforce and accounts for about 75% of GNP (Fitzsimmons and Fitzsimmons 1998; Zeithaml and Bitner 2000). Apart from national indicators, trade in services is growing globally. For the United States, the positive trade balance for services has helped to offset the negative trade balance for goods (Henkoff 1994; Zeithaml and Bitner 2000).

The increased importance of the service sector regarding both national economies and international trade has led to increased attention by marketers on the marketing of services during the last three decades (Swartz and Iacobucci 2000). The marketing field has moved quite rapidly beyond mere definitional issues to the development of models of service management and organization (Swartz et al. 1992). A major research topic in the marketing field currently is service quality (Parasuraman et al. 1985, 1988, 1991; Rust and Oliver 1994). This emphasis on service quality in marketing can be explained to a large extent by the fact that several authors have demonstrated a positive relationship between (service) quality and economic performance (Anderson and Fornell 1994; Buzzell and Gale 1987; Reichheld and Sasser 1990; Rust et al. 1995).

In Section 2, we will explore the nature of services. In Section 3, we will discuss the service encounter, which is at the heart of the majority of service organizations. During the service encounter, service quality is rendered to the customer in the interplay among customer, customer-contact service employee, and service organization. In Section 4, we will focus on defining service quality and discuss the conceptual model of service quality, a framework for the management of service quality. In Section 6, we will describe a measurement instrument, SERVQUAL, that has been derived from this model. In Section 7, we will present a critical review of the conceptual model of service quality and the SERVQUAL instrument.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.

2. THE NATURE OF SERVICES

Initially, in the marketing field it was assumed that the marketing of goods and services were essentially identical. However, marketers increasingly realized that the marketing of services is separated from the marketing of goods by a number of attributes (Grönroos 1978; Shostack 1977a, b; Zeithaml 1981). Generally, the following four attributes are used to distinguish goods from services (Zeithaml et al. 1985):

1. *Intangibility:* Services are much less tangible than physical goods. Services are experiences rather than objects that can be possessed.
2. *Inseparability of production and consumption:* Goods are first produced and then consumed. Services, on the other, hand, are characterized by simultaneous production and consumption.
3. *Heterogeneity:* The quality of a service may vary from service provider to service provider, from consumer to consumer, and from day to day.
4. *Perishability:* Because services are experiences rather than objects, they cannot be stored. As a result, service providers may find it difficult to synchronize supply and demand.

Intangibility is generally recognized as critical to the dichotomy between goods and services (Zeithaml et al. 1985). The other three attributes can be viewed as consequences of intangibility. Each attribute leads to specific problems for service marketers, which in turn necessitate special marketing strategies to solve them. For instance, intangibility may affect the marketing communications of an organization because services cannot be easily communicated to consumers.

Quality management in service organizations is especially strongly affected by these attributes of services vis-à-vis goods. First, because services are performances rather than objects, service organizations might find it difficult to understand how consumers perceive and evaluate service quality. Consequently, uniform and consistent quality standards can rarely be set (Berry 1980; Zeithaml 1981). Secondly, services are characterized by simultaneous production and consumption. Thus, services are not manufactured at a plant but are generally the result of the interaction between customer and service provider. Consequently, quality control will be rather difficult to ensure (Grönroos 1978). Thirdly, services, especially those with high labor content, are heterogeneous. As a result, consistent and uniform quality will be a serious problem because it is contingent on the interaction between customer and customer-contact service employee (Bitner 1990; Czepiel et al. 1985). Finally, perishability means that services cannot be stored and hence quality cannot be verified in advance of the sale (Shostack 1977a). In the next section, we will discuss the service encounter, which is at the heart of the majority of service organizations.

3. THE SERVICE ENCOUNTER

Findings from the American Customer Satisfaction Index and other national indexes reveal that services are consistently the lowest-scoring sector on customer satisfaction, with public services scoring lowest (Anderson and Fornell 1994). In service organizations, customer satisfaction is often determined by the quality of individual encounters—the service encounter (Bitner 1990; Solomon et al. 1985). The service encounter has been defined as ''a period of time during which a consumer directly interacts with a service'' (Shostack 1985, p. 243). This definition emphasizes that the service encounter encompasses all elements of the interaction between consumer and service organization: the intangible as well as the tangible elements. Others, however, indicate that the service encounter is mainly conceived as interpersonal interaction between service provider and customer (Chase 1978; Solomon et al. 1985). Solomon et al. (1985, p. 100) define the service encounter as ''the face-to-face encounter between a buyer and a seller in a service setting.'' Although we acknowledge the importance of the personal elements in the service encounter, we feel that tangible elements need to be included in the service encounter (cf. Bitner 1990). For instance, the use of advanced technology and equipment may bestow a feeling of trust and a connotation of high quality on the customer.

The nature of the service encounter is succinctly depicted in Figure 1. Essentially, the service organization consists of two parts: a visible and an invisible part (Chase 1978; Langeard et al. 1981; Shostack 1985). The invisible part is concerned with all organizational processes in the service organization that support the visible part in delivering the service to the customer. The visible part consists of the tangible elements (Bitner 1990) and intangible elements—the customer-contact service employee.

The evaluation of the service encounter can be approached from several perspectives (Bateson 1985; Czepiel et al. 1985): (1) an organizational perspective, (2) a customer perspective, and (3) a customer-contact service employee perspective. The service organization is mainly interested in the performance of the customer-contact service employee because this perspective allows the service organization to attain its objectives. It is therefore essential for the service organization to identify organizational factors that affect the performance of service employees. The customer is mainly

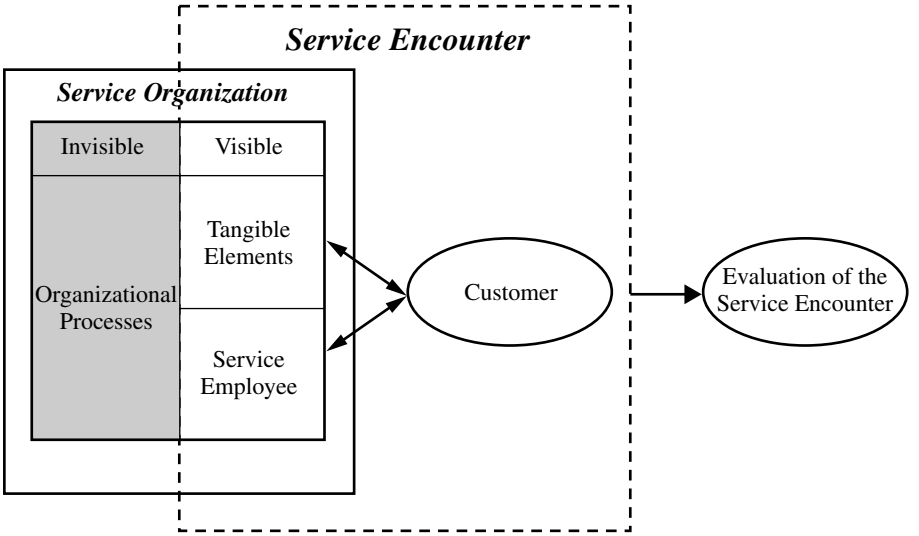

Figure 1 The Service Encounter. (Partly based on the SERVUCTION system model developed by Langeard et al. 1981)

interested in the service quality and customer satisfaction derived from the service encounter. If the evaluation of service quality and customer satisfaction is positive, the customer may decide to remain loyal to the service organization (Bateson 1985; Czepiel et al. 1985). The customer-contact service employee perspective is mainly concerned with the primary rewards of the service encounter, such as pay, promotion, job satisfaction, and recognition from the employee's colleagues and supervisor. These primary rewards are mainly contingent on the employee's performance in the service encounter. However, it should be noted that customer-contact personnel generally really care about the customer and are willing to exert the greatest possible effort to satisfy the customer's needs (Schneider 1980; Schneider and Bowen 1985).

The marketing field has concentrated mainly on the service customer. The customer-contact service employee has been relatively neglected in marketing academia (cf. Hartline and Ferrell 1996). One notable exception is the conceptual model of service quality (Parasuraman et al. 1985), where perceived service quality is determined by four organizational gaps. This model was later extended by adding organizational control and communication processes (Zeithaml et al. 1988). In the next section, we will explore the definition of service quality, which is used as the basis for conceptual model of service quality.

4. DEFINING SERVICE QUALITY

Quality is an elusive and fuzzy concept and as a result is extremely hard to define (Garvin 1984a, b; Parasuraman et al. 1985; Reeves and Bednar 1994; Steenkamp 1989). This may partly be caused by the different perspectives taken by scholars from different disciplines in defining quality. Multiple approaches to defining quality have been identified by various authors (Garvin 1984a, b; Reeves and Bednar 1994). Garvin (1984b) distinguishes five major approaches to define quality.

The *transcendent approach* defines quality as "innate excellence" (Garvin 1984b, p. 25): Proponents of this approach contend that quality cannot be precisely defined but rather is absolute and universally recognizable. This approach finds its origins in philosophy, particularly in metaphysics (Reeves and Bednar 1994; Steenkamp 1989). However, its practical applicability is rather limited because quality cannot be defined precisely using this perspective (Garvin 1984a, b; Steenkamp 1989).

The *product-based approach* posits that quality differences amount to differences in the quantity of a particular desired attribute of the product (Steenkamp 1989). Garvin (1984b, p. 26) provides the following illustration of this approach: "[H]igh-quality ice cream has a high butterfat content, just as fine rugs have a large number of knots per square inch." The assumption underlying this approach suggests two corollaries (Garvin 1984b). First, higher quality products can only be obtained at higher cost because quality is reflected in the quantity of a particular desired attribute. Secondly, quality can be evaluated against an objective standard, namely quantity.

The *user-based approach* to defining quality is based on the notion that ''quality lies in the eye of the beholder'' (Garvin 1984b, p. 27). In essence, this approach contends that different consumers have different needs. High quality is attained by designing and manufacturing products that meet the specific needs of consumers. As a result, this approach reflects a highly idiosyncratic and subjective view of quality. Juran (1974, p. 2-2), a proponent of this approach, defines quality as ''fitness for use.'' This approach is rooted in the demand side of the market (cf. Dorfman and Steiner 1954). Two issues should be addressed with regard to this approach (Garvin 1984b). The first issue concerns the aggregation of individual preferences at the higher level of the market. The second issue deals with the fact that this approach essentially equates quality with (a maximization) of satisfaction. In other words, as Garvin (1984b, p. 27) puts it: ''A consumer may enjoy a particular brand because of its unusual taste or features, yet may still regard some other brand as being of higher quality.'' As opposed to the user-based approach, the *manufacturing-based approach* to quality originates from the supply side of the market, the manufacturer. This approach is based on the premise that meeting specifications connotes high quality (Crosby 1979). The essence of this approach boils down to this: quality is ''conformance to requirements.'' (Crosby 1979, p. 15). This approach to defining quality is quite elementary, being based on an objective standard or specification (Reeves and Bednar 1994). A critical comment on this approach is articulated by Garvin (1984b), who finds that although a product may conform to certain specifications or standards, the content and validity of those specifications and standards are not questioned. The perspective taken in this approach is predominantly inward. As a result, firms may be unaware of shifts in customer preferences and competitors' (re)actions (Reeves and Bednar 1994).

The ultimate consequence of this approach is that quality improvement will lead to cost reduction (Crosby 1979; Garvin 1984b), which is achieved by lowering internal failure costs (e.g., scrap, rework, and spoilage) and external failure costs (e.g., warranty costs, complaint adjustments, service calls, and loss of goodwill and future sales) through prevention and inspection.

The *value-based approach* presumes that quality can be defined in terms of costs and prices. Garvin (1984b, p. 28) uses the following example to clarify this perspective: ''[A] $500 running shoe, no matter how well constructed, could not be a quality product, for it would find few buyers.'' Reeves and Bednar (1994) emphasize that this definition of quality forces firms to concentrate on internal efficiency (''internal conformance to specifications'') and external effectiveness (''the extent to which external customer expectations are met''). However, this approach mixes two distinct, though related, concepts: quality and value (Reeves and Bednar 1994). Because of its hybrid nature, this concept lacks definitional clarity and might result in incompatible designs when implemented in practice.

Reeves and Bednar (1994) propose one additional approach to quality: quality is meeting and/or exceeding customers' expectations. This approach is based on the definition of perceived service quality by Parasuraman et al. (1988, p. 17): ''Perceived service quality is therefore viewed as the degree and direction of discrepancy between consumers' perceptions and expectations.'' This definition was initially conceived in the services marketing literature and as such takes an extremely user-based perspective (Grönroos 1990; Parasuraman et al. 1985). Grönroos (1990, p. 37) in this respect emphasizes: ''It should always be remembered that *what counts is quality as it is perceived by the customers*'' (emphasis in original).

Relying on only a single approach to defining quality might seriously impede the successful introduction of high-quality products; a synthesis of the above approaches is clearly needed. Garvin (1984b) proposes a temporal synthesis, in which emphasis shifts from the user-based approach to the product-based approach and finally to the manufacturing-based approach as products move from design to manufacturing and to the market. The user-based approach is the starting point because market information must be obtained using marketing research to determine the features that connote high quality. Next, these features must be translated into product attributes (the product-based approach). Finally, the manufacturing approach will need to ensure that products are manufactured according to specifications laid down in the design of the product. This notion is readily recognizable in the conceptual model of service quality conceived by Parasuraman et al. (1985).

5. THE CONCEPTUAL MODEL OF SERVICE QUALITY

Parasuraman et al. (1985) distinguish three premises concerning service quality:

1. Service quality is more difficult for the consumer to evaluate than goods quality.
2. Service quality perceptions result from a comparison of consumer expectations with the actual service performance.
3. Quality evaluations are not made solely on the outcome of a service; they also involve evaluations of the process of service delivery.

From these three, Parasuraman et al. (1985) develop the conceptual model of service quality based on executive interviews and focus group interviews. In this model, GAP5 (perceived service quality)

is defined as perception (P) minus expectations (E) and is determined by the magnitude and direction of internal gaps, GAP1–GAP4. The four internal gaps can be described as follows:

1. *Marketing information gap* (*GAP1*)*:* the difference between actual customer expectations and management perception of customer expectations
2. *Standards gap* (*GAP2*)*:* the difference between management perception of customer expectation and service quality specifications
3. *Service performance gap* (*GAP3*)*:* the difference between service quality specifications and the service actually delivered
4. *Communication gap* (*GAP4*)*:* the difference between the service delivered and what is communicated about the service to customers

GAP5 (perceived service quality) is multidimensional in nature. Parasuraman et al. (1985) distinguish 10 underlying dimensions of perceived service quality. These dimensions are summarized in Table 1. Using these original 10 dimensions, Parasuraman et al. (1988) developed a measurement instrument for perceived service quality: SERVQUAL.

6. THE SERVQUAL INSTRUMENT

The SERVQUAL instrument for measuring service quality has evolved into a kind of gospel for academics and practitioners in the field of service quality. With the 10 dimensions in Table 1 as a starting point, 97 items were generated (Parasuraman et al. 1988). Each item consisted of two components: one component reflected perceived service or perceptions and the other component reflected expected service or expectations. Both components were measured on seven-point Likert scale with only the ends of scale anchored by ''Strongly disagree'' (1) and ''Strongly agree'' (7). The items were presented in a two consecutive parts. The first part contained the expectation components for the items, while the second part contained the perception components for the items. In order to prevent distortion of the responses by acquiescence bias or ''yea-saying or nay-saying'' tendencies, about half of the items were negatively worded and the other half positively worded—reverse statement polarization.

Two stages of data collection and scale purification were subsequently carried out. The first stage of data collection and scale purification, using coefficient α, item-to-total correlations and principal components analysis, resulted in a reduction of the number of factors to seven. Five of the original factors were retained in this configuration (see Table 1): (1) tangibles, (2) reliability, (3) responsiveness, (4) understanding/knowing the customer, and (5) access. The remaining five dimensions (communication, credibility, security, competence and courtesy), were collapsed into two dimensions. The number of factors was further reduced in the second stage of data collection and scale purification. The results of principal components analysis suggested an overlap between the dimensions understanding/knowing the customer and access and the dimensions communication, credibility, security, competence and courtesy. Consequently, the overlapping dimensions were combined to form two separate dimensions: (1) assurance and (2) empathy.

Parasuraman et al. (1991) present a replication and extension of their 1988 study. In particular, they propose a number of modifications to the original SERVQUAL instrument (Parasuraman et al. 1988). The first modification is concerned with the expectations section of SERVQUAL. Confronted with extremely high scores on the expectations components of the individual statements, Parasuraman et al. (1991) decided to revise the expectation part of the instrument. Whereas the original scale

TABLE 1 Dimensions of Service Quality

1. Reliability involves consistency of performance and dependability.
2. Responsiveness concerns the willingness or readiness of employees to provide service.
3. Competence means possession of the required skills and knowledge to perform the service.
4. Access involves approachability and ease of contact.
5. Courtesy involves politeness, respect, consideration, and friendliness of contact personnel.
6. Communication means keeping customers informed in language they understand and listening to them.
7. Credibility involves trustiness, believability and honesty.
8. Security is freedom from danger, risk, or doubt.
9. Understanding/knowing the customer involves making the effort to understand the customer's needs.
10. Tangibles include the physical evidence of the service.

Adapted from Parasuraman et al. 1985, p. 47.

reflected normative or ideal expectations, the revised instrument reflected predictive expectations relative to an excellent firm in the industry. For example, with regard to statement no. 5, the expectation item (E5) of the original instrument is formulated as follows: ''When these firms promise to do something by a certain time, they *should* do so'' (Parasuraman et al. 1988, p. 38). In the revised SERVQUAL instrument, the wording of expectation item no. 5 (E5) has been changed to ''When *excellent telephone companies* promise to do something by a certain time, they *will* do so'' (Parasuraman et al. 1991, p. 446).

A second modification related to the use of negatively worded items for the responsiveness and empathy dimensions in the original instrument. For the modified instrument, all negatively worded items were replaced by positively worded items. Moreover, in their 1991 study, Parasuraman and his colleagues suggest adding an importance measure to instrument in order to be able to calculate ''a composite, weighted estimate of overall service quality'' (Parasuraman et al. 1991, p. 424). Parasuraman et al. (1991) propose that importance should be measured by allocating 100 points to the individual dimensions of service quality in accordance with their perceived importance.

7. THE SERVQUAL INSTRUMENT: A CRITICAL REVIEW

Several conceptual and measurement concerns have been raised with regard to the SERVQUAL instrument. The single most important strength of the conceptual model underlying the SERVQUAL instrument is its inherent parsimony. However, Iacobucci et al. (1994) argue that this strength is simultaneously its major shortcoming. The conceptual model of service quality is based on relative evaluations. The absolute level of perceptions (P) and expectations (E) does not enter the equation. The ultimate consequence of this definition is that service quality will be evaluated favorably as long as expectations are met or exceeded. The absolute level of either perceptions or expectations is not explicitly taken into consideration. Iacobucci et al. (1994, p. 16) use the example of Joe's Diner, a truck-stop restaurant with very low expectations, to illustrate the importance of absolute levels of expectations: ''[T]he customer who enters Joe's Diner with appropriately low expectations and indeed experiences poor food and rude service. It is unlikely that predicting a favorable evaluation is valid, even though the customer's prior expectations had been met.''

Another consequence of this conceptualization of service quality is that services exceeding expectations in the same magnitude (and direction) are predicted to lead to similar levels of perceived service quality. For example, assume that a seven-point Likert-type rating scale is used to capture both perceptions and expectations. Further, assume service A scores 2 on expectations and service B scores a 6 on expectations. The corresponding perception scores are a 3 for service A and a 7 for service B. These results in the same perceived service quality score for both service A ($7 - 6 = 1$) and service B ($3 - 2 = 1$). However, it would be rather unrealistic to assume that both services result in the same level of perceived service quality, since service B exhibited both a higher level of perceptions and expectations.

The multidimensional nature of service quality has been acknowledged in the European as well as the North American research traditions in services marketing (Grönroos 1990; Parasuraman et al. 1988, 1991). Although the exact number of dimensions remains open to discussion, the general notion of multidimensionality seems to be generally accepted. The generalizability of the five SERVQUAL dimensions in other than the original industries (Parasuraman et al. 1988, 1991) is still rather problematic (e.g., Babakus and Boller 1992; Carman 1990; Cronin and Taylor 1992; Paulin and Perrien 1996).

Furthermore, it could be argued that a service encounter consists of two major components: (1) the service process and (2) the service outcome (Grönroos 1990; De Ruyter and Wetzels 1998). The five dimensions identified in the conceptual model of service quality are directed towards the interaction between customer and service provider and therefore focus on the service process (Lapierre 1996). De Ruyter and Wetzels (1998) find in an experimental study that service process and service outcome interact. Although service process is an important determinant of evaluative judgments (e.g., customer satisfaction), it may not wholly compensate for an unfavorable service outcome.

An additional problem with the conceptual model of service is its implicit assumption that each service encounter consists of only a single stage (Lemmink et al. 1998; De Ruyter et al. 1997). In particular, if a service encounter consisted of multiple stages, the dimensions of the conceptual model of service quality would require an extension at the level of the individual stage level. Rust et al. (1995) take this train of thought to an even more extreme position. They are structuring service quality as structures around the business process. Apart from introducing stages into the model, such an approach also ensures managerial relevance.

An issue that has received ample attention in academia in this respect is the differentiation between service quality and customer satisfaction (Cronin and Taylor 1992, 1994; Iacobucci et al. 1994, 1996; Oliver 1993). The confusion surrounding these two constructs in services research can be accounted for by the fact that both are based on the same canonical model (Iacobucci et al. 1996). Service quality and customer satisfaction models share the following characteristics (Iacobucci et al. 1996):

1. Customers are thought to hold the expectations prior to their purchases.
2. Customers make perceptions regarding their purchases.
3. Customers compare their perceptions to their expectations.
4. This comparative process results in evaluations of quality and/or satisfaction (and subsequent effects, e.g., future purchase intentions).

Oliver (1993) proposes that service quality and customer satisfaction differ in four fundamental characteristics. To begin with, the dimensions underlying quality are quite specific, while customer satisfaction can result from any dimension related to the service encounter. Secondly, service quality is based on ideals or "excellence" (Parasuraman et al. 1988, 1991), whereas customer satisfaction can be based on a host of alternative standards, such as predictive norms and experience-based norms (Iacobucci et al. 1994, 1996). Iacobucci et al. (1994, p. 15), following similar reasoning, propose a similar approach: "Perhaps satisfaction is indeed judged by consumers against their own internal standards, whereas quality is would be better defined as judgment relative to managerial or competitive standards." In fact, they propose that service quality is based on external standards and customer satisfaction on internal standards.

This classification of standards is closely related to the following third characteristic suggested by Oliver (1993), who contends that service quality does not require experience with service or service provider. Customer satisfaction, on the other hand, is an experiential construct. Customer satisfaction can only be evaluated by actually experiencing the service encounter (Anderson and Fornell 1994; Iacobucci et al. 1994). Anderson and Fornell (1994) suggest that in general, customer satisfaction is influenced by price, whereas service quality is viewed as independent from price. Price or costs incurred are often modeled using value; value is thus operationalized as the ratio of perceived quality relative to price (cf. Zeithaml 1988).

Finally, service quality and customer satisfaction are based on different sets of antecedents. The antecedents of service quality are mainly limited to communication, both personal and impersonal, and situational characteristics (Zeithaml et al. 1993). Customer satisfaction has been hypothesized to be influenced by a number of cognitive and affective processes, such as disconfirmation, equity, attribution, mood states, and emotions (Oliver 1993).

Another major weakness of the conceptual model of service quality is its omission of financial factors (Anderson and Fornell 1994; Iacobucci et al. 1994; Lemmink et al. 1998; De Ruyter et al. 1997). During the past decade, various competing models have been advanced to explain consumer evaluations of services (Iacobucci et al. 1996). Many of these models include service quality and satisfaction as their basic focal constructs, departing from a comparison between customer expectations and service provider performance (Iacobucci et al. 1994).

Value has frequently been conceptualized as the outcome of a price/quality ratio or the comparison of what one receives with the cost of acquisition (Anderson et al. 1994; Zeithaml 1988). According to this point of view, service customers will attempt to maximize the level of quality in relation to the disutility of price. Price in this case may be interpreted as a psychological price in terms of time and distance. It has been argued that customers will favor service providers that maximize quality minus the disutility from prices. Therefore, while the quality of a service may be conceived of as good, its net or marginal value may still be rated poor if the price of that service is perceived to be too high (Rust and Oliver 1994). This conceptualization of value as a proxy for the quality price ratio may be labeled the value-for-money approach. This approach closely focuses on value as a cognitive construct because an explicit comparison between price and quality is made by consumers. However, it has been emphasized recently that affect should also be considered in determining postpurchase responses (Oliver 1993). If value is perceived as a summary cognitive and affective response then an affective component should also be incorporated in a conceptualization of value. De Ruyter et al. develop a conceptualization of value, in which they introduce three dimensions: (1) emotional, (2) practical, and (3) logical (e.g., Lemmink et al. 1998; De Ruyter et al. 1997).

Moreover, several empirical concerns have also been raised with regard to the conceptual model of service quality, particularly with regard to the measurement instrument SERVQUAL instrument. The dimensionality of the SERVQUAL instrument is a well-researched issue (Asubonteng 1996; Buttle 1996; Paulin and Perrien 1996).

In their initial study, Parasuraman et al. (1988) report relatively high values of coefficient α for the individual dimensions of SERVQUAL. Moreover, using exploratory factor analysis to assess the convergent and discriminant validity, they find that each item loads high only on the hypothesized factor for the four participating companies.

These favorable results, however, seem not to have been replicated in their 1991 study (Parasuraman et al. 1991). Although the reliabilities in terms of coefficient α were still relatively high, their factor-analytic results seemed somewhat problematic. In particular, the tangibles dimension loaded on two dimensions (one representing equipment and facilities and one representing personnel and communication materials), thus casting considerable doubt on the unidimensionality of this dimen-

sion. Furthermore, responsiveness and assurance (and to some degree reliability) loaded on the same factor, while in general interfactor correlations were somewhat higher than in their 1988 study. These divergent results might be caused by an artifact: restraining the factor solution to five factors. Therefore, Parasuraman et al. (1991) proposed that a six-factor solution might lead to a more plausible result. Although responsiveness and assurance seemed to be slightly more distinct, tangibles still loaded on two factors, whereas the interfactor correlations remained high.

Replication studies by other authors have fared even less well than the studies by the original authors. Carman (1990) carried out a study using an adapted version of SERVQUAL in four settings: (1) a dental school patient clinic, (2) a business school placement center, (3) a tire store, and (4) an acute care hospital, and found similar factors (although not an equal number) as compared to Parasuraman et al. (1988, 1991). However the item-to-factor stability appeared to be less than in the original studies. Carman (1990) also notes that the applicability in some of the settings requires quite substantial adaptations in terms of dimensions and items. Babakus and Boller (1992) report on a study in which they applied the original SERVQUAL to a gas utility company. Using both exploratory and confirmatory (first-order and second-order) factor analysis, Babakus and Boller (1992) were unable to replicate the hypothesized five-dimensional structure of the original SERVQUAL instrument. Finally, Cronin and Taylor (1992, 1994) used confirmatory factor analysis and found that a five-factor structure did not provide an adequate fit to the data. Subsequently, they carried out exploratory factor analysis and a unidimensional factor structure was confirmed.

Authors using a more metaanalytic approach have reported similar results (Asubonteng et al. 1996; Buttle 1996; Parasuraman et al. 1991; Paulin and Perrien 1996). In general, they report relatively high reliabilities in terms of coefficient α for the individual dimensions. However, results differ considerably when looking at different service-quality dimensions. Paulin and Perrien (1996) find that for the studies included in their overview, coefficient α varies from 0.50 to 0.87 for the empathy dimension and from 0.52 to 0.82 for the tangibles dimension. However, the number of factors extracted and factor loading patterns are inconsistent across studies. Furthermore, interfactor correlations among the responsiveness, assurance and reliability dimensions are quite high (Buttle 1996; Parasuraman et al. 1991). Finally, Paulin and Perrien (1996) suggest that the limited replicability of the SERVQUAL instrument may be caused by contextuality (cf. Cronbach 1986). They find that studies applying SERVQUAL differ in terms of units of study, study observations, and type of study.

Empirical research, however, has found that the inclusion of an importance weight as suggested by Parasuraman et al. (1991) may only introduce redundancy (Cronin and Taylor 1992, 1994). Therefore, the use of importance weights is not recommended; it increases questionnaire length and does not add explanatory power.

The SERVQUAL instrument employs a difference score (perception minus expectation) to operationalize perceived service quality. However, the use of difference scores is subject to serious psychometric problems (Peter et al. 1993). To begin with, difference scores per se are less reliable than their component parts (perceptions and expectations in the case of SERVQUAL). Because reliability places an upper limit on validity, this will undoubtedly lead to validity problems. Peter et al. (1993) indicate that low reliability might lead to attenuation of correlation between measures. Consequently, the lack of correlations between measures might be mistaken as evidence of discriminant validity. Furthermore, difference scores are closely related to their component scores. Finally, the variance of the difference score might potentially be restricted. Peter et al. (1993) point out that this violates the assumption of homogeneity of variances in ordinary least-squares regression and related statistical techniques. Finally, an alternative might be the use of a nondifference score, which allows for the direct comparison of perceptions to expectations (Brown et al. 1993; Peter et al. 1993).

Empirical evidence indicates that the majority of the respondents locate their service quality score at the right-hand side of the scale (Brown et al. 1993; Parasuraman et al. 1988; 1991; Peterson and Wilson 1992). This distribution is referred to as negatively skewed. A skewed distribution contains several serious implications for statistical analysis. To begin with, the mean might not be a suitable measure of central tendency. In a negatively skewed distribution, the mean is typically to the left of the median and the mode and thus excludes considerable information about the variable under study (Peterson and Wilson 1992). Skewness also attenuates the correlation between variables. Consequently, the true relationship between variables in terms of a correlation coefficient may be understated (Peterson and Wilson 1992). Finally, parametric tests (e.g., t-test, F-test) assume that the population is normally or at least symmetrically distributed.

A less skewed alternative for measuring service quality is the nondifference score for service quality. Brown et al. (1993) report that the nondifference score for service quality is approximately normally distributed. Moreover, several authors have suggested that the number of scale points might have considerably contributed to the skewness of satisfaction measures (Peterson and Wilson 1992). Increasing the number of scale points may increase the sensitivity of the scale and consequently reduce skewness.

CHAPTER 22

Assessment and Design of Service Systems

MICHAEL HAISCHER
HANS-JÖRG BULLINGER
KLAUS-PETER FÄHNRICH
Fraunhofer Institute of Industrial Engineering

1. INTRODUCTION

1.1. Customer Service as a Key Success Factor in Competition

Services continuously gain relevance in all developed economies (Bullinger 1997). They are increasingly becoming a key issue in the discussion about growth and employment. Many firms now recognize the need, on the one hand, to strengthen ties with existing customers by offering innovative services and, on the other hand, to win over completely new customer groups and markets. Therefore, concepts for effective service management are relevant for both service companies entering into tougher and more global competition and manufacturing companies setting up a service business to support their core products by enhancing customer loyalty. Not only traditional service providers, but also companies for whom in the past services have only represented a small portion of total business, are nowadays required to satisfy ever-more complex needs by offering a whole series of new services to their customers. In particular, many companies are now awakening to the opportunities not merely for safeguarding and expanding their own competitive position with the aid of innovative services,

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

but also for acquiring entirely new business segments. At the same time, they are confronted with the problem of not being able to avail themselves of the systematic procedures and methods that are essential above all to develop and manage complex services. All too often, many successful services are still no more than the ad hoc outcome of individual projects and the personal efforts of employees or management.

Only a minority of firms have appreciated from the outset that crucial competitive advantages will no longer be secured by advanced technology, cost leadership, or product quality alone. On the contrary, innovative, subtly differentiated services are turning into unique selling features that set a company apart from its competitors, representing a promising strategy for success when it comes to tapping new market potentials. In Europe in particular, the discussion about services has been reduced for far too long to the simple formula "services = outsourcing = job cuts." The opportunities that lie in the exploitation of new business segments and the accompanying creation of new jobs—especially when high-quality services are exported—have not been fully recognized.

The main objective of this chapter is therefore to provide guidelines for systematic design, management, and assessment of service systems with particular attention to the management of service quality. To this end, fundamental approaches for defining *service* and *service quality* are described, leading to a conceptual framework for the structure of service systems. From this an assessment method is derived that supports continuous improvement in service organizations. Additionally, an emerging research area, service engineering, is outlined.

1.2. The Need for Systematic Engineering of Services

While there exists a broad range of methodologies, and tools are available on the development of goods, the development and engineering of services have not been a common topic in the scientific literature. The service discussion has focused primarily on such issues as service marketing, management of service processes, and human resource management in service industries. Service development and design have been largely ignored. Of the small number of authors who have discussed the issue (e.g., Bowers 1986; Easingwood 1986), the majority belong to the service marketing discipline. Approaches based on engineering science are still rare in the service sector to this day. One exception is Ramaswamy (1996). This deficit can be attributed to a single basic cause: the lack of tangibility of services as a research and development goal. That is to say, the development of services is a much more abstract process than the development of material goods or software. So far only a few, very generic attempts have been made to reduce this high level of abstraction and try to capture services operationally as the goal of a systematic development procedure. However, many companies have recently begun (not least as a result of the growing pressures of competition) to rethink their strategies for service provision. They want their services to be "regular products," that is, reproducible, exportable, even tangible and therefore developable. Services must undergo a systematic design process like any other product.

During the second half of the 1990s, service engineering has emerged as a new research discipline (Fähnrich 1998; Meiren 1999). It is a technical discipline that is concerned with the systematic development and design of service products using suitable methods and procedures. What distinguishes the development of services from the development of conventional, material products is that with services, the interaction between customers and employees plays a crucial role. Thus, several questions require special attention (Hofmann et al. 1998):

- The design of the customer interface and customer interaction
- The design of the service processes
- The selection and training of personnel
- Optimized support for front-office staff (i.e., those employees in direct contact with the customers).

An interdisciplinary approach is essential for solving development tasks of this nature. Service development must therefore integrate knowhow from a variety of scientific disciplines, notably engineering sciences, business studies, industrial engineering, and design of sociotechnical systems. Topics receiving particular attention within the field of service engineering are:

- *Definitions, classifications and standardization of services:* Until now there has been only a diffuse understanding of the topic of service. In particular, international definitions, classifications, and standards, which are necessary in order to develop, bundle, and trade services in the future in the same way as material products, are currently not available. Research questions to be solved include which structural elements of services can be identified, how they should be considered in the development, and how they can be made operational, as well as which methods and instruments could be used for the description and communication of internal and external services.

- *Development of service products:* The development and design of services requires reference models, methods, and tools. Research topics include reference models for different cases (e.g., development of new services, development of hybrid products, bundling of services, reengineering or redesigning of services) and different service types, analysis of the transferability of existing methods (e.g., from classic product development and software engineering) to the development of services, development of new service-specific engineering methods, and development of tools (e.g., ''computer-aided service engineering'').
- *Coengineering of products and services.* Offers of successful, high-quality products are often accompanied by service activities. Particularly for companies willing to make the move towards an integrated product/service package methods for combined product/service development are presently not available. Concepts for simultaneous engineering of products and services are necessary, for instance.
- *R&D management of services.* The development of services must be integrated into the organizational structure of companies. In practice, there are very few conclusive concepts. The consequences of this include a lack of allocation of resources and responsibilities, abstract development results, and insufficient registration of development costs. Research topics include which parts of a company must be integrated in the service development process; which organizational concepts (e.g., R&D departments for service development, virtual structures) are suitable; how information flow, communication, and knowledge can be managed; how the development process can be controlled; and how a company can continuously bring competitive services to market.

2. FUNDAMENTALS OF SERVICE MANAGEMENT

2.1. Differences between Services and Material Goods

Are services essentially different from material goods? Once service management had been addressed by several scientific disciplines, a considerable amount of research effort was spent on this question. The service marketing literature, in particular, provides an ample variety of theoretical arguments and examples from various industries that underscore the distinction between services and material goods (for an overview, see Fisk et al. 1993). Meanwhile, this distinction becomes more and more blurred. Almost any product can be seen as a combination of material goods and services, and thus the notion of hybrid products (i.e., bundles of material goods and services) has become widely accepted (Stanke and Ganz 1996).

However, three properties of services are assumed to be fundamental:

- *Intangibility:* Unlike material goods, services normally do not exist physically. They consist of concepts and activities fulfilling a value proposition given to the customer.
- *Simultaneity of production and consumption:* Generally speaking, services are delivered at the time the customer needs them and to the location where they are needed. Therefore they can hardly be stored and shipped. This property is usually labeled the ''uno-actu-principle.''
- *Customer integration:* In most cases, the customer is integrated in a service delivery process, either personally as an object of the service or by providing his or her property or information as input.

Counterexamples can be easily found at least for the first two properties, intangibility and uno-actu-principle. The last distinction, the involvement of the customer in the service delivery process, appears to be more fundamental. Some authors even label it the only valid difference between services and goods: ''With services, the customer provides significant inputs into the production process. With manufacturing, groups of customers may contribute ideas to the design of the product, however, individual customers' only part in the actual process is to select and consume the output'' (Sampson 1999).

Although the relevance of each of these basic properties varies considerably between different types of services, they indicate some basic challenges that must be met in managing almost any service:

- *Definition and description of an intangible product:* Because product properties are mostly immaterial, describing and—even more important—demonstrating them to the customer is much more difficult than with material goods. In most cases, the customer does not have an opportunity to look at or to test the service prior to purchase, as can be done with a car, for example. Therefore, buying a service creates a certain extent of risk for the customer. The challenge for a marketing department consists at this point of communicating the service's characteristics to the customer and reducing this feeling of risk as much as possible. For a development or an

operations department the challenge lies in defining and describing the service product in a way that ensures its delivery without failure.

- *Managing resources* in terms of quantity and quality: Most services cannot be produced "on stock," which requires that the service provider keep capacity available, whether the service is purchased or not. For this reason, concepts such as yield management are extremely important in numerous service industries, such as the airline industry.
- *Managing the customer* as a part of the service that can be controlled in an indirect manner at most. In many cases, proper service delivery depends on the customer behaving and cooperating in a certain way. Therefore, a service provider has to find ways to ensure that the customer assumes his or her role in the process.

2.2. Definitions and Terminology

According to ISO 9004/2, services are "the results generated by activities at the interface between the supplier and the customer and by supplier internal activities to meet customer needs." The following notes are added to this definition:

- "The supplier or the customer may be represented at the interface by personnel or equipment."
- "Customer activities at the interface with the supplier may be essential to the service delivery."
- "Delivery or use of tangible product may form part of the service delivery."
- "A service may be linked with the manufacture and supply of tangible product."

The standard provides a rather general definition that contains various essential aspects. For purposes of service management, the definition needs to be refined. This can be done by analyzing the most common definitions of the services concept, the most widely accepted of which was originally established by Donabedian (1980). It states that a service bears three distinct dimensions:

1. A structure dimension (the structure or potential determines the ability and willingness to deliver the service in question)
2. A process dimension (the service is performed on or with the external factors integrated in the processes)
3. An outcome dimension (the outcome of the service has certain material and immaterial consequences for the external factors)

Combining the aspects that are considered in the standard with Donabedian's dimensions of service yields Figure 1.

2.3. Service Typologies

Most approaches to defining services aim at giving an general explanation of service characteristics that applies to all types of services. While this approach is valuable from a theoretical point of view, due to the broad variety of different services, it hardly provides very detailed guidelines for the design and management of a specific service. Classification schemes and typologies that classify services and provide distinctive classes calling for similar management tools are needed. Classifying services with respect to the industry that the company belongs to hardly provides further insight, since a particular service may be offered by companies from very different industries. Industries in the service sector are merging, generating competition among companies that were acting in separate marketplaces before (e.g., in the media, telecommunications, or banking industries). On the other hand, services within one industry may require completely different management approaches. Thus, services have to be classified and clustered according to criteria that relate to the particular service product rather than to the industry. Such typologies can give deeper insight into the special characteristics of a service as well as implications concerning its management.

Several attempts have been made in order to design such typologies. Some of them are based on empirical studies. The study presented in Eversheim et al. (1993) evaluated questionnaires from 249 German companies representing different service industries. By the application of a clustering algorithm, seven types of services were finally identified, based on 10 criteria.

A recent study on service engineering (Fähnrich and Meiren 1999) used 282 answered questionnaires for the determination of service types. It derived four separate types of services that differ significantly in two ways:

1. The intensity of interaction between service provider and customer
2. The number of different variants of the service that the customer may obtain

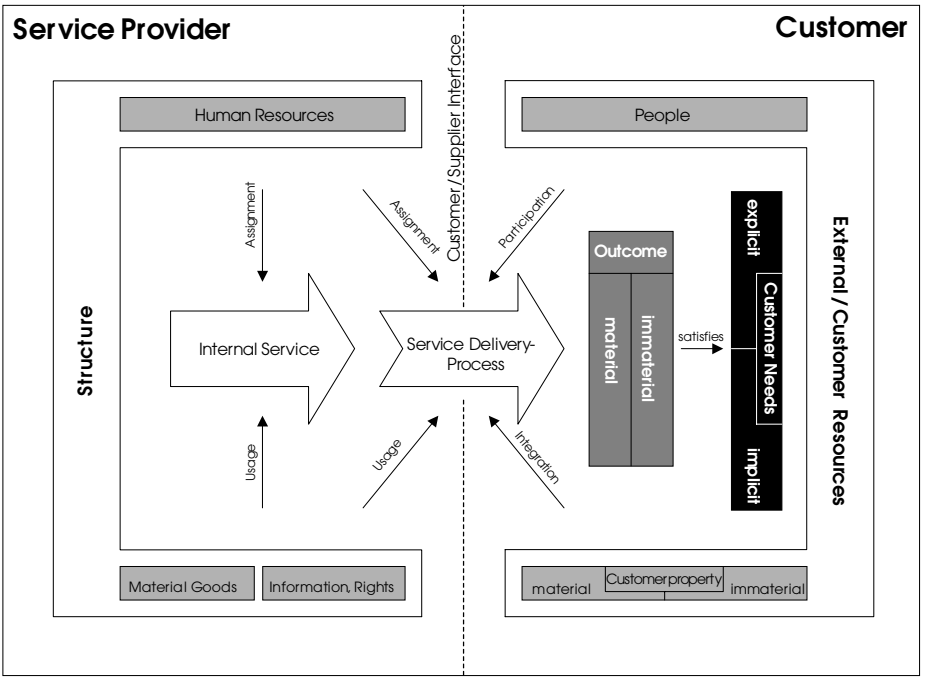

Figure 1 Elements of Service Definitions.

Strategies for service development and service operations can be assigned for the four types of services. Interestingly, these results are very similar to a typology of service operations introduced by Schmenner (1995), identifying four different types of service processes: service factory, service shop, mass service, and professional services. Figure 2 gives an overview of the typology, relating it to Schmenner's types.

3. MANAGEMENT OF SERVICE QUALITY

3.1. Service Quality Models

ISO 8402 defines quality as ''the totality of characteristics of an entity that bear on its ability to satisfy stated or implied needs.'' The standard explicitly applies to services, too, but it leaves space for interpretation. Therefore, some different notions of quality have emerged, depending on the scientific discipline or practical objective under consideration. Those notions can be grouped into five major approaches (Garvin 1984) and can be applied to goods as well as to services:

- The *transcendent approach* reflects a ''common sense'' of quality, defining it as something that is ''both absolute and universally recognizable, a mark of uncompromising standards and high achievement'' (Garvin 1984). Therefore, quality cannot be defined exactly, but will be recognized if one experiences it.
- The *product-based approach* links the quality of an item to well-defined, measurable properties or attributes. Therefore, it can be assessed and compared objectively by comparing the values of those attributes.
- The *user-based approach* focuses exclusively on the customer's expectations and therefore defines quality as the degree to which a product or service satisfies the expectations and needs of an individual or a group.
- The *manufacturing-based approach* derives quality from the engineering and manufacturing processes that deliver the product. Quality equals the degree to which a product meets its specifications.

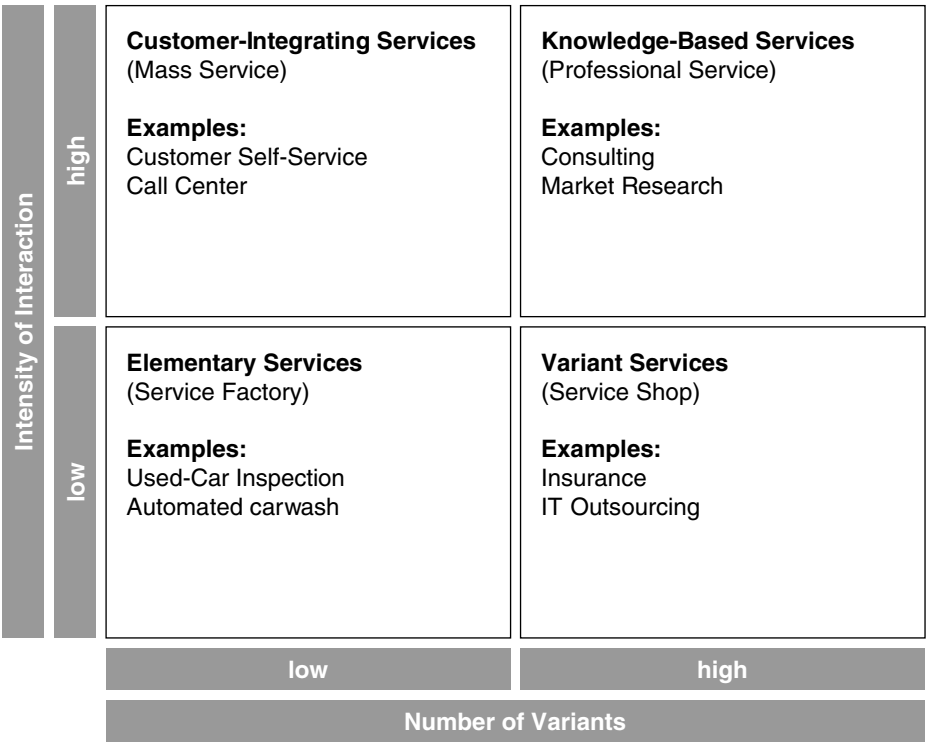

Figure 2 Four Basic Types of Service Products. (From Fähnrich and Meiren 1999)

- The *value-based approach* relates the performance of a product or service to its price or the cost associated with its production. According to this notion, those products that offer a certain performance at a reasonable price are products with high quality.

While the relevance of the transcendent approach is only theoretical or philosophical, the other approaches do influence quality management in most companies. Normally, they exist simultaneously in one organization: while the marketing department applies a user-based approach to quality, the manufacturing and engineering departments think of quality in a product- or manufacturing-based manner. The coexistence of the two views carries some risk because it might lead to diverging efforts in assuring product quality. On the other hand, today's competitive environment requires a combination of the different definitions (Garvin 1984) because each of them addresses an important phase in the development, production, and sale of a product. First, expectations and needs of the targeted customers have to be analyzed through market research, which requires a customer-based approach to quality. From those requirements, product features have to be derived such that the product meets the customers' expectations (product-based approach). Then the production process must be set up and carried out in a way that ensures that the resulting product in fact bears the desired characteristics. This implies that the production process should be controlled with respect to quality goals and therefore a manufacturing-based approach. Finally, the product is sold to its customers, who assess it against their expectations and express their satisfaction or dissatisfaction. The product specifications will eventually be modified, which again calls for a customer-based approach.

Because most definitions of service quality are derived from marketing problems, they reflect more or less the customer-based approach or value-based approach. There are several reasons for this one-sided view of service quality. In general, services do not bear attributes that can be measured physically. Furthermore, the customer is involved in the service-delivery process, so process standards are difficult to define. Additionally, the understanding of quality has moved from the product- and process-based view towards the customer- and value-based view in almost all industries, equaling

''quality'' and ''customer satisfaction.'' Therefore, the customer- and value-based approach has been used predominantly in recent research on service quality.

The most fundamental model for service quality that influences many other approaches is derived from Donabedian's dimensions, namely structure, process, and outcome (Donabedian 1980). Quality of potentials includes material resources and people, for example, the capability of customer agents. Process quality includes subjective experiences of customers (e.g., the friendliness of employees) during the service-delivery process, as well as criteria that can be measured exactly (e.g., the time needed for answering a phone call). In comparison to manufacturing, process quality has an even greater impact for services. A service-delivery process that is designed and performed extremely well ensures, as in manufacturing, the quality of its final outcome. Additionally, to the customer, the process is part of the service because the customer may observe it or even participate in it. The quality of the outcome of a service is the third component of service quality. It reflects the degree to which the service solves the customer's problems and therefore satisfies his or her needs and expectations.

Many models for service quality are derived from the concept of customer satisfaction. According to this notion, service quality results from the difference between the customers' expectations and their experiences with the actual performance of the service provider. If the expectations are met or even surpassed, the quality perceived by customers is good or very good, otherwise the customers will remain dissatisfied and rate the service quality as poor.

Based on this general assumption, several approaches to service quality aim at explaining the reasons for customer satisfaction (and therefore for service quality). This provides a basis for measuring the outcome quality of a service. Unfortunately, there are hardly any concepts that link the measurement of customer satisfaction or service quality to methods that influence it during service design or delivery. A first step towards this connection is the gap model, developed by Parasuraman et al. (1985) based on results from empirical research. The gap model identifies five organizational gaps within the process of service design and delivery that cause deficits in quality, leading to dissatisfied customers. The gaps occur in the following phases of the process:

- Gap 1 results from the fact that the management of the service provider fails to understand the customers' expectations correctly.
- Gap 2 denotes the discrepancy between management's conceptions of customers' expectations and the service specifications that are derived from it.
- Gap 3 is caused by a discrepancy between service specifications and the performance that is delivered by the service provider.
- Gap 4 consists of the discrepancy between the delivered perfomance and the performance that is communicated to the customer.
- Gap 5 is the sum of gap 1 through 4. It describes the discrepancy between the service the customer expected and the service that he or she actually experienced.

According to Parasuraman et al., customer satisfaction (i.e., gap 5) can be expressed in terms of five dimensions: tangibles, reliability, responsiveness, assurance, and empathy (Parasuraman et al. 1988). These dimensions are the basis for the SERVQUAL method, which is an well-known method for measuring the quality of services through assessing customer satisfaction. The following section addresses different approaches for measuring service quality.

3.2. Measuring Service Quality

Methods for the measurement of service quality are used during and after the delivery of a service in order to assess the customer's satisfaction and quality perception. They can be compared to quality tests in manufacturing, but there are some significant differences: service quality cannot be assessed by measuring physical attributes, and therefore some immaterial criteria that are related to quality have to be defined. Furthermore, if defects are detected, they generally cannot be ''repaired'' as can be done in case of material goods, since the customer normally participates in the service delivery process and therefore witnesses defects as they occur. Therefore, the main objective of measuring service quality is improving it on a mid- or long-term base rather than detecting and repairing defective units.

Depending on the chosen approach (see Section 3.1) service quality can be measured from the customer's and the service provider's point of view. Measuring from the service provider's point of view involves gathering data that are internally available, such as performance measures or quality cost (Eversheim 1997). They can be analyzed using well-known methods from quality management in manufacturing processes, such as statistical process control (Gogoll 1996). In addition, service quality can be assessed indirectly by an overall analysis of the quality system, which is done by a

quality audit or quality assessment. Those provide information regarding the capability of a service provider to deliver quality services rather than information about the quality of a specific service. Therefore, they are based on the assumption that there is a correlation between the quality of the structure and processes, on the one hand, and the outcome, on the other hand.

There are two basic approaches for measuring service quality from the customer's point of view. Both of them are based on assessing customer satisfaction.

Multiattribute methods are based on the assumption that the quality perception of customers is determined by assessing distinctive attributes of the particular service. With regard to each attribute, the customer compares the expected and the received quality. The overall judgment then results from a weighted addition of those comparisons. The most prominent example of this type of method is SERVQUAL (Parasuraman et al. 1988), a multiple-item scale consisting of 22 items grouped into five dimensions.

Another group of methods uses the assessment of *service encounters* or *moments of truth* (i.e., the contact between customers and the service provider) for measuring service quality. An example of those methods is the critical incident technique (Bitner et al. 1990). This method uses structured interviews to gather information about customers' experiences that have roused either very negative or very positive emotions. From those interviews, the most relevant problem areas are determined. This type of method allows the customer to describe the service encounter from his or her point of view instead of assessing it by predefined criteria. The method normally leads to the most significant causes of service failures.

Besides those activities that are initiated by the service provider, systematic analysis of customer complaints yields valuable information about quality problems. Typically, only a very small percentage of dissatisfied customers do complain, while most of them just buy from a competitor without further notice (Heskett et al. 1997). Effective complaint management therefore requires that the customer be encouraged to complain and that communication between customer and service provider be facilitated as much as possible. Customers whose complaints are treated in a satisfying manner often reward the service provider with increased loyalty (Reichheld 1997). Therefore, defective services can be ''repaired'' to a certain degree, which is normally described by the concept of service recovery (Heskett 1997)

3.3. Design of Service Processes

In addition to customer satisfaction, the process dimension of service quality has been addressed by numerous researchers and practitioners.

An important tool for service process design and management is the service blueprinting method, originally described in Shostack (1984). Service blueprinting subdivides each process into process steps, which are perceived by the customer directly, and supporting activities, which are necessary to deliver the service but are only perceived indirectly. The two areas are separated by a ''line of visibility.'' This differentiation is extremely important for customer-oriented service development processes because it permits concentration on the design of the customer interface at a very early stage. Service blueprinting was subsequently modified and named ''service mapping'' (Kingman-Brundage 1995). This method most notably includes two new lines of interaction. The first of these, the line of external interaction, subdivides the process as perceived by the customer into activities that are performed by the customer personally and activities in which the customer participates but which are in fact performed by the employees of the company offering the service. The second line, the line of internal interaction, differentiates between processes delivered by the supporting ''back office'' and those provided either by other companies or by other departments in the same company. Service blueprinting and service mapping are especially useful for service planning because they help identify potential errors very early on. Furthermore, they can be used as training material for employees and customers. Figure 3 shows an example of a service blueprint.

3.4. Resource-Related Quality Concepts

Approaches to service quality that apply to the *structure* dimension can be subsumed under the heading ''resource concepts.'' These include, most importantly, human resources concepts (especially qualification concepts), as well as the infrastructure necessary to deliver the service and service-support tools in the form of suitable information and communication technologies. The analysis of customer–employee interaction is crucial to enable appropriate recruiting and qualification of the employees who are to deliver the service.

Two questions arise immediately in regard to human resource management in services.

- There is an ongoing debate on whether the knowhow required for running a service system should be put into people or into processes. The job enlargement approach requires significant effort in recruiting, training, and retaining the kind of employees who are able to ensure high

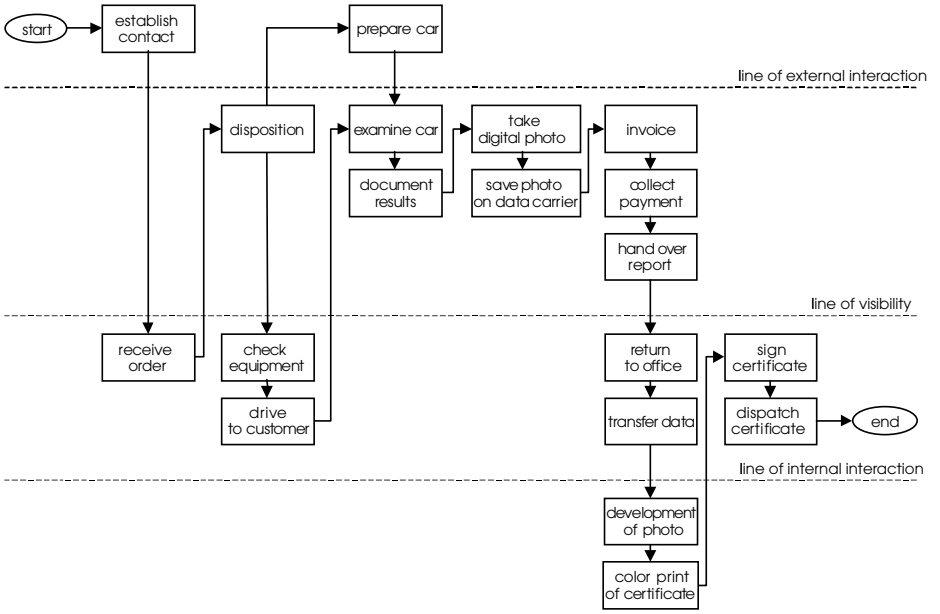

Figure 3 Service Blueprint of a Car Certification Service. (From Meiren 1999)

quality through personal effort and skills. The production line approach tries to ensure service quality by elaborated process design, therefore calling for lower requirements from the workforce involved.

- The management of capacity is crucial in services because they cannot be produced ''on stock.'' This calls for concepts that enable a service provider to assign the employees in a flexible way.

Role concepts are one way to deploy human resources during the service-delivery phase (Frings and Weisbecker 1998; Hofmann et al. 1998) that addresses both questions described above. ''Roles'' are defined groups of activities within the framework of a role concept. The roles are then linked to employees and customers. It is possible for several employees or several customers to perform one and the same role and for one employee or one customer to perform several different roles. Role concepts are a particularly useful tool for simplifying personnel planning, for instance in connection with the selection and qualification of the employees who will later be required to deliver the service. Most importantly, potential bottlenecks in the service-delivery phase can be identified extremely early on and suitable action taken to avoid them. Moreover, role concepts provide a starting point for formulating tasks in the area of work planning and enable customer behavior to be analyzed and planned prior to the service-delivery process. Finally, the use of roles does not imply any direct relationship to fixed posts or organizational units, and the concept is thus extraordinarily flexible.

4. THE STRUCTURE OF SERVICE SYSTEMS

Most service-management concepts discussed so far clearly show an affiliation to either the production line view or the human resource or customer and marketing-oriented view on services. These different views have not been integrated much, mainly because very different scientific disciplines are involved. Obviously, both approaches are needed. Nowadays service processes are highly complex and call for the application of sophisticated methods from industrial engineering, while on the other hand the outcome depends heavily on the performance of employees and customers.

One way to handle this complexity is to apply a system view to services, as proposed by several authors (e.g., Lovelock 1995; Kingman-Brundage 1995). Systems are made up of elements bearing attributes and the relationships between those elements. Elements may be (sub)systems themselves. If the elements of a service system are defined as those different components that have to be designed and managed, then the most elementary system model for services is made up of three basic elements:

1. *Customer:* The customer normally initiates a service delivery process and performs certain tasks within it. The customer partly reflects the outcome dimension of service quality by being either satisfied or dissatisfied with the service.
2. *Resources:* Human and material resources perform defined functions within a service process and interact with the customer. They reflect the structure dimension of service quality.
3. *Process:* Processes can be viewed as the definition of interactions between the resources and the customers in a service system. However, there are reasons for defining them as the third basic element within the system. Assuming the production line approach, processes are objects that carry information regarding the service, especially in IT-based services. They exchange information with other elements in the system or even control them to a certain degree.

For several reasons, it seems useful to define a fourth basic element within the system, namely service products. So far, the notion of a service product has not been used in a clearly defined way. However, in recent years the term *product* has been used more frequently to express the idea that services can be developed and produced in a defined and repeatable way. Defining the concept of products within a service system therefore yields several benefits:

- So far, the outcome dimension of a service has been considered mainly from the customer's point of view, taking outcome quality as equivalent to customer satisfaction. However, aiming only at customer satisfaction means that service quality easily becomes a moving target. This can be avoided by integrating all relevant information regarding the outcome of a service into a product model that is communicated internally and (to an appropriate extent) externally.
- The definition of a product clearly separates the outcome of a service from the way it is delivered. The product therefore acts as an interface between the market and customer view on a service (''what is delivered'') and a production or process view (''How it is delivered'').
- Product models support the modular set-up of services. Services that are offered with a wide range of variants are difficult to handle, particularly if the service depends heavily on information technology. A potential solution is the division of a service in separate modules that can be bundled according to the customer's needs. This also greatly supports the development of new products or variants because they (and the corresponding software systems) only have to be assembled from existing parts.

A product model for services cannot simply consist of a one-to-one application of traditional product concepts from manufacturing. Instead, the product model must be derived from the essential characteristics of service processes. This can be achieved by an analysis of generic models of service delivery (e.g., the universal service map [Kingman-Brundage 1995] or the process model [Eversheim et al. 1997]) that yields those points within a service process that require information from a product model. Thus, a typical service process can be described in the following way:

1. A service is initiated by the definition of a service concept (Heskett et al. 1997) that is communicated to the market and its targeted customers. The required resources are assigned in parallel.
2. Potential customers decide to contact the service provider in order to obtain additional information or to order the service instantaneously. For this purpose, the ways in which customers gain access to the service have to be defined and communicated. Traditionally, customers enter the service facility in person (e.g. a restaurant, a car repair shop). Depending on the particular service concept, this may be replaced by telephone or Internet access or a combination of those. In any case, an access system has to be defined that is located directly at the line of interaction between customer and service provider.
3. If the customer decides to order the service, some specifications regarding the desired variant have to be recorded by the access system.
4. The service delivery process must then be activated, using the specification that has been collected by the access system. First, however, a consistency check must be performed in order to verify whether the desired variant of the service is obtainable.
5. If the variant is valid, the configuration of the service will be set up, that is, those delivery processes that are required for the particular variant are activated.
6. If a process includes participation of the customer, the customer must be informed about the expected outcome and form of the cooperation. Results produced by the customer must be fed back into the delivery process.

7. As soon as all threads of the delivery process (carried out by the service provider or the customer) have been terminated, the outcome will be delivered and an invoice sent to the customer.
8. If the results are satisfactory, the contact between customer and service provider comes to an end and the overall process is finished. The customer may order some additional service or may return later to issue a new order. If the results leave the customer dissatisfied, a service-recovery procedure may be initiated or the customer may simply terminate the business relation.

The information needed to control such a process is normally distributed between the people involved (employees and customers) and the documents that define the processes. However, the reasoning outlined above shows that it is useful to combine some elements within a product model. These considerations lead to the product model depicted in Figure 4, which uses an object-oriented notation according to the Unified Modeling Language (UML).

Using the object-oriented notion of a system, the individual elements of the product model are displayed as classes that have a unique name (e.g., ''Service_Product''), bear attributes (e.g., ''External_Product_Information''), and use methods for interaction with other classes.

The product model is centered around the class Service_Product. This class identifies the product, carries information for internal use, and provides all information regarding valid configurations of the product. Service_Product may be composed of other, less complex products, or it may be an elementary product. It relates to a class Service_Concept that defines the customer value provided by the product, the customers and market it aims at, and the positioning in comparison to its competitors. The class Service_Product is activated by whatever provides the customer's access to the service system. Access_Module carries information on the product for external distribution and records the specification of the product variant as requested by the particular customer. Access_Module eventually activates Service_Product, which subsequently checks the consistency and validity of the requested product configuration and sets up the configuration by ''assembling'' individual modules of the service. Then Deliver_Product is carried out by activating one or several Service_Functions that make up the particular product configuration. During and after the service delivery process Service_Product may return statistics to the management system, such as cost and performance data. Also, Product_Features may be attached to a Service_Product, potentially including Material_Components.

Each Service_Product contains one or several Service_Functions that represent the Outcome of the service. A Service_Function carries information about the expected Quality Level (which may

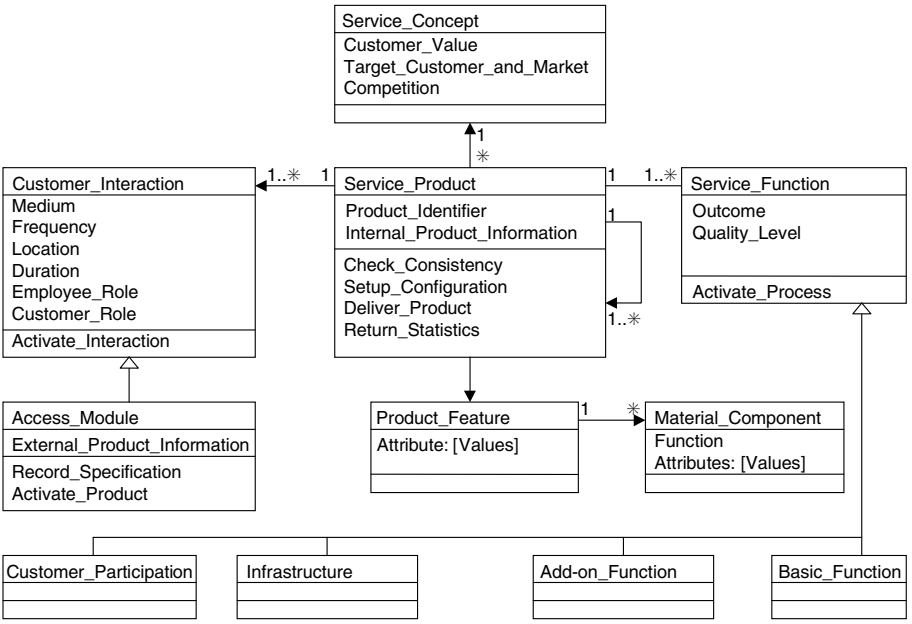

Figure 4 Service Product Model.

be expressed by criteria like the ones used in SERVQUAL and a relation to the internal or external service delivery processes that realize this function. Jaschinski (1998) names six different types of service functions, four of which can be expressed within the product model:

1. A Basic_Function contains the basic outcome a customer expects from the service, such as the transportation from location A to location B in the case of an airline.
2. An Add-on_Function realizes some additional features that enhance the service compared to its competitors. Staying with the airline example, the large variety of meals or the lounges in the airport are such Add-on_Functions.
3. Infrastructure is needed in many cases in order to enable the customer to use the service at all. An example is the check-in counters in the airport that provide the necessary preparation for boarding an airplane.
4. Customer_Participation denotes the part of the service's outcome that is produced by the customer. An example is the automated self-check-in that is used by several airlines.

According to Jaschinski (1998), interaction between customers and service provider and access to the service system represent two more functions. Within this product model, interaction is defined by the element Customer_Interaction, of which Access_Module must be regarded as a special instance.

The product model therefore acts as a central hub of a service system, coordinating the interactions of customers, employees, material resources, and processes. The product is activated by a customer, then initiates the required processes, which in turn call for necessary resources. This model explicitly shows the correlation between the elements of a service system and may serve as a template for designing a service from a product designer's point of view.

Based on this concept, a framework for the assessment of a service system will be introduced in the next section that serves as a methodology for continuous improvement.

5. CONCEPTUAL FRAMEWORK FOR THE ASSESSMENT OF A SERVICE SYSTEM

5.1. Quality Assessments

Usually the performance of a company is assessed by financial criteria. This may seem perfectly appropriate because the survival of a company depends on adequate profits. All other objectives (e.g., the quality of products and services) are pursued not for their own sake but rather in support of financial long-term success. Within the last decade, however, researchers and practitioners have come to the conclusion that because financial criteria relate to the past, they reflect only part of a company's performance. The future performance and growth of a company depend equally on soft factors that are difficult to quantify, such as the quality of leadership or the qualification of the employees. The idea of integrating soft and hard factors is realized in the balanced scorecard concept (Kaplan and Norton 1996), which is gaining increasing acceptance worldwide.

Assessment is another management concept that aims at integrating *all* relevant factors. Especially in the field of quality management, assessments have become very popular in recent years. There are numerous examples of successful application. Here the term *assessment* denotes several different but similar methods that serve mainly as a tool for analyzing and documenting the actual status of an organization. An assessment can also be used as the basis for a process of continuous improvement. This leads to three main objectives of an assessment:

1. Analysis of the status quo and determination of potential improvements
2. Support and acceleration of change processes
3. Measurement of whether objectives have been achieved

An assessment can be performed in different ways, depending on the particular objectives and the effort that is spent. Table 1 gives an overview of the most relevant variants.

Most companies use an established assessment model when they carry out a quality assessment. Well-known examples are the Malcolm Baldrige National Quality Award (MBNQA) in the United States and the European Quality Award in Europe. Several derivations of these models exist in different countries. All assessment models define criteria that address the various fields of improvement in an organization. Those criteria are grouped in categories and a procedure used both for gathering and evaluating information and for the calculation of the score is defined.

5.2. Areas for Quality Assessment in Service Organizations

While MBNQA and EQA address arbitrary organizations, this section presents ServAs (service assessment), an assessment model that has been specifically developed for service organizations. ServAs

TABLE 1 Various Types of Quality Assessment

Type	Objectives	Effort	Participants	Questionnaire	Shortcomings
Quick check	Getting started fast, overview of status quo		1 person, e.g., the quality manager	Complete questionnaire	The result shows the view of just one person
Assessment workshop	Awareness building for the management team, action plan		Ca. 5–7 persons	Complete questionnaire	Only the view of management is integrated
Survey	Appraisal of practices or processes by all relevant employees		All employees of the unit	Select and customized items	Broad understanding of the method and its topics has to be disseminated
Documented in-depth analysis	Profound analysis of all relevant processes and functions		Team of specialists	Specific questionnaire	Very high effort

contains 12 categories that describe those fields within a service organization that require attention from the management. Each category contains relevant criteria that describe the actual status of the organization with respect to the particular management field. The criteria are grouped within key areas. They have been derived from the relevant characteristics of a service system, combined with applicable elements from established assessment models (see Haischer 1996; Eversheim 1997). Figure 5 gives an overview of the categories of ServAs and the criteria.

According to the fundamental dimensions of service quality, the categories have been assigned to either the structure, the processes, or the outcome of a service. Five categories belong to the structure dimension:

1. *Customer focus:* How does the service organization ensure that the offered services meet the expectations and needs of customers?
2. *Leadership:* How is a service culture being established and maintained by senior management?
3. *Employees:* How are employees recruited, qualified and motivated in accordance with the company's overall objectives?
4. *Resources:* Is the usage of material resources effective and efficient?
5. *Quality system:* Does the service organization maintain a quality system that transfers quality objectives to products and processes?

Four categories assess process quality in a service organization:

1. *Service development:* Are service products systematically developed within a defined development process?
2. *Service delivery:* How does the service organization organize the core process of service delivery in an effective and efficient way?
3. *Cooperation management:* How does the organization build, use, and maintain partnerships along the value chain?
4. *Customer relationship and communication:* How does the service organization manage communication with customers and other external partners?

The three last categories address the fundamental dimensions of outcome any company strives for:

1. *Employee satisfaction:* How does the service organization measure and manage employee satisfaction?

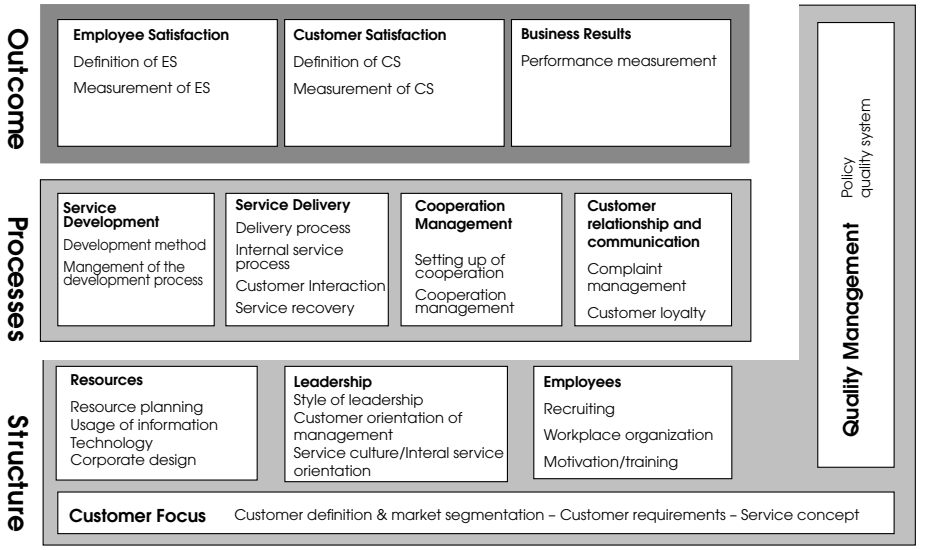

Figure 5 Categories and Key Areas for the Assessment of Service Systems.

2. *Customer satisfaction:* How does the service organization define and measure customer satisfaction?
3. *Business results:* How does the service organization establish performance measurements using financial and nonfinancial criteria?

A questionnaire has been derived from these categories and the related key areas. It is the most important tool in the assessment method. Each key area contains several criteria related to one or more items of the questionnaire. These items indicate the ''maturity level'' (see Section 5.3) of the service organization with respect to the criterion under consideration.

The questionnaire may be utilized for analyses at different depths, from an initial quick self-assessment by senior management to an in-depth discussion of the different key areas in workshops and quality circles. The results serve as a basis for planning improvement measures.

5.3. A Maturity Model for Quality Management in Service Organizations

The overall result of an assessment using ServAs is expressed in terms of the maturity level of the service organization. In recent years, models for maturity levels have been recognized as an appropriate base for improvement processes. They are based on the assumption that the development of an organization follows some distinctive steps or maturity levels. Several different maturity level models have recently been developed for particular industries (e.g., Humphrey 1989; Rommel 1995; Malorny 1996). They have been integrated into the development of ServAs.

Using a number between 1 and 5, the maturity levels indicate how far the service organization has proceeded towards total quality management (TQM). Each level describes a typical state that an organization assumes in developing quality management. Thus, the maturity level can be easily interpreted by management and employees. It can be used internally for motivating and communicating further efforts in an improvement program because it provides clear objectives: ''We have reached level 3—within a year we want to get to level 4!''

Table 2 displays the five maturity levels of ServAs with their underlying principles, their most important characteristics, and the key tasks at each level.

After the questionnaire is filled in, the overall maturity level of an organization is calculated using a two-step procedure. First, the maturity level has to be calculated for each individual category. For each category and each maturity level a certain threshold has to be passed (i.e., a given number of positive answers in the questionnaire must be met or exceeded) for the maturity level to be reached. Finally, the overall maturity level is calculated from the category levels according to several scoring rules.

5.4. The Assessment and Design Procedure

Usually, the conduction of a ServAs assessment is done within the organizational frame of a project. Figure 6 shows an overview of the main phases and activities of such a project.

TABLE 2 Maturity Levels of Service Organizations

Level	Principle	Characteristics	Key Tasks
1	Ad hoc management	Service quality is attained by coincidence or by repairing mistakes.	Quality and service policy, dissemination of a common understanding of quality
2	Repeatable	Given identical circumstances, a certain quality level can be reached repeatedly.	Structured documentation of processes and products
3	Process definition	ISO 9000 type of quality management.	Ensuring effectiveness and efficiency of processes by use of performance measures
4	Quantitative management	Feedback loops and performance measures are established.	Refining of feedback loops, ensuring the participation of each employee
5	Continuous improvement	All members of the company are involved in improvement actions.	Continuous review of measures and feedback loops

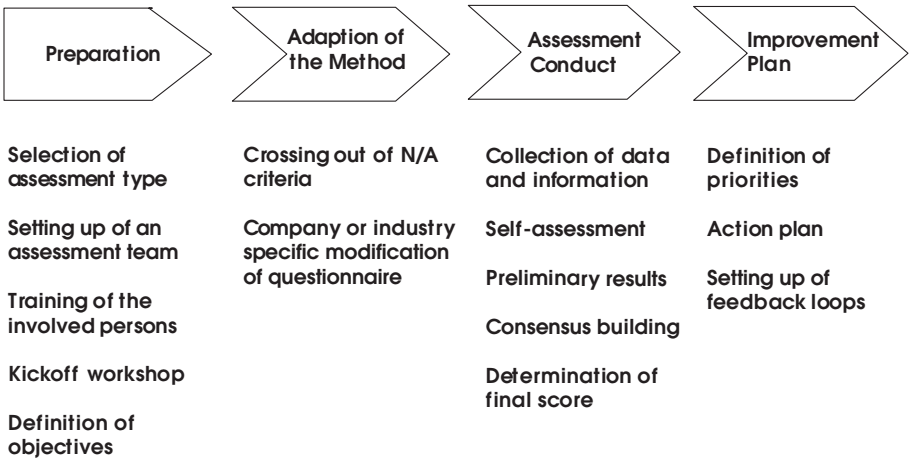

Figure 6 Procedure for Conducting an Assessment.

After the appropriate type of assessment is selected and the project team is set up and trained, the project should be initiated with a kickoff workshop that helps to communicate the project's background and objectives to all employees. During this workshop the most important and urgent problems can be gathered in order to fine-tune the project's objectives. In a second step the questionnaire has to be adjusted to company- and industry-specific requirements, which is done by eliminating criteria that do not apply or by adding company- and industry-specific criteria. Then information concerning the considered criteria is gathered within the organization, depending on the chosen mode of assessment. This information yields a preliminary result that has to be consolidated by eliminating contradictory statements, using different consensus-building methods. After the final score is determined, an action plan for improvement measures has to be decided on and its execution measured on a regular basis.

6. CONCLUSION

Managing customer service and service quality is a complex task that requires a holistic approach that takes into account people (customers and employees), material resources, and abstract entities such as products and processes. A system-oriented approach is useful for mastering this complexity because it supports the understanding of the manifold dependencies within a service organization.

The concept of a service product model that has been presented in this chapter helps to organize the variety of information that a service provider has to handle. It facilitates modularization of services and therefore the development of product bundles, variants, and entirely new products in service organizations. Defining service products enables service providers to distinguish the outcome of a service clearly from the processes and resources that lead to it, opening a variety of strategic options. However, one must keep in mind that service delivery can be never automated completely. The right balance between skilled people and intelligent products and processes is still required. The ServAs method helps to achieve this balance by supporting continuous improvement of the entire service system.

CHAPTER 23

Customer Service and Service Quality

RICHARD A. FEINBERG
Purdue University

1. INTRODUCTION TO THE CUSTOMER SERVICE PARADIGM

A fundamental change in understanding business success has occurred. The new paradigm stresses that sales and profit are the result of customer satisfaction (Anton 1996) (see Figure 1).

Competitive advantage is most likely to come from innovation and creativity, flexibility to shift quickly as markets and customers change, marketing and tailoring value to the specific needs of profitable customers, and developing and creating long-term customer relationships. Today (and even more so in the future) competitive advantage will come from doing things sooner and better than the competition to a customer who will want to do business with you for an extended period of time.

The essence of business is to create satisfied customers who purchase your products and services and come back for more, and products that do not come back. The lifetime value of a customer is often overlooked in the day-to-day strategic and operational decisions. But this lifetime value is the critical issue for understanding why investments in service quality and customer satisfaction are not just expense lines in some budget but investments in bottom-line profit and the future of the company

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

Figure 1 Customer Satisfaction Wheel of Success.

(Rust et al. 2000). Service quality and customer satisfaction must be calculated as a function of the sales and profitability related to the length of time a customer stays with your company as well as the costs involved in losing dissatisfied customers (see Tables 1 and 2). Research clearly shows that the longer a customer stays with a company the greater the sales and profits to the company because that consumer will buy more, buy more profitable items/services, requires smaller sales expenses, and be responsible for new customers through positive recommendations (see Figure 2 for a hypothetical look at this relationship).

TABLE 1 Increased Revenues That Can Result over Time from Improved Customer Service

Year	Revenues at 70% Retention Rate	Revenues at 80% Retention Rate	Revenues at 90% Retention Rate	Revenues at 100% Retention Rate
1	$1,000,000	$1,000,000	$1,000,000	$1,000,000
2	770,000	880,000	990,000	1,100,000
3	593,000	774,000	980,000	1,210,000
4	466,000	681,000	970,000	1,331,000
5	352,000	600,000	961,000	1,464,100
6	270,000	528,000	951,000	1,610,510
7	208,000	464,000	941,000	1,771,561
8	160,000	409,000	932,000	1,948,717
9	124,000	360,000	923,000	2,143,589
10	95,000	316,000	914,000	2,357,948
Totals	$4,038,000	$6,012,000	$9,562,000	$15,937,425

Figures are based on 10% account growth annually.

TABLE 2 Annual Revenue Loss from Customer Defection

If you Lose:	*SPENDING* **$5 Weekly**	*SPENDING* **$10 Weekly**	*SPENDING* **$50 Weekly**	*SPENDING* **$100 Weekly**	*SPENDING* **$200 Weekly**	*SPENDING* **$300 Weekly**
1 *customer a day*	$94,900	$189,800	$949,000	$1,898,000	$3,796,000	$5,694,000
2 *customers a day*	189,800	379,600	1,898,000	3,796,000	7,592,000	11,388,000
5 *customers a day*	474,500	949,000	4,745,000	9,490,000	18,980,000	28,470,000
10 *customers a day*	949,000	1,898,000	9,490,000	18,980,000	37,960,000	56,940,000
20 *customers a day*	1,898,000	3,796,000	18,980,000	37,960,000	75,920,000	113,880,000
50 *customers a day*	4,745,000	9,490,000	47,450,000	94,900,000	189,800,000	284,700,000
100 *customers a day*	9,490,000	18,980,000	94,900,000	189,800,000	379,600,000	569,400,000

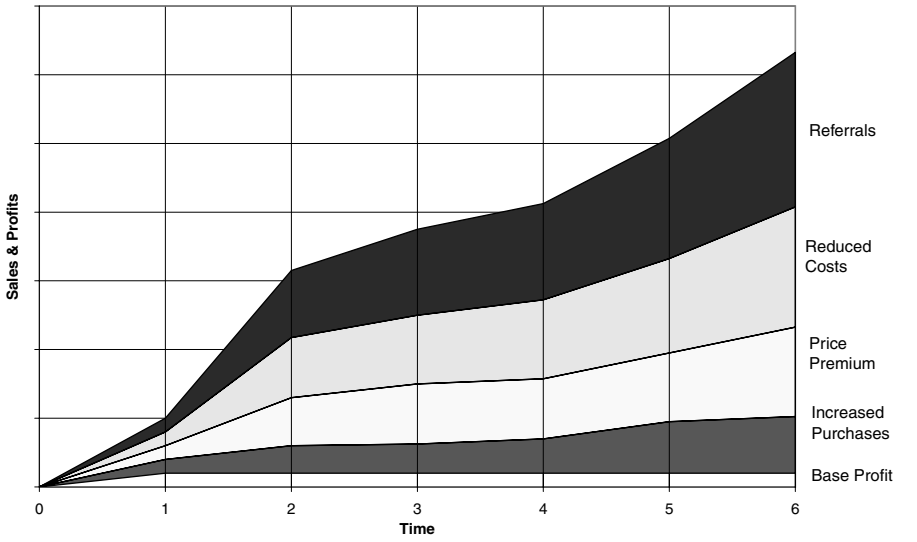

Figure 2 The Lifetime Value of One Customer.

Service quality and customer satisfaction are not new constructs. As early as the mid-1960s, Peter Drucker, the original management guru, prescribed the following questions for all businesses: Who is your customer? What is the essence of your business? What does your customer value? And how can your business serve the customer better than the competition?

It is clear that although the 1990s were an era of talking about service quality and customer satisfaction, business has a long way to go in delivering on a customer satisfaction promise. It would certainly be depressing if all we have accomplished since the 1982 publication of Peters and Waterman's *In Search of Excellence* is to add a customer service customer satisfaction statement to the mission statements of our Fortune 500 companies. Five years ago, we would have been pleased to state that customer satisfaction was being discussed in the boardrooms and had a chance to become a part of business strategy. Now this is not enough. Delighting customers must become a focal strategy. Every business, every executive, and every manager must assess how their ''function/work'' contributes to customer satisfaction.

2. IT'S THE CUSTOMER, STUPID . . . NOT SERVICE QUALITY, PRODUCT QUALITY, OR CUSTOMER SERVICE!

The issue is satisfaction. Consumers will pay for two things: solutions to problems and good feelings. When the consumer can purchase almost any product from multiple channels (TV, catalog, Internet, multiple stores) the only thing that can differentiate one business from another is the way it makes the customer feel. Businesses must decide whether they will simply be a vending machine and wait for the customer to deposit money in the slot and pick up their product/service, or whether they will add value. If businesses choose to be a vending machine, consumers will choose the cheapest, most convenient vending machine. But if businesses add value, consumers will expend effort, remain loyal, and purchase at greater margin for longer periods of time.

The issue is not simply service and product quality. Businesses can make their ''stuff'' better and better, but if it is not the stuff that consumers want, then consumers will not buy. In the 1960s, the big names in slide rules were Post, Pickett, and K&E. Each made considerable profit by selling better-quality and better-functioning slide rules—year after year after year. These three companies did exactly what the experts say is important—make quality products. Yet in the late 1970s slide rule sales disappeared, and so did these companies, not because they made slide rules of lower quality but because new companies by the name of Hewlett-Packard and Texas Instruments began making electronic calculators. Not a single slide rule company exists today. None of the three dominant companies noticed the shift. All three continued to make quality slide rules for customers who were now buying electronic calculators. Making the best-functioning product does not guarantee survival. The customer passed them by. Satisfaction results not simply from quality products and services but from products and services that consumers want in the manner they want. The side of the business highway is littered with companies that continued to make their stuff better without watching where the consumer was headed. In 1957, the top 10 businesses in Chicago were Swift, Standard Oil, Armour, International Harvester, Inland Steel, Sears, Montgomery Wards, Prudential, and the First Bank of Chicago. Thirty-five years later, the list includes only Sears and First National Bank from the original list, plus Ameritech, Abbott Labs, McDonald's, Motorola, Waste Management, Baxter, CAN Financial, and Commonwealth Edison. These two lists dramatically show the evolution that business goes through.

The discussion of a customer-satisfaction orientation is not limited to a few select businesses and industries. A satisfaction orientation exists in profit, not-for-profit, public and private, and business-to-business, and business to consumer (see Table 3).

2.1. Return on Investment for Service-Quality Improvements

Increases in service quality and customer satisfaction have direct bottom-line benefits. According to Robert LaBant of IBM, a 1% increase in customer satisfaction is worth $275,000,000 to IBM. Reichheld and Sasser (1990) estimated that a 5% increase in customer retention yields a 20% profit increase for catalog companies, 30% for auto service chains, 35% for software companies, 50% for insurance companies, and 125% for credit card companies. Costs associated with satisfaction and service-quality improvements are not costs but investments in sales, profit, and long-term viability. Assistance in figuring the return on investment for service quality and satisfaction improvements is available in books (Rust et al. 1994) and ROI calculators available on the Web (www.1to1.com—click on tools and ideas—look for downloads; www.e-interactions.com/download.html); (www.cfs.purove.edu/conscirt/quality.html).

3. HOW TO CREATE A CUSTOMER-FOCUSED BUSINESS

3.1. Step 1: Mission, Values, and Purpose

A customer-service focus emanates from the core values implicitly and explicitly expressed throughout the organization. It is represented in the mission statement of the company and the development

TABLE 3 Examples of Customer Service Applications

Consumer		Business		Public/Institutional/Associations/Not for Profit	
Products	Services	Products	Services	Products	Services
Retail, general	Insurance	Manufacturing to inventory	Transportation	Infrastructure	Defense
Retail, special	Banking, financial	Manufacturing to order	Warehousing	Currency/stamps	Education
Mail order	Travel	Commodities	Insurance	Publications	Licensing, regulation
Do-it-yourself	Health care	Finished goods	Financial	Power/light	Police protection
Home delivery	Real estate	Hi-tech/low-tech	Factoring	Museums, parks	Health
Party sales	Domestic help	Bulk/packaged	Engineering	Sheltered workshops	Information
Door-to-door	Lawn, yard care	Consumer/industrial	Environmental	Research spinoff	Postal service
In-home demos	Bridal counseling	Original equipment manufacturers/distributors	Computer services	Surplus goods	Subsidies
Auctions	Catering		Security services	Timberlands	Taxes
Estate/yard sales	Riding, sports	Direct/indirect	Consulting	Oil, minerals	Lotteries
Equipment rental	Recreation	Consignment	Leasing		Agriculture department
Subscriptions	Entertainment	Site delivery	Waste management		Disaster relief
Negative options	Beauty	On-site construction			Standards
	Diet plans				Export/import
	Child care				Social services
	Education				Fire department
	Consulting				Waste management

of a functional department to oversee customer relationship management and an executive responsible for the voice of the consumer.

A customer-focused mission statement should make it clear to all who work in the company and do business with the company that the customer is not to be ignored and should be the focal point of all components of the business. Every department and every individual should understand how they are serving the customer or serving someone who is serving the customer. The mission can be something as simple as Lands' End's ''guaranteed period'' or the engraving on a two-ton granite rock that marks the entrance to Stew Leonard's grocery stores in Connecticut:'' Stew's Rules—Rule 1. The customer is always right. Rule 2. If you think the customer is wrong reread rule number 1.'' Then there is the elegant mission statement on the walls of the Ritz-Carlton: ''We are Ladies and Gentleman Serving Ladies and Gentleman. . . . The Ritz-Carlton experience enlivens the senses, instills well-being, and fulfills even the unexpressed wishes and needs of our guests.'' And the mission statement that helps explain why Wal-Mart is the top retailer in the world: ''We exist to provide value to our customers. To make their lives better via lower prices and greater selection; all else is secondary.''

The foundation for a visionary company is the articulation of a core ideology (values and guiding principles) and essence (the organizations fundamental reason for existence beyond just making money) (Collins and Porras 1994).

3.2. Step 2: Proactive Policies and Procedure

Once an organization has established the principles of customer orientation and service quality as part of its reason for being, it must implement that vision throughout in specific policies and procedures that define doing business as and at that company.

These policies can be taught as simply as they do at Nordstrom's, where customer service training consists of the prescription ''Use your good judgment always,'' or as complex as a 250-page policies and procedures manual covering acceptance or orders, handling major and minor accounts, order changes, new customers, phone inquiries, return policies, ship dates, orders for future delivery, and hundreds of other specific policies and procedures.

In a business world that no longer has time for a five-year apprenticeship in which the policies and procedures are passed through in one-on-one learning, how things are done and their standards must be available for all. High levels of turnover means that teaching policies and procedures is a 7-day a week, 24-hour-a-day requirement.

3.2.1. One Very Important Policy: The Guarantee

One of the more important policies and procedures for creating service quality and satisfaction is the guarantee. In a world in which products and services are commodities (interchangeable products that can be purchased at a number of channels), customers want to know that the company stands behind the purchase. Companies may not be able to guarantee that they won't make mistakes or that the product will never fail, but they can guarantee that they will stand behind it. Unfortunately, many companies have policies that state what they will not do rather than reassuring the customer with what they will do. Lands' End tells us that everything is ''Guaranteed period.'' Restoration Hardware tells us, ''Your satisfaction is not only our guarantee, it's why we're here. To be perfectly clear, we insist you're delighted with your purchase. If for any reason, a selection doesn't meet your expectations, we stand ready with a full refund or exchange.'' Nordstrom's has been built on its legendary policy of taking back *anything* (it is part of the Nordstrom's legend that they once accepted a set of tires despite never having sold tires). Same-day delivery, ''If something goes wrong in 30 days after we fix it we will repair it free,'' ''We accept merchandise for 30 days after purchase but only with a sales slip'' are examples of policies affecting guarantees.

In establishing guarantees, there are a number of factors that should be considered. First, the costs of administering return/guarantee policies may outweigh their benefits. For example, if a manager must approve all returns and the approval rate exceeds 90% anyway, the costs of the manager's time and effort probably exceed the benefit. Second, uncertain and restrictive policies that increase the probability that irate consumers will confront poorly prepared front-line people will decrease morale and increase turnover. Third, guarantees can be a significant source of profit when companies sell extended guarantees for products and services that have naturally low levels of failure. Electronics companies have found these extended policies to be very profitable. Fourth, guarantees, which lay out an organization to outperform historical or market standards, force companies to become extraordinary. Making extraordinary goals public may force companies to aim at and reach high levels of customer service and satisfaction. Finally, return policies and product service guarantees must be developed in light of the lifetime value of the customer. The probability of losing a customer for life because of a restrictive policy must be balanced against the value of the potential purchasing power and loyalty of the consumer in the formation of policies. Sewell Cadillac in Texas estimates the value of each customer to be over $250,000 (the value of car sales, leasing, repairs to customers buying

cars over their lifetime). To create policies that drive these customers away for what really are insignificant dollar amounts given this lifetime value is tantamount to stealing future income.

On the other hand, very liberal guarantees and return policies may be inappropriate and silly. A contractor who has a satisfaction-guaranteed policy might be giving away the business when the customer is dissatisfied with the room design they selected and approved although the workmanship was outstanding. Although unlimited guarantees are an inducement to consumers and may be a competitive advantage, a profitable business must be run. Unlimited and liberal policies may require higher prices, which will allow competitors to offer comparable products and services at lower prices.

For most businesses, a guarantee in the form of a limited warranty probably makes sense. These limited warranties spell out the conditions that define replacement or exchange. Customer abuses are less likely, but reasonable customers will still find these guarantees an inducement.

3.3. Step 3: Determining What Is Important to the Customer

Perhaps the biggest drawback to developing exceptional customer satisfaction is that information about what is important to customers comes from talking to ourselves (the executives of the company), not the customer. Understanding the customer experience from representative samples of customers using qualitative measurement and analysis is generally possible, and it guarantees that policies and procedures instituted by a company are not based on idiosyncratic and/or nonrepresentative (of all a company's customers) pieces of data or belief.

The customer satisfaction measurement system must connect to the internal measures of a company and to external customer evaluations. To provide evidence, surveys can be performed to make possible a gap analysis (the gap is the difference between what the customer should experience and what the customer actually experiences). The data of actual-to-expected performance allow the application of advanced statistical techniques such as regression analysis to determine empirically the relative impact and/or importance of attributes and processes to customer satisfaction (the power of this technique and an example of its application are illustrated in Anton [1996]). To improve customer satisfaction, identifying the specific attributes and processing the most predictive of customer satisfaction decisions about investment of resources will yield the greatest benefit.

4. THE CUSTOMER SERVICE DEPARTMENT

Companies at the forefront of customer satisfaction have found that positioning, organizing, and staffing a department for consumer affairs/customer satisfaction is essential. The growth in importance of customer service departments is dramatically shown by the proliferation of professional associations and professional newsletters. The Society of Consumer Affairs Professionals (SOCAP, at www.socap.org) serves to professionalize the industry and provides a range of training, educational material, and meetings. The *Customer Service Newsletter,* offered by the Customer Service Group (www.alexcommgrp.com), is part of a set of useful newsletters and practical materials for improving and understanding a company's customer service offerings.

4.1. Organization

Organizing a department whose top executive reports to the CEO is likely to send a signal to the organization that customer service/satisfaction is important. Direct reporting to the CEO allows policies about customers to be made at the highest levels and reduces the probability that these policies will get lost in the history and bureaucracy of the business.

4.2. Centralization

There is much to be gained from having a centralized customer service initiative. These advantages include economies of scale, greater practicality for using state of the art computers and telephone strategies, adaptability, easy adherence to standards, better access to top management, opportunities to create career paths, and being well suited for manufacturing and consumer products businesses. Probably the greatest advantage of centralization is the centralization of information. Information is easily aggregated and analyzed for use by the strategic areas in the business.

4.3. Setting Service-Quality Standards

Service standards are the measuring stick that guides a customer service report card. Standards must be carefully engineered to be consistent with the operational and strategic goals of the business. One of the more common standards in customer call centers may actually be antithetical to the customer satisfaction goals of the organizations. Forcing customer service agents to take too many calls per hour or make each call as short as possible (both metrics logical under a cost cutting/control mission) may interfere with a mission to maximize customer satisfaction (which might require longer calls and therefore fewer calls per hour).

Mystery shoppers, mystery callers, and quality monitoring are all techniques used to monitor service quality standards. Unfortunately, more attention is paid to how those standards are measured than to the establishment of standards that are really related to outcome measures that matter.

Simply stated, what gets measured gets done. What gets rewarded gets repeated. Telling front-line people that they must greet the customer within 25 seconds can easily be monitored and will increase the chance that the front-line person will greet the customer quickly. If a standard is established, it should be related to satisfaction, purchase, or loyalty in some way. Standards should be related to issues of bottom-line significance. Unfortunately, many customer satisfaction and service quality standards are set because they can be easily measured and monitored (greet customers within 25 seconds when they enter the store, answer the phone by the fourth ring, respond to the e-mail with 24 hours). Or they are set because they have been historically used in the organization.

Creating meaningful customer service and service quality standards plays a role in establishing the company as an outstanding customer-oriented organization. Few companies and organizations have standards, and those who have them do not tie them to strategy and mission. But a few have standards that they have found to be causal determinants of customer satisfaction and profitability. These companies are leaders in their fields.

4.4. Managing Complaints

At any time, almost 25% of your customers are dissatisfied with your products or service. Yet fewer than 5% of these consumers ever complain. Complaints are a fertile source of consumer intelligence. Businesses should do everything to maximize the number of complaints from dissatisfied customers. Complaints define what companies are doing wrong so that systemic changes can be made if needed. Second, research is clear in showing that a dissatisfied consumer who complains and is taken care of is significantly more loyal than a consumer who does not complain. Complaints are strategic opportunities. Most consumers who complain are not irate. Systems and employees who are not responsive create irate consumers. Training and empowerment allow front-line employees to reduce anger and create loyal customers.

Companies that understand the strategic value of complaints have instituted systems and access points that literally encourage consumers to complain. Internet access sites and e-mail addresses are the wave of the future, and companies will need to be prepared for the volume of contacts received in this manner. More likely today's companies have a call center at the center of their complaint-management system.

With simple training and sound procedures and policies, most consumer complaints can be resolved quickly and effectively at the lowest levels of contact. It costs five times as much to get new customers as it does to keep customers. Call centers, and in the future e-mail and Web access, provide companies with the cost-effective ability to manage complaints, turning a dissatisfied customer into a loyal one. But maybe more important, a company that recognizes a complaint as a strategic opportunity encourages complaints and is more likely to use the information to make strategic development and marketing decisions. What you do not hear can and will hurt you.

4.5. Call Centers

The call center has emerged as a vital link between customers and businesses after the consumer has purchased the products and/or services. These centers range from small operations to massive operations employing thousands of telephone service representatives.

The birth of the 800 toll-free number made access to companies cheap and easy for consumers. Subsequent advances in telecommunications technology have enabled businesses to handle volumes of calls unimaginable five years ago at affordable costs.

4.5.1. Call Center Operations and Logistics

Inbound and outbound communications form the thrust of call center operations. The Internet is forming the basis of low-cost communication for the business-to-business and consumer-to-business enterprise. EDI (electronic data interchange) was a novelty five years ago. Now consumers (and businesses who are consumers of other businesses) would probably prefer to be able to order, check order, check inventory, locate where the products are en route, pay, and follow up without having to touch or talk to a live person.

Sophisticated natural language recognition voice recognition programs (interactive voice response technology [IVR]) are replacing the boring and ineffective first-generation IVR (''press or say 1 if you . . . press or say 2 if you . . . ''). IVR can become a cost-effective means of handling 50–75% of all incoming phone conversations. Telephonic advances allow a consumer to speak in his or her natural voice about the problem he or she is experiencing and the call to be routed so that the most qualified customer service agents will get the call before it has even been picked up.

More importantly, switch technology allows routing of customers based on their value to the company. High-priority customers can get through quickly, while lower-valued customers can wait in the queue.

4.6. Hiring, Training, and Keeping Customer-Oriented Professionals

The customer is the most important part of a business. No customer means no sales means no reason to exist. If the customer is so important, do we see few executive-level positions with customer satisfaction in the title? The financial side of the business is important, so we have a vice president of finance. The marketing side of the business is important, so we have a vice president of marketing. The consumer is important, but we do not have a vice president for consumer satisfaction.

Where to begin:

1. Make a commitment to exceptional customer satisfaction by making certain that job descriptions have customer satisfaction accountabilities. Have a person whose only responsibility is to think about how the operations and marketing and recruitment affects the customer. Because we believe that hiring minority individuals is important, we put into place an executive who audits all aspects of this part of the company. Without a key individual whose focus is customer satisfaction, customer satisfaction may be lost in the day-to-day pressures.
2. The expression is, if you are not serving the customer, you'd better be serving someone who is. Thus, positions should include some accountability for customer satisfaction. What gets measured and rewarded gets done. If customer satisfaction is important, then monitoring, measuring, and rewarding based on customer satisfaction are critical.
3. Customer satisfaction must be lived by the top executives. Customer-oriented cultures wither when senior executives only talk the talk. Every Saturday morning, executives at Wal-Mart's Bentonville, Arkansas, headquarters gather for a meeting that is satellite linked to each of their 2600+ stores. They do a number of things at this meeting (point out and discuss hot items, cost savings, the Wal-Mart cheer, etc.), but nothing is more important than the senior executive at the meeting getting up and asking all there, ''Who is the most important person in Wal-Mart's life?'' and then hearing all respond, ''The customer.''
4. Hire for attitude, train for skill. There is simply too much looking for skilled people and then hoping they can learn customer service skills. In studying at the best-in-class companies, we have observed that selecting people at all levels who are ''eagles'' (show evidence of the ability to soar) and then teaching them the skill set for the job is better than getting people who have some skills and hoping they will become eagles.
5. There are any number of commercially available screening and selection tools focusing on customer satisfaction.

Selecting, training, and developing a fanatical devotion to the customer in employees is the critical piece of the puzzle.

4.6.1. Training for Exceptional Customer Service

Most companies expect a great deal from their customer service professionals. Yet formal training is sketchy and infrequent and lacks specificity and impact. Training works well because it sets expectations, teaches skills, and allows employees to be successful in the job.

Instituting customer service training in companies with established training programs requires a customer-orientation module in existing training programs and the development of a complete customer service representative training program for those individuals with total customer service functionality.

Some companies find that a call center is the best place for any new hire to gain experience. Few engineers at Ford will forget the customer in their later jobs after spending some time in the Ford Customer Call Center listening to problems and complaints. In addition, after working in a call center, these future leaders of the company (whether they come from sales, finance, marketing, legal, or administration) become sensitive to customer satisfaction issues and see more clearly how customer service fits the big picture.

Stories of companies with exceptional customer service orientation and excellent training obscures the fact that training alone will never work. The organization, its people, and its processes must support the jobs of people who have direct customer service functionality. Customer service training is a continuous process. Measuring performance, holding people accountable, providing feedback, cross-training, refresher training, and customer visits all allow the growth and development of a customer service culture and mission.

4.7. Serving the Internal Customer

One of the greater gaps found in organizations attempting to become more customer focused is the lack of attention to the internal customer. A good example of an internal customer orientation is provided by the Haworth Company, an office systems manufacturer. Their quality-improvement program revolved around the internal customer. Each work unit identified all its internal customers. They prioritized these customers, identified key work output in measurable terms, set standards, and mea-

sured their performance with their internal customers. Many companies have instituted internal help desks to which employees can call to get answers and solutions to their work problems much the same way that external customers use call centers for answers to questions and solutions to problems.

5. THE FUTURE OF CUSTOMER SERVICE AND SERVICE TECHNOLOGY

The 21st century will be an era when customer satisfaction and service quality will be defined by providing customers (business to business and consumer to business) consistent accessibility. Total customer touch, at anytime, from anywhere, in any form. However, few businesses use customer access as a key component of a business strategy. Access seems to be developing piecemeal, not as the central core of an overall strategy to allow customer access and deliver customer value anytime and anywhere.

5.1. Customer Access Is the New Marketing Paradigm

It really is very simple. If you want people to solve problems right now, give them right-now information. And magically, if you want employees to create an enhanced customer experience (internal and/or external), give them the right information exactly when they need it. Access will be realized in a combination of bricks-and-mortar storefronts, the call center, and the Internet. If you don't deliver consistent accessibility, someone else will.

Dell Computers understands the new paradigm probably better than any company as we enter the new millennium. It began selling products online in 1996. In 1999, it received 2 million hits per week and did 40% of its business on the Web. That is 20 million dollars of computers and "stuff" each day. No computer is built until it is ordered, making inventory expenses minimal. Michael Dell believes that three words control the future of business. Businesses that understand the power of these words and can implement them will win. What are these three words? "The consumer experience." That expression placed on or in view of everyone's desk reminds all Dell employees that their salaries, cars, desks, and retirement accounts and the presents they give all depend on the experience they provide to the customer at all customer touch points. To make certain they are on top of that "experience," Dell created the Consumer Experience Council, a group that scrutinizes every aspect of how Dell interacts with the customer.

Technological advances have made the ability to integrate telephone and computer technologies with front- and back-office functions a realistic weapon in creating and maintaining long-term customer relations. The business that treats the telephone, the Internet, e-mail, and storefronts as complementary channels will just create more opportunities for capturing market share and the share of the consumer.

There are some very strong reasons why accessibility is the central issue, but none more important than the simple fact that lack of accessibility turns out to be the prime customer dissatisfier and reason why consumers desert a company. Research at our Center for Customer Driven Quality at Purdue University has affirmed that over 50% of consumers who desert a company because of bad service experience (Figure 3) and that bad service is primarily defined as an accessibility issue (Figure 4).

In order to support the total customer experience with information and intelligence at all points of contact, businesses must develop systems that can pull information from many differing databases. This requires a technology platform that allows for real-time reporting to the business and immediate updating to the customer experience file. Our points of contact must be aligned with all databases. Finally, the people who work in all of the customer access channels (contact centers, storefronts, and webcenters) need to understand the value that is added at each and every point of customer contact. This requires a redefinition of the role of each person who is acting in one of these contact channels. As an example, storefront people need to be comfortable with the Web and the call center. They need to be aware of how each of these access channels operates. This will require them to access to these other channels within the store. The company face to the customer should be such that whatever channel the customer selects, he or she will be able to conduct the business he or she wants and be recognized by his or her contact point as a person, not a transaction. No story will need to be told twice. No problem will go unsolved. No question will go unanswered. The customer will be proactively informed of any changes.

The organization must realize that this is not simply a technology purchase. This is not just pasting the latest electronic gizmo or switch or software onto your call center or website. Technology only enables the organization to enhance the customer experience. Customer relationship management (CRM) is not a toolbox; it is a new way of seeing the customer and then using a set of tools to enhance the total customer experience.

In a similar manner, the director, manager, or senior executive will have access to a set of cockpit-like analytical tools that will provide her or him enterprise-wide access to aggregate real-time information. So while the individual performance of a telephone service representative may not be

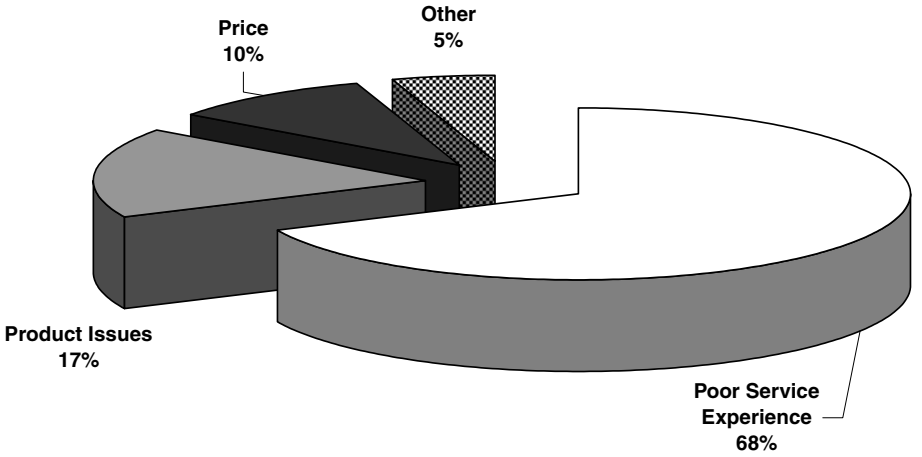

Figure 3 Why Do Customers Desert?

important to her/him, the enterprise-wide customer issues being probed in the contact centers are an issue—and this cockpit-type software provides that information when requested in real time.

So companies must remember to keep the customer at the focus of the decisions and solutions. Systems must be based on processes and technology that allow for simplified customer relationship management. General Electric has over 200,000 products across 80+ industries but only one number to call with a question, problem, concern whether it is about a jet engine, MRI machine, or a lightbulb . . . and they do this 24 hours a day, 7 days a week, 365 days a year. The systems must be open and easily integrated. The news is that this version of the future is available with technology today (and it will only get better and cheaper and easier).

Perhaps the most critical but undervalued aspect in creating total enterprise access will be the development of a layer of technology infrastructure called middleware. This middleware is critical for integrating the information now housed in separate and disparate databases. This ''plumbing'' does not get the attention it deserves. It is not glamorous or fashionable, partly because it is difficult to get a handle on, and it represents separate and distinct territories, each protected by herds of executives and workers who have vested interests in status quo systems. Middleware is the bridge between the databases. It is the piece that prevents the customer from hearing, ''I am sorry, but the system does not allow me to do that'' (heard often at airline counters) or ''I don't have access to that database here'' (heard often at banks)—the kinds of things that frustrate consumers and drive them elsewhere. No more ''Why is it so hard for you people to get the order right?''

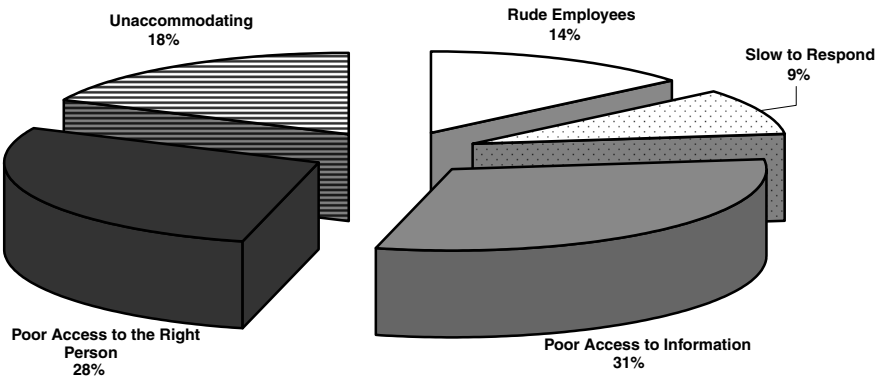

Figure 4 What Does the Customer Mean by Poor Service Experience?

Accessibility is clearly a business issue. Dell has recently moved past Compaq computer as the leading PC in the United States, yet Dell doesn't sell a single computer in the store. Intel and Cisco will book more from direct Internet orders than all the business-to-consumer sales that have taken place up until now. We can check inventory levels, place orders, and track these orders and delivery dates from these companies anytime we want to from our desk (as well as answer or have answered any of the questions we might have).

Accessibility is a control issue. Our ability to track our FedEx and UPS packages gives us power (and satisfaction). Imagine my smile when, after the recipient of a report I sent by FedEx claimed not to have received it, meaning my bonus for doing the work at that date would not be forthcoming, I was able to access (while we were speaking) the very signature that signed for the FedEx package exactly one hour before the due time (signed by this guy's secretary).

Accessibility is not just a marketing issue but an enterprise one. The story of how Avis trains its people better and more efficiently is the story of accessibility. Avis had the goal of consistent training across all employees anywhere anytime in the organization. The company developed a system called Spotlight, a virtual multimedia learning center that can be accessed in any of the 15,000 offices across 1,210 countries. After hearing a greeting and motivational talk by the CEO and learning the basic Avis skill set, the new employee meets a customer who takes him or her through the most common problems (representing 80% of all the escalated customer dissatisfaction issues). There are multiple lessons of accessibility here. First, anyone in the organization has immediate access to training. Classes do not have to be scheduled. Trainers do not have to be trained. The associate in Asia can access the training as well as an associate in New York City. This training is infinitely repeatable. But less obvious is the accumulation of customer information so that employees can know and learn from the top consumer problems, questions, and difficulties in an almost real-time process. While Avis is training to the specific situation, the competition is talking about general issues of customer dissatisfaction/satisfaction. Accessibility of information has led to specificity of attack.

Accessibility is an inventory issue. Accessibility among vendors, manufacturers, and retailers will lead to automatic replenishment. The complex accessibility among Dell, FedEx, and the many manufacturers who make Dell's parts results in FedEx managing just-in-time delivery of all the parts needed to build that special PC that the consumer just ordered today. At the end of the day, the system will tell us what we have on hand compared with what we want. If there is a difference, the difference will be ordered and the system will learn about proper inventory levels so that differences will be less likely in the future. In other words, the system learns from its experiences today and adjusts for tomorrow.

Accessibility is a retooling issue. Retooling a company for customer access means reengineering the technology and the people.

Most importantly, whatever the bottom-line impact of accessibility is on running a better business, the bottom-line impact on consumers is key. Accessibility enhances the customer's total experience. Accessibility builds customer and employee relationships with the company that empower them to change the enterprise and the enterprise to change them.

Accessibility builds brand meaning and value. Consumers are finding accessibility as a differentiating brand value.

Accessibility can create ''delight''—the difference between the just satisfied and the WOWed.

In addition to accessibility, the future of service quality and customer satisfaction has to do with how information about the consumer will lead to extraordinary relationship building. Many names are emerging for this, such as database marketing, relationship marketing, and one to one marketing. This is not a new name for direct mail, or an order-taking system, or a substitute for a solid marketing strategy, or a solution to a bad image, or quick fix for a bad year. This is a new paradigm that Peppers and Rogers (1997, 1999) call ''one to one marketing.'' The goal is to identify your best customers (''best'' can mean more profitable, most frequent purchasers, highest proportions of business, loyalty) and then spend the money to get them, grow them, and keep them loyal. You need to fence your best customers off from competition. How easy would it be for another company to come in and steal these clients? How easy would it be for these best customers to form a relationship similar to what they have with you with another company?

6. THE CUSTOMER SERVICE AUDIT

The list of questions in Table 4 is a useful checklist to monitor performance of your company for customer service and satisfaction.

7. A FINAL WORD

Customer satisfaction is everything. (For a free downloadable collection of customer service and customer satisfaction quotes, go to customer service graffiti at www.cfs.purdue.edu\conscirt\quality.html—click on customer service graffiti). In the 21st century, satisfaction will be driven by

TABLE 4 Customer Service Audit Checklist

OBJECTIVE: The following list is an aid to measure and monitor customer orientation.

PROCEDURE
- Do you have a written customer service policy?
- Is this given a wide circulation within the company?
- Do customers receive a copy of this policy?
- Is customer service included in the marketing plan?
- What elements of customer service do you regularly monitor?
- Do you think other aspects of service should be monitored?
- Do you monitor competitive service performance?
- Do you know the true costs of providing customer service?
- Do customers have direct access to information on stock availability and delivery?
- How do you report to customers on order status?
- Is there a single point of contact for customers in your company?
- Do customers know who this individual is?
- Is any attempt made to estimate the cost of customer service failures (for example, a part delivery, late delivery, etc.)?
- Do you seek to measure the costs of providing different levels of service?
- Do you have internal service measures as well as external measures?
- How do you communicate service policies to customers?
- What is your average order cycle time?
- How does this compare with that of your major competitors?
- Do you monitor actual order-to-delivery lead-time performance?
- Do you have a system for accounting for customer profitability?
- Does the chief executive regularly receive a report on customer service performance?
- Do you consciously seek to hire individuals with a positive attitude towards customer service?
- Does customer service feature in the criteria for staff promotion?
- Do you use quality control concepts in managing customer service?
- Do you differentiate service levels by product?
- Do you differentiate customer service levels by customer type?
- Do you have a standard cost for an out of stock situation (for example, cost of lost sales, cost of back orders, etc.)?
- Do you provide customers with a customer service manual?
- Do you monitor the internal customer service "climate" on a regular basis?
- Does your customer service organization effectively manage the client relationship from order to delivery and beyond?
- How do you monitor and respond to complaints?
- How responsive are you to claims from customers?
- Do you allocate adequate resources to the development of customer service?
- How do you seek to maintain a customer focus?
- Does customer service regularly feature at management meetings and in training programs?
- What specific actions do you take to ensure that staff motivation re customer service is maintained at a high level?
- Is the company image re customer service adequate for the markets in which it operates?

customer access. But first, senior executives must agree that providing customers with a consistent, thoughtful, and value-added total customer experience at any and all touch points is vital to their retention and loyalty and future acquisition. This will allow their organizations to be moving towards a yet-to-be-defined level of enhanced total enterprise access for employees and customers . . . which will enhance the employee and customer experience . . . which will create loyal and long-lasting employee and consumer relationships with your company . . . which means happy customers, happy employees, happy senior executives, happy shareholders, happy bankers, and of course happy consumers.

CHAPTER 24
Pricing and Sales Promotion

KENT B. MONROE
University of Illinois at Urbana-Champaign

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION TO PRICING MANAGEMENT

A husband and wife were interested in purchasing a new full-sized automobile. They found just what they were looking for, but its price was more than they could afford—$28,000. They then found a smaller model for $5,000 less that seemed to offer the features they wanted. However, they decided to look at some used cars and found a one-year-old full-size model with only 5,000 miles on it. The used car included almost a full warranty and was priced at $20,000. They could not overlook the $8,000 difference between their first choice and the similar one-year-old car and decided to purchase the used car.

This simple example illustrates an important aspect of pricing that often is not recognized: buyers respond to price differences rather than to specific prices. While this basic point about how prices influence buyers' decisions may seem complex and not intuitive, it is this very point that drives how businesses are learning to set prices. You may reply that this couple was simply responding to the lower price of the used car. And you would be correct—up to a point. These buyers were responding to a *relatively* lower price, and it was the *difference* of $8,000 that eventually led them to buy a used car.

Now consider the automobile maker who has to set the price of new cars. This decision maker needs to consider how the price will compare (1) to prices for similar cars by other car makers; (2) with other models in the seller's line of cars; and (3) with used car prices. The car maker also must consider whether the car dealers will be able to make a sufficient profit from selling the car to be motivated to promote the car in the local markets. Finally, if the number of new cars sold at the price set is insufficient to reach the profitability goals of the maker, price reductions in the form of cash rebates or special financing arrangements for buyers might have to be used. Besides these pricing decisions, the car maker must decide on the discount in the price to give to fleet buyers like car rental companies. Within one year, these new rental cars will be sold at special sales to dealers and to individuals like the buyer above.

Pricing a product or service is one of the most important decisions made by management. Pricing is the only marketing strategy variable that directly generates income. All other variables in the marketing mix—advertising and promotion, product development, selling effort, distribution—involve expenditures. The purpose of this chapter is to introduce this strategically important marketing decision variable, define it, and discuss some of the important ways that buyers may respond to prices. We will also discuss the major factors that must be considered when setting prices, as well as problems managers face when setting and managing prices.

1.1. The Definition of Price

It is usual to think of price as the amount of money we must give up to acquire something we desire. That is, we consider price as a formal ratio indicating the quantities of money (or goods and services) needed to acquire a given quantity of goods or services. However, it is useful to think of price as a ratio of what buyers receive in the way of goods and services relative to what they give up in the way of money or goods and services. In other words, price is the ratio of what is *received* relative to what is *given up*.

Thus, when the price of a pair of shoes is quoted as $85, the interpretation is that the seller receives $85 from the buyer and the buyer receives one pair of shoes. Similarly, the quotation of two shirts for $55 indicates the seller receives $55 and the buyer receives two shirts. Over time, a lengthy list of terms that are used instead of the term *price* has evolved. For example, we pay a postage *rate* to the Postal Service. *Fees* are paid to doctors and dentists. We pay *premiums* for insurance coverage, *rent* for apartments, *tuition* for education, and *fares* for taxis, buses, and airlines. Also, we pay *tolls* to cross a bridge, *admission* to go to a sporting event, concert, movie, or museum. Banks may have *user fees* for credit charges, *minimum required balances* for a checking account service, *rents* for safety deposit boxes, and fees or *interest charges* for automatic teller machine (ATM) use or cash advances. Moreover, in international marketing, *tariffs* and *duties* are paid to import goods into another country.

The problem that this variety of terms creates is that we often fail to recognize that the setting of a rent, interest rate, premium, fee, admission charge, or toll is a pricing decision exactly like that for the price of a product purchased in a store. Moreover, most organizations that must set these fees, rates, and so on must also make similar pricing decisions to that made by the car maker discussed above.

1.2. Proactive Pricing

The need for correct pricing decisions has become even more important as global competition has become more intense. Technological progress has widened the alternative uses of buyers' money and time and has led to more substitute products and services. Organizations that have been successful in making profitable pricing decisions have been able to raise prices successfully or reduce prices without competitive retaliation. Through careful analysis of pertinent information and deliberate acquisition of relevant information, they have become successful pricing strategists and tacticians (Cressman 1997).

There are two essential prerequisites to becoming a successful proactive pricer. First, it is necessary to understand how pricing works. Because of the complexities of pricing in terms of its impact on suppliers, salespeople, distributors, competitors, and customers, companies that focus primarily on their internal costs often make serious pricing errors.

Second, it is essential for any pricer to understand the pricing environment. It is important to know how customers perceive prices and price changes. Most buyers do not have complete information about alternative choices and most buyers are not capable of perfectly processing the available information to arrive at the ''optimum'' choice. Often, price is used as an indicator not only of how much money the buyer must give up, but also of product or service quality. Moreover, differences between the prices of alternative choices also affect buyers' perceptions. Thus, the price setter must know who makes the purchase decision for the products being priced and how these buyers perceive price information.

1.3. Factors to Consider When Setting Price

There are five essential factors to consider when setting price. *Demand* considerations provide a ceiling or maximum price that may be charged. This maximum price depends on the customers' perceptions of value in the seller's product or service offering. On the other hand, *costs* provide a floor or minimum possible price. For existing products or services, the relevant costs are those costs that are directly associated with the production, marketing, and distribution of these products or services. For a new product or service, the relevant costs are the *future costs* over that offering's life. The difference between the maximum price that some buyers are willing to pay (value) and the minimum cost-based price represents an initial pricing discretion. However, this range of pricing discretion is narrowed by *competition, corporate profit and market objectives,* and *regulatory constraints*.

2. PRICING OBJECTIVES

2.1. Profit Objectives

Pricing objectives need to be measured precisely. Performance can then be compared with objectives to assess results. In practice, the objective of profit maximization may be realized in multiple ways. In some markets, relatively low prices result in greater sales and higher profits. But in other markets, relatively high prices result in slightly decreased unit sales and also higher profits. Thus, the profits of some firms may be based on low prices and high sales volume, while for other firms high prices and low sales volume may be more profitable. Another common pricing objective is some form of target return on investment, that is, regaining a specified percentage of investment as income. Return on investment (ROI) is expressed as the ratio of profits to investments. For manufacturers, investments include capital, machinery, buildings, and land, as well as inventory. For wholesalers and retailers, inventory and buildings constitute the bulk of investments.

2.2. Volume-Based Objectives

Some organizations set pricing objectives in terms of sales volume. A common goal is sales growth, in which case the firm sets prices to increase demand. Other firms may seek sales maintenance, knowing that growth does not ensure higher profits and that they may not have the resources needed to pursue sales growth.

If capturing a high market share is a marketing objective, pricing objectives should reflect this goal. In general, a high market share is achieved by setting prices relatively low to increase sales. From a profitability perspective, the organization must be willing to accept lower initial profits in exchange for the profits that may be produced over time by increased volume and high market share. However, other companies achieve a strong position in selected markets by setting high prices and offering high-quality products and service.

2.3. Competitive Objectives

At times, firms base their pricing objectives on competitive strategies. Sometimes, the goal is to achieve price stability and engage in nonprice competition, while at other times, they price aggressively. When marketing a mature product and when the firm is the market leader, it may seek to stabilize prices. Price stability often leads to nonprice competition in which a firm's strategy is advanced by other components of the marketing mix: the product itself, the distribution system, or the promotional efforts.

In some markets, a firm may choose to price aggressively, that is, price below competition, to take advantage of market changes, for example, when products are in early stages of the life cycle, when markets are still growing, and when there are opportunities to establish or gain a large market share. As with a market share or volume objective, this aggressiveness must be considered within the context of a longer term perspective.

3. DEMAND CONSIDERATIONS

One of the most important cornerstones of price determination is demand. In particular, the volume of a product that buyers are willing to buy at a specific price is that product's demand. In this section we will review some important analytical concepts for practical pricing decisions.

3.1. Influence of Price on Buyer Behavior

In economic theory, price influences buyer choice because price serves as an indicator of product or service cost. Assuming the buyer has perfect information concerning prices and wants satisfaction of comparable product alternatives, he or she can determine a product/service mix that maximizes satisfaction within a given budget constraint. However, lacking complete and accurate information about the satisfaction associated with the alternative choices, the buyer assesses them on the basis of known information. Generally, one piece of information available to the buyer is a product's price. Other pieces of information about anticipated purchases are not always known, and buyers cannot be sure how reliable and complete this other information is. And because this other information is not always available, buyers may be uncertain about their ability to predict how much they will be satisfied if they purchase the product. For example, if you buy a new car, you do not know what the relative incidence of car repairs will be for the new car until after some months or years of use. *As a result of this imperfect information, buyers may use price both as an indicator of product cost as well as an indicator of quality* (*want satisfaction attributes*).

3.2. Useful Economic Concepts

This brief outline of how price influences demand does not tell us about the extent to which price and demand are related for each product/service choice, nor does it help us to compare, for example, engineering services per dollar to accounting services per dollar. The concept of elasticity provides a quantitative way of making comparisons across product and service choices.

3.2.1. Demand Elasticity

Price elasticity of demand measures how the quantity demanded for a product or service changes due to a change in the price of that product or service. Specifically, price elasticity of demand is defined as the percentage change in quantity demanded relative to the percentage change in price. Normally, it is assumed that quantity demanded falls as price increases; hence, price elasticity of demand is a negative value ranging between 0 and $-\infty$.

Because demand elasticity is relative, various goods and services show a range of price sensitivity. Elastic demand exists when a given percentage change in price results in a greater percentage change in the quantity demanded. That is, price elasticity ranges between -1.0 and $-\infty$. When demand is inelastic, a given percentage change in price results in a smaller percentage change in the quantity demanded. In markets characterized by inelastic demand, price elasticity ranges between 0 and -1. Another important point about price elasticity: it does change and is different over time for different types of products and differs whether price is increasing or decreasing.

A second measure of demand sensitivity is cross price elasticity of demand, which measures the responsiveness of demand for a product or service relative to a change in price of another product or service. Cross price elasticity of demand is the degree to which the quantity of one product demanded will increase or decrease in response to changes in the price of another product. If this relation is negative, then, in general, the two products are complementary; if the relation is positive, then, in general, the two products are substitutes.

Products that can be readily substituted for each other are said to have high cross price elasticity of demand. This point applies not only to brands within one product class but also to different product classes. For example, as the price of ice cream goes up, consumers may switch to cakes for dessert, thereby increasing the sales of cake mixes.

3.2.2. Revenue Concepts

There is a relationship between sellers' revenues and the elasticity of demand for their products and services. To establish this relationship we need to define the concepts of total revenue, average revenue, and marginal revenue. Total revenue is the total amount spent by buyers for the product ($TR = P \times Q$). Average revenue is the total outlay by buyers divided by the number of units sold, or the price of the product ($AR = TR/Q$). Marginal revenue refers to the change in total revenue resulting from a change in sales volume.

The normal, downward-sloping demand curve reveals that to sell an additional unit of output, price must fall. The change in total revenue (marginal revenue) is the result of two forces: (1) the revenue derived from the additional unit sold, which is equal to the new price; and (2) the loss in revenue which results from marking down all prior saleable units to the new price. If force (1) is greater than force (2), total revenue will increase, and total revenue will increase only if marginal revenue is positive. Marginal revenue is positive if demand is price elastic *and* price is decreased, or if demand is price inelastic *and* price is increased.

3.2.3. Consumers' Surplus

At any particular price, there are usually some consumers willing to pay more than that price in order to acquire the product. Essentially, this willingness to pay more means that the price charged for the product may be lower than some buyers' perceived value for the product. The difference between the maximum amount consumers are willing to pay for a product or service and the lessor amount they actually pay is called consumers' surplus. In essence, it is the money value of the willingness of consumers to pay in excess of what the price requires them to pay. This difference represents what the consumers gain from the exchange and is the money amounts of value-in-use (what is gained) minus value-in-exchange (what is given up). Value-in-use always exceeds value-in-exchange simply because the most anyone would pay must be greater than what they actually pay, otherwise they would not enter into the trade.

3.3. Understanding How Buyers Respond to Prices

As suggested above, a successful pricer sets price consistent with customers' perceived value (Leszinski and Marn 1997). To understand how customers form value perceptions, it is important to recognize the relative role of price in this process. Because of the difficulty of evaluating the quality of products before and even after the product has been acquired, how customers form their perceptions of the product becomes an important consideration when setting prices. During this perceptual process, buyers make heavy use of information cues, or clues. Some of these cues are price cues and influence buyers' judgments of whether the price differences are significant. For example, buyers may use the prices of products or services as indicators of actual product quality.

3.3.1. Price, Perceived Quality, and Perceived Value

Would you buy a package of 25 aspirin that costs only 50 cents? Would you be happy to find this bargain, or would you be suspicious that this product is inferior to other brands priced at 12 for $1.29? In fact, many consumers would be cautious about paying such a low relative price. Thus, the manufacturers of Bayer and Excedrin know that some people tend to use price as an indicator of quality to help them assess the relative value of products and services.

Since buyers generally are not able to assess product quality perfectly (i.e., the ability of the product to satisfy them), it is their *perceived quality* that becomes important. Under certain conditions, the perceived quality in a product is positively related to price. Perceptions of value are directly related to buyers' preferences or choices; that is, the larger a buyer's perception of value, the more likely would the buyer express a willingness to buy or preference for the product. Perceived value represents a trade off between buyers' perceptions of quality and sacrifice and is positive when perceptions of quality are greater than the perceptions of sacrifice. Figure 1 illustrates this role of price on buyers' perceptions of product quality, sacrifice, and value. Buyers may also use other cues, such as brand name, and store name as indicators of product quality.

3.3.2. Price Thresholds

Those of us who have taken hearing tests are aware that some sounds are either too low or too high for us to hear. The low and high sounds that we can just barely hear are called our lower and upper absolute hearing thresholds. From psychology, we learn that small, equally perceptible changes in a response correspond to proportional changes in the stimulus. For example, if a product's price being raised from $10 to $12 is sufficient to deter you from buying the product, then another product originally priced at $20 would have to be repriced at $24 before you would become similarly disinterested.

Our aspirin example above implies that consumers have lower and upper price thresholds; that is, buyers have a range of acceptable prices for products or services. Furthermore, the existence of

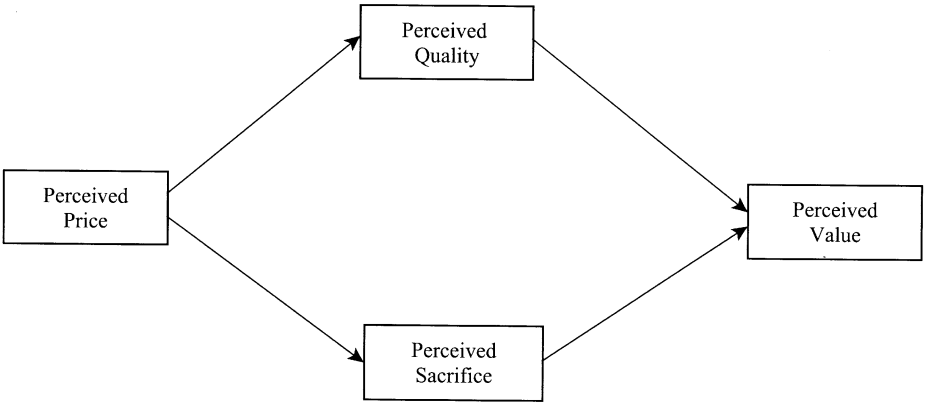

Figure 1 Perceived Price–Perceived Value Relationship

a lower price threshold implies that there are prices greater than $0 that are unacceptable because they are considered to be too low, perhaps because buyers are suspicious of the product's quality. Practically, this concept means that rather than a single price for a product being acceptable to pay, buyers have some range of acceptable prices. Thus, people may refrain from purchasing a product not only when the price is considered to be too high, but also when the price is considered to be too low. The important lesson to learn is that there are limits or absolute thresholds to the relationship between price and perceived quality and perceived value (Monroe 1993).

When buyers perceive that prices are lower than they expect, they may become suspicious of quality. At such low prices, this low perceived quality may be perceived to be less than the perceived sacrifice of the low price. Hence, the mental comparison or trade-off between perceived quality and perceived sacrifice may lead to an unacceptable perceived value. Thus, a low price may actually reduce buyers' perceptions of value. At the other extreme, a perceived high price may lead to a perception of sacrifice that is greater than the perceived quality, also leading to a reduction in buyers' perceptions of value. Thus, not only is it important for price setters to consider the relationship among price, perceived quality, and perceived value, but to recognize that there are limits to these relationships.

Usually a buyer has alternative choices available for a purchase. However, even if the numerical prices for these alternatives are different, it cannot be assumed that the prices are perceived to be different. Hence, the price setter must determine the effect of perceived price differences on buyers' choices. As suggested above, the perception of a price change depends on the magnitude of the change.

Generally, it is the perceived relative differences between prices that influence buyers' use of price as an indicator of quality. In a similar way, relative price differences between competing brands, different offerings in a product line, or price levels at different points in time affect buyers' purchase decisions. A recent experience of a major snack food producer illustrates this point. At one time, the price of a specific size of this brand's potato chips was $1.39 while a comparable size of the local brand was $1.09, a difference of 30 cents. Over a period of time, the price of the national brand increased several times until it was being retailed at $1.69. In like manner, the local brand's price also increased to $1.39. However, while the local brand was maintaining a 30-cent price differential, the national brand obtained a significant gain in market share. The problem was buyers perceived a 30-cent price difference relative to $1.69 as less than a 30-cent price difference relative to $1.39. This example illustrates the notion of differential price thresholds, or the degree that buyers are sensitive to relative price differences.

From behavioral price research, a number of important points about price elasticity have emerged:

1. Buyers, in general, are more sensitive to perceived price increases than to perceived price decreases. In practical terms, this difference in relative price elasticity between price increases vs. price decreases means it is easier to lose sales by increasing price than it is to gain sales by reducing price.
2. Sometimes a product may provide a unique benefit or have a unique attribute that buyers value. These unique benefits or attributes serve to make the product less price sensitive.

3. The frequency of past price changes can influence buyers' sensitivity to price changes. If prices have been changing relatively frequently, buyers may not have adjusted to the previous price change when a new change occurs. If buyers have not adjusted to the last price increase, then another price increase will be perceived as a larger increase than it actually is, making them more sensitive to the increase. The issue this point raises is the concept of reference prices and is discussed next.

3.3.3. Effects of Reference Prices on Perceived Value

In the past few years, evidence has emerged confirming the existence of a reference price serving as an anchor for price judgments. One of the most important points stemming from the concept of reference prices is that buyers do judge or evaluate prices comparatively. That is, for a price to be judged acceptable, too high, or too low, it has to be compared to another price. This other comparative price is the buyer's reference price for that particular judgment. The reference price serves as an anchor for buyers' price judgments. Buyers may use as a reference point the range of prices last paid, the current market price or perceived average market price, a belief of a fair price to pay, or an expected price to pay to judge actual prices.

Price perceptions are relative. That is, a specific price is compared to another price or a reference price. The illustration for relating this important point to pricing strategy and tactics comes from a firm introducing a new product with an introductory low price. Initially, the product was targeted to sell at a price of $17.50. However, the firm used the tactic of introducing the product at a low price of $14.95. Later, when it was time to remove the introduction price because of increased costs, the regular price was set at $20.00. The product failed to sustain sufficient sales volume to warrant its continued existence. The error in this situation was that the pricing tactic of a low introductory price established a baseline or reference price of $14.95 rather than $17.50. Hence, the $20.00 price, when compared to $14.95, was perceived to be too expensive and buyers stopped buying.

Recent behavioral research has provided additional explanations of how people form value judgments and make decisions when they do not have perfect information about alternatives. Moreover, these explanations further our understanding of why buyers are more sensitive to price increases than to price decreases and how they respond to comparative price advertisements, coupons, rebates, and other special price promotions. The common element in these explanations is that buyers judge prices comparatively, that is, a reference price serves to anchor their judgments (Monroe 1993).

3.4. The Effect of E-commerce on Pricing

There is a clear emerging trend toward electronic commerce becoming a significant aspect of the economy. Estimates of online sales indicate that the $7.8 billion in sales in the United States recorded in 1998 grew to approximately $15 billion in 1999 and is expected to grow to $23–28 billion in 2000 (Schmeltzer 2000; Sparks 2000). Accompanying this rapid growth of electronic sales is an emphasis on exchanges occurring at lower prices than in conventional exchanges. Several questions naturally arise with this knowledge of increasing electronic sales at relatively lower prices:

1. How does information play a role in this phenomenon?
2. What forces exist to pressure or enable online sellers to sell at lower prices?
3. Can these relatively lower prices (and accompanying lower profit margins) be sustained?

3.4.1. The Role of Information

In Section 3.1, we pointed out that traditional economic theory assumes that buyers and sellers have perfect information about prices, their own tastes and preferences, and their budget or income available for purchasing goods and services. However, when buyers are faced with imperfect information and the inability to assess quality, and therefore the ability to determine their degree of satisfaction prior to purchase, they may use price to infer quality and their expected degree of satisfaction. However, the quality of the attributes of some goods can be assessed prior to purchase. We call these goods search products. Examples of search products would include books, videotapes and music CDs, brand-name hard goods, airline tickets, toys, pet supplies, and standard industrial supplies. Indeed, a recent survey indicated that online shoppers purchased more books and videotapes online than in stores (*Chicago Tribune* 2000). Further, the CPI inflation rate for November 1999 for recreational products was 0.7% compared to the overall CPI inflation rate of 2.2% (Cooper and Madigan 1999). Products in the recreational category include toys, music, books, and pet supplies. Buyers perceive less risk in buying products that they believe vary little in quality across alternative sellers. Thus, searching online for the lowest prices for these types of products is convenient, quick, and virtually costless. For example, CompareNet offers detailed information on more than 100,000 products. Other sites provide software agents to find products (Green 1998). Moreover, the online shopper

can search in a wider geographical area than in the local community. Finally, consumers and corporate buyers can pool their purchasing power and get volume discounts. General Electric Co. was able to reduce its purchase cost by 20% on more than $1 billion in purchases of operating materials by pooling orders from divisions on a worldwide basis (Hof 1999).

3.4.2. Pressures on E-commerce Prices

As indicated above, the online buyer may be able to reduce search costs while not incurring any significant increase in risk. At the same time, the direct supplier–buyer relationship in e-commerce transactions reduces or eliminates the various intermediaries in traditional distribution systems. Further, the information intermediary may take a smaller percentage of the final selling price for the information service provided (perhaps 10% as opposed to 40–50% traditional intermediary margins) (Hof 1999). Also, a large and growing number of information intermediaries, manufacturers, distributors, and retailers are providing buyers access to buying on the internet. This increasing competitive pressure will keep prices relatively low, as expected from traditional economic theory. But the question is, how long will we see both this intensive competition and these relatively very low prices?

3.4.3. The Feasibility of Sustainable Low Internet Prices

Currently almost all online sellers are losing money because they do not have sufficient sales at the relatively low profit margins to recover their fixed costs (Sparks 1999). Further, to get the sales growth necessary to become profitable will require increasing amounts of investment in marketing, that is, increasing fixed costs. Without infusion of large amounts of venture capital, many of these enterprises will not succeed and will either fail outright or will be acquired by more successful online sellers or manufacturers and retailers with the financial and marketing capital to generate the necessary sales growth.

Further, as more manufacturers, distributors, and retailers enter electronic selling, it is likely that their online sales will be at lower unit profit margins, given the current pressure on prices. Initially, their online sales will be at the expense of their higher-margin conventional sales, reducing their overall profit margins. Overcoming this negative effect on profitability will require new sales growth from new buyers who may shift from other electronic sellers. At some point there will be a shakeout between the e-commerce sellers and prices will likely stabilize at relatively higher levels than we encounter in this early stage of electronic commerce. This expectation is not different from the various revolutions in selling that have occurred over the years. The real problem will be predicting when the shakeout will occur leading to prices stabilizing profits at sustainable levels from electronic sellers. And if there is little perceived quality variation across sellers, then buyers are more likely to minimize the price paid for these items.

However, searching for the lowest price from alternative sellers can be time consuming in traditional shopping. Most busy people have neither the time nor the willingness to visit multiple outlets seeking the lowest price for a purchase they are considering.

4. THE ROLE OF COSTS IN PRICING

As indicated earlier, demand provides an upper limit on the pricing discretion the firm has. This limit is the willingness of buyers to purchase at a stated price. On the other hand, the other variable directly affecting profits—costs—sets a floor to a firm's pricing discretion. If prices are too low in comparison with costs, volume may be high but profitless. By determining the difference between costs and the price under consideration and then balancing that margin against the estimated sales volume, the seller can determine whether the product or service will contribute sufficient money to enable the firm to recover its initial investment. In considering the cost aspect of a pricing decision, a crucial question is what costs are relevant to the decision.

It is important for the seller to know the causes and behavior of product costs in order to know when to accelerate cost recovery, how to evaluate a change in selling price, how to profitably segment a market, and when to add or eliminate products. Even so, costs play a limited role in pricing. They indicate whether the product or service can be provided and sold profitably at any price, but they do not indicate the actual prices that buyers will accept. Proper costs serve to guide management in the selection of a profitable product mix and determine how much cost can be incurred without sacrificing profits.

4.1. Cost Concepts

To determine profit at any volume, price level, product mix, or time, proper cost classification is required. Some costs vary directly with the rate of activity, while others do not. If the cost data are classified into their fixed and variable components and properly attributed to the activity causing the cost, the effect of volume becomes apparent and sources of profit are revealed.

In addition to classifying costs according to ability to attribute a cost to a product or service, it is also important to classify costs according to variation with the rate of activity (Ness and Cucuzza

1995). Some costs vary directly with the activity level, while other costs, although fixed, are directly attributable to the activity level. Hence, it is important to clarify specifically what is meant by the terms *direct* and *indirect*. The directly traceable or attributable costs are those costs that we can readily determine as contributing to the product or service's cost. However, whether a direct cost is variable, fixed, or semivariable depends on properly determining the cause of that cost. Perhaps more than anything else, managers need to exert the will to understand how costs are incurred and how they behave as activity levels change in their organizations.

4.2. Profitability Analysis

Virtually every planned action or decision in an organization affects costs and therefore profits. Profit analysis attempts to determine the effect of costs, prices, and volume on profits. The goal of this analysis is to provide accurate information about the profit contributions made by each product, thereby giving management a sound basis for managing its product lines.

One of the most important pieces of data resulting from a profit analysis is the contribution ratio, which is usually referred to as the profit-volume ratio (PV). The PV ratio is the proportion of sales dollars available to cover fixed costs and profits after deducting variable costs:

$$\text{PV} = \frac{\text{unit price} - \text{unit variable cost}}{\text{unit price}}$$

This PV ratio is an important piece of information for analyzing the profit impact of changes in sales volume, changes in the cost structure of the firm (i.e., the relative amount of fixed costs to total costs), as well as changes in price.

For a single product situation, the elements of profitability that the firm must consider are price per unit, sales volume per period, variable costs per unit, and the direct and objectively assignable fixed costs per period. However, typically firms sell multiple products or offer multiple services, and the cost-classification requirements noted above become more difficult. Further, many companies now recognize that it is important to avoid arbitrary formulas for allocating overhead (common costs) so that each product carries its fair share of the burden. In part, these companies understand that the concept of variable costs extends beyond the production part of the business. That is why we have stressed the notion of activity levels when defining variable costs. These companies have found out that using the old formula approach to cost allocation has meant that some products that were believed to be losing money were actually profitable and that other so-called profitable products were actually losing money.

A key lesson from the above discussion and the experiences of companies that use this approach to developing the relevant costs for pricing is that profits must be expressed in monetary units, not units of volume or percentages of market share. Profitability is affected by monetary price, unit volume, and monetary costs.

4.3. Profit Analysis for Multiple Products

In multiproduct firms, it is important to place emphasis on achieving the maximum amount of contribution revenue for each product instead of attempting to maximize sales revenues. Each product offering faces different competition, has a different demand elasticity, and perhaps depends for its sales, at least in part, on the sales of the other products in the line.

Within a multiproduct firm, each offering generates a different amount of volume, a different cost structure, including variable and fixed costs, different unit prices, and, of course, different revenues. Not only are these important factors different, but they are changing. The PV ratio can be used to analyze the relative profit contributions of each product in the line. Each product has a different PV value and different expected dollar sales volume as a percentage of the line's total dollar volume. In multiple-product situations, the PV is determined by weighting the PV of each product by the percentage of the total dollar volume for all products in the line.

This issue of managing the prices and profitability of the firm's product line is extremely important. For example, consider the prices of a major hotel chain. For the same room in a given hotel, there will be multiple rates: the regular rate (commonly referred to as the rack rate), a corporate rate that represents a discount for business travelers, a senior citizen rate, a weekend rate, single vs. double rates, group rate, and conference rate, to name just a few. Over time, the hotel's occupancy rate expressed as a percentage of rooms sold per night had increased from about 68% to 75%. Yet despite increasing prices that more than covered increases in costs, and increasing sales volume, profitability was declining.

After a careful examination of this problem, it was discovered that they were selling fewer and fewer rooms at the full rack rate while increasing sales, and therefore occupancy, of rooms at discounted rates that were as much as 50% off the full rack rate. As a result, the composite weighted PV ratio had significantly declined, indicating this demise in relative profitability. Further, to illustrate the importance of considering buyers' perceptions of prices, the price increases had primarily been

at the full rack rate, creating a greater and more perceptible difference between, for example, the full rate and the corporate rate. More and more guests were noticing this widening price difference and were requesting and receiving the lower rates.

When there are differences in the PVs among products in a line, a revision in the product selling mix may be more effective than an increase in prices. That is, a firm, by shifting emphasis to those products with relatively higher PVs, has a good opportunity to recover some or all of its profit position. Hence, profit at any sales level is a function of prices, volume, costs and the product dollar sales mix (Monroe and Mentzer 1994).

5. TYPES OF PRICING DECISIONS

As shown in Table 1, there are many kinds of pricing decisions that a firm must make. There is the decision on the specific price to set for each product and service marketed. But this specific price depends on the type of customer to whom the product is sold. For example, if different customers purchase in varying quantities, should the seller offer volume discounts?

The firm must also decide whether to offer discounts for early payment and, if so, when a customer is eligible for a cash discount and how much to allow for early payment. Should the firm attempt to suggest retail or resale prices, or should it only set prices for its immediate customers? When a firm uses other business firms as intermediaries between itself and its customers, it does not have direct contact with its ultimate customers. Yet the way customers respond to prices depends on how they perceive the prices and the relationships between prices. Hence, the manufacturer is very interested in having the prices that the final customer responds to correspond to its strategic objectives.

Normally, the firm sells multiple products and these questions must be answered for each product or service offered. Additionally, the need to determine the number of price offerings per type of product and the price relationships between the products offered make the pricing problem more complex. Further, different types of market segments respond differently to prices, price differences, and price changes.

The firm must also decide on whether it will charge customers for the transportation costs incurred when shipping the products to them. Customers located at different distances from the manufacturer will pay a different total price if they are charged for the transportation costs. Yet if the seller quotes a uniform price that includes the transportation costs regardless of distance from the manufacturer, some buyers may receive the products at a total price that is less than the costs incurred to the manufacturer while other customers will pay a price that exceeds the total costs incurred by the manufacturer. Such differences in prices to similar types of customers may lead to some concerns about the legality of the pricing policy.

5.1. Pricing New Products

One of the most interesting and challenging decision problems is that of determining the price of a new product or service. Such pricing decisions are usually made with very little information on demand, costs, competition, and other variables that may affect the chances of success. Many new products fail because they do not provide the benefits desired by buyers, or because they are not available at the right time and place. Others fail because they have been incorrectly priced, and the error can as easily be in pricing too low as in pricing too high. Pricing decisions usually have to be made with little knowledge and with wide margins of error in the forecasts of demand, cost, and competitors' capabilities.

The core of new product pricing takes into account the price sensitivity of demand and the incremental promotional and production costs of the seller. What the product is worth to the buyer, not what it costs the seller, is the controlling consideration. What is important when developing a

TABLE 1 Basic Pricing Decisions

1. What to charge for the different products and services marketed by the firm
2. What to charge different types of customers
3. Whether to charge different types of distributors the same price
4. Whether to give discounts for cash and how quickly payment should be required to earn them
5. Whether to suggest resale prices or only set prices charged one's own customers
6. Whether to price all items in the product line as if they were separate or to price them as a "team"
7. How many different price offerings to have of one item
8. Whether to base prices on the geographical location of buyers (i.e., whether to charge for transportation)

Source: Monroe 1990, p. 278.

new product's price is the relationship between the buyers' perceived benefits in the new product relative to the total acquisition cost (i.e., financial value), and relative to alternative offerings available to buyers.

It has been generally presumed that there are two alternatives in pricing a new product: *skimming* pricing, calling for a relatively high price, and *penetration* pricing, calling for a relatively low price. There are intermediate positions, but the issues are made clearer by comparing the two extremes.

5.1.1. Skimming Pricing

Some products represent drastic improvements upon accepted ways of performing a function or filling a demand. For these products, a strategy of high prices during market introduction (and lower prices at later stages) may be appropriate. Skimming is not always appropriate and does have drawbacks. A skimming strategy is less likely to induce buyers into the market and does not encourage rapid adoption or diffusion of the product. Moreover, if skimming results in relatively high profit margins, competitors may be attracted into the market.

5.1.2. Penetration Pricing

A penetration strategy encourages both rapid adoption and diffusion of new products. An innovative firm may thus be able to capture a large market share before its competitors can respond. One disadvantage of penetration, however, is that relatively low prices and low profit margins must be offset by high sales volumes. One important consideration in the choice between skimming and penetration pricing at the time a new product is introduced is the ease and speed with which competitors can bring out substitute offerings. If the initial price is set low enough, large competitors may not feel it worthwhile to make a big investment for small profit margins. One study has indicated that a skimming pricing strategy leads to more competitors in the market during the product's growth stage than does a penetration pricing strategy (Redmond 1989).

5.2. Pricing During Growth

If the new product survives the introductory period, as demand grows, usually a number of competitors are producing and selling a similar product and an average market price begins to emerge. Normally there is a relatively wide range of market prices early in the growth stage, but this market price range narrows as the product approaches maturity.

In regard to pricing products during the growth stage, three essential points should be noted: (1) the range of feasible prices has narrowed since the introductory stage; (2) unit variable costs may have decreased due to the experience factor; and (3) fixed expenses have increased because of increased capitalization and period marketing costs. The pricing decision during the growth stage is to select a price that, subject to competitive conditions, will help generate a sales dollar volume that enables the firm to realize its target profit contribution.

5.3. Pricing During Maturity

As a product moves into the maturity and saturation stages, it is necessary to review past pricing decisions and determine the desirability of a price change. Replacement sales now constitute the major demand, and manufacturers may also incur regional competition from local brands. Market conditions do not appear to warrant a price increase, hence the pricing decision usually is to reduce price or stand pat.

When is a price reduction profitable? We know that when demand is price elastic it is profitable to reduce prices if costs do not rise above the increase in revenues. But since it can be expected that any price decrease will be followed by competitors, it is also necessary that the market demand curve be elastic within the range of the price reduction. Moreover, the requirements for a profitable price reduction strategy include beginning with a relatively high contribution margin (i.e., relatively high PV ratio), opportunity for accelerating sales growth and a price-elastic demand (Monroe and Mentzer 1994). When a product has reached the maturity stage of its life cycle, it is most likely that these conditions will not exist.

At the maturity stage of the life cycle, the firm probably should attempt to maximize short-run direct product contribution to profits. Hence, the pricing objective is to choose the price alternative leading to maximum contribution to profits. If competition reduces prices, the firm may, however reluctantly, match the price reduction. On the other hand, it may try to reduce costs by using cheaper materials, eliminating several labor operations, or reducing period marketing costs. All or any of these actions may allow the firm to match competitively lower prices and still maintain target contributions to profit.

5.4. Pricing a Declining Product

During the declining phase of a product's life, direct costs are very important to the pricing decision. Normally, competition has driven the price down close to direct costs. Only those sellers who were

able to maintain or reduce direct costs during the maturity stage are likely to have remained. If the decline is not due to an overall cyclical decline in business but to shifts in buyer preferences, then the primary objective is to obtain as much contribution to profits as possible.

So long as the firm has excess capacity and revenues exceed all direct costs, the firm probably should consider remaining in the market. Generally, most firms eliminate all period marketing costs (or as many of these costs as possible) and remain in the market as long as price exceeds direct variable costs. These direct variable costs are the minimally acceptable prices to the seller. Thus, with excess capacity, any market price above direct variable costs would generate contributions to profit. Indeed, the relevant decision criterion is to maximize contributions per sales dollar generated. In fact, it might be beneficial to raise the price of a declining product to increase the contributions per sales dollar. In one case, a firm raised the price of an old product to increase contributions while phasing it out of the product line. To its surprise, sales actually grew. There was a small but profitable market segment for the product after all!

5.5. Price Bundling

In marketing, one widespread type of multiple products pricing is the practice of selling products or services in packages or bundles. Such bundles can be as simple as pricing a restaurant menu for either dinners or the items à la carte, or as complex as offering a ski package that includes travel, lodging, lift and ski rentals, and lessons. In either situation, there are some important principles that need to be considered when bundling products at a special price.

5.5.1. Rationale for Price Bundling

Many businesses are characterized by a relatively high ratio of fixed to variable costs. Moreover, several products or services usually can be offered using the same facilities, equipment, and personnel. Thus, the direct variable cost of a particular product or service is usually quite low, meaning that the product or service has a relatively high profit–volume (PV) ratio. As a result, the incremental costs of selling additional units are generally low relative to the firm's total costs.

In addition, many of the products or services offered by most organizations are interdependent in terms of demand, either being substitutes for each other or complementing the sales of another offering. Thus, it is appropriate to think in terms of relationship pricing, or pricing in terms of the inherent demand relationships among the products or services. The objective of price bundling is to stimulate demand for the firm's product line in a way that achieves cost economies for the operations as a whole, while increasing net contributions to profits.

5.5.2. Principles of Price Bundling

Underlying the notion of bundling is the recognition that different customers have different perceived values for the various products and services offered (Simon et al. 1995). In practical terms, these customers have different maximum amounts they would be willing to pay for the products. For some customers, the price of the product is less than this maximum acceptable price (upper price threshold), resulting in some consumer surplus. However, for these customers, the price of a second product or service may be greater than they are willing to pay and they do not acquire it. If the firm, by price bundling, can shift some of the consumer surplus from the highly valued product to the less valued product, then there is an opportunity to increase the total contributions these products make to the firm's profitability.

The ability to transfer consumer surplus from one product to another depends on the complementarity of demand for these products. Products or services may complement each other because purchasing them together reduces the search costs of acquiring them separately. It is economical to have both savings and checking accounts in the same bank to reduce the costs of having to go to more than one bank for such services. Products may complement each other because acquiring one may increase the satisfaction of acquiring the other. For the novice skier, ski lessons will enhance the satisfaction of skiing and increase the demand to rent skis. Finally, a full product-line seller may be perceived to be a better organization than a limited product-line seller, thereby enhancing the perceived value of all products offered.

5.6. Yield Management

A form of segmentation pricing that was developed by the airlines has been called yield management. Yield management operates on the principle that different segments of the market for airline travel have different degrees of price sensitivity. Therefore, seats on flights are priced differently depending on the time of day, day of the week, length of stay in the destination city before return, when the ticket is purchased, and willingness to accept certain conditions or restrictions on when to travel. Besides the airlines, hotels, telephone companies, rental car companies, and banks and savings and loans have used yield management to increase sales revenues through segmentation pricing. It seems likely that retail firms could use yield management to determine when to mark down slow-moving

merchandise and when to schedule sales, or how to set a pricing strategy for products with short selling seasons.

The unique benefits of the yield-management pricing program is it forces management to continuously monitor demand for its products. Further, changes in demand lead to pricing changes to reflect these changes. If the product is not selling fast enough, then price reductions can be initiated to stimulate sales. Because of a relatively high fixed costs to total variable costs cost structure, these focused price reductions can provide leverage for increasing operating profits, by the effect on sales volume. With relatively high contribution margins (high PV ratios), small price reductions do not require large increases in volume to be profitable.

6. ADMINISTERING THE PRICING FUNCTION

Perhaps the most difficult aspect of the pricing decision is to develop the procedures and policies for administering prices. Up to this point, the issue has been on the setting of base or list prices. However, the list price is rarely the actual price paid by the buyer. The decisions to discount from list price for volume purchases or early payment, to extend credit, or to charge for transportation effectively change the price actually paid. In this section, we consider the problems of administering prices.

An important issue relative to pricing is the effect that pricing decisions and their implementation have on dealer or distributor cooperation and motivation as well as on salespeople's morale and effort. While it is difficult to control prices legally through the distribution channel, nevertheless, it is possible to elicit cooperation and provide motivation to adhere to company-determined pricing policies. Also, because price directly affects revenues of the trade and commissions of salespeople, it can be used to foster desired behaviors by channel members and salespeople.

Price administration deals with price adjustments or price differentials for sales made under different conditions, such as:

1. Sales made in different quantities
2. Sales made to different types of middlemen performing different functions
3. Sales made to buyers in different geographic locations
4. Sales made with different credit and collection policies
5. Sales made at different times of the day, month, season, or year

Essentially, price structure decisions define how differential characteristics of the product and/or service will be priced. These price structure decisions are of strategic importance to manufacturers, distributors or dealers, and retailers (Marn and Rosiello 1992). In establishing a price structure, there are many possibilities for antagonizing distributors and even incurring legal liability. Thus, it is necessary to avoid these dangers while at the same time using the price structure to achieve the desired profit objectives.

We have noted that the definition of price includes both the required monetary outlay by the buyer, plus a number of complexities including terms of agreement, terms of payment, freight charges, offering a warranty, timing of delivery, or volume of the order. Moreover, offering different products or services in the line with different features or benefits at different prices permits the opportunity to develop prices for buyers who have different degrees of sensitivity to price levels and price differences. Moving from a simple one-price-for-all-buyers structure to a more complex pricing structure provides for pricing flexibility because the complexity permits price variations based on specific product and service characteristics as well as buyer or market differences. Moreover, a more complex price structure enhances the ability of firms to (Stern 1986):

1. Respond to specific competitive threats or opportunities
2. Enhance revenues while minimizing revenue loss due to price changes
3. Manage the costs of delivering the product or service
4. Develop focused price changes and promotions
5. Be more effective in gaining distributors' cooperation

To accomplish this goal of differential pricing requires identifying the key factors that differentiate price-market segments. Then the elements of the price structure may be developed that reflect these factors.

A product's list price is the product's price to final buyers. Throughout the distribution system, manufacturers grant intermediaries discounts, or deductions from the list price. These price concessions from producers may be seen as payment to intermediaries for performing the distribution function and for providing time and place utilities. The difference between the list price and the amount that the original producer receives represents the total discounts provided to channel members.

Channel members themselves employ discounts in various ways. Wholesalers pass on discounts to retailers just as manufacturers pass along discounts to wholesalers. Retailers may offer promotional discounts to consumers in the form of sweepstakes, contests, and free samples. Some stores offer quantity and cash discounts to regular customers. Even seasonal discounts may be passed along—for example, to reduce inventory of Halloween candy or Christmas cards.

7. PRICE AND SALES PROMOTIONS

Price promotions consist of tactics designed to achieve specific objectives in a limited time in a target market. Price promotions are directed at two primary audiences: consumers and the trade. Some commonly used promotion tactics are summarized next.

Aimed at both consumers and distributors, price-off promotions involve temporary price reductions to retailers with the intent that savings will be passed along to consumers. In an immediate price-off promotion, the marketer usually affixes a special label to the product's package to indicate the percentage or cash savings, which the retailer then honors. In a delayed price-off promotion, the consumer has to pay the normal price but can send the marketer a proof-of-purchase label to claim a cash rebate (refund).

Coupons offer buyers price reductions at the point of sale (most often at a retail checkout counter). Coupons are made available to consumers in a variety of ways. Some can be clipped from daily newspaper ads for supermarkets; some come as colorful freestanding inserts in Sunday newspapers; and some are distributed as fliers to homes within a store's immediate vicinity. Coupons are also mailed directly to consumers, often in booklets or packets assembled by distributors or companies specializing in such promotions. Finally, in-pack and on-pack coupons may be affixed to the product and allow savings on the current or a future purchase.

7.1. Price Promotion as Price Segmentation

As mentioned earlier, manufacturers and retailers have made increasing use of coupons, rebates and refunds, and short-term price reductions to stimulate short-term demand for their products and services. However, despite the popularity of these price deals, it is not at all clear that a majority of these deals are profitable. Simply offering a coupon, rebate, or price-off deal to current buyers in the hope of stimulating a substantial increase in unit sales likely will reduce profits unless mostly new buyers take advantage of the deal. Thus, the underlying objective of a price promotion to final customers should be to focus on a price-market segment that is more price sensitive or deal responsive than existing buyers. Essentially, then, price promotions to final customers simply becomes an aspect of segment pricing.

Not all buyers of a product on price promotion take advantage of the promotion. Redemption rates for coupons and rebates indicate that many buyers do not redeem coupons, nor do they follow through and take the rebate that is offered. One reason for this lack of redemption or follow-through is that the perceived cost of redeeming coupons or qualifying for the rebate is larger than the perceived value of the coupon or rebate. Thus, buyers who do not take advantage of the price promotion pay the regular price. Therefore, by offering a coupon or rebate, the seller has effectively segmented the market into two price segments.

For this type of segmented pricing to be profitable, some additional conditions must prevail. First, the segments must be separable to some degree. This separation must either be due to some natural separation, such as geographic region or location, time of purchase, or category of buyer, e.g., business buyer vs. consumer. Second, these segments must have different degrees of price sensitivity and/or different variable purchasing costs. Third, the variable costs of selling to these segments must not be so different that the effect of the lower price is not canceled by increased selling costs.

7.2. Price Promotion Decision Variables

To understand the complexity of developing a price promotion policy, it is useful to review the types of decisions that need to be made before a promotion can be implemented. The decisions outlined below indicate there is a need to plan this activity carefully.

1. Should a price promotion be offered? The first decision is simply whether the seller should offer a coupon, rebate, cents-off deal, or promotional discount.
2. To whom should the deal be offered: dealers or final customers? Offering a price promotion to dealers or distributors in anticipation that the deal will be offered to final customers is not the same as offering it directly to final customers. Dealers may choose to reduce their prices in the full amount or less, or not at all. Further, they may buy excess amounts of the deal merchandise, relative to actual demand, and sell some units at full price after the deal period is over.
3. When should the promotion be offered? This question refers not only to the specific time of the year but also to whether to offer the deal during peak or slack selling seasons. For example,

should ketchup manufacturers offer price promotions during the peak outdoor cooking season (May–September) or during the winter months?

4. How frequently should a promotion be run? If a product is offered frequently on some form of a price deal, customers may come to expect the deal and only buy on deal. The effect is that the product is rarely sold at full list price and the advantage of price segmentation is lost.
5. How long should the promotion be run? This decision is related to the issue of promotion frequency, peak vs. slack selling periods, and the length of buyers' repurchase periods. Some consumer coupons do not have an expiration date, thereby extending the promotion period indefinitely and making it difficult to measure the effectiveness of the coupon promotion.
6. How many units should be covered by the promotion? When deals are offered to the trade, there often is a restriction on the amount that a dealer can order on deal. This restriction may be related to the dealer's usual order size for the length of the promotion period.
7. What products and/or sizes should be promoted? Should a coffee producer offer a coupon on all package sizes of coffee, or only the 13 oz. size? Should a luggage manufacturer feature all of its luggage in the promotion, or only certain models?
8. How much should the price be reduced? What should be the amount of the rebate? What should be the value of the coupon? As discussed earlier, the degree of buyer sensitivity to the price reduction, or the degree that buyers perceive additional transaction value, will have an impact on the success of the promotion. The important issue here is how much of a price difference (reduction) is necessary to induce buyers to take advantage of the offer.

7.3. Some Perspectives on Price and Sales Promotions

Promotions comprise a significant portion of the marketing communications budget. With this increased managerial importance of price and sales promotions has come considerable research on how promotions affect sales. However, much of this new research information is still quite recent, and the evidence on how promotions affect sales is still emerging. In this section we will look at three different time frames to consider these effects (Blattberg and Neslin 1989): (1) the week or weeks in which the promotion occurs (immediate); (2) the weeks or months following the promotion (intermediate); and (3) the months or years following the implementation of several promotions (long term).

7.3.1. Immediate Effects of Price and Sales Promotions

Promotions seem to have a substantial immediate impact on brand sales. For example, price cuts for bathroom tissue are accompanied by immediate increases in brand sales. When such price promotions are coordinated with special point-of-purchase displays and local feature advertising, sales might increase as much as 10 times normal sales levels. Because of such observable immediate sales impact, many brands of packaged consumer goods are frequently promoted.

A large proportion of this immediate increase in sales is due to nonloyal buyers (brand switchers). For example, one study showed that 84% of the increase in coffee brand sales generated by promotions came from brand-switching consumers (Gupta 1988). However, not all brands have the same capability of inducing consumers to switch brands with a promotional activity.

The effect of brand A's promotions on brand B's sales likely is different than the effect of brand B's promotions on brand A's sales. This asymmetry of the promotion cross-elasticities is a very important managerial finding. That is, a strong brand, say brand A, may be more successful in inducing buyers of brand B to switch to brand A with a promotion than the weaker brand B would be in using a similar promotion to induce buyers of brand A to switch to brand B. This finding implies that when there are simultaneous promotions by both brands, brand A likely will experience a more positive sales impact than will brand B.

Another important finding is that different forms of price and sales promotions have separate effects on sales. Further, when several forms are used together, the total impact may be greater than the sum of the effects due to each form.

An important reason for the immediate sales effect is purchase acceleration, which occurs because loyal consumers buy larger quantities when the brand is promoted and/or purchase the brand sooner than normal. The issue of purchase acceleration is very important when we try to determine whether a promotion has been profitable. Indeed, if buyers do not change their rate of consumption of the product, then larger purchase quantities or earlier purchases means that there will be fewer sales later at the regular price.

7.3.2. Intermediate Effects of Price and Sales Promotions

Usually, promotions have been considered short-term tactics to provide for an immediate increase in sales. However, as in advertising, there are effects that occur even after a particular promotion campaign has expired. For example, if a consumer purchases brand A for the first time when A is being promoted, will that consumer buy brand A on the next purchase occasion (repeat purchase)? Or will

the consumer develop a loyalty to the deal and look for another promoted brand on the next purchase occasion? The managerial implications of a promotion extend beyond the immediate sales effect of that promotion.

While there has been considerable research on whether brand purchasing enhances repeat brand purchases, such research provides conflicting results. There is some evidence that a prior brand purchase may increase the likelihood of buying that brand again. However, given the increasing use of promotions, other research shows no evidence that promotions enhance repeat brand purchases.

A reason why promotions may not enhance repeat brand purchases involves the question of why consumers may decide to buy the brand initially. It has been suggested that people may attribute their purchase to the deal that was available and not to the brand itself being attractive (Scott and Yalch 1980). If consumers indicate a negative reason for a purchase decision, there is a smaller likelihood that the experience will be a positive learning experience relative to the brand itself. If a brand is promoted quite frequently, then the learning to buy the brand occurs because of the reward of the deal, not the positive experience of using the brand itself.

7.3.3. Long-Term Effects of Price and Sales Promotions

In the long run, the relevant issue is the ability of the brand to develop a loyal following among its customers (Jones 1990). The important objective is to develop favorable brand attitudes of the customers such that they request that the retailer carry the brand and are unwilling to buy a substitute. As we observed above, many marketing practitioners fear that too-frequent promotional activity leads to loyalty to the deal, thereby undermining the brand's franchise. And if buyers come to expect that the brand will often be on some form of a deal, they will not be willing to pay a regular price and will be less likely to buy because they do not believe that the brand provides benefits beyond a lower price.

A second problem develops if consumers begin to associate a frequently promoted brand with lower product quality. That is, if consumers believe that higher-priced products are also of higher quality, then a brand that is frequently sold at a reduced price may become associated with a lower perceived quality level. Thus, the result may be that buyers form a lower reference price for the product. Products that are perceived to be of relatively lower quality have a more difficult time trying to achieve market acceptance.

8. LEGAL ISSUES IN PRICING

The development of a price structure to implement a pricing strategy is not only a difficult and complex task but is fraught with the potential for violating federal and state laws. In fact, the legal aspects of pricing strategy comprise one of the most difficult parts of marketing strategy and have left many business people not only frightened of making pricing decisions but often vulnerable to legal action because of their pricing activities.

As indicated earlier, the short-term effects of reducing price on profits likely will not be positive. Yet many firms attempting to gain volume or market share often resort to price reductions. Other competing firms often feel compelled to follow these price reductions and often to undercut the original price-reducing firm. Also, there is pressure, real or perceived, to provide certain buyers a favored status by giving them additional discounts for their business. To counteract these pressures to reduce prices and stabilize profits, some businesses have attempted by either overt or covert actions to stabilize prices and market share. In other situations, a larger firm has aggressively reduced prices in one market area or to a specific set of customers in order to reduce competition or drive a competitor out of business. Moreover, we have suggested that there are typically several price-market segments distinguished by different degrees of sensitivity to prices and price differences. Thus, the opportunity exists to set different prices or to sell through different channels to enhance profits.

Each of these various possible strategies or tactics is covered by some form of legislation and regulation. In fact, there are laws concerning price fixing amongst competitors, exchanging price information or price signalling to competitors, pricing similarly to competitors (parallel pricing), predatory pricing, and price discrimination. This section briefly overviews the laws that cover these types of activities.

8.1. Price Fixing

The Sherman Antitrust Act (1890) specifically addresses issues related to price fixing, exchanging price information, and price signaling. It also has an effect on the issue of predatory pricing. Section 1 of the Act prohibits all agreements in restraint of trade. Generally, violations of this section are divided into per se violations and rule of reason violations. Per se violations are automatic. That is, if a defendant has been found to have agreed to fix prices, restrict output, divide markets by agreement, or otherwise act to restrict the forces of competition, he or she is automatically in violation of the law and subject to criminal and civil penalties. There is no review of the substance of the situation, that is, whether there was in fact an effect on competition. In contrast, the rule-of-reason doctrine calls for an inquiry into the circumstances, intent, and results of the defendants' actions. That is, the

courts will examine the substantive facts of the case, including the history, the reasons for the actions, and the effects on competition and the particular market. The current attitude of federal and state agencies and courts is that price fixing is a per se violation and that criminal sanctions should be applied to the guilty persons.

Section 2 of the Act prohibits the act of monopolizing, that is, the wrongful attempt to acquire monopoly power. Thus, having a monopoly is not illegal, but the deliberate attempt to become a monopoly is illegal. The issue here in recent cases has been not whether a firm had acquired a monopoly per se, but the methods of achieving such market power. Thus, the courts have been somewhat more aware of a firm's need to develop a strong competitive position in the markets it serves and that these strong competitive actions may lead to dominant market shares. However, if this dominant market share leads to above-market-average prices, some form of legal or regulatory action may take place.

8.2. Exchanging Price Information

Many trade associations collect and disseminate price information from and to their members. The legal issue arises when there is an apparent agreement to set prices based on the exchanged price information. Thus, if members discuss prices and production levels in meetings and prices tend to be uniform across sellers, it is likely that the exchange of information led to some form of price fixing. Again, the issue is whether the exchange of price information seems to have the effect of suppressing or limiting competition, which is a violation of section 1 of the Sherman Act. Care must be exercised about when and how price information is exchanged by competing sellers. The trend in recent years has been to make it more difficult to prove that such exchanges do not violate section 1.

8.3. Parallel Pricing and Price Signaling

In many industries and markets, one firm may emerge as a price leader. That is, one firm often is the first to announce price changes, and most rival sellers will soon follow the price changes made by the leader. At other times, another firm may initiate the price changes, but if the price leader does not introduce similar price changes, the other firms as well as the initial firm will adjust their prices to correspond to the price leader's prices. The legal question arises as to whether these somewhat concerted prices and price changes constitute a tacit, informal, and illegal agreement in violation of section 1.

Recently, some questions have been raised as to whether the public announcement of prices and price changes has been used by sellers to signal prices and achieve this common understanding about prices. That is, do sellers achieve this common understanding about prices through public announcements about their prices and price changes? If so, then a violation of section 1 may exist. For example, if one company announces a price increase effective 60 days later, some legal people have suggested that the announcement serves as a signal to competition. The suggestion seems to imply that if others follow with similar announcements, then the price increase will remain in effect; if others do not follow, the price increase will be rescinded. Announcing price increases ahead of the effective date provides time for customers, distributors, and the sales force to adjust their price frame of reference. However, what may be an effective managerial practice could be interpreted as a mechanism for attempting to achieve a common understanding among rival sellers. The ramifications of price signaling from a legal perspective remain to be determined by either legislative action, litigation, or further debate.

8.4. Predatory Pricing

Predatory pricing is the cutting of prices to unreasonably low and/or unprofitable levels so as to drive competitors from the market. If this price cutting is successful in driving out competitors, then the price cutter may have acquired a monopoly position via unfair means of competition—a violation of section 2 of the Sherman Act.

There is considerable controversy about predatory pricing, particularly how to measure the effect of a low-price strategy on the firm's profits and on competitors. Predatory pricing occurs whenever the price is so low that an equally efficient competitor with smaller resources is forced from the market or discouraged from entering it. Primarily, the effect on the smaller seller is one of a drain on cash resources, not profits per se. Much of the controversy surrounding measuring the effects of an alleged predatory price relates to the proper set of costs to be used to determine the relative profitability of the predator's actions. Recently, the courts seem to have adopted the rule that predatory pricing exists if the price does not cover the seller's average variable or marginal costs. However, the intent of the seller remains an important consideration in any case.

8.5. Illegal Price Discrimination

The Robinson-Patman Act was passed in 1936 to protect small independent wholesalers and retailers from being charged more for products than large retail chains were. Sellers can, however, defend

themselves against discrimination charges by showing that their costs of selling vary from customer to customer. Cost savings can then be passed along to individual buyers in the form of lower prices. The Robinson-Patman Act therefore permits price discrimination in the following cases:

1. If the firm can demonstrate that it saves money by selling large quantities to certain customers, it can offer these buyers discounts equal to the amount saved.
2. Long-term sales agreements with customers also reduce costs; again, discounts may be granted equal to the amount saved.
3. In cases where competitors' prices in a particular market must be met, it is legal to match the competitors' lower prices in such a market while charging higher prices in other markets.

9. FOUR BASIC RULES FOR PRICING

The four rules given below are intended to capture the essence of the analysis necessary to determine and evaluate pricing strategies. The order in which the rules are presented does not imply a hierarchy of importance; each rule is equally important.

9.1. Know Your Objectives

As demonstrated earlier, many firms stress the profit objective of return on investment. Other firms stress the objective of maintaining specified profit margins, while still other firms seek to achieve market-share goals. It is not necessary for each product to maintain the same profit margin in order to achieve a particular return on investment. Similarly, different margins on products may still produce an overall desired corporate profit goal. Finally, firms stressing market share may utilize the experience curve factor and build profits by reducing prices.

The important point to remember is that differences in corporate profit objectives eventually will lead to differences in prices and the role of price in influencing actual profits. Ultimately, regardless of the financial goal, the pricing objective is behavioral in nature. That is, whether buyers buy more, whether nonbuyers decide to buy now, and whether buyers decide to purchase less frequently but in greater volume per order, or to pay earlier, are influenced by the prices and price structure of the seller. Further, the degree to which distributors and dealers are cooperative and motivated to sell the firm's products depends largely on the financial incentives provided by the suppliers' prices and price structure. Also, the sales force's motivation to help the firm achieve its financial objectives depends on its understanding and acceptance of the pricing strategy being followed. Price has an important role in developing incentives for distributors, salespeople, and buyers to perform in ways that will be beneficial to the firm. Thus, it is important that the seller develop a positive attitude toward pricing, leading to a proactive pricing approach.

9.2. Know Your Demand

This prescription suggests that the firm understand fully the factors influencing the demand for its products and services. The key question is the role of price in the purchaser's decision process. Price and price differentials influence buyer perceptions of value. Indeed, many companies have achieved positive results from differentially pricing their products and services.

Coupled with knowing how price influences buyers' perceptions of value, it is necessary to know how buyers use the product or service. Is the product used as an input in the buyer's production process? If so, does the product represent a significant or insignificant portion of the buyer's manufacturing costs? If the product is a major cost element in the buyer's production process, then small changes in the product's price may significantly affect the buyer's costs and the resulting price of the manufactured product. If the final market is sensitive to price increases, then a small price increase to the final manufacturer may significantly reduce demand to the initial seller of the input material. Thus, knowing your buyers also means understanding how they react to price changes and price differentials as well as knowing the relative role price plays in their purchase decisions.

Further, the seller should also know the different types of distributors and their functions in the distribution channel. This prescription is particularly important when the manufacturer sells both to distributors and to the distributors' customers.

9.3. Know Your Competition and Your Market

In addition to the influence of buyers, a number of other significant market factors influence demand. It is important to understand the operations of both domestic and foreign competitors, their rate of capacity utilization, and their products and services. In many markets, the dynamic interaction of supply and demand influences prices. Moreover, changes in capacity availability due to capital investment programs will influence supply and prices. A second important aspect of knowing the market is the need to determine price–volume relationships.

9.4. Know Your Costs

It is important to determine the basic cost data necessary for the pricing decision. As stated earlier, it is necessary to know which costs vary directly with changes in levels of activity and the underlying causes of the changes in costs. It is also necessary to identify the costs that are directly related to the product or service being costed but do not vary with activity levels-direct period or fixed costs. Furthermore, marketing and distribution costs should be objectively assigned to the products and not simply lumped into a general overhead category.

Valid cost data provide an objective basis for choosing between pricing alternatives, determining discounts, and establishing differential pricing alternatives. Furthermore, objective cost studies that are completed before the pricing decisions provide the firm with a valid legal justification for its price structure.

10. SUMMARY

It is important to realize there is no one right way to determine price. Pricing simply cannot be reduced to a formula—there are too many interacting factors. Successful pricing requires considering all internal and external factors and adapting to changes as they occur. Successful pricing is adaptive pricing. Pricing decisions should be logically made and should involve rigorous thinking, with minimum difficulty from human and organizational factors. Further, it should be recognized that judgment and prediction are needed about the future, not the past. Finally, pricing decisions should be made within a dynamic, long-run corporate and marketing strategy.

CHAPTER 25
Mass Customization

MITCHELL M. TSENG
Hong Kong University of Science and Technology

JIANXIN JIAO
Nanyang Technological University

1. INTRODUCTION

With the increasing competition in the global market, the manufacturing industry has been facing the challenge of increasing customer value. Much has been done to reduce costs and improve quality. Quality does not mean only conforming to specifications. More importantly, quality means ensuring customer satisfaction and enhancing customer value to the extent that customers are willing to pay for the goods and services. To this end, a well-accepted practice in both academia and industry is the exploration of flexibility in modern manufacturing systems to provide quick response to customers with new products catering to a particular spectrum of customer needs. Consequently, there is a growing trend toward increasing product variety, as evident in supermarkets. Various food and beverage companies are fighting for shelf space to display the explosive growth of product varieties. Rapidly changing design and product technologies further accentuate this trend. The key to success in the highly competitive manufacturing enterprise often is the company's ability to design, produce,

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

and market high-quality products within a short time frame and at a price that customers are willing to pay. These counterdemands for final products create enormous productivity challenges that threaten the very survival of manufacturing companies. In addition, increasingly high labor and land costs often put developed countries or regions at a disadvantage in attracting manufacturing plants comparing with neighboring developing countries. In order to meet these pragmatic and highly competitive needs of today's industries, it is imperative to promote high-value-added products and services (Ryan 1996). It was reported that 9 out of 10 bar code scanner vendors were planning to repackage their product offerings in 1997 to include a larger scope of value-added features and pursue application-specific solution opportunities (Rezendes 1997).

This chapter discusses the opportunities brought by mass customization for high-value-added products and services. Mass customization enhances profitability through a synergy of increasing customer-perceived values and reducing the costs of production and logistics. Therefore, mass customization inherently makes high-value-added products and services possible through premium profits derived from customized products. The chapter also introduces techniques of integrating product lifecycle concerns in terms of how to connect customer needs proactively with the capabilities of a manufacturer or service provider during the product-development process. Major technical challenges of mass customization are also summarized.

1.1. Concept Implication

Mass customization is defined here as "producing goods and services to meet individual customer's needs with near mass production efficiency" (Tseng and Jiao 1996). The concept of *mass customization* was anticipated by Toffler (1971) and the term was coined by Davis (1987). Pine (1993) documented its place in the continuum of industrial development and mapped out the management implications for firms that decide to adopt it. Mass customization is a new paradigm for industries to provide products and services that best serve customer needs while maintaining near-mass production efficiency. Figure 1 illustrates the economic implications of mass customization (Tseng and Jiao 1996). Traditionally, mass production demonstrates an advantage in high-volume production, where the actual volume can defray the costs of huge investments in equipment, tooling, engineering, and training. On the other hand, satisfying each individual customer's needs can often be translated into higher value, in which, however, low production volume is unavoidable and thus may lend itself to becoming economically not viable. Accommodating companies to garner economy of scale through repetitions, mass customization is therefore capable of reducing costs and lead time. As a result, mass customization can achieve higher margins and thus be more advantageous. With the increasing flexibility built into modern manufacturing systems and programmability in computing and communication technologies, companies with low to medium production volumes can gain an edge over competitors by implementing mass customization.

In reality, customers are often willing to pay premium price for their unique requirements being satisfied, thus giving companies bonus profits (Roberts and Meyer 1991). From an economic perspective, mass customization enables a better match between the producers' capabilities and customer needs. This is accomplished through either developing the company's portfolio, which includes prod-

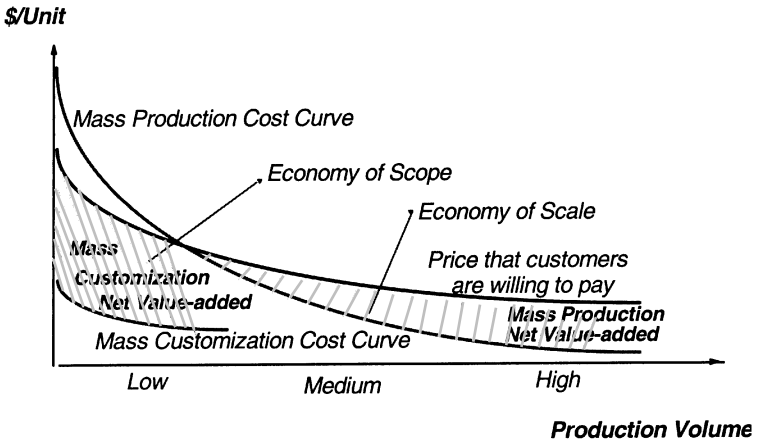

Figure 1 Economic Implications of Mass Customization.

ucts, services, equipment, and skills, in response to market demands, or leading customers to the total capability of the company so that customers are better served. The end results are conducive to improvement in resources utilization. Mass customization also has several significant ramifications in business. It can potentially develop customer loyalty, propel company growth, and increase market share by widening the product range (Pine 1993).

1.2. Technical Challenges

The essence of mass customization lies in the product and service providers' ability to perceive and capture latent market niches and subsequently develop technical capabilities to meet the diverse needs of target customers. Perceiving latent market niches requires the exploration of customer needs. To encapsulate the needs of target customer groups means to emulate existing or potential competitors in quality, cost, quick response. Keeping the manufacturing cost low necessitates economy of scale and development of appropriate production capabilities. Therefore, the requirements of mass customization depend on three aspects: time-to-market (quick responsiveness), variety (customization), and economy of scale (volume production efficiency). In other words, successful mass customization depends on a balance of three elements: features, cost, and schedule. In order to achieve this balance, three major technical challenges are identified as follows.

1.2.1. Maximizing Reusability

Maximal amounts of repetition are essential to achieve the efficiency of mass production, as well as efficiencies in sales, marketing, and logistics. This can be attained through maximizing commonality in design, which leads to reusable tools, equipment, and expertise in subsequent manufacturing. From a commercial viewpoint, mass customization provides diverse finished products that can be enjoyed uniquely by different customers. Customization emphasizes the differentiation among products. An important step towards this goal will be the development and proliferation of design repositories that are capable of creating various customized products. This product proliferation naturally results in the continuous accretion of varieties and thus engenders design variations and process changeovers, which seemingly contradict the pursuit of low cost and high efficiency of mass production. Such a setup presents manufacturers with a challenge of ensuring ''dynamic stability'' (Boynton and Bart 1991), which means that a firm can serve the widest range of customers and changing product demands while building upon existing process capabilities, experience, and knowledge. Due to similarity over product lines or among a group of customized products, reusability suggests itself as a natural technique to facilitate increasingly efficient and cost-effective product realization. Maximizing reusability across internal modules, tools, knowledge, processes, components, and so on means that the advantages of low costs and mass production efficiency can be expected to maintain the integrity of the product portfolio and the continuity of the infrastructure. This is particularly true in savings resulting from leveraging downstream investments in the product life cycle, such as existing design capabilities and manufacturing facilities.

Although commonality and modularity have been important design practices, these issues are usually emphasized for the purpose of physical design or manufacturing convenience. To achieve mass customization, the synergy of commonality and modularity needs to be tackled starting from the functional domain characterized by customer needs or functional requirements, and needs to encompass both the physical and process domains of design (Suh 1990). In that way, the reusability of both design and process capabilities can be explored with respect to repetitions in customer needs related to specific market niches.

1.2.2. Product Platform

The importance of product development for corporate success has been well recognized (Meyer and Utterback 1993; Roberts and Meyer 1991). The effectiveness of a firm's new product generation lies in (1) its ability to create a continuous stream of successful new products over an extended period of time and (2) the attractiveness of these products to the target market niches. Therefore, the essence of mass customization is to maximize such a match of internal capabilities with external market needs.

Towards this end, a product platform is impelled to provide the necessary taxonomy for positioning different products and the underpinning structure describing the interrelationships between various products with respect to customer requirements, competition information, and fulfillment processes. A product platform in a firm implicates two aspects: to represent the entire product portfolio, including both existing products and proactively anticipated ones, by characterizing various perceived customer needs, and to incorporate proven designs, materials, and process technologies.

In terms of mass customization, a product platform provides the technical basis for catering to customization, managing variety, and leveraging existing capabilities. Essentially, the product platform captures and utilizes reusability underlying product families and serves as a repertoire of knowledge bases for different products. It also prevents variant product proliferation for the same set of customer requirements. The formulation of product platform involves inputs from design concepts,

process capabilities, skills, technological trends, and competitive directions, along with recognized customer requirements.

1.2.3. Integrated Product Life Cycle

Mass customization starts from understanding customers' individual requirements and ends with a fulfillment process targeting each particular customer. The achievement of time-to-market through telescoping lead times depends on the integration of the entire product-development process, from customer needs to product delivery. Boundary expansion and concurrency become the key to the integration of the product development life cycle from an organizational perspective. To this end, the scope of the design process has to be extended to include sales and service.

On the other hand, product realization should simultaneously satisfy various product life cycle concerns, including functionality, cost, schedule, reliability, manufacturability, marketability, and serviceability, to name but a few. The main challenge for today's design methodologies is to support these multiple viewpoints to accommodate different modeling paradigms within a single, coherent, and integrated framework (Subrahmanian et al. 1991).

In other words, the realization of mass customization requires not only integration across the product development horizon, but also the provision of a context-coherent integration of various viewpoints of product life cycle. It is necessary to employ suitable product platforms with unified product and product family structure models serving as integration mechanisms for the common understanding of general construction of products, thereby improving communication and consistency among different aspects of product life cycle.

2. DESIGN FOR MASS CUSTOMIZATION

Design has been considered as a critical factor to the final product form, cost, reliability, and market acceptance. The improvements made to product design may significantly reduce the product cost while causing only a minor increase in the design cost. As a result, it is believed that mass customization can best be approached from design, in particular, the up-front effort in the early stages of the product-development process.

Design for Mass Customization (DFMC) (Tseng and Jiao 1996) aims at considering economies of scope and scale at the early design stage of the product-realization process. The main emphasis of DFMC is on elevating the current practice of designing individual products to designing product families. In addition, DFMC advocates extending the traditional boundaries of product design to encompass a larger scope, from sales and marketing to distribution and services. To support customized product differentiation, a product family platform is required to characterize customer needs and subsequently to fulfill these needs by configuring and modifying well-established modules and components. Therefore, there are two basic concepts underpinning DFMC: product family architecture and product family design. Figure 2 summarizes the conceptual implications of DFMC in terms of the expansion of context from both a design scope perspective and a product-differentiation perspective.

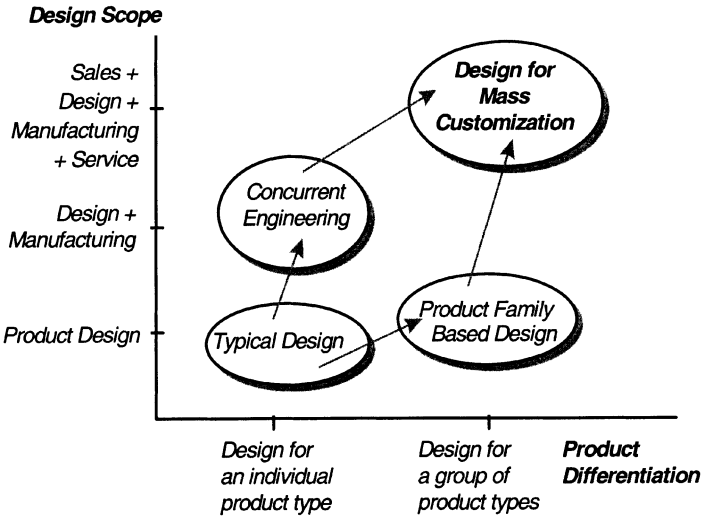

Figure 2 Understanding DFMC.

2.1. Product Family

A product family is a set of products that are derived from a common platform (Meyer and Lehnerd 1997). Each individual product within the family (i.e., a product family member) is called a product variant. While possessing specific features/functionality to meet a particular set of customer requirements, all product variants are similar in the sense that they share some common customer-perceived value, common structures, and/or common product technologies that form the platform of the family. A product family targets a certain market segment, whereas each product variant is developed to address a specific set of customer needs of the market segment.

The interpretation of product families depends on different perspectives. From the marketing/sales perspective, the functional structure of product families exhibits a firm's product portfolio, and thus product families are characterized by various sets of functional features for different customer groups. The engineering view of product families embodies different product and process technologies, and thereby product families are characterized by different design parameters, components, and assembly structures.

2.1.1. Modularity and Commonality

There are two basic issues associated with product families: modularity and commonality. Table 1 highlights different implications of modularity and commonality, as well as the relationship between them.

The concepts of modules and modularity are central in constructing product architecture (Ulrich 1995). While a module is a physical or conceptual grouping of components that share some characteristics, modularity tries to separate a system into independent parts or modules that can be treated as logical units (Newcomb et al. 1996). Therefore, decomposition is a major concern in modularity analysis. In addition, to capture and represent product-structures across the entire product-development process, modularity is achieved from multiple viewpoints, including functionality, solution technologies, and physical structures. Correspondingly, there are three types of modularity involved in product realization: functional modularity, technical modularity, and physical modularity.

What is important in characterizing modularity is the *interaction* between modules. Modules are identified in such a way that between-module (intermodule) interactions are minimized, whereas within-module (inframodule) interactions may be high. Therefore, three types of modularity are characterized by specific measures of interaction in particular views. As for functional modularity, the interaction is exhibited by the relevance of functional features (FFs) across different customer groups. Each customer group is characterized by a particular set of FFs. Customer grouping lies only in the functional view and is independent of the engineering (including design and process) views. That is, it is solution neutral. In the design view, modularity is determined according to the technological feasibility of design solutions. The interaction is thus judged by the coupling of design parameters (DPs) to satisfy given FFs regardless of their physical realization in manufacturing. In the process view, physical interrelationships among components and assemblies (CAs) are mostly derived from manufacturability. For example, on a PCB (printed circuit board), physical routings of CAs determine the physical modularity related to product structures.

It is the commonality that reveals the difference of the architecture of product families from the architecture of a single product. While modularity resembles decomposition of product structures and is applicable to describing module (product) types, commonality characterizes the grouping of similar module (product) variants under specific module (product) types characterized by modularity. Corresponding to the three types of modularity, there are three types of commonality in accordance with functional, design, and process views. Functional commonality manifests itself through functional classification, that is, grouping similar customer requirements into one class, where similarity is measured by the Euclidean distance among FF instances. In the design view, each technical module, characterized by a set of DPs corresponding to a set of FFs, exhibits commonality through clustering similar DP instances by chunks (Ulrich and Eppinger 1995). Instead of measuring similarity among CA instances, physical instances (instances of CAs for a physical module type) are grouped mostly

TABLE 1 A Comparison of Modularity and Commonality

Issues	Modularity	Commonality
Focused Objects	Type (Class)	Instances (Members)
Characteristic of Measure	Interaction	Similarity
Analysis Method	Decomposition	Clustering
Product Differentiation	Product Structure	Product Variants
Integration/Relation	Class-Member Relationship	

according to appropriate categorization of engineering costs derived from assessing existing capabilities and estimated volume, that is, economic evaluation.

The correlation of modularity and commonality is embodied in the class-member relationships. A product structure is defined in terms of its modularity where module types are specified. Product variants derived from this product structure share the same module types and take on different instances of every module type. In other words, a class of products (product family) is described by modularity and product variants differentiate according to the commonality among module instances.

2.1.2. Product Variety

Product variety is defined as the diversity of products that a manufacturing enterprise provides to the marketplace (Ulrich 1995). Two types of variety can be observed: functional variety and technical variety. *Functional variety* is used broadly to mean any differentiation in the attributes related to a product's functionality from which the customer could derive certain benefits. On the other hand, *technical variety* refers to diverse technologies, design methods, manufacturing processes, components and/or assemblies, and so on that are necessary to achieve specific functionality of a product required by the customer. In other words, technical variety, though it may be invisible to customers, is required by engineering in order to accommodate certain customer-perceived functional variety. Technical variety can be further categorized into product variety and process variety. The technical variety of products is embodied in different components/modules/parameters, variations of structural relationships, and alternative configuration mechanisms, whilst process variety involves those changes related to process planning and production scheduling, such as various routings, fixtures/setups, and workstations. While functional variety is mostly related to customer satisfaction from the marketing/sales perspective, technical variety usually involves manufacturability and costs from the engineering perspective.

Even though these two types of variety have some correlation in product development, they result in two different variety design strategies. Since functional variety directly affects customer satisfaction, this type of variety should be encouraged in product development. Such a design for "functional" variety strategy aims at increasing functional variety and manifests itself through vast research in the business community, such as product line structuring (Page and Rosenbaum 1987; Sanderson and Uzumeri 1995), equilibrium pricing (Choi and DeSarbo 1994), and product positioning (Choi et al. 1990). In contrast, design for "technical" variety tries to reduce technical variety so as to gain cost advantages. Under this category, "research" includes variety reduction program (Suzue and Kohdate 1990), design for variety (Ishii et al. 1995a; Martin and Ishii 1996, 1997), design for postponement (Feitzinger and Lee 1997), design for technology life cycle (Ishii et al. 1995b), function sharing (Ulrich and Seering 1990), and design for modularity (Erixon 1996).

Figure 3 illustrates the implications of variety and its impact on variety fulfillment. While exploring functional variety in the functional view through customer requirement analysis, product

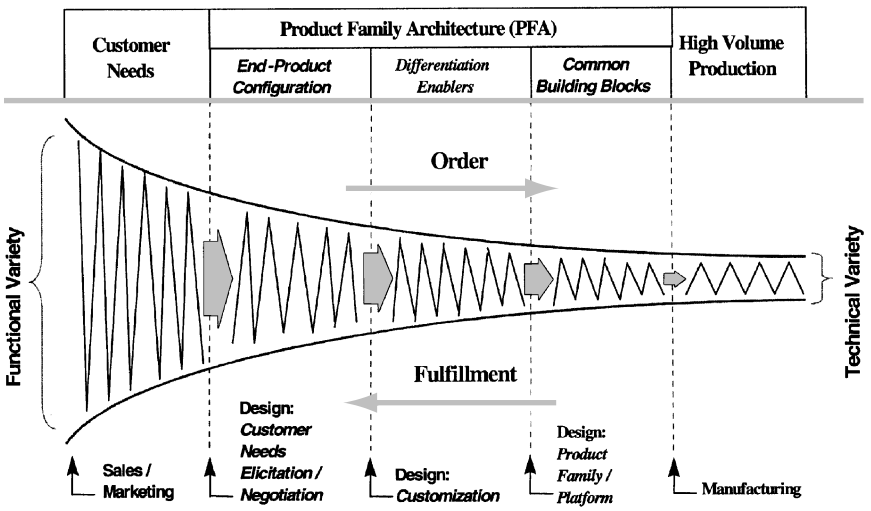

Figure 3 Variety Leverage: Handling Variety for Mass Customization.

family development should try to reduce technical variety in the design and process views by systematic planning of modularity and commonality so as to facilitate plugging in modules that deliver specific functionality, reusing proven designs and reducing design changes and process variations.

2.2. Product Family Architecture

As the backdrop of product families, a well-planned product family architecture (PFA)—the conceptual structure and overall logical organization of generating a family of products—provides a generic umbrella for capturing and utilizing commonality, within which each new product instantiated and extends so as to anchor future designs to a common product line structure. The rationale of such a PFA resides not only in unburdening the knowledge base from keeping variant forms of the same solution, but also in modeling the design process of a class of products that can widely variegate designs based on individual customization requirements within a coherent framework.

Figure 4 illustrates the principle of PFA with respect to product family development for mass customization. From the sales point of view, customers are characterized by combinations of functional features, $\{f\}$, and associated feature values, $\{f^*\}$. A product family, $\{V_1, V_2, V_3, \ldots, V_i, \ldots, V_m\}$, is designed to address the requirements of a group of customers in the market segment, $\{\text{Customer}_1, \text{Customer}_2, \text{Customer}_3, \ldots, \text{Customer}_i, \ldots, \text{Customer}_m\}$, in which customers share certain common requirements, f_0^* along with some similar and/or distinct requirements, $\{f_1^*, f_2^*, f_3^*, \ldots, f_n^*\}$. From the engineering perspective, product variants of the product family are derived from configuring common bases, {C}, and differentiation enablers, {E}, that are predefined for a product family. Configuration mechanisms determine the generative aspect of PFA. They guarantee that only both technically feasible and market-wanted product variants can be derived (Baldwin and Chung 1995).

2.2.1. Composition of PFA

The PFA consists of three elements: the common base, the differentiation enabler, and the configuration mechanism.

1. *Common base:* Common bases (CBs) are the shared elements among different products in a product family. These shared elements may be in the form of either common (functional) features from the customer or sales perspective or common product structures and common components from the engineering perspective. Common features indicate the similarity of

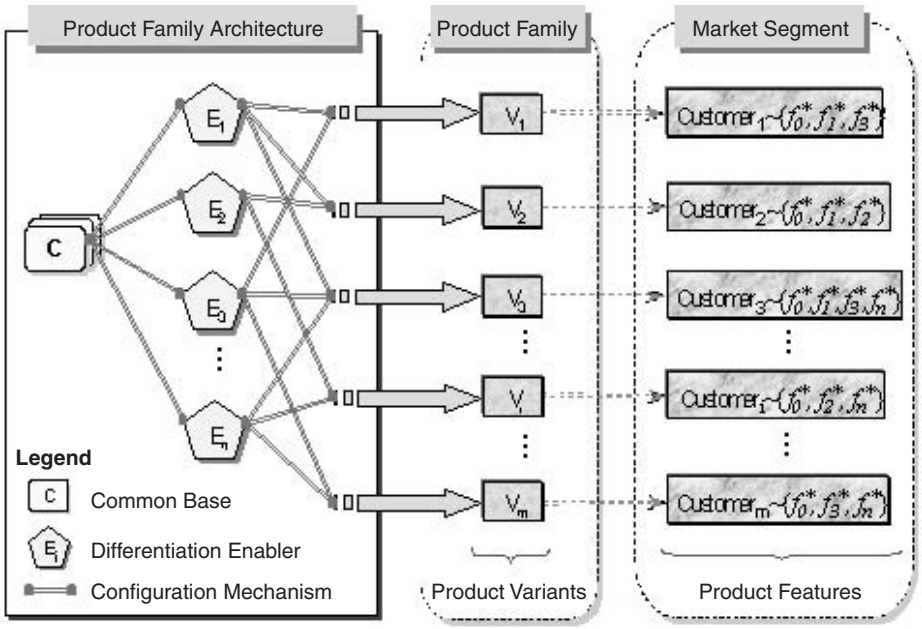

Figure 4 PFA and Its Relationships with Market Segments.

customer requirements related to the market segment. Common product structures and components are determined by product technologies, manufacturing capabilities and economy of scale.

2. *Differentiation enabler:* Differentiation enablers (DEs) are basic elements making products different from one another. They are the source of variety within a product family. From the customer perspective, DEs may be in the form of optional features, accessories, or selectable feature values. In a computer, for example, while a CD drive is an optional feature (yes/no), the RAM must be one instance of a set of selectable feature values, such as 64K, 128K, and 256K bites. In the engineering view, DEs may be embodied in distinct structural relationship (structural DEs) and/or various modules with different performance (constituent DEs). Each engineering DE usually has more than one alternative applicable to product variant derivation for specific applications.
3. *Configuration mechanism:* Configuration mechanisms (CMs) define the rules and means of deriving product variants. Three types of configuration mechanisms can be identified: selection constraints, include conditions, and variety generation.

Selection constraints specify restrictions on optional features because certain combinations of options (i.e., alternative values of optional features) are not allowed or feasible or, on the contrary, are mandatory. An example of the selection constraint for a car might be: ''If cylinder (feature) is 1.3 liter (option) and fuel (feature) is diesel (option), a five-speed (option) gearbox (feature) is mandatory.'' Selection constraints eliminate those technically infeasible or market-unwanted products from all possible combinations of the offered options (Baldwin and Chung 1995). The theoretical number of combination is the Cartesian product of possible feature values (options).

Include conditions are concerned with the determination of alternative variants for each differentiation enabler. The include condition of a variant defines the condition under which the variant should be used or not used with respect to achieving the required product characteristics. It may be in the form of a logic function with parameter values of the differentiation enabler or with its parent constituent as independent variables. For example, an office chair (a parent) consists of one supporting module (a child), which performs as a differentiation enabler. Supposed there are two variants for this supporting module: ''using wheels'' and ''using pads.'' The include condition of ''using wheels'' is ''the office chair is drivable,'' while the include condition of ''using pads'' is ''the office chair is not drivable.'' This include condition is defined in the form of a logic function of the parent's (office chair) variable, ''drivable or not.'' Essentially, include conditions involve the engineering definition stage of product development.

Variety generation refers to the way in which the distinctiveness of product features can be created. It focuses on the engineering realization of custom products in the form of product structures. Such variety fulfillment is related to each differentiation enabler. This chapter identifies three basic methods of variety generation (Figure 5): attaching, swapping, and scaling, in light of the rationale of modular product architecture (Ulrich 1995; Ulrich and Tung 1991). More complex variety-generation methods can be composed by employing these basic methods recursively with reference to the hierarchical decomposition of product structures.

2.2.2. Synchronization of Multiple Views

It has been a common practice for different departments in a company have different understandings of product families from their specific perspectives. Such incoherence in semantics and subsequent deployment of information represents a formidable hindrance to current engineering data management systems (EDBS) (Krause et al. 1993). It is necessary to maintain different perspectives of product family representation in a single context. In addition, variety originates from the functional domain and propagates across the entire product-development process. Therefore, the representation of product families should characterize various forms of variation at different stages of product development.

The strategy is to employ a generic, unified representation and to use its fragments for different purposes, rather than to maintain consistency among multiple representations through transformation of different product data models to standard ones. Figure 6 illustrates such a representation scheme of PFA, where functional, behavioral, and structural (noted as FBS) views are tailored for specific departments and design phases.

While corresponding to and supporting different phases of product development, the FBS view model integrates several business functions in a context-coherent framework. This is embodied by mappings between the three views (Figure 6). Various types of customer needs (customer groups) are mapped from the functional view to the behavioral view characterized by solution principles (TPs and modular structures). Such a mapping manifests design activities. The mapping between the behavioral view and the structural view reflects considerations of manufacturing and logistics, where the modular structure and technical modules in terms of TPs are realized by physical modules in terms of components and assemblies through incorporating assessments of available process capa-

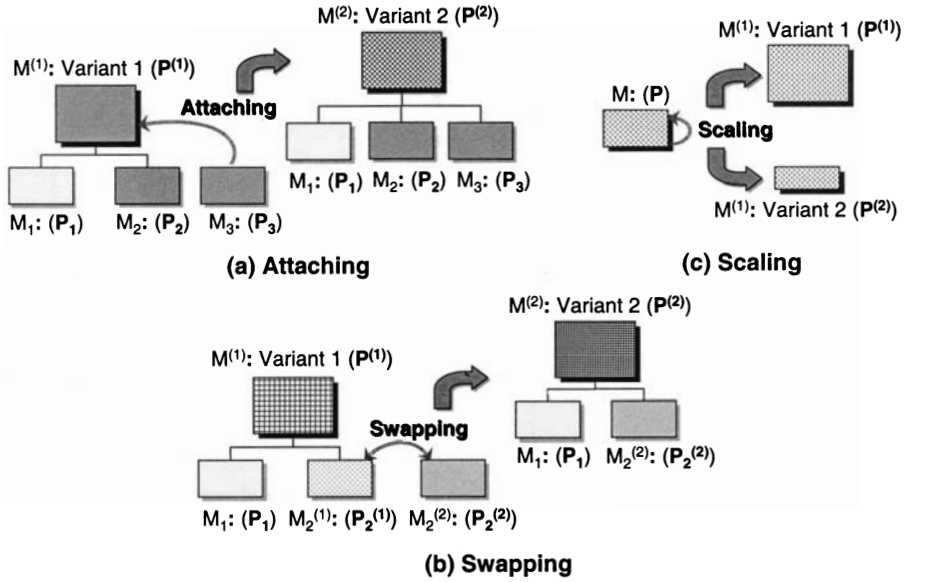

Figure 5 Basic Methods of Variety Generation.

bilities and the economy of scale. The sales and marketing functions involve mapping between the structural and functional views, where the correspondence of a physical structure to its functionality provides necessary information to assist in negotiation among the customers, marketers, and engineers, such as facilitating the request for quotation (RFQ).

2.3. Product Family Design

Under the umbrella of PFA, product family design manifests itself through the derivation processes of product variants based on PFA constructs. Figure 7 illustrates the principle of PFA-based product

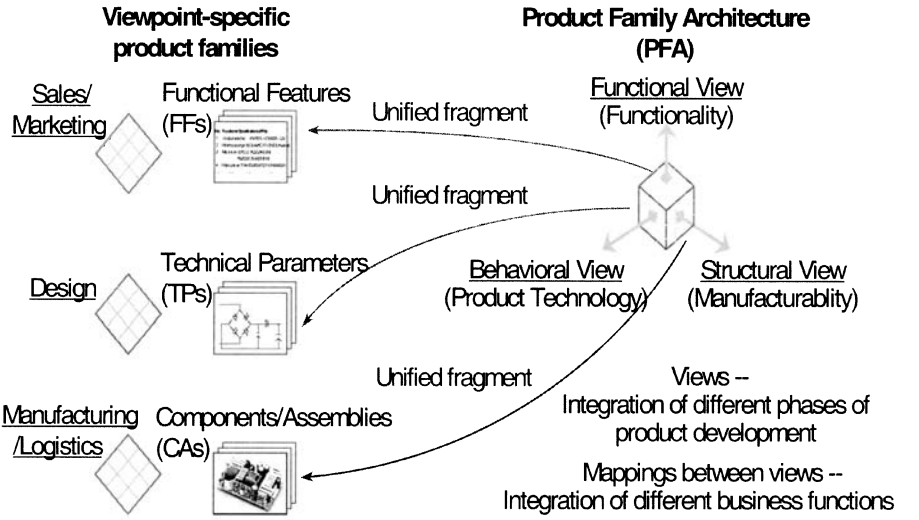

Figure 6 Representing Multiple Views of Product Family within a Single Context.

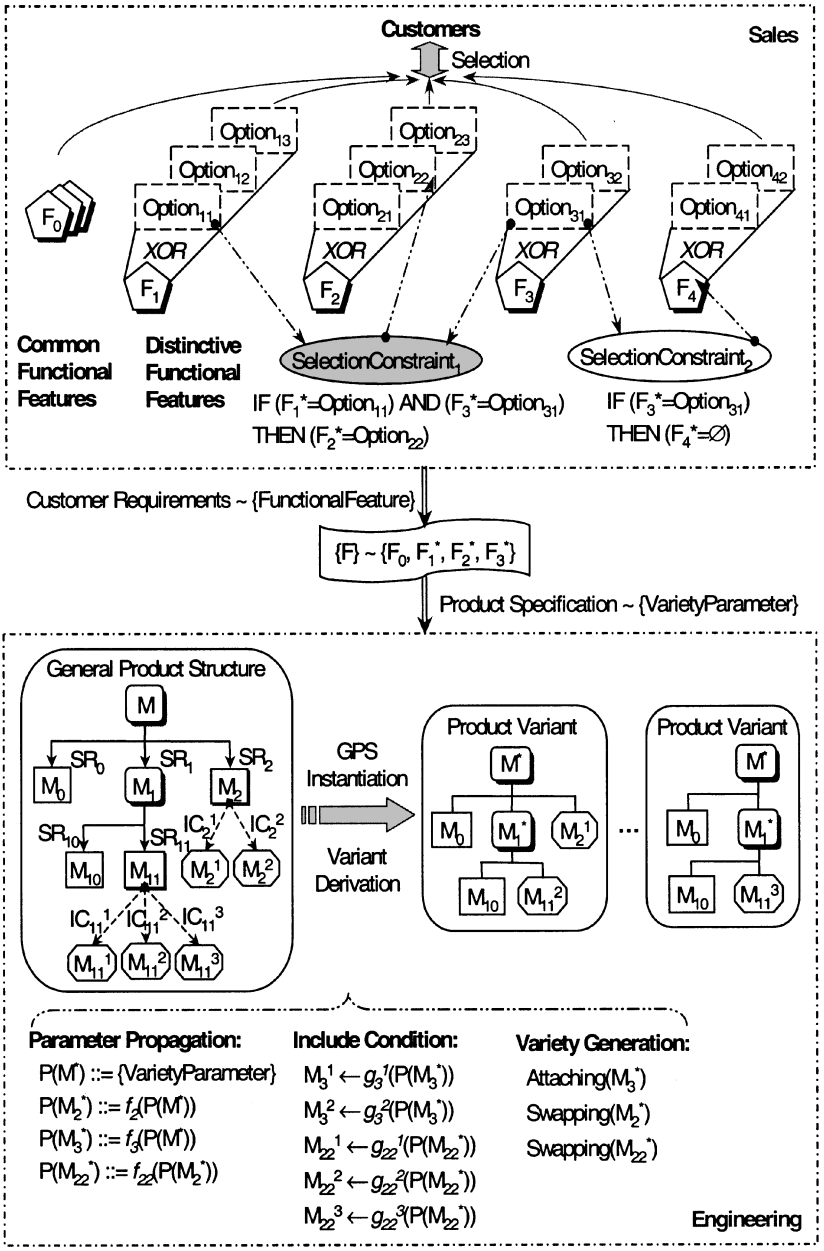

Figure 7 PFA-Based Product Family Design: Variant Derivation through GPS Instantiation.

family design. Customers make their selections among sets of options defined for certain distinctive functional features. These distinctive features are the differentiation enablers of PFA in the sales view. Selection constraints are defined for presenting customers only feasible options, that is, both technically affordable and market-wanted combinations. A set of selected distinctive features together with those common features required by all customers comprise the customer requirements of a customized product design. As shown in Figure 7, customized products are defined in the sales view in the form of functional features and their values (options), whereas in the engineering view, product

family design starts with product specifications in the form of variety parameters. Within the PFA, variety parameters correspond to distinctive functional features and the values of each variety parameter correspond to the options of each functional feature.

To realize variety, a general product structure (GPS) is employed as a generic data structure of product family in the engineering view. The derivation of product variants becomes the instantiation of GPS. While the GPS characterizes a product family, each instance of GPS corresponds to a product variant of the family. Each item in the GPS (either a module or a structural relationship) is instantiated according to certain include conditions that are predefined in terms of variety parameters. Variety parameters originate from functional features specified by the customers and propagate along levels of abstraction of GPS. Variety generation methods, such as attaching, swapping, and scaling, are implemented through different instantiations of GPS items. While the GPS provides a common base for product family design, distinctive items of GPS, such as distinctive modules and structural relationships, perform as the differentiation enablers of the family. Distinctive items are embodied in different variants (instances) that are identified by associated conditions. Therefore, these include conditions and the variety generation capability constitutes configuration mechanisms of PFA in the engineering view.

3. MASS CUSTOMIZATION MANUFACTURING

Competition for mass customization manufacturing is focused on the flexibility and responsiveness in order to satisfy dynamic changes of global markets. The traditional metrics of cost and quality are still necessary conditions for companies to outpace their competitors, but they are no longer the deciding factors between winners and losers. Major trends are:

1. A major part of manufacturing will gradually shift from mass production to the manufacturing of semicustomized or customized products to meet increasingly diverse demands.
2. The ''made-in-house'' mindset will gradually shift to distributed locations, and various entities will team up with others to utilize special capabilities at different locations to speed up product development, reduce risk, and penetrate local markets.
3. Centralized control of various entities with different objectives, locations, and cultures is almost out of the question now. Control systems to enable effective coordination among distributed entities have become critical to modern manufacturing systems.

To achieve this, it is becoming increasingly important to develop production planning and control architectures that are modifiable, extensible, reconfigurable, adaptable, and fault tolerant. Flexible manufacturing focuses on batch production environments using multipurpose programmable work cells, automated transport, improved material handling, operation and resource scheduling, and computerized control to enhance throughput. Mass customization introduces multiple dimensions, including drastic increase of variety, multiple product types manufactured simultaneously in small batches, product mixes that change dynamically to accommodate random arrival of orders and wide spread of due dates, and throughput that is minimally affected by transient disruptions in manufacturing processes, such as breakdown of individual workstations.

3.1. Managing Variety in Production Planning

Major challenge of mass customization production planning results from the increase of variety. The consequence of variety may manifest itself through several ramifications, including increasing costs due to the exponential growth of complexity, inhibiting benefits from economy of scale, and exacerbating difficulties in coordinating product life cycles. Facing such a variety dilemma, many companies try to satisfy demands from their customers through engineering-to-order, produce-to-order, or assembly-to-order production systems (Erens and Hegge 1994).

At the back end of product realization, especially at the component level and on the fabrication aspect, today we have both flexibility and agility provided by advanced manufacturing machinery such as CNC machines. These facilities accommodate technical variety originating from diverse needs of customers. However, at the front end, from customer needs to product engineering and production planning, managing variety is still very ad hoc. For example, production control information systems, such as MRPII (manufacturing resource planning) and ERP (enterprise resource planning), are falling behind even though they are important ingredients in production management (Erens et al. 1994). The difficulties lie in the necessity to specify all the possible variants of each product and in the fact that current production management systems are often designed to support a production that is based on a limited number of product variants (van Veen 1992).

The traditional approach to variant handling is to treat every variant as a separate product by specifying a unique BOM for each variant. This works with a low number of variants, but not when customers are granted a high degree of freedom in specifying products. The problem is that a large

number of BOM structures will occur in mass customization production, in which a wide range of combinations of product features may result in millions of variants for a single product. Design and maintenance of such a large number of complex data structures are difficult, if not impossible. To overcome these limitations, a generic BOM (GBOM) concept has been developed (Hegge and Wortmann 1991; van Veen 1992). The GBOM provides a means of describing, with a limited amount of data, a large number of variants within a product family, while leaving the product structure unimpaired. Underlying the GBOM is a generic variety structure for characterizing variety, as schematically illustrated in Figure 8. This structure has three aspects:

1. *Product structure:* All product variants of a family share a common structure, which can be described as a hierarchy containing constituent items (I_i) at different levels of abstraction, where $\{I_i\}$ can be either abstract or physical entities. Such a breakdown structure (AND tree) of $\{I_i\}$ reveals the topology for end-product configuration (Suh 1997). Different sets of I_i and their interrelationships (in the form of a decomposition hierarchy) distinguish different common product structures and thus different product families.
2. *Variety parameters:* Usually there is a set of attributes, A, associated with each I_i. Among them, some variables are relevant to variety and thus are defined as variety parameters, $\{P_j\} \subset A$. Like attribute variables, parameters can be inherited by child node(s) from a parent node. Different instances of a particular P_j, e.g., $\{V_k\}$, embody the diversity resembled by, and perceived from, product variants.

   Two types of class-member relationships can be observed between $\{P_j\}$ and $\{V_k\}$. A leaf P_j (e.g., *P32*) indicates a binary-type instantiation, meaning whether *I32* is included in *I3* ($V32 = 1$), or not ($V32 = 0$). On the other hand, a node P_j (e.g., *P2*) indicates a selective type instantiation, that is, *I2* has several variants in terms of values of *P2*, i.e., $V2 \sim \{V2\_1, V2\_2\}$.
3. *Configuration constraints:* Two types of constraint can be identified. Within a particular view of product families, such as the functional, behavioral, or physical view, restrictions on the

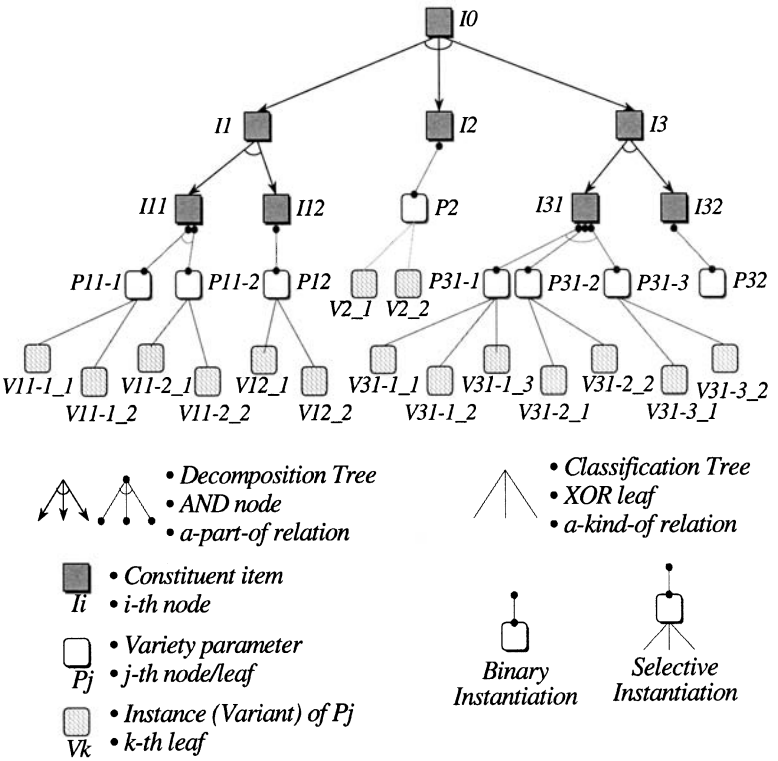

Figure 8 A Generic Structure for Characterizing Variety.

combination of parameter values, $\{V_k\}$, are categorized as Type I constraints. For example, *V11-1_1* and *V31-3_2* are incompatible, that is, only one of them can be selected for a product variant, indicating an exclusive all (XOR) relationship. The mapping relationships of items and their variety parameters across the functional, behavioral, and structural views are referred to as Type II constraints. This type of constraint deals mostly with configuration design knowledge. Usually they are described as rules instead of being graphically depicted in a generic structure. While the functional and behavioral views of product families are usually associated with product family design, the major concern of managing variety in production is Type I constraints which mostly involves the structural view.

Table 2 illustrates the above generic variety structure using a souvenir clock example. As far as variant handling is concerned, the rationale of the generic variety structure lies in the recognition of the origin and subsequent propagation of variety. Three levels of variation have been indicated, that is, at the structure, variety parameter, and instance levels. Different variation levels have different variety implications. To understand the ''generic'' concept underlying such a variety representation, two fundamental issues need to be highlighted:

1. *Generic item:* A generic item represents a set of similar items (called variants) of the same type (a family). The item may be an end product, a subassembly, an intermediate part, or a component part (van Veen, 1992). It may also be a goes-into-relationship or an operation. For example, a red front plate (I_1^*), a blue front plate (I_2^*) and a transparent front plate (I_3^*) are three individual variants, whereas a generic item, I, represents such a set of variants (a family of front plates), that is $\boldsymbol{I} \sim \{I_1^*, I_2^*, I_3^*\}$. However, these variants are similar in that they share a common structure (e.g., BOM structure) in configuring desk clocks.
2. *Indirect identification:* Instead of using part numbers (referred to as direct identification), the identification of individual variants from a generic item (within a family) is based on variety parameters and their instances (a list if parameter values). Such identification is called indirect identification (Hegge and Wortmann. 1991). In the above example, a variety parameter, color, and its value list, , can be used for an indirect identification of a particular variant, i.e., $I_1^* \sim$

TABLE 2 The Generic Variety Structure for Souvenir Clocks

Structural Items $\{I_i\}$	Variety Parameter $\{P_j\}$	Variety Instance $\{V_k\}$
..3/Hands	Setting Type	Two-hand Setting, Three-hand Setting

4	Base.Color FrontPlate.Color	Color Compatible

$\{\boldsymbol{I}|\text{color} = \text{“red”}\}$ and $\boldsymbol{I}_3^* \sim \{\boldsymbol{I}|\text{color} = \text{“transparent”}\}$. On the other hand, the identification of product family “front plate” is $\boldsymbol{I}$.

3.2. Coordination in Manufacturing Resource Allocation

Mass customization manufacturing is characterized by shortened product life cycle with high-mixed and low-volume products in a rapidly changing environment. In customer-oriented plants, orders consisting of a few parts, or even one part, will be transferred directly from vendors to producers, who must respond quickly to meet short due dates. In contrast to mass production, where the manufacturer tells consumers what they can buy, mass customization is driven by customers telling the manufacturer what to manufacture. As a result, it is difficult to use traditional finite capacity scheduling tools to support the new style of manufacturing. Challenges of manufacturing resource allocation for mass customization include:

1. The number of product variety flowing through the manufacturing system is approaching an astronomical scale.
2. Production forecasting for each line item and its patterns is not often available.
3. Systems must be capable of rapid response to market fluctuation.
4. The system should be easy for reconfiguration—ideally, one set of codes employed across different agents.
5. The addition and removal of resources or jobs can be done with little change of scheduling systems.

Extensive research on coordination of resource allocation has been published in connection with scenarios of multiple resource providers and consumers. In the research, existence of demand patterns is the prerequisite for deciding which algorithm is applicable. The selection of a certain algorithm is often left to empirical judgment, which does not alleviate difficulties in balancing utilization and level of services (e.g., meeting due dates).

As early as 1985, Hatvany (1985) pointed out that the rigidity of traditional hierarchical structures limited the dynamic performance of systems. He suggested a heterachical system, which is described as the fragmentation of a system into small, completely autonomous units. Each unit pursues its own goals according to common sets of laws, and thus the system possesses high modularity, modifiability, and extendibility. Following this idea, agent-based manufacturing (Sikora and Shaw 1997) and holonic manufacturing (Gou et al. 1994), in which all components are represented as different agents and holons, respectively, are proposed to improve the dynamics of operational organizations.

From traditional manufacturing perspectives, mass customization seems chaotic due to its large variety, small batch sizes, random arrival orders, and wide span of due dates. It is manageable, however, owing to some favorable traits of modern manufacturing systems, such as inherent flexibility in resources (e.g., increasing use of machining centers and flexible assembly workstations) and similarities among tools, production plans, and product designs. The challenge is thus how to encode these characteristics into self-coordinating agents so that the invisible hand, in the sense of Adam Smith’s market mechanism (Clearwater 1996), will function effectively.

Market-like mechanisms have been considered as an appealing approach for dealing with the coordination of resource allocation among multiple providers and consumers of resources in a distributed system (Baker 1991; Malone et al. 1988; Markus and Monostori 1996). Research on such a distributed manufacturing resource-allocation problem can be classified into four categories: the bidding/auction approach (Shaw 1988; Upton and Barash 1991), negotiation approach (Lin and Solberg 1992), cooperative approach (Burke and Prosser 1991) and pricing approach (Markus and Monostori 1996).

Major considerations of scheduling for resource allocation include:

1. Decompose large, complex scheduling problems into smaller, disjointed allocation problems.
2. Decentralize resource access, allocation, and control mechanisms.
3. Design a reliable, fault-tolerant, and robust allocation mechanism.
4. Design scalable architectures for resource access in a complex system and provide a plug-and-play resource environment such that resource providers and consumers can enter or depart from the market freely.
5. Provide guarantees to customers and applications on performance criteria.

In this regard, the agent-based, market-like mechanism suggests itself as a means of decentralized, scalable, and robust coordination for resource allocation in a dynamic environment (Tseng et al. 1997). In such a collaborative scheduling system, each workstation is considered as an autonomous agent seeking the best return. The individual work order is considered as a job agent that vies for

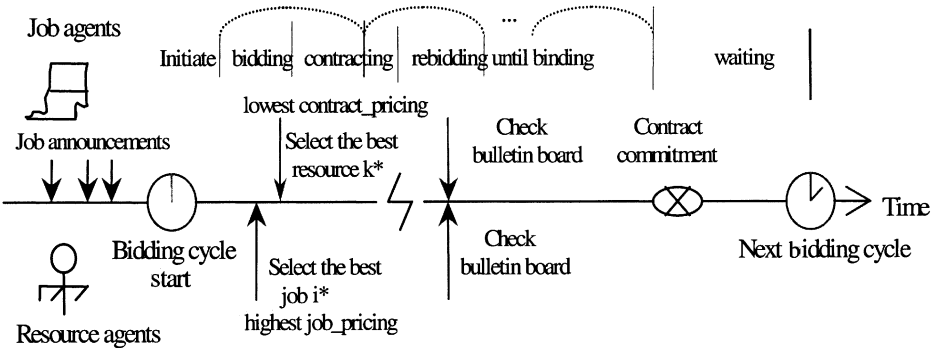

Figure 9 A Market Structure for Collaborative Scheduling.

the lowest cost for resource consumption. System scheduling and control are integrated as an auction-based bidding process with a price mechanism that rewards product similarity and response to customer needs. A typical market model consists of agents, a bulletin board, a market system clock, the market operating protocol, the bidding mechanism, pricing policy, and the commitment mechanism. Figure 9 illustrates how the market operating protocol defines the rules for synchronization among agents.

The satisfaction of multiple criteria, such as costs and responsiveness, cannot be achieved using solely a set of dispatching rules. A price mechanism should be constructed to serve as an invisible hand to guide the coordination in balancing diverse requirements and maximizing performance in a dynamic environment. It is based on market-oriented programming for distributed computation (Adelsberger and Conen 1995). The economic perspective on decentralized decision making has several advantages. It overcomes the narrow view of dispatching rules, responds to current market needs, uses maximal net present value as the objective, and coordinates agents' activities with minimal communication. In collaborative scheduling, objectives of the job agent are transformed into a set of evaluation functions. The weights of the functions can be adjusted dynamically on basis of system states and external conditions. Resource agents adjust the charging prices based on their capability and utilization and the state of current system. Mutual selection and mutual agreement are made through two-way communication. Figure 10 depicts the market price mechanism. In the market model, the job agents change routings (i.e., select different resource agents), and adjust Job_Price as a pricing tool to balance the cost of resources and schedule exposure. Resource agents adjust their prices according to market demands on their capability and optimal utilization and returns. For example, a powerful machine may attract many job agents, and thus the queue will build up and

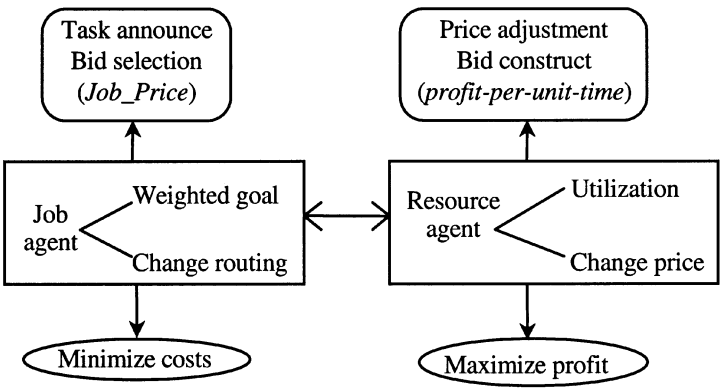

Figure 10 The Price Mechanism of a Market Model.

waiting time will increase. When a resource agent increases its price, the objective of bidding job will decrease, thus driving jobs to other resources and diminishing the demand for this resource.

Specifically, the price mechanism can be expressed as follows:

1. The job agent calculates the price to be paid for the i operation:

$$\text{Job\_price} = \text{Basic\_price} + \text{Penalty\_price} \tag{1}$$

where the Penalty_price reflects the due date factor:

$$\text{Penalty\_price} = \text{penalty} \times e^{-(d_i - c_i)} \tag{2}$$

where d_i represents the due date of the operation i and c_i represents the completion time of the operation i.

2. The resource agent gets the Job_price and then starts to rank the job according to profit per unit time:

$$\text{Profit/time} = (\text{Job\_price} - \text{PFAindex} \times s - \text{Opportunity\_cost})/tp \tag{3}$$

where s represents the setup cost, tp denotes the processing time of the operation, and PFAindex represents the product family consideration in setting up the manufacturing system. For instance, we can let PFAindex = 0, if two consecutive jobs, i and j, are in the same product family, and hence the setup charge can be eliminated in the following job. Otherwise, PFAindex = 1. The Opportunity_cost in Eq. (3) represents the cost of losing particular slack for other job agents due to the assignment of resource for one job agent's operation i, as expressed below:

$$\text{Opportunity\_cost} = \sum_j e^{-c(\min(0,t_{sj}))} \left(e^{c\delta t_{sj}} - 1\right) \tag{4}$$

where $t_{sj} = t_{dj} - t - w_j$, t_{dj} represents the due date of the corresponding job, t represents the current time (absolute time), w_j represents the remaining work content of the job, and c is a system opportunity cost parameter, setting to 0.01. In Eq. (4), δt_{sj} represents the critical loss of slack of operation j due to the scheduling of the operation i before j, as depicted below:

$$\delta t_{sj} = \begin{cases} tp_i, & t_{sj} \le 0 \\ 0 & tp_i \ge t_{sj} \\ tp_i - t_{sj}, & t_{sj} \ge tp_i \end{cases} \tag{5}$$

Meanwhile, the resource agent changes its resource price p_i:

$$p_i = q \sum_k \text{Job\_price}_k \tag{6}$$

where q is a normalized constant.

3. The job agent, in a period of time, collects all bids and responds to its task announcement and selects the resource agent with minimal Actual_cost to confirm the contract:

$$\text{Actual\_cost} = p_i \times tp_i + \max((c_i - d_i),0) \times \text{penalty} \tag{7}$$

Based on the above formulations, the collaborative control can be modeled as a message-based simulation, as shown in Figure 11. The control process is driven by an event and/or an abnormal event, such as machine breakdown or a new due date. All events can be represented as messages.

3.3. High-Variety Shop-Floor Control

Mass customization manufacturing motivates a new generation of shop-floor control systems that can dynamically respond to customer orders and unanticipated changes in the production environment. The requirements of the new control systems include reconfigurability, decomposability, and scalability to achieve make-to-order with very short response time. A systematic approach has been developed to design control system by leveraging recent progresses in computing and communication hardware and software, including new software engineering methods and control technologies, such as smart sensors and actuators, open architectures, and fast and reliable networks (Schreyer and Tseng

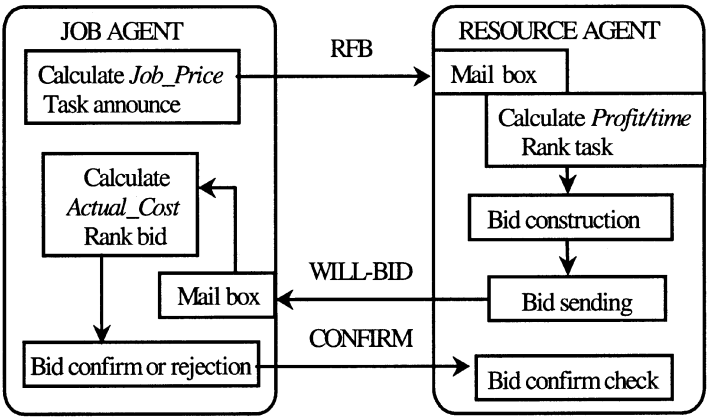

Figure 11 Message-Based Bidding and Dynamic Control.

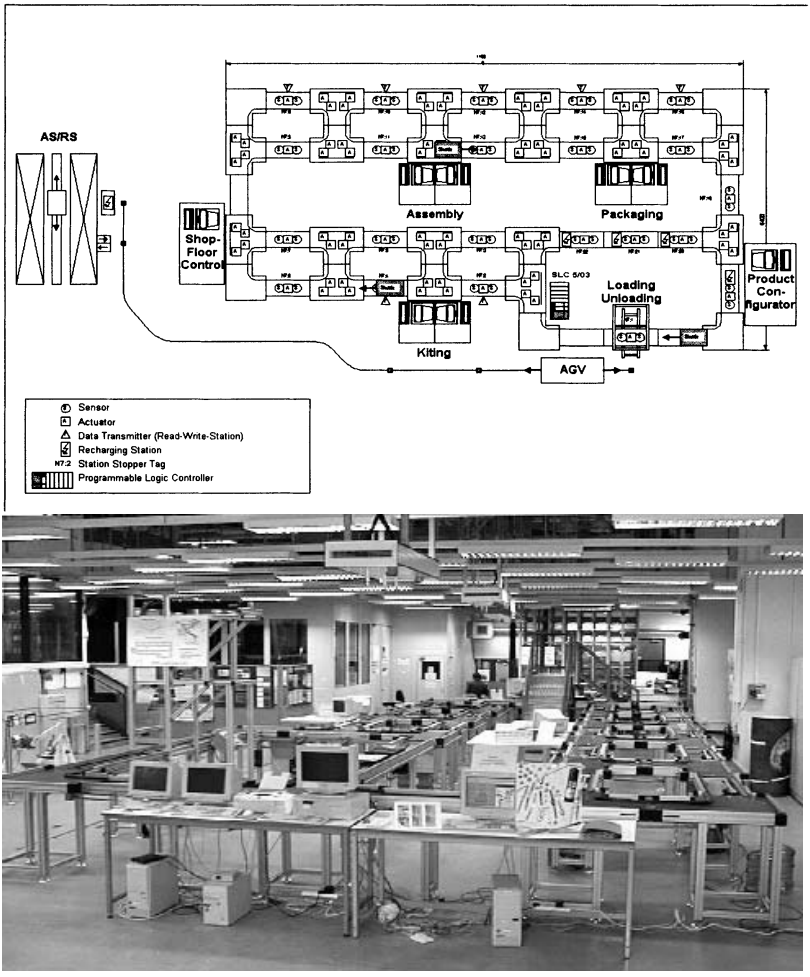

Figure 12 Example of Installation of Mass Customization Manufacturing System at the Hong Kong University of Science and Technology.

1998). Figure 12 illustrates an actual example of installation of a mass customization manufacturing system in the Hong Kong University of Science and Technology.

4. SALES AND MARKETING FOR MASS CUSTOMIZATION

In the majority of industries and sectors, customer satisfaction is a powerful factor in the success of products and services. In the era of mass production, customers were willing to constrain their choices to whatever was available, as long as the price was right. However, customers today are liberated and better informed. This leads them to be choosy about their purchases and less willing to compromise with what is on the shelf. Meeting customer requirements requires full understanding of customers' values and preferences. In addition, it is important that customers know what the company can offer as well as their possible options and the consequences of their choices, such as cost and schedule implications.

4.1. Design by Customers

The setup time and its resulting economy of scale have been widely accepted as the foundation for the mass production economy, where batch size and lead time are important instruments. Consequently, the popular business model of today's firms is design *for* customers. Companies design and then produce goods for customers through conforming a set of specifications that anticipates customer's requirements. Often the forecasting of end users' requirements is developed by the marketing department. It is usually carried out through aggregating the potential needs of customers with the consideration of market direction and technology trends. Given the complexities of modern products, the dynamic changes in customers' needs, and the competitive environment in which most businesses have to operate, anticipating potential customers' needs can be very difficult. Chances are that forecasting will deviate from the reality by a high margin. Three major economic deficiencies are often encountered.

Type A is the possibility of producing something that no customers want. The waste is presented in the form of inventory, obsolescence, or scrap. Although a significant amount of research and development has been conducted on improving the forecast accuracy, inventory policy, increased product offerings, shortened time-to-market, and supply chain management, avoiding the possibility of producing products that no customer want is still a remote, if not impossible, goal.

Type B waste comes from not being able to provide what customers need when they are ready to purchase. It often presents itself in the form of shortage or missing opportunity. The costs of retail stores, marketing promotion, and other sales expenditures on top of the goods themselves will disappoint the customers who are ready to purchase. The cost of missing opportunities can be as significant as the first type.

Type C deficiency results from customers making compromises between their real requirements and existing SKUs (stock keeping units), that is, what is available on the shelf or in the catalogue. Although these compromises are usually not explicit and are difficult to capture, they lead to customer dissatisfaction, reduce willingness to make future purchases, and erode the competitiveness of a company.

To minimize the effect of these deficiencies, one approach is to revise the overall systems design of a manufacturing enterprise. Particularly with the growing flexibility in production equipment, manufacturing information systems and workforce, the constraints of setup cost and lead time in manufacturing have been drastically reduced. The interface between customers and product realization can be reexamined to ensure that total manufacturing systems produce what the customers want and customers are able to get what the systems can produce within budget and schedule. Furthermore, with the growing trends of cultural diversity and self-expression, more and more customers are willing to pay more for products that enhance their individual sizes, tastes, styles, needs, comfort, or expression (Pine 1993).

With the rapid growth of Internet usage and e-commerce comes an unprecedented opportunity for manufacturing enterprise to connect directly customers scattered around the world. In addition, through the Internet and business-to-business e-commerce, manufacturing enterprise can now acquire access to the most economical production capabilities on a global basis. Such connectivity provides the necessary condition for customers to become connected to the company. However, by itself it will not enhance effectiveness.

In the last decade, concurrent engineering brought together design and manufacturing, which has dramatically reduced the product development life cycle and hence improved quality and increased productivity and competitiveness. Therefore, design *by* customers has emerged as a new paradigm to further extend concurrent engineering by extending connectivity with customers and suppliers (Tseng and Du 1998). The company will be able to take a proactive role in helping customers define needs and negotiate their explicit and implicit requirements. Essentially, it brings the voice of customers into design and manufacturing, linking customer requirements with the company's capabilities and extending the philosophy of concurrent engineering to sales and marketing as part of an integrated

product life cycle. Table 3 summarizes the comparison of these two principles for customer-focused product realization.

The rationale of design by customers can be demonstrated by the commonly accepted value chain concept (Porter 1986). The best match of customer needs and company capability requires several technical challenges:

1. Customers must readily understand the capability of a company without being a design engineer or a member in the product-development team.
2. Company must interpret the needs of customers accurately and suggest alternatives that are closest to the needs.
3. Customers must make informed choices with sufficient information about alternatives.
4. Company must have the ability to fulfill needs and get feedback.

To tackle these challenges, it is necessary that customers and the company share a context-coherent framework. Product configuration has been commonly used as a viable approach, primarily because it enables both sides to share the same design domain. Based on the product configuration approach, the value chain, which includes the customer interface, can be divided into four stages:

1. *Formation:* Presenting the capability that a company can offer in the form of product families and product family structure.
2. *Selection:* Finding customers' needs and then matching the set of needs by configuring the components and subassemblies within the constraints set by customers.
3. *Fulfillment:* Includes logistics, manufacturing and distribution so that customer' needs can be satisfied within the cost and time frame specified.
4. *Improvement:* Customers' preferences, choices, and unmet expressed interests are important inputs for mapping out the future improvement plan.

Formation and selection are new dimensions of design for customer. They are explained further below.

4.2. Helping Customers Making Informed Choices: Conjoint Analysis

Design *by* customers assumes customers are able to spell out what they want with clarity. Unfortunately, this is often not the case. To begin with, customers may not be able to know what is possible. Then the system needs to pull the explicit and implicit needs from customers. Conjoint analysis is a set of methods in marketing research originally designed to measure consumer preferences by assessing the buyers' multiattribute utility functions (Green and Krieger, 1989; IntelliQuest 1990). It assumes that a product could be described as vectors of M attributes, $Z_1, Z_2, \ldots, Z_M$. Each attribute can include several discrete levels. Attribute Z_m can be at any one of the L_m levels, $Z_{m1}, Z_{m2}, \ldots, Z_{m,Lm}$, $m \in [1, M]$. A utility functions is defined as (McCullagh and Nelder 1989):

$$U_r = \sum_{m=1}^{M} W_m \left(\sum_{l=1}^{L_m} d_{ml} X_{rml} \right) = \sum_{m=1}^{M} \sum_{l=1}^{L_m} U_{ml} X_{rml} \tag{8}$$

$$U_{ml} = W_m * d_{ml} \tag{9}$$

where U_r = customer's utility for profile r, $r \in [1, R]$
W_m = importance of attribute Z_m for the customer
d_{rml} = desirability for l^{th} level of attribute m, $l \in [1, L_m]$, $m \in [1, M]$
U_{ml} = utility of attribute m's l^{th} level

TABLE 3 A Comparison of Design for Customers and Design by Customers

Principle	Design for Customers	Design by Customers
Manufacturing Practice	Mass production	Mass customization
Design	Anticipate what customers would buy	Create platforms and capabilities
Manufacturing	Build to forecast	Build to order
Sales	Promote what is available	Assist customers to discover what can be done and balance their needs

In the above formulation, X_{rml} is a dummy variable indicating whether or not the particular level of an attribute is selected, as expressed by:

$$X_{rml} = \begin{cases} 1 & \text{if attribute } m \text{ is on } l^{\text{th}} \text{ level;} \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

Usually, a large number of attributes, discrete levels, and their preference indices is required to define the preferred products through customer interaction, and thus the process may become overwhelming and impractical. There are several approaches to overcoming this problem. Green et al. (1991) and IntelliQuest (1990) have proposed adaptive conjoint analysis to explore customers' utility with iterations. Customers are asked to rate the relative importance of attributes and refine the tradeoffs among attributes in an interactive setting through comparing a group of testing profiles. Other approaches, such as Kano diagram and analytic hierarchy process (AHP), can also be applied to refine the utility value (Urban and Hauser 1993).

With the utility function, U_{ml}, customers can find the relative contribution of each attribute to their wants and thus make necessary tradeoffs. Customers can finalize their design specifications by maximizing their own personal value for the unit price they are spending.

4.3. Customer Decision-Making Process

Design by customers allows customers to directly express their own requirements and carry out the mapping to the physical domain. It by no means gives customers free hand to design whatever they want in a vacuum. Instead, it guides customers in navigating through the capabilities of a firm and defining the best alternative that can meet the cost, schedule, and functional requirements of the customers. Figure 13 illustrates the process of design by customers based on a PFA platform. In the figure, arrows represent data flows, ovals represent processes, and variables in uppercase without subscript represent a set of relevant variables. This process consists of two phases: the front-end customer interaction for analyzing and matching customer needs, and the back-end supporting process for improving the compatibility of customer needs and corporate capabilities. There are two actors in the scenario: the customers and the system supported by the PFA.

4.3.1. Phase I: Customer Needs Acquisition

1. *Capability presentation:* In order to make informed decisions, customers are first informed of the capabilities of the firm, which is in the form of the spectrum of product offerings, product attributes, and their possible levels. By organizing these capabilities, the PFA provides a systematic protocol for customers to explore design options.
2. *Self-explication:* Customers are then asked to prioritize desired attributes for their requirements according to their concern about the difference. Customers must assess the value they attach to each attribute and then specify their degree of relative preference between the most desirable and the least desirable levels. The results of this assessment are a set of W_m reflecting the relative importance of each attribute.
3. Utility exploration: Based on W_m, the next task is to find a set of $d^{(0)}_{rml}$ that reflect the desirability of attribute levels. Response surface can be applied here to create a set of testing profiles to search for the value of desirability of each selected level. The AHP can be used to estimate $d^{(0)}_{rml}$. Substituting W_m and $d^{(0)}_{rml}$ in Eq. (9), the utility of each attribute level can be derived.

4.3.2. Phase II: Product Design

1. *Preliminary design:* With $d^{(0)}_{rml}$ and W_m, $U^{(0)}_{ml}$ can be calculated with Eq. (8). A base product (BP) can be determined in accordance with a utility value close to $U^{(0)}_{ml}$. Base product selection can be further fine-tuned through iterative refinement of U_{ml}.
2. *Customization:* Customers can modify the attributes from Z to $Z + \Delta Z$ through the customization process of adding building blocks. Z will be adjusted, and the utility will be recalculated, until the customer gets a satisfactory solution.
3. *Documentation:* After it is confirmed by the customers, the design can be delivered. The results include refined Z and ΔZ and customized BP and ΔBP. These will be documented for the continuous evolution of PFA. Over time, the PFA can be updated so that prospective customers can be better served. This includes changes not only in the offerings of product families but also in production capabilities so that the capabilities of a firm can be better focused to the needs of its customers.

In practice, customers may found this systematic selection process too cumbersome and time consuming. Research in the area of customer decision-making process is still undergoing.

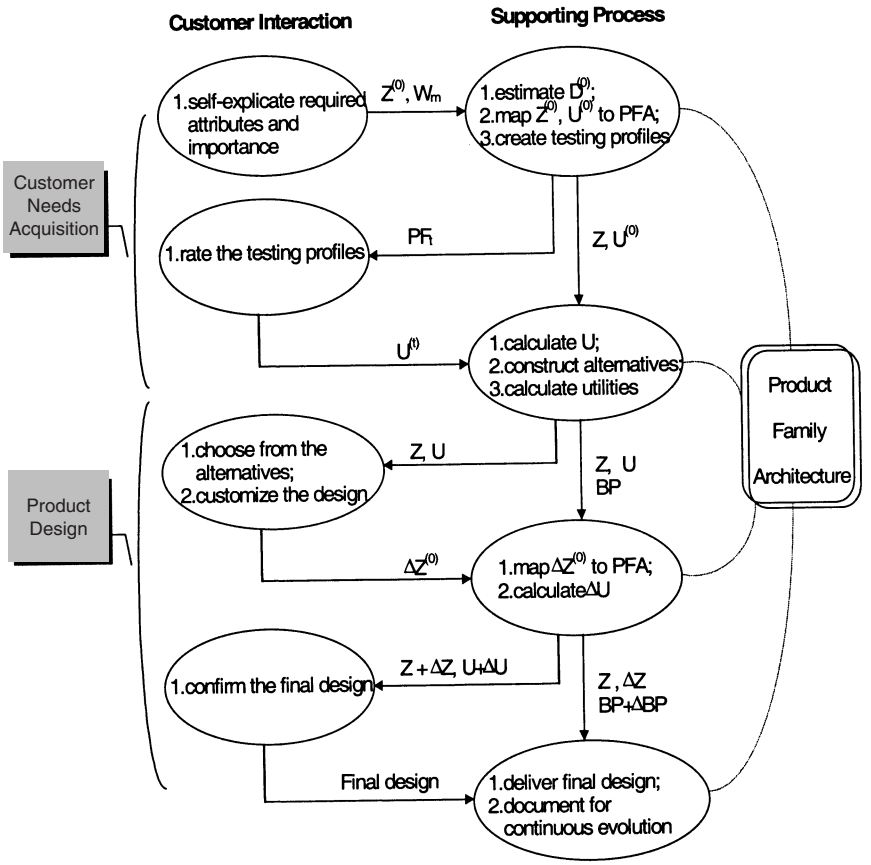

Figure 13 The Process of Customer Decision Making.

4.4. One-to-One Marketing

With the rapid transmission of mass media, globalization, and diverse customer bases, the market is no longer homogeneous and stable. Instead, many segmented markets now coexist simultaneously and experience constant changes. Customers cast their votes through purchasing to express their preferences on products. With the fierce competition, customers can easily switch from one company to another. In addition, they become less loyal to a particular brand. Because a certain portion of customers may bring more value-added to the business than the average customers, it is imperative to keep customer loyalty by putting customers at the center point of business. Such a concept has been studied by many researchers (e.g., Greyser 1997) Peppers and Rogers (1997, p. 22) state: ''The 1:1 enterprise practices 1:1 marketing by tracking customers individually, interacting with them, and integrating the feedback from each customer into its behavior towards that customer.''

With the growing popularity of e-commerce, customers can directly interact with product and service providers on a real-time basis. With the help of system support, each individual customer can specify his or her needs and make informed choices. In the meantime, the providers can directly conduct market research with more precise grasp of customer profiles. This will replace old marketing models (Greyser 1997). At the beginning, the concern is the capability of manufacturers to make products—that is, it is production oriented. Then the focus shifts towards the capability to sell products that have already been made—that is, it is sales oriented. Later on, the theme is customers' preferences and how to accommodate these preferences with respect to company capabilities—that is, it is marketing oriented. With the paradigm shift towards mass customization, manufacturers aim at providing best values to meet customers' individual needs within a short period. The closed-loop

interaction between clients and providers on a one-to-one basis will increase the efficiency of matching buying and selling.

Furthermore, the advent of one-to-one marketing transcends geographical and national boundaries. The profile of customers' individual data can be accessed from anywhere, and in turn the company can serve the customers from anywhere at any time. Nonetheless, it also creates a borderless global market that leads to global competition. To be able to sustain, companies are putting more attention on one-to-one marketing.

5. MASS CUSTOMIZATION AND E-COMMERCE

The Internet is becoming a pervasive communication infrastructure connecting a growing number of users in corporations and institutions worldwide and hence providing immense business opportunities for manufacturing enterprises. The Internet has shown its capability to connect customers, suppliers, producers, logistics providers, and almost every stage in the manufacturing value chain. Leading companies have already started to reengineer their key processes, such as new product development and fulfillment, to best utilize the high speed and low cost of the Internet. Impressive results have been reported with significant reduction in lead time, customer value enhancements, and customer satisfaction improvement. Some even predict that a new industrial revolution has already quietly started, geared towards e-commerce-enabled mass customization (*Economist* 2000; Helander and Jiao 2000).

In essence, mass customization attempts to bring customers and company capabilities closer together. With the Internet, customers and providers in different stages of production can be connected at multiple levels of the Web. How this new capability will be utilized is still at a very early stage. For examples, customers can be better informed about important features and the related costs and limitations. Customers can then make educated choices in a better way. In the meantime, through these interactions the company will then be able to acquire information about customers' needs and preferences and can consequently build up its capabilities in response to these needs. Therefore, e-commerce will be a major driving force and an important enabler for shaping the future of mass customization.

Rapid communication over the Internet will revolutionize not only trade but also all the business functions. A paradigm of electronic design and commerce (eDC) can be envisioned as shown in Figure 14. Further expanded to the entire enterprise, it is often referred to as electronic enterprise (eEnterprise). Three pillars support eDC or eEnterprise: the integrated product life cycle, mass customization, and the supply chain.

The integrated product life cycle incorporates elements that are essential to companies, including marketing/sales, design, manufacturing, assembly, and logistics. Using the Internet, some of these activities may be handed over to the supply chain. There may also be other companies similar to the regular supply chain that supplies services. These constitute business-to-service functions.

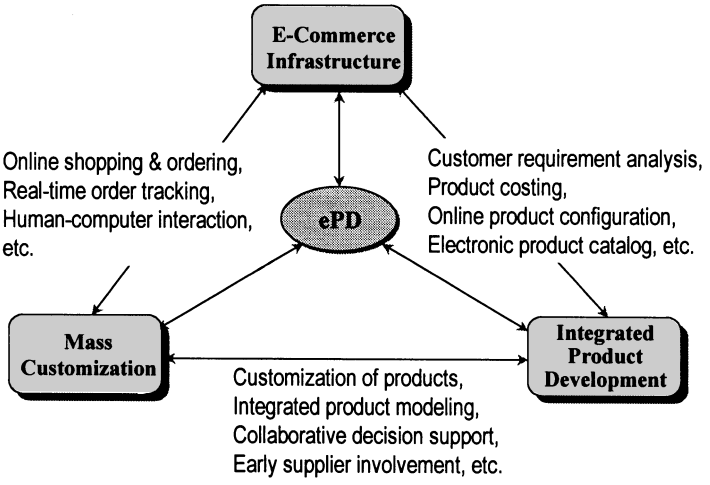

Figure 14 A Systems Model of eDC/eEnterprise.

With the communication and interactivity brought by the Internet, the physical locations of companies may no longer be important. The common business model with a core company that engages in design, manufacturing, and logistics will become less common. Manufacturing, as well as design and logistics, may, for example, be conducted by outside service companies. As a result, in view of the supply chain and service companies, the core of business-to-business e-commerce is flourishing.

Figure 14 also illustrates a systems approach to manufacturing. It is a dynamic system with feedback. For each new product or customized design, one must go around the loop. The purpose is to obtain information from marketing and other sources to estimate customer needs. The product life cycle is therefore illustrated by one full circle around the system.

The company can sell products to distributors and/or directly to customers through business-to-customer e-commerce. In some cases, products may be designed by the customer himself or herself. This is related to mass customization. Customer needs are then captured directly through the customers' preferences—the customers understand what they want and can submit their preferred design electronically. A well-known example is Dell Computers, where customers can select the elements that constitute a computer according to their own preferences.

Usually information about customer needs may be delivered by sales and marketing. Typically, they rely on analyses of customer feedback and predictions for the future. These remain important sources of information for new product development. From this kind of information, the company may redesign existing products or decide to develop a new one. The design effort has to take place concurrently, with many experts involved representing various areas of expertise and parties that collaborate through the system. The supply chain companies may also participate if necessary.

For manufacturing the product, parts and/or other services may be bought from the supply chain and delivered just-in-time to manufacturing facilities. These constitute typical business-to-business e-commerce.

Some important technical issues associated with eDC include human–computer interaction and usability (Helander and Khalid 2001), the customer decision-making process over the Internet (So et al. 1999), product line planning and electronic catalog, and Web-based collaborative design modeling and design support.

6. SUMMARY

Mass customization aims at better serving customers with products and services that are closer to their needs and building products upon economy of scale leading to mass production efficiency. To this end, an orchestrated effort in the entire product life cycle, from design to recycle, is necessary. The challenge lies in how to leverage product families and how to achieve synergy among different functional capabilities in the value chain. This may lead to significant impact on the organizational structure of company in terms of new methods, education, division of labor in marketing, sales, design, and manufacturing. The technological roadmap of mass customization can also lead to redefinition of job, methodology, and investment strategies as witnessed in current practice. For instance, the sales department will be able to position itself to sell its capabilities instead of a group of point products.

As a new frontier of business competition and production paradigm, mass customization has emerged as a critical issue. Mass customization can best be realized by grounding up, instead of by directly synthesizing, existing thrusts of advanced manufacturing technologies, such as JIT, flexible, lean and agile manufacturing, and many others. Obviously, much needs to be done. This chapter provides materials for stimulating an open discussion on further exploration of mass customization techniques.

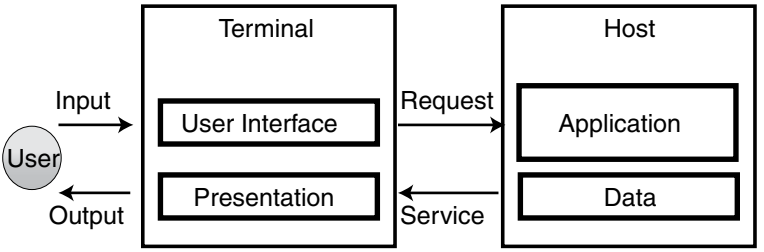

Figure 1 Host-Centered Processing System.

1. INTRODUCTION

1.1. Concept of C/S Systems

In a traditional, centralized mainframe system, a user interacts with an application via a dumb terminal that has a keyboard for entering commands and a display to show the results. All applications and databases are placed on the mainframe (host), and the terminal does not have any ability to process applications. That is, the functions of the user interface and the presentation are placed on the terminal and other applications are placed on the host side, as shown in Figure 1.

In a client/server (C/S) system, by contrast, a user advances processing by using a program called a server, from a workstation or personal computer connected to the server computer by network. The program that receives services from the server is called a client. As in the host-centric system, the functions of user interface and presentation are placed on the user (client) side. Databases that are used for processing requests are placed on the server side. Each application is divided into several processes that run on the client and server sides and cooperate for processing the application. The difference between the two systems is the way of distribution of applications. As shown in Figure 2, some applications can be placed on the user side in the C/S system. Figure 3 shows the physical and logical structures for a host-centric system and a C/S system.

In the physical structure of the host-centric system, applications and databases are placed on a mainframe. That is, the physical structure is almost the same as the logical structure described above. On the other hand, in the C/S system, all the processes that comprise the service are not necessarily placed in the same computer. In many cases, they are distributed in separate computers connected to each other via network.

The features of C/S systems are:

- They contain the basic functional components: presentation, application service, and database.
- Generally, each application service is divided into several processes.
- In many cases, the service is offered by cooperative work of several processes placed on separate computers.

1.2. Roles of Client and Server

There is a many-to-one relationship between clients and servers, but the relationship is relative. In some cases, a client may pass a reference to a callback object when it invokes a service. This lets

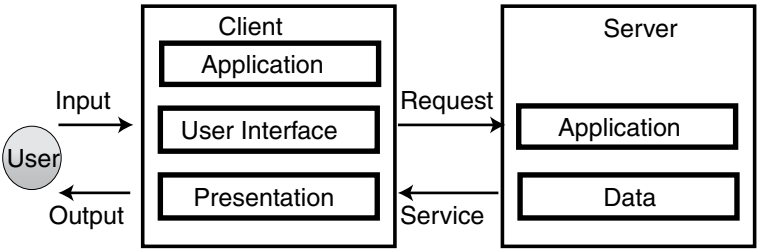

Figure 2 Relationship of Client and Server.

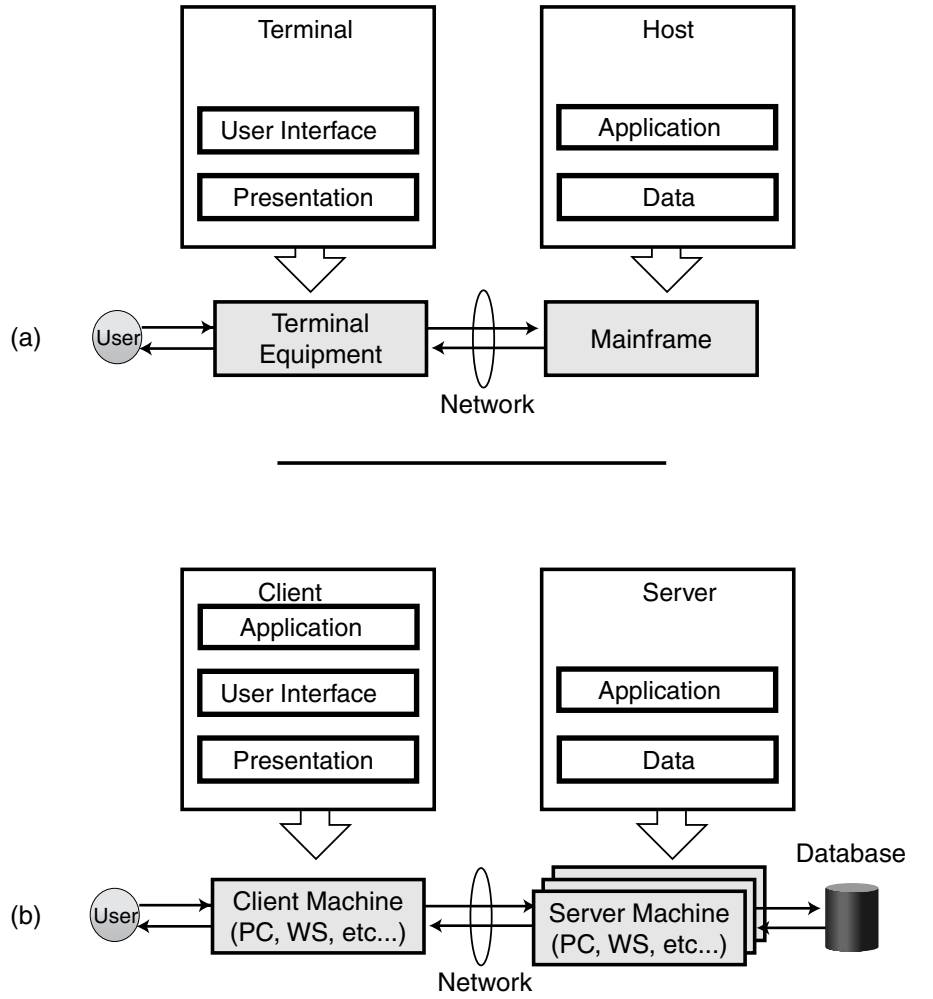

Figure 3 Logical Structure vs. Physical Structure. (*a*) Host processing model. (*b*) C/S processing model.

the server call back the client, so the client becomes a server. For example, in an Internet banking system, a user program (WWW browser) is a client and a program located at the bank that offers services to the client is a server. However, the role of the program located at the bank is not always fixed to the server. To offer a fund transfer service to the user, the program located at bank A asks for a fund acceptance process that is located at bank B. In this case, the program at bank A becomes a client and the program at bank B becomes a server. Thus, the roles of the client and server change dynamically depending on the circumstances. In this chapter, ''client'' means a program that is located on the user side and provides the user interface and presentation functions, and ''server'' means a program that receives requests from the client and provides services to the client.

1.3. Computer Technology Trends

1.3.1. Web Technologies

A C/S system is realized by a network over which clients and servers work together to accomplish a task. To develop the network applications, it is important for a developer to select an appropriate communication protocol from the viewpoint of cost and performance. The communication protocol

is a set of rules by which reliable end-to-end communication between two processes over a network is achieved. In recent years, the TCP/IP protocol stack has been adopted for constructing many network applications and has become the standard protocol for the Internet. World Wide Web (or Web) technologies using HTTP (Hypertext Transfer Protocol), an application layer protocol based on TCP/IP, have been applied to C/S systems. At present, Web technologies are the most widespread for C/S applications. The client side of the Web application is called the browser. Microsoft's Internet Explorer and Netscape's Navigator are the most widely used browsers.

Figure 4 shows the progression of the Web structure of C/S applications:

- At the initial stage, the main service of the Web system was distribution of static information such as a text or an image stored in the storage device of the server machine (the Web server). (Figure 4[*a*]).
- In the middle stage, in addition to distribution of information, more interactive services were provided to the user by applications added to the Web server. For example, in an online shopping service, monthly expenditure is calculated using inputs of the purchase amount of daily shopping (Figure 4[*b*]).
- In the recent stage, external systems such as legacy systems are placed on the back end of the Web server and more advanced services can be provided. An Internet banking service is realized by this structure (Figure 4[*c*]).

The advantage of a C/S system using the Web technologies is that users can unify various kinds of operations and the maintenance of the client software becomes easier. In the future, the proliferation of the Internet means that Web technologies will gain more popularity for realizing C/S systems.

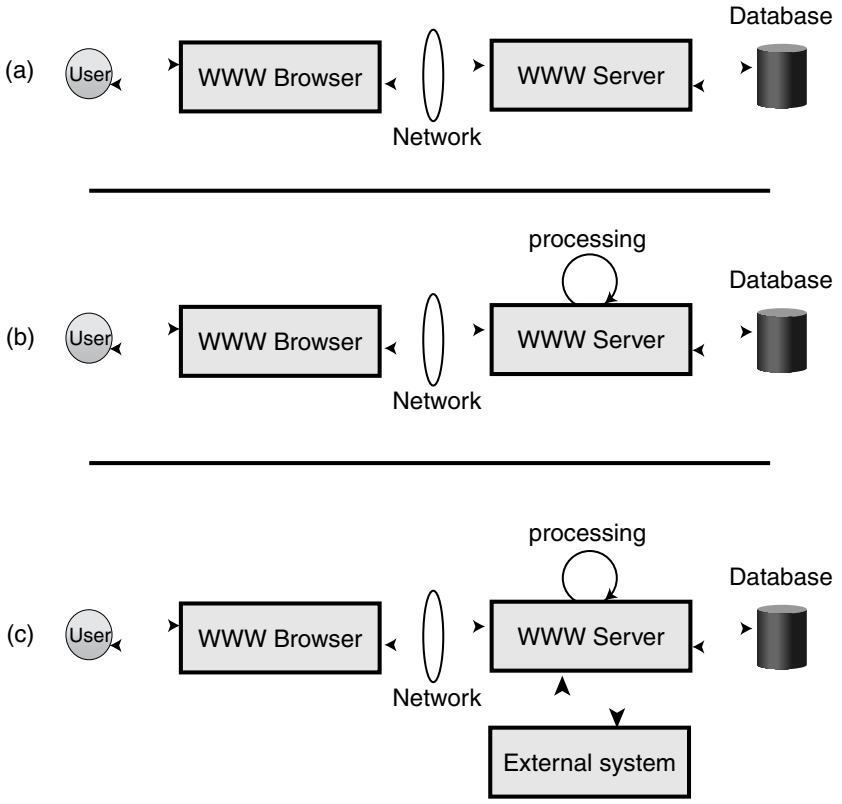

Figure 4 Progressive Stages of Web-Style C/S System. (*a*) WWW information-providing system. (*b*) WWW information-processing system. (*c*) WWW information-processing system with external systems processing.

1.3.2. Open System Technologies

A C/S system is one of distributed models of computing in the environment of heterogeneous computers. This is because open system technologies such as communication protocols and developing languages are required. For example, the adoption of the Java language as the developing language has increased, as has the adoption of CORBA (common object request broker architecture) as interconnection technology. Java is a new object-oriented programming language from Sun Microsystems and a portable operating system environment that enables the writing of portable components. CORBA is a standard architecture created by the OMG (Object Management Group) for a message broker called object request broker, a software component that enables communication among objects in a distributed environment. The common feature of Java and CORBA is platform independence. The most commonly used operating system on which C/S systems are developed is UNIX, which mainly works on workstations or Windows NT, which mainly runs on server-class personal computers. Java and CORBA are designed for running on both operating systems and cooperate mutually. In the future, technology like Java or CORBA that works in heterogeneous computing environments will become more and more important.

Due to the recent progress in hardware technologies, the processing capacity of a personal computer has become almost equal to that of a workstation. Therefore, there are too many choices among various technologies to allow appropriate system components to be selected. The system configuration has become more complex because of a combination of distributed components as well as heterogeneity.

2. FEATURES OF C/S SYSTEMS

2.1. Advantages

The advantages of C/S systems derive from their distributed processing structure, which C/S systems adopt, where processing is handled by two or more cooperating geographically distinct processors.

1. *Performance tuning:* In a distributed processing environment, the service requests from a client are not concentrated on a single server but can be distributed among several servers. Therefore, it becomes possible to distribute required workload among processing resources and improve the performance, such as response time to the client. Furthermore, adopting an efficient algorithm of request distribution such as an adaptive algorithm taking account of current loads of all servers makes it possible to improve the throughput (the amount of work processed per unit time) of the system.
2. *Availability improvement:* Clients are sensitive to performance of the system, but they do not perceive the physical structure of the distribution for requests. In other words, the group of networked servers seems to the client like one server. In a distributed processing environment, even if one server breaks, other servers can substitute for the broken server and continue to process its tasks. This can guarantee the high availability of services to the client compared to a host-centric processing environment.
3. *Scalability and cost-efficiency:* Scalability is the capacity of the system to perform more total work in the same elapsed time when its processing power is increased. With a distributed system, the processing capacity of the system can be scaled incrementally by adding new computers or network elements as the need arises, and excessive investment in a system can be avoided at the introduction stage of the C/S system. On the other hand, with a host-centric system, if the load level is going to saturate the system, the current system will be replaced by a more powerful computer. If further growth is planned, redundant computer capacity will need to be built into the current system to cope with future growth in requirements.

2.2. Disadvantages

1. *Strong dependence on the network infrastructure:* Because a distributed environment is largely based on a networking infrastructure, the performance and availability of the distributed system are strongly influenced by the state of the network. For example, if a network failure, such as of the router or transmission line, occurs, performance and availability for services may seriously deteriorate. The system designer and manager should design the fault-tolerant system and plan the disaster recovery taking account of the networking infrastructure.
2. *Security:* From the viewpoint of security, the possibility exists that confidential information stored on the database may leak out through the network. The system manager should take security measures such as authentication, access control, and cryptographic control according to the security level of information.
3. *Complexity of system configuration:* C/S systems are composed of several components from multiple vendors. Distributed applications often have more complex functionality than cen-

tralized applications, and they are built from diverse components. Multitier architectures, which will be explained in the next section, provide a nearly limitless set of choices for where to locate processing functions and data. In addition to choices about locations, there are also more hardware and software choices, and more data sharing occurs. These cause the difficulty in developing a C/S system and the complexity of managing it.

3. C/S SYSTEM ARCHITECTURES

3.1. Functional Elements of C/S Systems

Since vendors began releasing RDBMS (relational database management system) products in the 1970s, the processing model in which various business data are divided into distributed databases and are accessed via network has been widely adopted. Client/server systems are composed of the various functional elements associated with data processing.

The logical functions of C/S systems are roughly divided into three layers:

1. *Presentation logic:* This function contains all the logic needed to manage screen formats, the content of windows, and interaction with the user, that is, the user interface. In recent years, the use of graphical user interface (GUI) features such as buttons has become general.
2. *Application logic:* This is a generic name for application functions that do not belong to other layers. It includes business logic and the flow of control among application components.
3. *Data logic:* This contains all the logic relating to the storage and retrieval of data, and enforcing business rules about data consistency. Generally, databases are treated and are maintained by a DBMS (database management system).

In addition to these application-functional layers, some functions are needed to support interactions between clients and servers via networks. All the distributed software that supports interaction between application components and network software is called middleware. Middleware is a generic term for all the software components that allow us to connect separate layers or components and put them into a complete distributed system. It provides an application programming interface (API) that isolates application codes from the underlying network communication formats and protocols. It also supplies intermediate system services such as security, naming, directory, messaging, and transaction management services:

1. *Naming service:* In C/S systems, names of clients and servers must be unique within the range in which they are used. A naming service uniquely names a physical entity such as a client or server and associates logical structure such as a tree with physical entities.
2. *Directory service:* This is a directory service that provides a way for clients to locate servers and their services on the network and controls the address of messages and processing requests through a tree structure.
3. *Security service:* This service provides authentication, authorization, access control, and user account management.
4. *Messaging service:* This service provides the ability to send and receive messages between and among applications and users.
5. *Transaction service:* This service manages distributed transaction processing, such as consistency control, that maintains a database in a consistent state and enables recovery control from failures.

3.2. Two-Tier Architecture

Client/server architectures can be characterized by how the applications are distributed between the client and the server. In a two-tier architecture, the application logic is placed on either the client or the server undivided or split into two parts, which are placed on the client and the server respectively. In most cases, the presentation logic and the application logic are placed on the client side and the data logic is placed on the server side. Examples of two-tier C/S systems are file servers and database servers with stored procedures. Figure 5 shows a two-tier architecture.

The advantage of the two-tier architecture is ease of development. Because the two-tier architecture is simple, a developer can create applications quickly using a 4GL (fourth-generation language) development environment such as Microsoft's Visual Basic or Inprise's Delphi. However, as C/S systems grew up to run mission-critical or enterprise-wide applications, shortcomings of the two-tier architecture emerged:

1. *Performance:* Performance may deteriorate markedly as the number of clients, the size of the database, or the volume of transferred data increases. This deterioration is caused by a lack of capacity of resources such as the processing unit, the memory area, and the network bandwidth

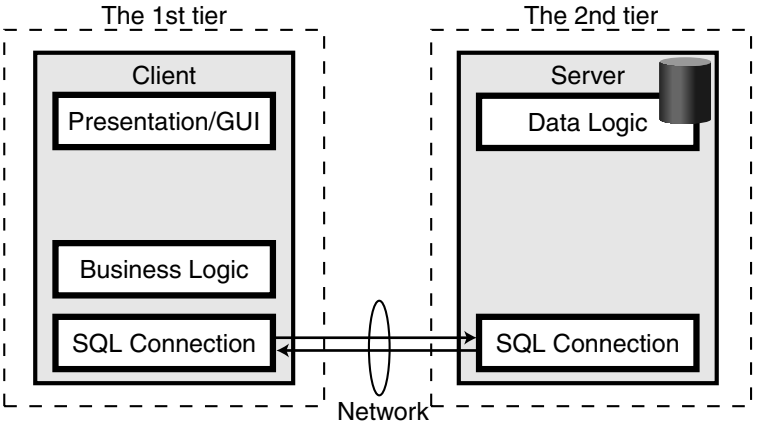

Figure 5 Two-Tier Architecture.

when the processing load is concentrated on the database server. Placing a part of application logic on the database server allows network traffic between the client and the database server to be reduced and the performance even improved. For example, a set of database access commands is compiled and saved in the database of the server. This scheme is called stored procedure. Some DBMS packages support this scheme. But there remains the problem that the application maintenance becomes complicated.

2. *Maintenance:* Because the business logic is placed on the client side in most two-tier C/S systems, version control of applications becomes complex. For example, in the case of an online shopping system, the business logic (or rule), such as tax rate, is implemented on the client side. Although this structure is effective in reducing network traffic between the client and the server, a system manager has to replace the application of all the clients every time the business rule or version of application is changed. This becomes a big problem in the total cost of ownership of two-tier C/S systems: costs of maintaining, operating, and managing large-scale systems accommodating many users and services.

3.3. Three-Tier Architecture

To solve some problems of the two-tier architecture and improve the reliability and performance of the system, a three-tier architecture has been adopted. In a three-tier architecture, the business logic is separated from the presentation and data layers and becomes the middle layer between them. The presentation logic resides in the first tier (the client side), and the data logic in the third tier (the server side), and the business logic in the second tier (the middle) between both tiers. This solves the problems occurring with the two-tier architecture. Figure 6 shows a three-tier architecture where the business logic and some connection functions are placed in the second tier.

In a three-tier architecture, the second tier plays the most important role. Many functions such as data access and connection with other systems are located in the second tier and can be used by any client. That is, the second tier becomes the gateway to other systems. The second tier is often called the application server.

The advantages of three-tier architecture derived from the application server are:

1. *Reduction of network traffic:* Concentrating the function of accessing database and other systems on the application server makes it possible to reduce network traffic between the client and the server. That is, instead of interacting with the database directly, the client calls the business logic on the application server, and then the business logic accesses the database on the database server on behalf of the client. Therefore, only service requests and responses are sent between the client and the server. From the viewpoint of network traffic, comparisons of two-tier architecture and three-tier architecture are shown in Figure 7.
2. *Scalability:* Adding or removing application servers or database servers allows the system to be scaled incrementally according to the number of clients and volume of requests.
3. *Performance:* Because workloads can be distributed across application servers and database servers, this architecture can prevent an application server from becoming a bottleneck and can keep the performance of the system in a permissible range.

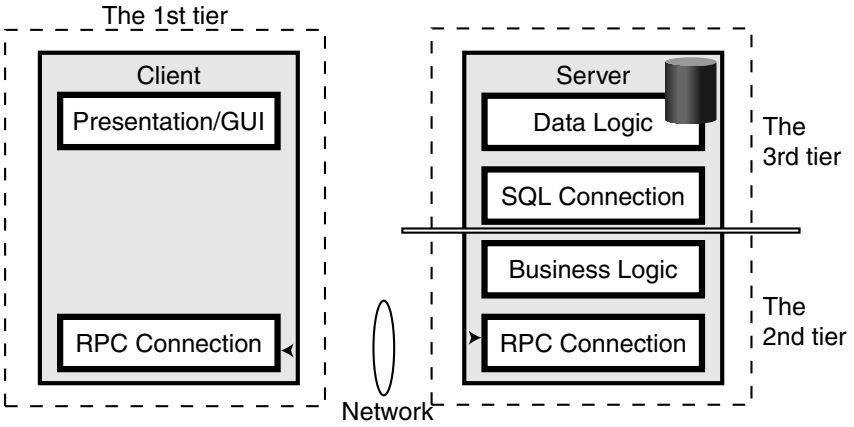

Figure 6 Three-Tier Architecture.

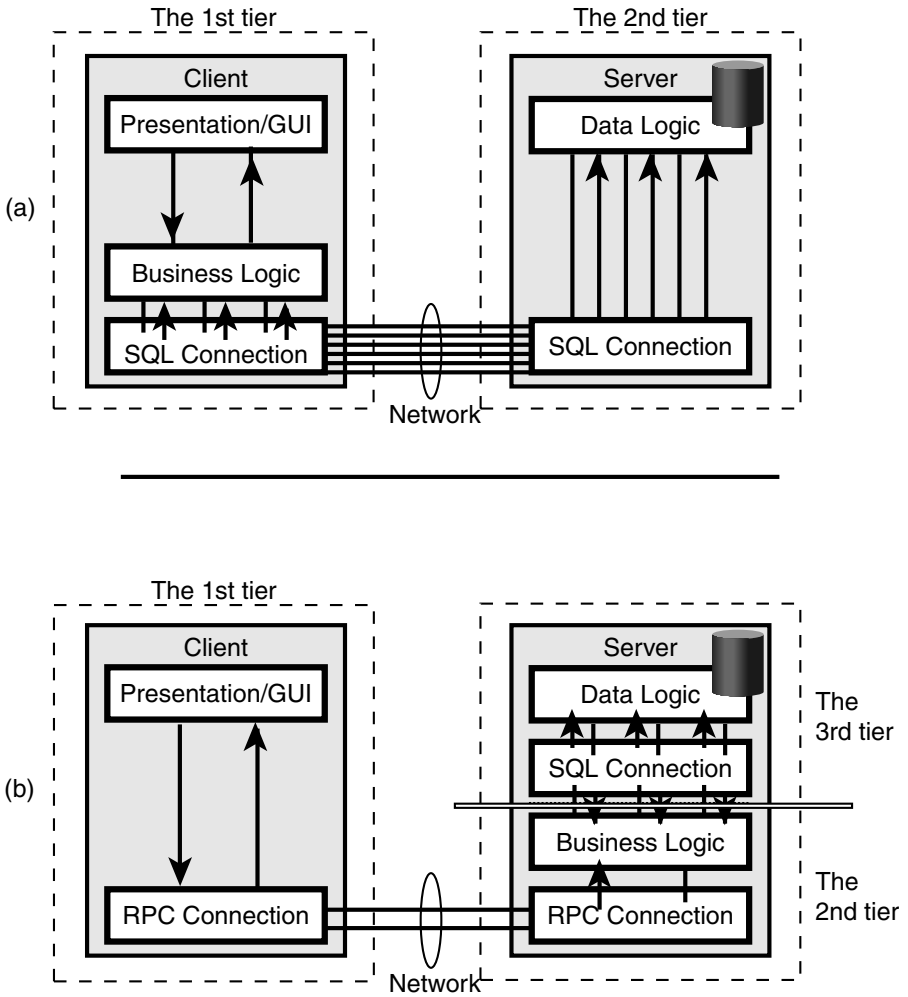

Figure 7 Network Traffic Comparison. (*a*) Two-tier architecture model. (*b*) Three-tier architecture model.

4. *Availability:* Even if an application server fails during processing the business logic, the client can restart the business logic on other application servers.

4. FUNDAMENTAL TECHNOLOGIES FOR C/S SYSTEMS

4.1. Communication Methods

The communication method facilitating interactions between a client and a server is the most important part of a C/S system. For easy development of the C/S systems, it is important for processes located on physically distributed computers to be seen as if they were placed in the same machine. Socket, remote procedure call, and CORBA are the main interfaces that realize such transparent communications between distributed processes.

4.1.1. Socket

The socket interface, developed as the communication port of Berkeley UNIX, is an API that enables communications between processes through networks like input/output access to a local file. Communications between two processes by using the socket interface are realized by the following steps (see Figure 8):

1. For two processes in different computers to communicate with each other, a communication port on each computer must be created beforehand by using ''socket'' system call.
2. Each socket is given a unique name to recognize the communication partner by using ''bind'' system call. The named socket is registered to the system.
3. At the server process, the socket is prepared for communication and it is shown that the server process is possible to accept communication by using ''listen'' system call.
4. The client process connects to the server process by using ''connect'' system call.

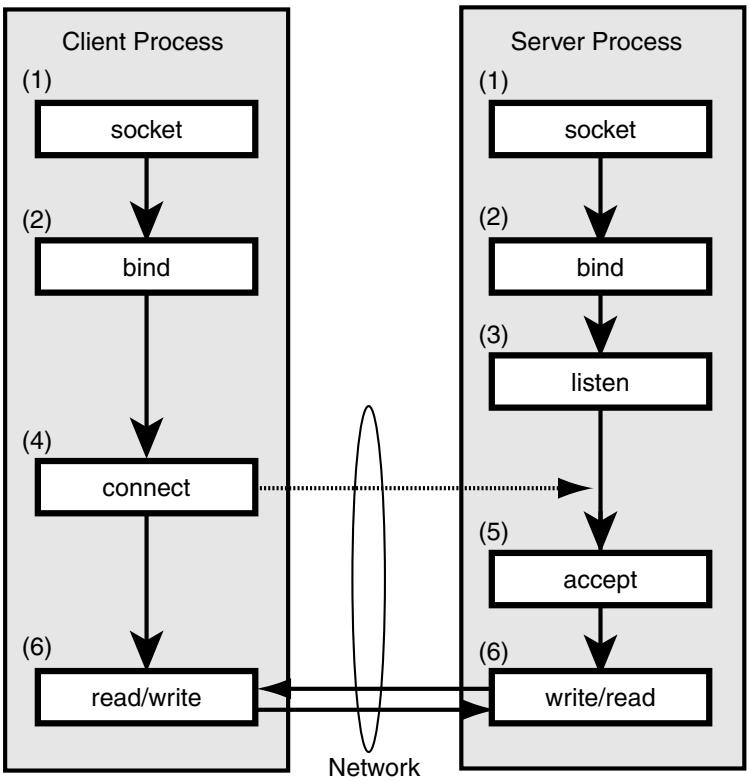

Figure 8 Interprocess Communication via Socket Interface.

5. The communication request from the client process is accepted by using ''accept'' system call in the server process. Then the connection between the client process and the server process is established.
6. Finally, each process begins communicating mutually by using ''read'' or ''write'' system calls.

4.1.2. Remote Procedure Call

Because the application programming interface (API) for socket programming uses system calls, the overhead associated with an application that communicates through the socket interface is rather small. However, because API is very primitive, socket programming depends on operating systems and the development of a system with a socket interface becomes complicated. For example, where programmers develop a system in which communications between processes on different platforms (such as Windows and UNIX) are required, they should master several versions of socket API supported by each platform.

One of the earliest approaches to facilitating easier use of sockets is realized by a remote procedure call (RPC). An RPC is a mechanism that lets a program call a procedure located on a remote server in the same fashion as a local one within the same program. It provides a function-oriented interface, and necessary preparation for communication is offered beforehand. An RPC is realized by a mechanism called a stub. The functions of stubs at client and server sides are to mimic the missing code, convert the procedure's parameters into messages suitable for transmission across the network (a process called marshaling) and unmarshal the parameters to a procedure, and dispatch incoming calls to the appropriate procedure.

Communications between two processes by using an RPC is realized by the following steps (see Figure 9):

1. The client program invokes a remote procedure function called the client stub.
2. The client stub packages (marshals) the procedure's parameters in several RPC messages and uses the runtime library to send them to the server.
3. At the server, the server stub unpacks (unmarshals) the parameters and invokes the requested procedure.
4. The procedure processes the request.
5. The results are sent back to the client through the stubs on both sides that perform the reverse processing.

The sequence from 1 to 5 is concealed from application programmers. One of the advantages of an RPC is that it hides the intricacies of the network and these procedures behave much the same as ordinary procedures to application programmers.

4.1.3. CORBA

An object is an entity that encapsulates data and provides one or more operations (methods) acting on those data; for example, ''the bank object'' has data from his client's account and operations by

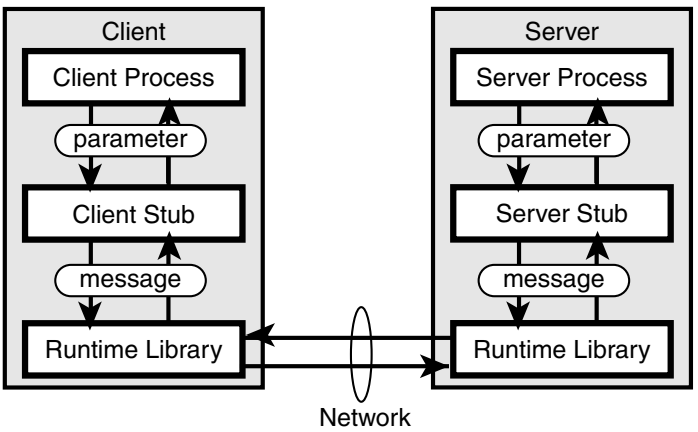

Figure 9 Interprocess Communication via an RPC.

which to manipulate them. Object-oriented computing is enabling faster software development by promoting software reusability, interoperability, and portability. In addition to enhancing the productivity of application developers, object frameworks are being used for data management, enterprise modeling, and system and network management. When objects are distributed, it is necessary to enable communications among distributed objects.

The Object Management Group, a consortium of object technology vendors founded in 1989, created a technology specification named CORBA (Common Object Request Broker Architecture). CORBA employs an abstraction similar to that of RPC, with a slight modification that simplifies programming and maintenance and increases extensibility of products.

The basic service provided by CORBA is delivery of requests from the client to the server and delivery of responses to the client. This service is realized by using a message broker for objects, called object request broker (ORB). An ORB is the central component of CORBA and handles distribution of messages between objects. Using an ORB, client objects can transparently make requests to (and receive responses from) server objects, which may be on the same computer or across a network.

An ORB consists of several logically distinct components, as shown in Figure 10.

The Interface Definition Language (IDL) is used to specify the interfaces of the ORB as well as services that objects make available to clients. The job of the IDL stub and skeleton is to hide the details of the underlying ORB from application programmers, making remote invocation look similar to local invocation. The dynamic invocation interface (DII) provides clients with an alternative to using IDL stubs when invoking an object. Because in general the stub routine is specific to a particular operation on a particular object, the client must know about the server object in detail. On the other hand, the DII allows the client to dynamically invoke a operation on a remote object. The object adapter provides an abstraction mechanism for removing the details of object implementation from the messaging substrate: generation and destruction of objects, activation and deactivation of objects, and invocation of objects through the IDL skeleton.

When a client invokes an operation on an object, the client must identify the target object. The ORB is responsible for locating the object, preparing it to receive the request, and passing the data needed for the request to the object. Object references are used for the ORB of the client side to identify the target object. Once the object has executed the operation identified by the request, if there is a reply needed, the ORB is responsible for returning the reply to the client.

The communication process between a client object and a server object via the ORB is shown in Figure 11.

1. A service request invoked by the client object is handled locally by the client stub. At this time, it looks to the client as if the stub were the actual target server object.
2. The stub and the ORB then cooperate to transmit the request to the remote server object.
3. At the server side, an instance of the skeleton instantiated and activated by the object adapter is waiting for the client's request. On receipt of the request from the ORB, the skeleton passes the request to the server object.
4. Then the server object executes the requested operations and creates a reply if necessary.
5. Finally, the reply is sent back to the client through the skeleton and the ORB that perform the reverse processing.

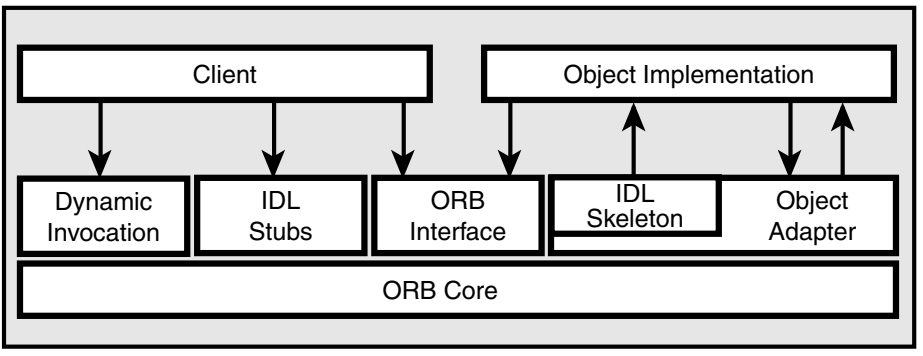

Figure 10 The CORBA Architecture.

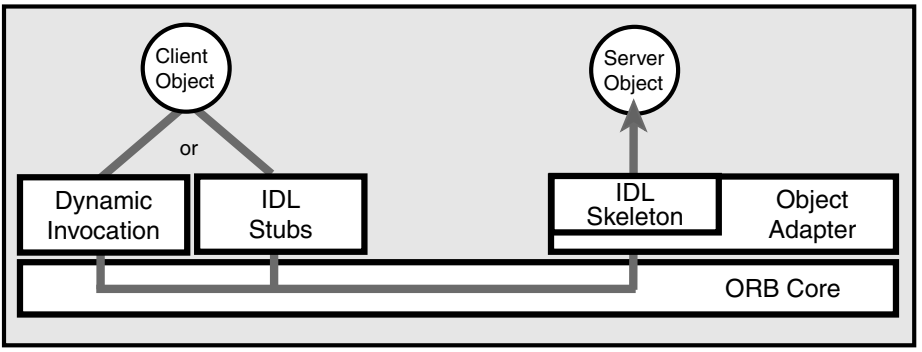

Figure 11 Communication between Objects in the CORBA Environment.

The main features of the CORBA are as follows:

1. *Platform independence:* Before the ORB transmits the message (request or result) from the client object or the server object into the network, the ORB translates the operation and its parameters into the common message format suitable for sending to the server. This is called marshaling. The inverse process of translating the data is called unmarshaling. This mechanism realizes communications between objects on different platforms. For example, a client object implemented on the Windows operating system can communicate with a server object implemented on the UNIX operating system.
2. *Language independence:* Figure 12 shows the development process of a CORBA C/S application. The first step of developing the CORBA object is to define the interface of the object (type of parameters and return values) by using the intermediate language IDL. Then the definition file described in IDL is translated into the file containing rough program codes in various development languages such as C, C++, Java, and COBOL.

IDL is not a programming language but a specification language. It provides language independence for programmers. The mapping of IDL to various development languages is defined by OMG. Therefore, a developer can choose the most appropriate one from various development languages to implement objects. Also, this language independence feature enables the system to interconnect with legacy systems developed by various languages in the past.

4.1.4. Other Communication Methods

In addition to Socket, RPC, and CORBA, there are several methods for realizing communication between processes.

- Java RMI (remote method invocation) is offered as a part of the JAVA language specification and will be a language-dependent method for the distributed object environment. Although there is the constraint that all the environments should be unified into Java, the developing process with it is a little easier than with CORBA or RPC because several functions for distributed computing are offered as utility objects.
- DCOM (distributed component object model) is the ORB that Microsoft promotes. A DCOM is implemented on the Windows operating system, and the development of applications can be practiced by using a Microsoft development environment such as Visual Basic.

4.2. Distributed Transaction Management

In a computer system, a transaction consists of an arbitrary sequence of operations. From a business point of view, a transaction is an action that involves change in the state of some recorded information related to the business. Transaction services are offered on both file systems and database systems.

The transaction must have the four properties referred to by the acronym ACID: atomicity, consistency, isolation, and durability:

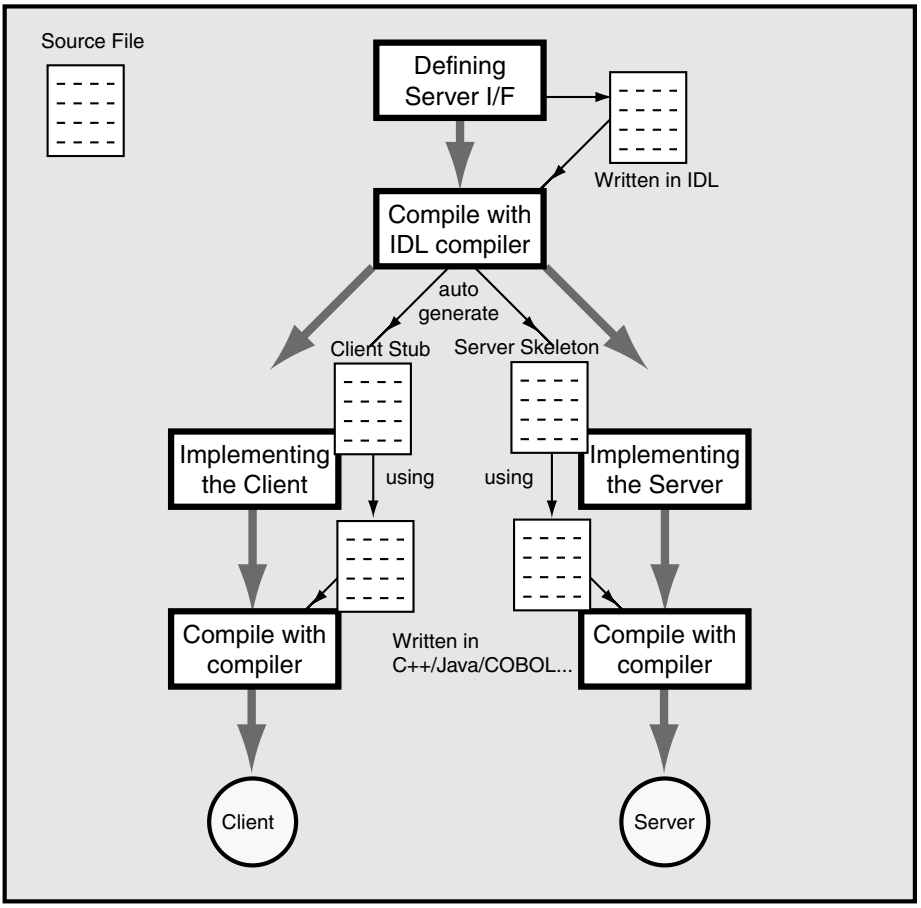

Figure 12 Development Process of a CORBA C/S Application.

- *Atomicity* means that all the operations of the transaction succeed or they all fail. If the client or the server fails during a transaction, the transaction must appear to have either completed successfully or failed completely.
- *Consistency* means that after a transaction is executed, it must leave the system in a correct state or it must abort, leaving the state as it was before the execution began.
- *Isolation* means that operations of a transaction are not affected by other transactions that are executed concurrently, as if the separate transactions had been executed one at a time. The transaction must serialize all accesses to shared resources and guarantee that concurrent programs will not affect each other's operations.
- *Durability* means that the effect of a transaction's execution is permanent after it completes commitments. Its changes should survive system failures.

The transaction processing should ensure that either all the operations of the transaction complete successfully (commit) or none of them commit. For example, consider a case in which a customer transfers money from an account A to another account B in a banking system. If the account A and the account B are registered in two separate databases at different sites, both the withdrawal from account A and the deposit in account B must commit together. If the database crashes while the updates are processing, then the system must be able to recover. In the recovery procedure, both the updates must be stopped or aborted and the state of both the databases must be restored to the state before the transaction began. This procedure is called rollback.

In a distributed transaction system, a distributed transaction is composed of several operations involving distributed resources. The management of distributed transactions is provided by a transaction processing monitor (TP monitor), an application that coordinates resources that are provided by other resources.

A TP monitor provides the following management functions:

- *Resource management:* it starts transactions, regulates their accesses to shared resources, monitors their execution, and balances their workloads.
- *Transaction management:* It guarantees the ACID properties to all operations that run under its protection.
- *Client/server communications management:* It provides communications between clients and servers and between servers in various ways, including conversations, request-response, RPC, queueing, and batch.

Available TP monitor products include IBM's CICS and IMS/TP and BEA's Tuxedo.

4.3. Distributed Data Management

A database contains data that may be shared between many users or user applications. Sometimes there may be demands for concurrent sharing of the data. For example, consider two simultaneous accesses to an inventory data in a multiple-transaction system by two users. No problem arises if each demand is to read a record, but difficulties occur if both users attempt to modify (write) the record at the same time. Figure 13 shows the inconsistency that arises when two updates on the same data are processed at nearly the same time.

The database management must be responsible for this concurrent usage and offer concurrency control to keep the data consistent. Concurrency control is achieved by serializing multiple transactions through use of some mechanism such as locking or timestamp.

Also, in case the client or the server fails during a transaction due to a database crash or a network failure, the transaction must be able to recover. Either the transaction must be reversed or else some previous version of the data must be available. That is, the transaction must be rolled back. ''All conditions are treated as transient and can be rolled back anytime'' is the fundamental policy of control in the data management.

In some C/S systems, distributed databases are adopted as database systems. A distributed database is a collection of data that belong logically to the same system but are spread over several sites of a network. The main advantage of distributed databases is that they allow access to remote data transparently while keeping most of the data local to the applications that actually use it.

The primary concern of transaction processing is to maintain the consistency of the distributed database. To ensure the consistency of data at remote sites, a two-phase commit protocol is sometimes used in a distributed database environment. The first phase of the protocol is the preparation phase, in which the coordinator site sends a message to each participant site to prepare for commitment. The second phase is the implementation phase, in which the coordinator site sends either an abort or a commit message to all the participant sites, depending on the responses from all the participant sites. Finally, all the participant sites respond by carrying out the action and sending an acknowledgement message. Because the commitment may fail in a certain site even if commitments are completed in other sites, in the first phase of the two phase commit protocol, temporary ''secure'' commitment that can be rolled back anytime is done at each site. After it is confirmed that all the sites succeeded, the ''official'' commitment is performed.

The two-phase commit protocol has some limitations. One is the performance overhead that is introduced by all the message exchanges. If the remote sites are distributed over a wide area network, the response time could suffer further. The two-phase commit is also very sensitive to the availability of all sites at the time of update, and even a single point of failure could jeopardize the entire transaction. Therefore, decisions should be based on the business needs and the trade-off between the cost of maintaining the data on a single site and the cost of the two-phase commit when data are distributed at remote sites.

5. CAPACITY PLANNING AND PERFORMANCE MANAGEMENT

5.1. Objectives of Capacity Planning

Client/server systems are made up of many hardware and software resources, including client workstations, server systems, and network elements. User requests share the use of these common resources. The shared use of these resources gives rise to contention that degrades the system behavior and worsens users' perception of performance.

In the example of the Internet banking service described in the Section 7, the response time, the time from when a user clicks the URL of a bank until the home page of the bank is displayed on

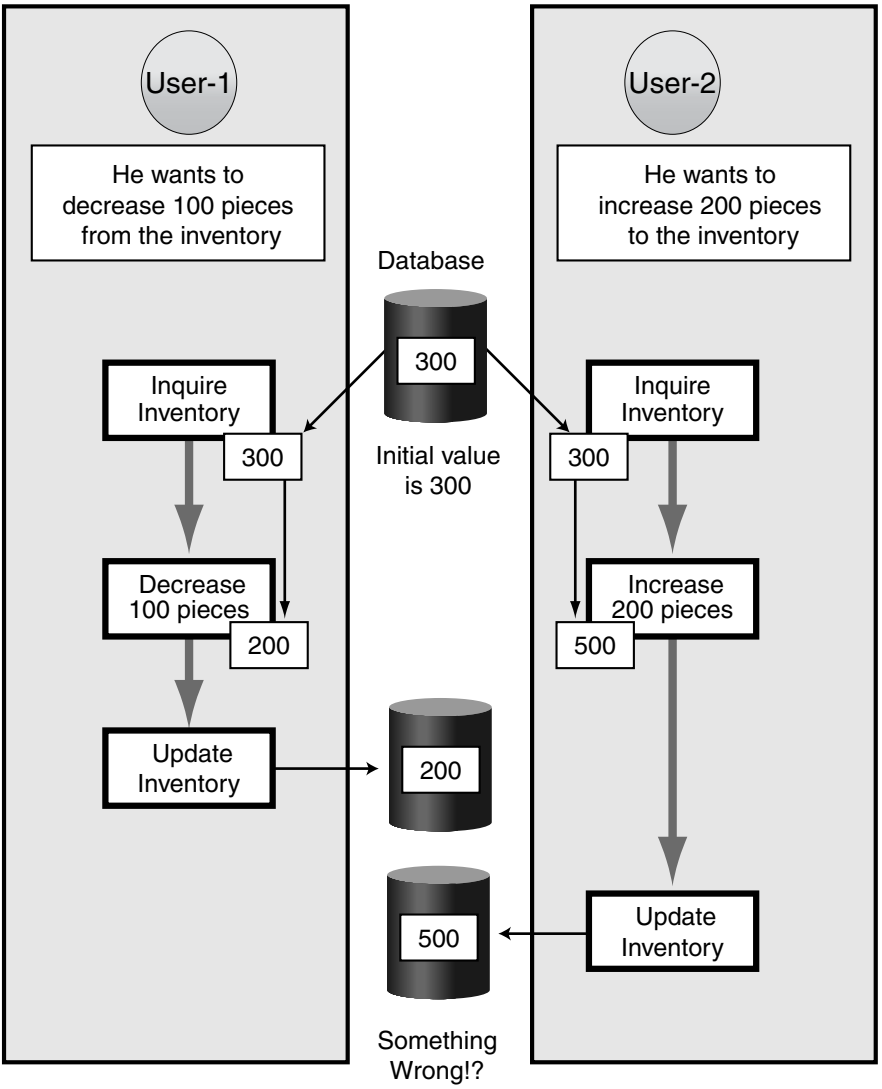

Figure 13 Inconsistency Arising from Simultaneous Updates.

the user's Web page, affects user's perception of performance and quality of service. In designing a system that treats requirements from multiple users, some service levels may be set; for example, average response time requirements for requests must not exceed 2 sec, or 95% of requests must exhibit a response time of less than 3 sec. For the given service requirements, service providers must design and maintain C/S systems that meet the desired service levels. Therefore, the performance of the C/S system should be evaluated as exactly as possible and kinds and sizes of hardware and software resources included in client systems, server systems, and networks should be determined. This is the goal of capacity planning.

The following are resources to be designed by capacity planning to ensure that the C/S system performance will meet the service levels:

- Types and numbers of processors and disks, the type of operating system, etc.
- Type of database server, access language, database management system, etc.
- Type of transaction-processing monitor

- Kind of LAN technology and bandwidth or transmission speed for clients and servers networking
- Kind of WAN and bandwidth when WAN is used between clients and servers

In the design of C/S systems, processing devices, storage devices, and various types of software are the building blocks for the whole system. Because capacity can be added to clients, servers, or network elements, addition of capacity can be local or remote. The ideal approach to capacity planning is to evaluate performance prior to installation. However, gathering the needed information prior to specifying the elements of the system can be a complicated matter.

5.2. Steps for Capacity Planning and Design

Capacity planning consists of the steps shown in Figure 14, which are essentially the same as those for capacity planning of general information systems.

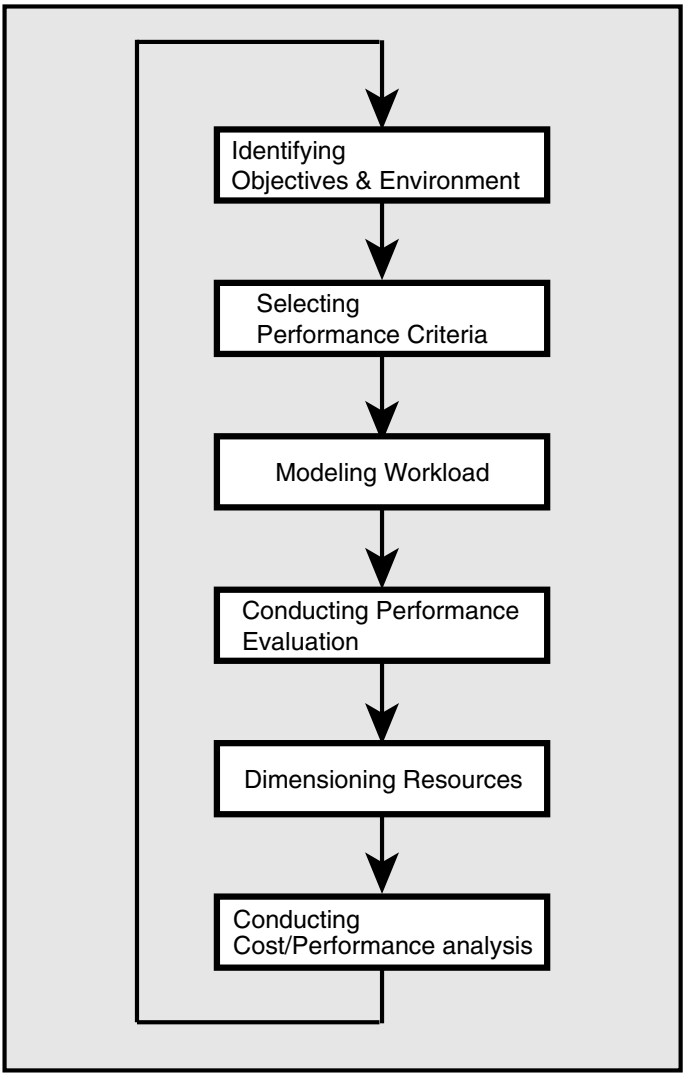

Figure 14 The Steps in Capacity Planning and Design.

Because new technology, altered business climate, increased workload, change in users, or demand for new applications affects the system performance, these steps should be repeated at regular intervals and whenever problems arise.

5.3. Performance Objectives and System Environment

Specific objectives should be quantified and recorded as service requirements. Performance objectives are essential to enable all aspects of performance management. To manage performance, we must set quantifiable, measurable performance objectives, then design with those objectives in mind, project to see whether we can meet them, monitor to see whether we are meeting them, and adjust system parameters to optimize performance. To set performance objectives, we must make a list of system services and expected effects.

We must learn what kind of hardware (clients and servers), software (OS, middleware, applications), network elements, and network protocols are presented in the environment. Environment also involves the identification of peak usage periods, management structures, and service-level agreements. To gather these information about the environment, we use various information-gathering techniques, including user group meetings, audits, questionnaires, help desk records, planning documents, and interviews.

5.4. Performance Criteria

1. *Response time* is the time required to process a single unit of work. In interactive applications, the response time is the interval between when a request is made and when the computer responds to that request. Figure 15 shows a response time example for a client/server database access application. As the application executes, a sequence of interactions is exchanged among the components of the system, each of which contributes in some way to the delay that the user experiences between initiating the request for service and viewing the DBMS's response to the query. In this example, the response time consists of several time components, such as (a) interaction with the client application, (b) conversion of the request into a data stream by an API, (c) transfer of the data stream from the client to the server by communication stacks, (d) translation of the request and invocation of a stored procedure by DBMS, (e) execution of SQL (a relational data-manipulation language) calls by the stored procedure, (f) conversion of the results into a data stream by DBMS, (g) transfer of the data stream from the server to the client by the API, (h) passing of the data stream to the application, and (i) display of the first result.
2. *Throughput* is a measure of the amount of work a component or a system performs as a whole or of the rate at which a particular workload is being processed.
3. *Resource utilization* normally means the level of use of a particular system component. It is defined by the ratio of what is used to what is available. Although unused capacity is a waste of resources, a high utilization value may indicate that bottlenecks in processing will occur in the near future.

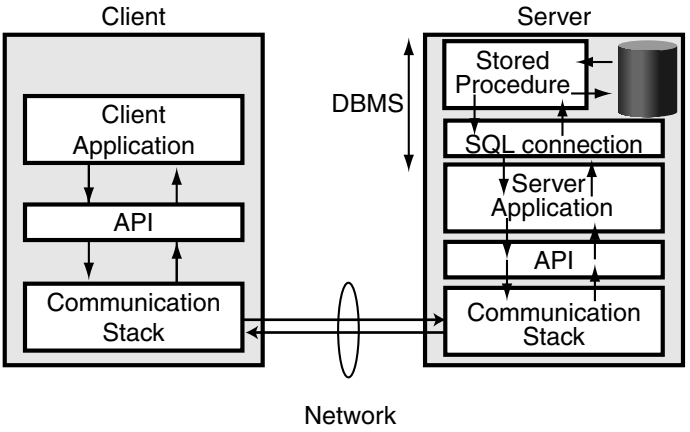

Figure 15 Response Time Example for a Database Access.

4. *Availability* is defined as the percentage of scheduled system time in which the computer is actually available to perform useful work. The stability of the system has an effect on performance. Unstable systems often have specific effects on the performance in addition to the other consequences of system failures.
5. *Cost–Performance ratio:* Once a system is designed and capacity is planned, a cost model can be developed. From the performance evaluation and the cost model, we can make an analysis regarding cost–performance trade-offs.

In addition to these criteria, resource queue length and resource waiting time are also used in designing some resources.

Response time and availability are both measures of the effectiveness of the system. An effective system is one that satisfies the expectations of users. Users are concerned with service effectiveness, which is measured by response time for transaction processing, elapsed time for batch processing, and query response time for query processing. On the other hand, a system manager is concerned with optimizing the efficiency of the system for all users. Both throughput and resource utilization are measures for ensuring the efficiency of system operations. If the quality of performance is measured in terms of throughput, it depends on the utilization levels of shared resources such as servers, network elements, and application software.

5.5. Workload Modeling

Workload modeling is the most crucial step in capacity planning. Misleading performance evaluation is possible if the workload is not properly modeled.

5.5.1. Workload Characterization

Workload refers to the resource demands and arrival intensity characteristics of the load brought to the system by the different types of transactions and requests. A workload consists of several components, such as C/S transactions, web access, and mail processing. Each workload component is further decomposed into basic components such as personnel transactions, sales transactions, and corporate training.

A real workload is one observed on a system being used for normal operations. It cannot be repeated and therefore is generally not suitable for use as a test workload in the design phase. Instead, a workload model whose characteristics are similar to those of real workload and can be applied repeatedly in a controlled manner, is developed and used for performance evaluations.

The measured quantities, service requests, or resource demands that are used to characterize the workload, are called workload parameters. Examples of workload parameters are transaction types, instruction types, packet sizes, source destinations of a packet, and page-reference patterns. The workload parameters can be divided into workload intensity and service demands. Workload intensity is the load placed on the system, indicated by the number of units of work contending for system resources. Examples include arrival rate or interarrival times of component (e.g., transaction or request), number of clients and think times, and number of processors or threads in execution simultaneously (e.g., file reference behavior, which describes the percentage of accesses made to each file in the disk system) The service demand is the total amount of service time required by each basic component at each resource. Examples include CPU time of transaction at the database server, total transmission time of replies from the database server in LAN, and total I/O time at the Web server for requests of images and video clips used in a Web-based learning system.

5.5.2. Workload Modeling Methodology

If there is a system or service similar to a newly planned system or service, workloads are modeled based on historical data of request statistics measured by data-collecting tools such as monitors.

A monitor is used to observe the performance of systems. Monitors collect performance statistics, analyze the data, and display results. Monitors are widely used for the following objectives:

1. To find the frequently used segments of the software and optimize their performance.
2. To measure the resource utilization and find the performance bottleneck.
3. To tune the system; the system parameters can be adjusted to improve the performance.
4. To characterize the workload; the results may be used for the capacity planning and for creating test workloads.
5. To find model parameters, validate models, and develop inputs for models.

Monitors are classified as software monitors, hardware monitors, firmware monitors, and hybrid monitors. Hybrid monitors combine software, hardware, or firmware.

If there is no system or service similar to a newly planned system or service, workload can be modeled by estimating the arrival process of requests and the distribution of service times or processing times for resources, which may be forecast from analysis of users' usage patterns and service requirements.

Common steps in a workload modeling process include:

1. Specification of a viewpoint from which the workload is analyzed (identification of the basic components of the workload of a system)
2. Selecting the set of workload parameters that captures the most relevant characteristics of the workload
3. Observing the system to obtain the raw performance data
4. Analyzing and reducing of the performance data
5. Constructing of a workload model.

The basic components that compose the workload must be identified. Transactions and requests are the most common.

5.6. Performance Evaluation

Performance models are used to evaluate the performance of a C/S system as a function of the system description and workload parameters. A performance model consists of system parameters, resource parameters, and workload parameters. Once workload models and system configurations have been obtained and a performance model has been built, the model must be examined to see how it can be used to answer the questions of interest about the system it is supposed to represent. This is the performance-evaluation process. Methods used in this process are explained below:

5.6.1. Analytical Models

Because generation of users' requests and service times vary stochastically, analytical modeling is normally done using queueing theory. Complex systems can be represented as networks of queues in which requests receive services from one or more groups of servers and each group of servers has its own queue. The various queues that represent a distributed C/S system are interconnected, giving rise to a network of queues, called a queueing network. Thus, the performance of C/S systems can be evaluated using queueing network models. Figure 16 shows an example of queueing network model for the Web server, where the client and the server are connected through a client side LAN, a WAN, and a server-side LAN.

5.6.2. Simulation

Simulation models are computer programs that mimic the behavior of a system as transactions flow through the various simulated resources. Simulation involves actually building a software model of

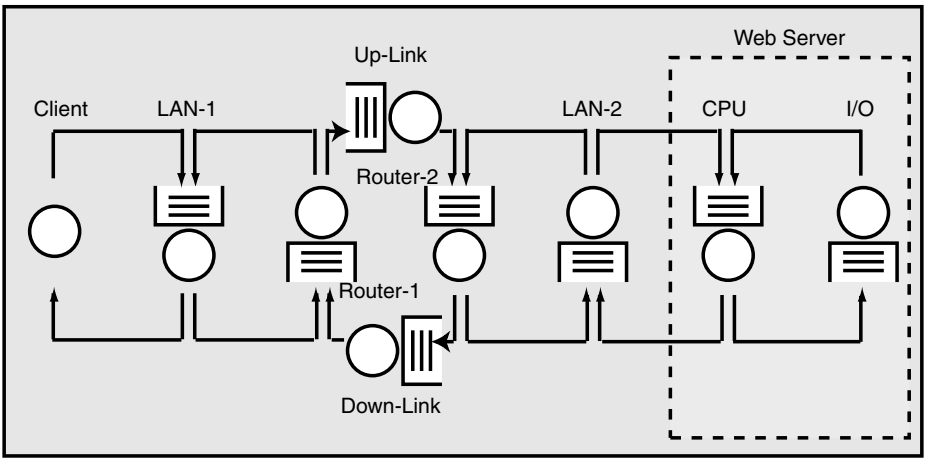

Figure 16 An Example of a Queueing Network Model for a Web Server.

each device, a model of the queue for that device, model processes that use the devices, and a model of the clock in the real world. Simulation can be accomplished by using either a general programming languages such as FORTRAN or C or a special-purpose language such as GPSS, SIMSCRIPT, or SLAM. For network analysis, there are special-purpose simulation packages such as COMNET III and BONeS are available.

5.6.3. Benchmarking

A benchmark is a controlled test to determine exactly how a specific application performs in a given system environment. While monitoring supplies a profile of performance over time for an application already deployed, either in a testing or a production environment, benchmarking produces a few controlled measurements designed to compare the performance of two or more implementation choices.

Some of the most popular benchmark programs and most widely published benchmark results come from groups of computer hardware and software vendors acting in consort. RISC workstation manufacturers sponsor the Systems Performance Evaluation Cooperative (SPEC), and DBMS vendors operate the transaction Processing Council (TPC). The TPC developed four system-level benchmarks that measure the entire system: TPC-A, B, C, and D. TPC-A and TPC-B are a standardization of the debit/credit benchmark. TPC-C is a standard for moderately complex online transaction-processing systems. TPC-D is used to evaluate price/performance of a given system executing decision support applications. The SPEC developed the standardized benchmark SPECweb, which measures a system's ability to act as a web server for static pages.

5.6.4. Comparing Analysis and Simulation

Analytic performance modeling, using queueing theory, is very flexible and complements traditional approaches to performance. It can be used early in the application development life cycle. The actual system, or a version of it, does not have to be built as it would be for a benchmark or prototype. This saves tremendously on the resources needed to build and to evaluate a design. On the other hand, a simulation shows the real world in slow motion. Simulation modeling tools allow us to observe the actual behavior of a complex system; if the system is unstable, we can see the transient phenomena of queues building up and going down repeatedly.

Many C/S systems are highly complex, so that valid mathematical models of them are themselves complex, precluding any possibility of an analytical solution. In this case, the model must be studied by means of simulation, numerically exercising the model for the inputs in question to see how they affect the output measures of performance.

6. MAINTENANCE AND ADMINISTRATION OF C/S SYSTEMS

Although system maintenance and administration is a complicated task even for a single centralized system, the complexity increases significantly due to the scalability, heterogeneity, security, distribution, naming, and so on in a C/S system. Efficient network and system-management tools are critical for reliable operation of distributed computing environments for C/S systems. In recent years, open and multivendor technologies have been adopted in construction of C/S systems. To administrate and maintain those systems totally, a standardized system management is needed for equipment from different vendors.

6.1. Architecture of System Management

6.1.1. OSI Management Framework

The OSI has defined five functional areas of management activities that are involved in distributed system management:

1. *Configuration management:* This involves collecting information on the system configuration and managing changes to the system configuration. Inventory control, installation, and version control of hardware and software are also included in this area.
2. *Fault management:* This involves identifying system faults as they occur, isolating the cause of the faults, and correcting them by contingency fallback, disaster recovery and so on.
3. *Security management:* This involves identifying locations of sensitive data and securing the system access points as appropriate to limit the potential for unauthorized intrusions. Encryption, password requirements, physical devices security, and security policy are also included in this area.
4. *Performance management:* This involves gathering data on the usage of system resources, analyzing these data, and acting on the performance prediction to maintain optimal system

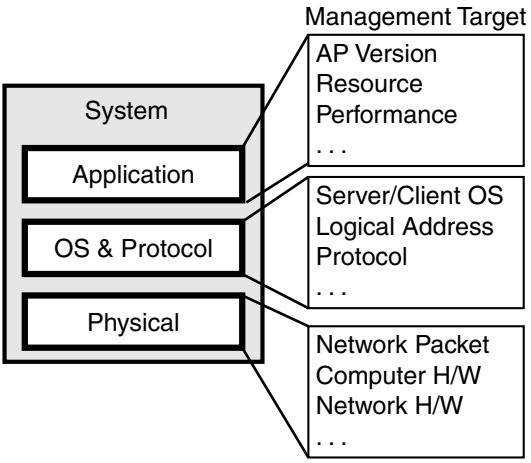

Figure 17 System Management Items.

performance. Real-time and historical statistical information about traffic volume, resource usage, and congestion are also included in this area.

5. *Accounting management:* This involves gathering data on resource utilization, setting usage shares, and generating charging and usage reports.

6.1.2. System Management Architecture

The items that are managed by system management can be classified into three layers: physical layer, operating system and network protocol layer, and application layer, as shown in Figure 17.

1. The physical layer includes client devices, server devices, and network elements, including LANs, WANs, computing platforms, and systems and applications software.
2. The operating system and network protocol layer includes the items for managing communication protocols to ensure interoperability between some units. In recent years, the adoption of TCP/IP standard protocol for realizing the Internet has been increasing. In a system based on the TCP/IP protocol stack, SNMP can be used for system management.
3. The application layer includes the items for managing system resources, such as CPU capacity and memory.

The system management architecture consists of the following components. These components may be either physical or logical, depending on the context in which they are used:

- A *network management station* (NMS) is a centralized workstation or computer that collects data from agents over a network, analyzes the data, and displays information in graphical form.
- A *managed object* is a logical representation of an element of hardware or software that the management system accesses for the purpose of monitor and control.
- An *agent* is a piece of software within or associated with a managed object that collects and stores information, responds to network management station requests, and generates incidental messages.
- A *manager* is software contained within a computer or workstation that controls the managed objects. It interacts with agents according to rules specified within the management protocol.
- A *management information base* (MIB) is a database containing information of use to network management, including information that reflects the configuration and behavior of nodes, and parameters that can be used to control its operation.

6.2. Network Management Protocol

An essential function in achieving the goal of network management is acquiring information about the network. A standardized set of network management protocols has been developed to help extract the necessary information from all network elements. There are two typical standardized protocols

for network management: simple network management protocol (SNMP), developed under Internet sponsorship, and common management information protocol (CMIP), from ISO (International Organization for Standardization) and ITU-T (International Telecommunication Union-Telecommunication Standardization Sector).

SNMP is designed to work with the TCP/IP protocol stack and establishes standards for collecting and for performing security, performance, fault, accounting, and configuration functions associated with network management. The communication protocol for the SNMP is UDP, which is a very simple, unacknowledged, connectionless protocol. CMIP is designed to support a richer set of network-management functions and work with all systems conforming to OSI standards. Both SNMP and CMIP use an object-oriented technique to describe information to be managed, where the software describing actions is encapsulated with the rest of agent code within the managed object. CMIP requires considerably more overhead to implement than SNMP.

Because SNMP is the most widely implemented protocol for network management today, an SNMP management system is described below. An SNMP management system consists of the following components, as shown in Figure 18:

1. An SNMP agent is a software entity that resides on a managed system or a target node, maintains the node information, and reports on its status to managers.
2. An SNMP manager is a software entity that performs management tasks by issuing management requests to agents.
3. An MIB is a database containing the node information. It is maintained by an agent.

SNMP is an asynchronous request/response protocol that supports the following operations (Version 2):

- Get: a request issued by a manager to read the value of a managed object
- GetNext: a request made by a manager to traverse an MIB tree

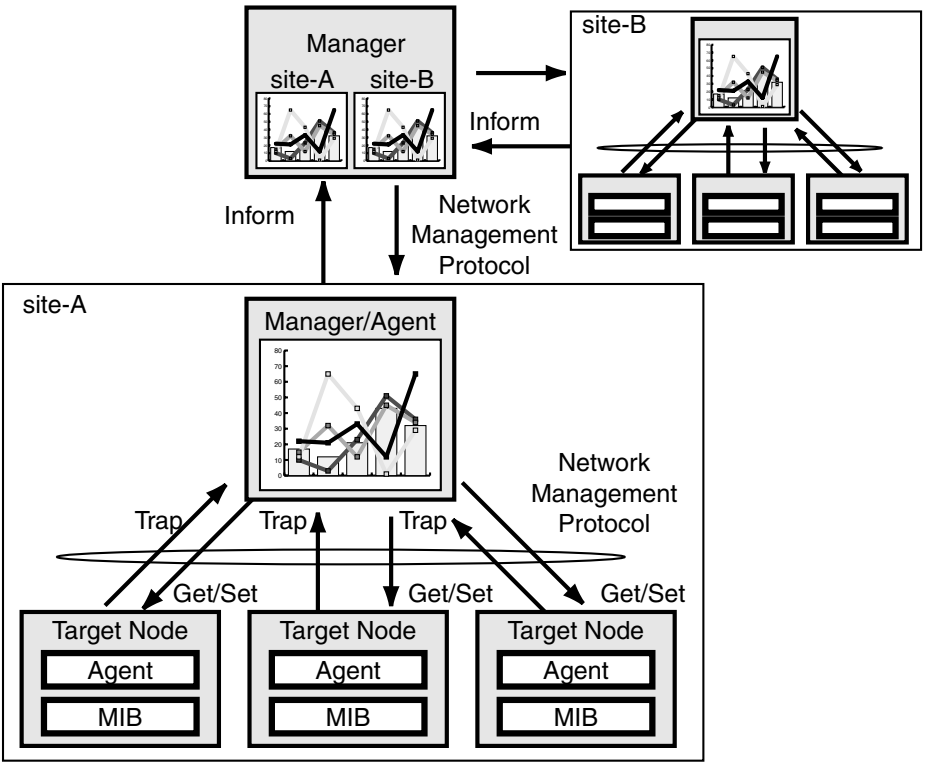

Figure 18 SNMP Management System.

- GetBulk: a command issued by a manager, by which an agent can return as many successor variables in the MIB tree as will fit in a message
- Set: a request issued by a manager to modify the value of a managed object
- Trap: a notification issued from an agent in the managed system to a manager that some unusual event has occurred
- Inform: a command sent by a manager to other managers, by which managers can exchange management information

In this case, the managed system is a node such as a workstation, personal computer, or router. HP's OpenView and Sun Microsystem's SunNet Manager are well-known commercial SNMP managers.

System management functions are easily decomposed into many separate functions or objects that can be distributed over the network. It is a natural idea to connect those objects using CORBA ORB for interprocess communications. CORBA provides a modern and natural protocol for representing managed objects, defining their services, and invoking their methods via an ORB. Tivoli Management Environment (TME) is a CORBA-based system-management framework that is rapidly being adopted across the distributed UNIX market.

6.3. Security Management

C/S systems introduce new security threats beyond those in traditional host-centric systems. In a C/S system, it is more difficult to define the perimeter, the boundary between what you are protecting and the outside world. From the viewpoint of distributed systems, the problems are compounded by the need to protect information during communication and by the need for the individual components to work together. The network between clients and servers is vulnerable to eavesdropping crackers, who can sniff the network to obtain user IDs and passwords, read confidential data, or modify information. In addition, getting all of the individual components (including human beings) of the system to work as a single unit requires some degree of trust.

To manage security in a C/S system, it is necessary to understand what threats or attacks the system is subject to. A threat is any circumstance or event with the potential to cause harm to a system. A system's security policy identifies the threats that are deemed to be important and dictates the measures to be taken to protect the system.

6.3.1. Threats

Threats can be categorized into four different types:

1. *Disclosure or information leakage:* Information is disclosed or revealed to an unauthorized person or process. This involves direct attacks such as eavesdropping or wiretapping or more subtle attacks such as traffic analysis.
2. *Integrity violation:* The consistency of data is compromised through any unauthorized change to information stored on a computer system or in transit between computer systems.
3. *Denial of service:* Legitimate access to information or computer resources is intentionally blocked as a result of malicious action taken by another user.
4. *Illegal use:* A resource is used by an unauthorized person or process or in an unauthorized way.

6.3.2. Security Services

In the computer communications context, the main security measures are known as security services. There are some generic security services that would apply to a C/S system:

- *Authentication:* This involves determining that a request originates with a particular person or process and that it is an authentic, nonmodified request.
- *Access control:* This is the ability to limit and control the access to information and network resources by or for the target system.
- *Confidentiality:* This ensures that the information in a computer system and transmitted information are accessible for reading only by authorized persons or processes
- *Data integrity:* This ensures that only authorized persons or processes are able to modify data in a computer system and transmitted information.
- *Nonrepudiation:* This ensures that neither the sender nor the receiver of a message is able to deny that the data exchange occurred.

6.3.3. Security Technologies

There are some security technologies fundamental to the implementation of those security services.

6.3.3.1. Cryptography Cryptographic systems or cryptosystems can be classified into two distinct types: symmetric (or secret-key) and public-key (or asymmetric) cryptosystems. In a symmetric cryptosystem, a single key and the same algorithm are used for both encryption and decryption. The most widely used symmetric cryptosystem is the Data Encryption Standard (DES), which is the U.S. standard for commercial use. In a public-key cryptosystem, instead of one key in a symmetric cryptosystem, two keys are employed to control the encryption and the decryption respectively. One of these keys can be made public and the other is kept secret. The best-known the public-key cryptosystem is RSA, developed by Rivest, Shamir, and Adleman at MIT (1978).

The major problem in using cryptography is that it is necessary to disseminate the encryption/decryption keys to all parties that need them and ensure that the key distribution mechanism is not easily compromised. In a public-key cryptosystem, the public key does not need to be protected, alleviating the problem of key distribution. However, a public key also needs to be distributed with authentication for protecting it from frauds. Public-key cryptosystems have some advantages in key distribution, but implementation results in very slow processing rates. For example, encryption by RSA is about 1000 times slower than by DES in hardware and about 100 times slower than DES in software. For these reasons, public-key cryptosystems are usually limited to use in key distribution and the digital signature, and symmetric cryptosystems are used to protect the actual data or plaintexts.

Data integrity and data origin authentication for a message can be provided by hash or message digest functions. Cryptographic hash functions involve, instead of using keys, mapping a potentially large message into a small fixed-length number. Hash functions are used in sealing or digital signature processes, so they must be truly one-way, that is, it must be computationally infeasible to construct an input message hashed to a given digest or to construct two messages hashed to the same digest. The most widely used hash function is message digest version 5 (MD5).

6.3.3.2. Authentication Protocol In the context of a C/S system, authentication is the most important of the security services because other security services depend on it in some way. When a client wishes to establish a secure channel between the client and a server, the client and the server will wish to identify each other by authentication. There are three common protocols for implementing authentication: three-way handshake authentication, trusted-third-party authentication, and public-key authentication. One of the trusted third-party protocols is Kerberos, a TCP/IP-based network authentication protocol developed as a part of the project Athena at MIT. Kerberos permits a client and a server to authenticate each other without any message going over the network in the clear. It also arranges for the secure exchange of session encryption keys between the client and the server. The trusted third-party is sometimes called an authentication server.

A simplified version of the third-party authentication in Kerberos is shown in Figure 19. Kerberos protocol assumes that the client and the server each share a secret key, respectively K_c and K_s, with the authentication server. In Figure 19, $[M]K$ denotes the encryption of message M with key K.

1. The client first sends a message to the authentication server that identifies both itself and the server.
2. The authentication server then generates a timestamp T, a lifetime L, and a new session key K and replies to the client with a two-part message. The first part, $[T, L, K, ID_s]K_c$, encrypts the three values T, L, and K, along with the server's identifier ID_s, using the key K_c. The second part, $[T, L, K, ID_c]K_s$, encrypts the three values T, L, and K, along with the client's identifier ID_c using the key K_s.
3. The client receives this message and decrypts only the first part. The client then transfers the second part to the server along with the encryption $[ID_c, T]K$ of ID_c and T using the session key K, which is decrypted from the first part.
4. On receipt of this message, the server decrypts the first part, $[T, L, K, ID_c]K_s$, originally encrypted by the authentication server using K_s, and in so doing recovers T, K, and ID_c. Then the server confirms that ID_c and T are consistent in the two halves of the message. If they are consistent, the server replies with a message $[T + 1]K$ that encrypts $T + 1$ using the session key K.
5. Now the client and the server can communicate with each other using the shared session key K.

6.3.3.3. Message Integrity Protocols There are two typical ways to ensure the integrity of a message. One uses a public-key cryptosystem such as RSA to produce a digital signature, and the other uses both a message digest such as MD5 and a public-key cryptosystem to produce a digital

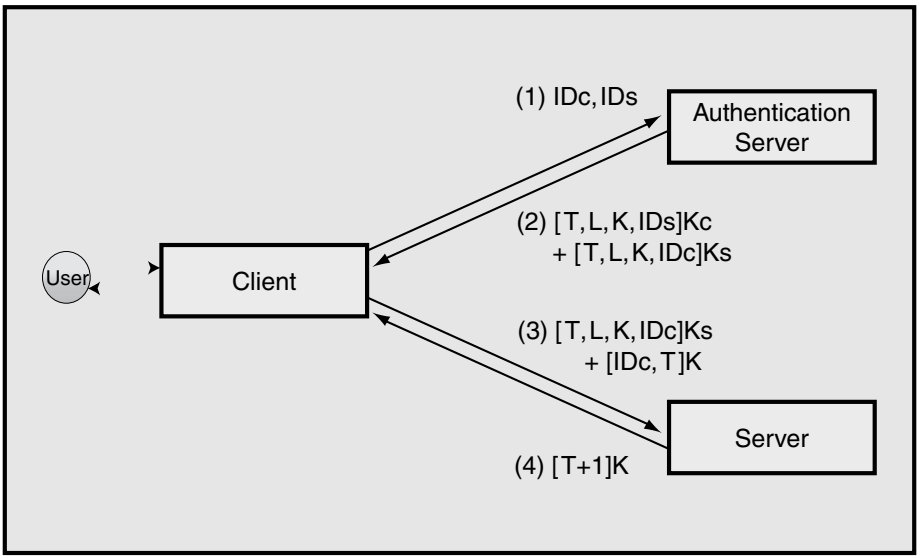

Figure 19 Third-Party Authentication in Kerberos.

signature. In the latter type, a hash function is used to generate a message digest from the message content requiring protection. The sender encrypts the message digest using the public-key cryptosystem in the authentication mode; the encryption key is the private key of the sender. The encrypted message digest is sent an appendix along with the plaintext message. The receiver decrypts the appendix using the corresponding decryption key (the public key of the sender) and compares it with the message digest that is computed from the received message by the same hash function. If the two are the same, then the receiver is assured that the sender knew the encryption key and that the message contents were not changed en route.

6.3.3.4. Access Control Access control contributes to achieving the security goals of confidentiality, integrity, and legitimate use. The general model for access control assumes a set of active entities, called subjects, that attempt to access members of a set of resources, called objects. The access-control model is based on the access control matrix, in which rows correspond to subjects (users) and columns correspond to objects (targets). Each matrix entry states the access actions (e.g., read, write, and execute) that the subject may perform on the object. The access control matrix is implemented by either:

- *Capability list:* a row-wise implementation, effectively a ticket that authorizes the holder (subject) to access specified objects with specified actions
- *Access control list* (ACL): a column-wise implementation, also an attribute of an object stating which subjects can invoke which actions on it

6.3.3.5. Web Security Protocols: SSL and S-HTTP As the Web became popular and commercial enterprises began to use the Internet, it became obvious that some security services such as integrity and authentication are necessary for transactions on the Web. There are two widely used protocols to solve this problem: secure socket layer (SSL) and secure HTTP (S-HTTP). SSL is a general-purpose protocol that sits between the application layer and the transport layer. The security services offered by the SSL are authentication of the server and the client and message confidentiality and integrity. The biggest advantage of the SSL is that it operates independently of application-layer protocols. HTTP can also operate on top of SSL, and it is then often denoted HTTPS. Transport Layer Security (TLS) is an Internet standard version of SSL and is now in the midst of the IETF standardization process. Secure HTTP is an application-layer protocol entirely compatible with HTTP and contains security extensions that provide client authentication, message confidentiality and integrity, and nonrepudiation of origin.

6.3.3.6. Firewall Because the Internet is so open, security is a critical factor in the establishment and acceptance of commercial applications on the Web. For example, customers using an Internet

banking service want to be assured that their communications with the bank are confidential and not tampered with, and both they and the bank must be able to verify each other's identity and to keep authentic records of their transactions. Especially, corporate networks connected to the Internet are liable to receive attacks from crackers of the external network. The prime technique used commercially to protect the corporate network from external attacks is the use of firewalls.

A firewall is a collection of filters and gateways that shields the internal trusted network within a locally managed security perimeter from external, untrustworthy networks (i.e., the Internet). A firewall is placed at the edge of an internal network and permits a restricted set of packets or types of communications through. Typically, there are two types of firewalls: packet filters and proxy gateways (also called application proxies).

- A packet filter functions by examining the header of each packet as it arrives for forwarding to another network. It then applies a series of rules against the header information to determine whether the packet should be blocked or forwarded in its intended direction.
- A proxy gateway is a process that is placed between a client process and a server process. All incoming packet from the client is funneled to the appropriate proxy gateway for mail, FTP, HTTP, and so on. The proxy then passes the incoming packets to the internal network if the access right of the client is verified.

7. A PRACTICAL EXAMPLE: INTERNET BANKING SYSTEM

Here we will explain an Internet banking system as a practical example of a C/S system. An Internet banking service is an online financial service that is offered on the Internet. The system offers various financial services, such as inquiry for bank balance, inquiry for payment details, and fund transfer to customers via the Internet.

We will explain the flow of transactions in C/S processing through an example of fund transfer service between a customer's account in bank A and another account in bank B. Figure 20 shows the flow of processing for the example.

Step 1: A customer connects to the Internet from a desktop personal computer in his home or office and accesses the site of bank A, which offers the Internet banking service, by using a Web browser.

Step 2: At the top menu of the Web page, the user is asked to enter his or her user ID and password already registered. According to the indication on the Web page, the user inputs user ID and password into the input field on the Web page.

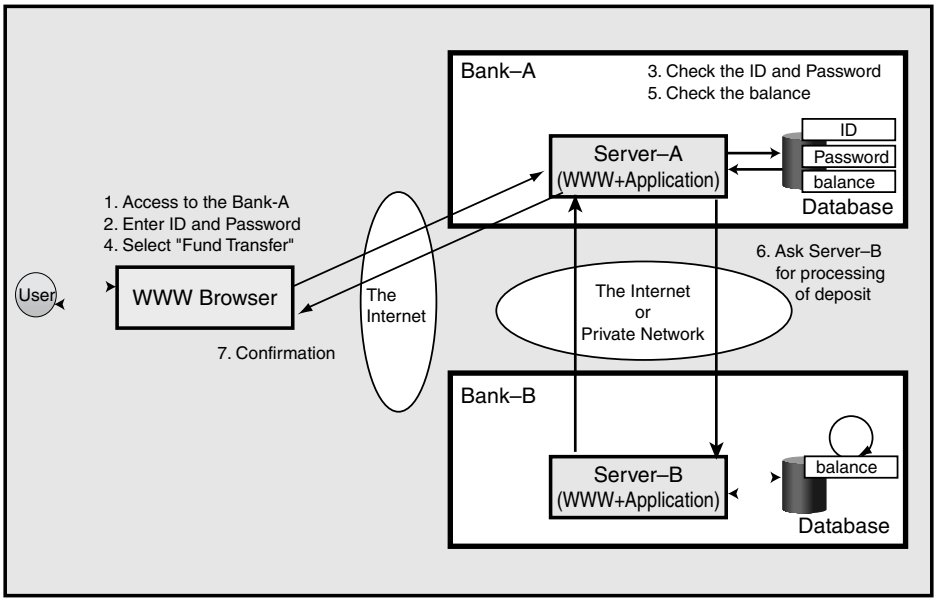

Figure 20 Internet Banking System.

Step 3: The entered user ID and password are sent back to the server via the Internet by the secured communication protocol HTTPS. The server receives that information and checks information on the database that accumulates information about the client and other various data. If the user ID and password correspond to those already registered, the customer is permitted to use the service.

Step 4: The customer selects ''fund transfer'' from the menu displayed on the Web page.

Step 5: The server receives the above request, searches the database, and retrieves the customer's account information.

Step 6: After confirming that there is enough money for payment in the customer's account, the server asks another server in bank B for processing of deposit. In this case, the server of bank A becomes ''client'' and the server of bank B becomes ''server.''

Step 7: After the server of bank A confirms that the processing was completed normally in the server of bank B, it updates (withdraws) the account information of the customer in the database. The acknowledgement that the request for fund transfer is successfully completed is also displayed on the customer's Web page.

CHAPTER 27

Industrial Engineering Applications in Health Care Systems

SWATANTRA K. KACHHAL
University of Michigan-Dearborn

1. INTRODUCTION TO HEALTH CARE DELIVERY SYSTEMS

This section gives a brief history of health care delivery in the United States for readers who may be unfamiliar with the health care industry. It also addresses government regulations and health care financing issues that impact the delivery of health care.

1.1. History of Health Care Delivery Systems

Historically, most health care has been delivered in hospitals. Initially, hospitals were founded, many of them by charitable organizations, to house poor people during epidemics. As medical technology

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

advanced, hospitals actually became centers for treating patients. They also became resources for community physicians, enabling them to share high-cost equipment and facilities that they could not afford by themselves.

Some hospitals are government-owned, including federal, state, county, and city hospitals. Federal hospitals include Army, Navy, Air Force, and Veterans Administration hospitals. Nongovernment hospitals are either not-for-profit or for-profit. The not-for-profit hospitals are owned by church-related groups or communities and constitute the bulk of the hospitals in the country. Investor-owned for-profit hospitals are mostly owned by chains such as Hospital Corporation of America (HCA) and Humana.

1.2. Government Regulations

A number of federal, state, county, and city agencies regulate hospitals. These regulations cover various elements of a hospital, including physical facilities, medical staff, personnel, medical records, and safety of patients. The Hill-Burton law of 1948 provided matching funds to towns without community hospitals. This resulted in the development of a large number of small hospitals in the 1950s and 1960s. The enactment of Medicare legislation for the elderly and the Medicaid program for the poor in 1965 resulted in rapid growth in hospitals. Because hospitals were paid on the basis of costs, much of the cost of adding beds and new expensive equipment could be recovered. Many states developed ''certificate-of-need'' programs that required hospitals planning to expand or build a new facility to obtain approval from a state agency (Mahon 1978). To control expansion and associated costs, the National Health Planning and Resources Development Act was enacted in 1974 to require hospitals that participated in Medicare or Medicaid to obtain planning approval for capital expenditures over $100,000. The result was a huge bureaucracy at local, state, and national levels to implement the law. Most of the states have revised or drastically reduced the scope of the law. Many states have changed the review limit to $1 million. In other states, only the construction of new hospitals or new beds is reviewed (Steinwelds and Sloan 1981).

1.3. Health Care Financing

Based on the method of payment for services, patients can be classified into three categories. The first category includes patients that pay from their own pocket for services. The second category includes patients covered by private insurance companies. The payment for services for patients in the last category is made by one of the government programs such as Medicare. A typical hospital receives approximately 35% of its revenue from Medicare patients, with some inner-city hospitals receiving as much as 50%. A federal agency called the Health Care Financing Administration (HCFA) manages this program. Medicare formerly paid hospitals on the basis of cost for the services rendered to Medicare patients. Under this system of payment, hospitals had no incentive to control costs and deliver the care efficiently. To control the rising costs, a variety of methods were used, including cost-increase ceilings, but without much success. In 1983, a new means of payment was introduced, known as the diagnostic related group (DRG) payment system. Under this system, hospital cases are divided into 487 different classes based on diagnosis, age, complications, and the like. When a patient receives care, one of these DRGs is assigned to the patient and the hospital receives a predetermined amount for that DRG irrespective of the actual cost incurred in delivering the services. This system of payment encouraged the hospitals to deliver care efficiently at lower cost. Many of the commercial insurance companies such as Blue Cross and Blue Shield have also adopted this method of payment for the hospitals.

1.4. Emerging Trends

During the past decade, a few key trends have emerged. A shift to managed health care from traditional indemnity insurance is expected to continue. This has resulted in the growth of health maintenance organizations (HMOs) and preferred provider organizations (PPOs), which now account for as much as 60–70% of the private insurance in some markets. Employers have also been changing health care benefits for their employees, increasingly going to so-called cafeteria plans, where employers allocate a fixed amount of benefit dollars to employees and allow them to allocate these dollars among premiums for various services. This has resulted in increased out of pocket costs and copayments for health care for the employees.

Medicare has reduced payments for DRGs and medical education to the hospitals. It has put many health care systems in serious financial trouble. The increase in payments is expected to stay well below the cost increases in the health care industry. These trends are expected to continue in the near future (Sahney et al. 1986.)

Since the advent of the DRG system of payment, the length of stay has continually dropped in hospitals from an average of over 10 days in the 1970s to below 5 days. Hospital admission rates have also dropped because many of the procedures done on an inpatient basis are now being performed on an ambulatory care basis. Inpatient admissions and length of stay are expected to continue to decline, and ambulatory care is expected to continue to grow over the next decade.

Medically indigent people who have neither medical insurance nor coverage by federal and/or state programs continue to place a serious financial burden on health care institutions. In the past, hospitals were able to transfer the cost of indigent care to other payers under a cost-based payment system. But under the DRG-based payment systems, hospitals are unable to do so.

Hospitals have been experiencing shortages in RN staffing, especially in inpatient units and emergency rooms. The nursing shortages can be attributed to low starting salaries for nurses and potential nursing students opting for other carriers with regular daytime work hours. Nurses also have other opportunities within health care aside from the inpatient setting that do not require night shift rotation or weekend coverage. The nursing shortage is projected to continue for positions in inpatient units.

Another trend in the health care industry has been an increase in ambulatory care clinics and ambulatory surgical centers. Hospitals have developed freestanding ambulatory care centers as a means of penetrating new markets by providing easy access to primary care services to the growing number of HMO patients.

The other major trend is consolidation within the industry. Hospitals have been facing a bleak financial future. Hospitals have been consolidating to form larger and leaner health care delivery systems to take advantage of economies of scale. Usually there is a reduction in the number of excess inpatient beds and an elimination of duplicate services in a community as a result of these mergers. Industry consolidation is expected to continue in the coming years. It is expected that in most large cities only a few large health systems will account for most of the inpatient health care services.

2. INTRODUCTION TO INDUSTRIAL ENGINEERING IN HEALTH CARE DELIVERY SYSTEMS

Frank Gilbreth is considered to be the first to use industrial engineering tools for methods improvement in a hospital situation. He applied his motion study techniques to surgical procedures in 1913 (Nock 1913); (Gilbreth 1916). In the 1940s, Lillian Gilbreth published articles explaining the benefits of using methods-improvement techniques in hospitals and in nursing (Gilbreth 1945, 1950). In 1952, a two-week workshop was conducted at the University of Connecticut on the application of methods improvement in hospitals (Smalley 1982). Also in 1952, the American Hospital Association (AHA) created a Committee on Methods Improvement. This committee prepared several papers on methods-improvement activities in hospitals and published them in its interim report in 1954.

In the late 1950s, the American Hospital Association started offering workshops on methods improvement around the country. Universities added courses on the application of methods improvement in hospital administration and industrial engineering programs. Gradually, other industrial engineering techniques were studied and applied to various hospital problems. The growing use of industrial engineering techniques in hospitals resulted in the foundation of the Hospital Management Systems Society (HMSS) in Atlanta in 1961, which subsequently moved to Chicago in 1964. The Institute of Industrial Engineers also recognized the expanding role of industrial engineering techniques and formed a hospital section in 1964. This section changed its name to the Health Services Division in 1977, reflecting the broader scope of the field. In 1988, the Institute of Industrial Engineers approved the formation of the Society for Health Systems (SHS) to replace the Health Services Division. In 1987, HMSS changed its name to Healthcare Information and Management Systems Society (HIMSS) to recognize the growing role of information systems in health care. Both HIMSS and SHS offer a number of seminars and workshops throughout the year related to the application of information systems and industrial engineering in health care. They also cosponsor annual HIMSS conference in February and the annual SHS conference in September/October of each year. Many of the industrial engineers working in the health care industry are members of both organizations.

Educational institutions started offering industrial engineering programs with specialization in health care systems. Many industrial engineers today work for hospitals and health systems, while others work as consultants in health care. The industrial engineers working in health care systems are usually referred as management engineers or operations analysts. Smalley (1982) gives a detailed history of the development of the use of industrial engineering in hospitals.

Industrial engineers gradually realized that many industrial engineering techniques initially applied to manufacturing/production systems were equally applicable in service systems such as health care systems. Almost all of the industrial engineering tools and techniques have been applied to health care systems. In this chapter, the application of only some of these techniques to health care systems will be discussed. From the examples presented here, readers should be able to appreciate the application of other techniques to health care systems. The application of the following techniques in health care systems is discussed here:

1. Methods improvement and work simplification
2. Staffing analysis
3. Scheduling
4. Queuing and simulation

5. Statistical analysis
6. Optimization
7. Quality improvement
8. Information systems/decision support systems

The emphasis will be on the application in health care, not on the techniques themselves, because the details of industrial engineering techniques are given in the other chapters of this Handbook. Applications will be discussed using various hospital departments as examples. For individuals not familiar with health care systems, Goldberg and Denoble (1986) describe various hospital departments.

3. APPLICATIONS OF METHODS IMPROVEMENT AND WORK SIMPLIFICATION

3.1. Introduction

The terms *methods improvement, methods engineering, operations analysis,* and *work simplification* have been used synonymously in industrial engineering literature. These techniques use a systematic procedure to study and improve methods for carrying out any set of activities to accomplish a task. In health care systems, these could be the work methods used in the actual delivery of health care to the patients or the work methods utilized in support activities. One common tool used to document an existing process or work method is a flowchart, which can also be used to document a new process as it is developed prior to implementation. A flowchart allows a critical examination of the various steps of the process and assists in the identification of unnecessary steps and inefficiencies in the process. Flowcharts show each step of the process as well as decision points and various courses of action based upon the decision.

Other tools available for methods improvement that have been used in health care systems include a flow diagram and a paperwork simplification chart. A flow diagram can be used to visualize the flow of material and patients in a facility. It can help identify areas of congestion and assist in the planning of the physical layout of facilities. Paperwork-simplification charts are used to analyze and improve paper documents to provide the needed control and communication.

3.2. Application of a Flowchart to Document Patient Flow in an Outpatient Clinic

Figure 1 shows the flowchart for patient flow in an outpatient clinic starting from the time when a patient arrives at the reception counter to the time the patient leaves the clinic after the visit. This chart shows all the steps a patient goes through to complete a visit with the physician. Management engineers can critically examine each step to study the possibility of eliminating, simplifying, or modifying it. For example, this flowchart indicates that patients have to stand in line till a receptionist is available to serve them. If this wait is excessive, one alternative could be to have a sign-up sheet so the patients could sign it and then take a seat. When available, the receptionists could then call the patients to the counter to serve them.

4. APPLICATION OF STAFFING METHODOLOGIES

4.1. Introduction

Staffing refers to the number of employees of a given skill level needed in a department to meet a given demand for services. The determination of the staffing is basically a problem of work measurement. It requires listing all the different tasks done by a certain skill level in the department. The departmental tasks are classified as constant or variable. Constant tasks are those tasks that are not directly related to the departmental output, that is, they are independent of the level of demand for services. For example, cleaning the work area and equipment every morning in a blood-testing laboratory is a constant task that does not depend upon the number of specimens tested. Variable tasks are those that are directly related to the output of the department. For example, a variable task may be the actual testing of a specimen. The total time spent during a day in testing specimens would be equal to the time taken to test one specimen multiplied by the total number of specimens tested in a day.

After the identification of constant and variable tasks, the work content associated with each task is measured. The work content could be measured using any of the traditional work-measurement techniques such as stopwatch time study, predetermined motion time systems, and work sampling. Work content could also be established using the Delphi approach in which a group of individuals familiar with a well-defined task try to reach a consensus about the time required to accomplish the task. The frequency at which each variable task occurs per day is also determined. The total number of hours of work to be performed for each skill level is then determined by adding the time taken

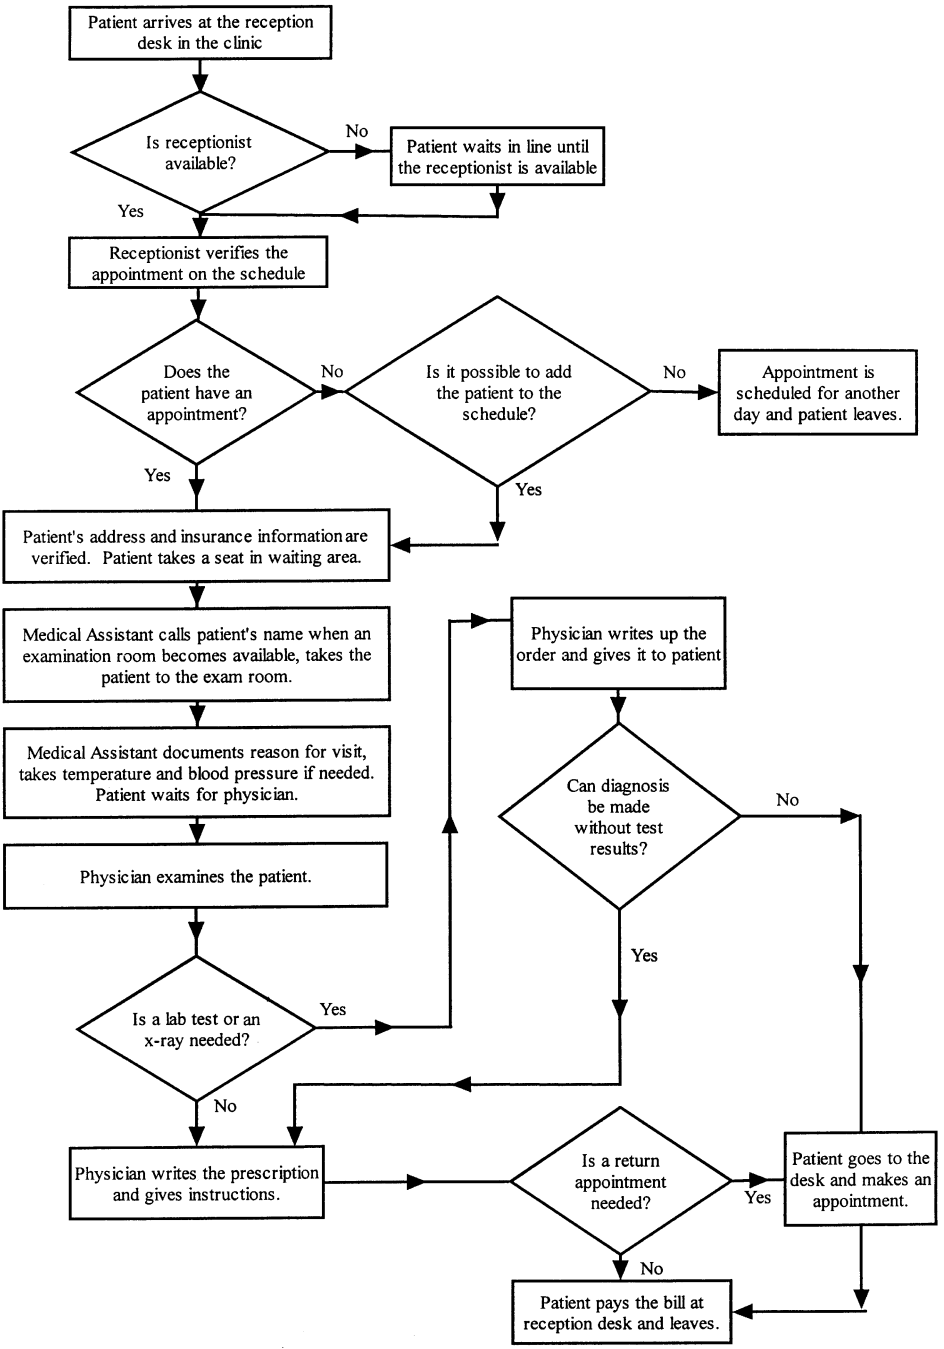

Figure 1 Patient Flowchart in an Outpatient Clinic.

to perform the constant tasks and the variable tasks at a given frequency level associated with a given demand for services.

One disadvantage of using the common work-measurement techniques is that the process is very cumbersome and time-consuming. Moreover, any time the method changes, the work content of various tasks has to be measured again. Another alternative may be to use one of the standard-staffing methodologies available in the health care industry. These methodologies describe the typical tasks that are performed in a particular hospital department and assign a standard time to each task. Resource Monitoring System (RMS), developed by the Hospital Association of New York State, is an example of one such system.

The time available per full time equivalent (FTE) is also calculated. If the department is open 8 am to 5 pm with a one-hour lunch break and if two 15-minute breaks are allowed during the shift, the time available per FTE per day will be 7.5 hours. The actual required FTE depends on demand variability, coverage issues, scheduling constraints, skill level requirements, and similar factors. One approach is to determine the efficiency level (a number less than one) that could be expected because of these factors. Efficiency is defined as the ratio of the actual hours of work done to the actual number of hours used to do the work, including idle time, if any. The FTE needed is then determined using the following equation:

$$\text{FTE needed} = \frac{\text{total number of hours of work to be performed per day}}{\text{time available per FTE per day} \times \text{efficiency level}}$$

4.2. A Case Study in the Ambulatory Surgery Center

An ambulatory surgery center can be defined as a specialized facility organized to perform surgical cases in an ambulatory setting. Ambulatory surgery centers are normally staffed by registered nurses (RNs), who provide care in preoperative, operating, and recovery rooms. A staff of nurse anesthetists (CRNAs) works in the operating rooms and also performs patient assessments in the preoperative area before the patient enters surgery. Nurses' aides clean and package surgical instruments and assist with room turnover between cases. Room turnover involves cleaning and restocking the operating room between cases. The patient registration and all the initial laboratory work are done prior to the day of the surgery. On the day of surgery, the patient is asked to arrive one hour prior to the scheduled surgery time. After checking in with the receptionist, the patient is sent to preoperative area for assessment by CRNAs. After the surgery, the patient is in the recovery room until the patient is stable enough to be sent home.

The objective of the study was to determine the staffing requirement for each skill level including RNs, CRNAs, and nursing aides. As stated above, all the constant and variable tasks were identified for each skill level. The time required to perform each task was determined using a combination of approaches including direct observation and Delphi consensus-building methodology. The calculations for determining staffing requirements for nursing aides are shown in Table 1.

The actual efficiency should be computed and monitored each week. If there are definite upward or downward trends in efficiency, adjustments in staffing levels should be made. The work level at which a department is staffed is a critical parameter. One approach could be to perform a sensitivity analysis and compute the FTE requirement at various levels of case activity and then decide on the appropriate staffing level.

5. APPLICATION OF SCHEDULING METHODOLOGIES

5.1. Introduction

In health care systems, the term *scheduling* is used in a number of different ways. It can refer to the way in which appointments are scheduled for patient visits, testing procedures, surgical procedures, and the like. This form of scheduling is called work scheduling because patients represent work. In certain departments, it may be possible to move the workload from peak periods to periods of low demand to balance the workload. An example is an outpatient clinic where only a given number of appointment slots are made available. The number of appointment slots in a session determines the maximum number of patients that can be seen during that session, thereby restricting the workload to a defined level. In other departments, such as an emergency room, the patients or workload cannot be scheduled.

Another use of the this term is in the scheduling of personnel in a department based on the varying demand for services during the various hours of the day and days of the week while providing equitable scheduling for each individual over weekends and holidays. It must be noted that in the inpatient setting in health care, certain staff, such as nursing staff, need to be scheduled for work even over holidays. In the scheduling of personnel, each individual is given a schedule indicating what days of the week and what hours of the day he or she would be working over a period.

TABLE 1 Staffing Requirements for Nursing Aides

(A) Variable Activities		
Room Turnover		10.0 min/case
Cleaning of Instruments		12.0 min/case
Sorting and Wrapping of Instrument Sets		6.0 min/case
Total for Variable Activities		28.0 min/case
(B) Constant Activities		Minutes per Day
Testing Equipment	5 min/day	5 min/day
Morning Set-up	10 min/day	10 min/day
Cleaning of Sterilizers	30 min × 9 sterilizers per week	54 min/day
Running Spordi Test	90 min/day	90 min/day
Stocking Supply Room	15 min/day	15 min/day
Checking for Outdates	2 hrs/week	24 min/day
Operation of Sterilizers	3 hrs/day	180 min/day
Stocking Scrub Area	20 min/day	20 min/day
Prepare Suction Containers	30 min/day	30 min/day
Taking Specimens to Lab	1 hr/day	60 min/day
Taking Supplies to Station	1 hr/day	60 min/day
Prepare Wrapper/Stock	1 hr/week	12 min/day
Other Misc. Tasks	1 hr/week	12 min/day
	Total Constant Activity Time	572 min/day
(C) Total Work Per Day at 100 Cases per Day		
Constant Activity Time		572 min/day
Variable Activity Time	23 min/case × 100 cases/day	2300 min/day
	Total Work per Day	2872 min/day
(D) Staffing Requirement at 90% Efficiency		
Time Available per FTE per Day	7.5 hr/day × 60 min/hr	450 min/day
Required FTE = (Work per Day in Minutes)/(Available min/day/FTE × Efficiency)		
= (2872 min/day)/(450min/day/FTE × 0.9)		
= 7.1 FTE		

5.2. Work Scheduling

Some of the areas where work scheduling is possible are elective admission scheduling, case scheduling in operating rooms, appointment scheduling in outpatient clinics, and appointments for radiological procedures and other testing such as amniocentesis. These are the areas where there is not an immediate and urgent need for services. To help determine the demand for services and understand the variability in demand, the workload data are collected by day of the week and hour of the day. In certain areas, it may be possible to smooth out the peaks and valleys in demand. For example, workload at a call center, where patients call by phone to schedule an appointment, can be shifted from busy hours to slow hours by playing a message on the phone as the patients wait to be served advising them to call during specific periods for reduced wait. After the workload has been smoothed, a decision is made to meet the demand a certain percentage of the time. After the staffing requirements are determined for this demand level using the methodologies discussed in the last section, staff is scheduled. Workload will then basically be restricted by the staff schedule.

Appointment slots are created based upon the type of work to be done and the number of providers available by hour of the day and day of the week. Appointments are scheduled as patients call for appointments. Once the appointment slots are filled, no additional work is scheduled. Appointment scheduling can be done using a manual system where an appointment book is maintained and the appointments are made by filling in the available slots. A number of computerized systems are on the market that basically allow the computerization of manual appointment books. These systems have the capability to search for available appointment slots meeting the time restrictions of the patient.

5.2.1. Appointment Scheduling in a Primary Care Clinic

Most people have a specific physician whom they see when they have a health-related problem. Individuals belonging to an HMO (health maintenance organization) select a primary care physician

who takes care of all of their health care needs. For infants and young children, this would be a pediatrician, and for adults and teenagers, an internist or a family practitioner. Appointment scheduling or work scheduling in a primary care clinic (internal medicine) is discussed here.

An internal medicine clinic had been struggling with the appointment scheduling issue for a period of time. In particular, they wanted to determine the number of slots to be provided for physical exams, same-day appointments, and return appointments. The first step was to estimate the total demand for physical exams and for other appointments in the clinic. Data on average number of visits per person per year to the internal medicine clinic were available from past history. Multiplying this number by the total number of patients seen in the clinic yielded an estimate of total number of visits to be handled in the clinic.

The number of visits to the clinic varied by month. For example, clinic visits were higher during the flu season than in the summer months. Past data helped in the estimation of the number of visits to be handled each month. It was determined that the number of visits varied by day of the week, too. Mondays were the busiest and Fridays the least busy. The number of visits to be handled each day of the month was estimated based on this information. Staff scheduling was done to meet this demand. The total number of appointment slots was divided among physical exams, same-day visits, and return visits based on historical percentages. Other issues such as no-show rates and overbooking were also taken into account in appointment scheduling.

5.3. Personnel Scheduling

Once the work has been scheduled in areas where work scheduling is possible and the staffing requirements have been determined based upon the scheduled work, the next step is to determine which individuals will work which hours and on what days. This step is called personnel scheduling. In other areas of the hospital, such as the emergency room, where work cannot be scheduled, staffing requirements are determined using historical demand patterns by day of the week and hour of the day. The next step again is to determine the schedule for each staff member.

The personnel schedule assigns each staff member to a specific pattern of workdays and off days. There are two types of scheduling patterns: cyclical and noncyclical. In cyclical patterns, the work pattern for each staff is repeated after a given number of weeks. The advantage of this type of schedule is that staff members know their schedules, which are expected to continue until there is a need for change due to significant change in the workload. The disadvantage is the inflexibility of the schedule in accommodating demand fluctuations and the individual needs of workers. In noncyclical schedules, a new schedule is generated for each scheduling period (usually two to four weeks) and is based on expected demand and available staff. This approach provides flexibility to adjust the staffing levels to expected demand. It can also better accommodate requests from workers for days off during the upcoming scheduling period. But developing a new schedule every two to four weeks is very time consuming.

A department may allow working five 8-hour days, four 10-hour days, or three 12-hour shifts plus one 4-hour day. The personnel schedule has to be able to accommodate these various patterns. The schedule must also provide equitable scheduling for each individual when coverage is needed over weekends and holidays.

Personnel schedules are developed by using either a heuristic, trial-and-error approach or some optimization technique. Several computerized systems are available using both types of approaches.

Warner (1974) developed a computer-aided system for nurse scheduling that maximizes an expression representing the quality of schedule subject to a constraint that minimum coverage be met. Sitompul and Randhawa (1990) give detailed review and bibliography of the various nurse-scheduling models that have been developed.

6. APPLICATION OF QUEUING AND SIMULATION METHODOLOGIES

There are a number of examples of queues or waiting lines in health care systems where the customers must wait for service from one or more servers. The customers are usually the patients but could be hospital employees too. When patients arrive at the reception desk in a clinic for an appointment, they may have to wait in a queue for service. A patient calling a clinic on the phone for an appointment may be put on hold before a clinic service representative is able to answer the call. An operating room nurse may have to wait for service at the supply desk before a supply clerk is able to handle the request for some urgently needed supply. These are all examples of queuing systems where the objective may be to determine the number of servers to obtain a proper balance between the average customer waiting time and server idle time based on cost consideration. The objective may also be to ensure that only a certain percentage of customers wait more than a predetermined amount of time (for example, that no more than 5% of the patients wait in the queue for more than five minutes.)

In simple situations, queueing models can be applied to obtain preliminary results quickly. Application of queueing models to a situation requires that the assumptions of the model be met. These assumptions relate to the interarrival time and service time probability distributions. The simplest model assumes Poisson arrivals and exponential service times. These assumptions may be approxi-

mately valid for certain queues in health care systems. Incoming phone calls to a call center for scheduling appointments have been shown to follow Poisson distribution. Usually the service times are also approximately exponentially distributed. Queueing models with Poisson arrivals and exponential service times have also been applied to emergency rooms for determining proper staffing of nurses and physicians (Hale 1988). From the data collected over a period of time, he was able to verify the validity of assumptions made in the model and determine the average waiting time and average number of patients waiting for service.

In situations where a simple queueing model is not applicable or a more accurate result is desired, simulation models are used. Simulation models are also used when there are complex probabilistic systems with a number of entities interacting with each other. These models are also useful during the design stage to investigate the effect of changes in various parameters in a system.

Simulation models have been extensively used in the analysis of emergency rooms (Weissberg 1977; Saunders et al. 1989). Ortiz and Etter (1990) used general-purpose simulation system (GPSS) to simulate the emergency room. They found simulation modeling to be a better approach even for simple, less complex systems because of its flexibility and capacity to investigate various alternatives. Dawson et al. (1994) used simulation models to determine optimal staffing levels in the emergency room. McGuire (1997) used a simulation model to investigate various process changes and choose a solution that significantly reduced the length of stay for patients in the emergency room.

Simulation models have also been extensively used in other areas of health care systems. Roberts and English (1981) published a bibliography of over 400 articles in literature related to simulation in health care. The *Journal of the Society for Health Systems* (1992b, 1997) published two issues dedicated to health care applications of simulation. Bressan et al. (1988) and Mahachek (1992) discussed generic structure for simulation in health care. Dumas and Hauser (1974) developed a simulation model to study various hospital admission policies. Kachhal et al. (1981) used GPSS to simulate outpatient internal medicine clinics in order to investigate various clinic consolidation options. They used another model to determine optimal staffing for audiologists administering hearing tests ordered by ear, nose, and throat (ENT) physicians. Dumas (1984) used simulation in hospital bed planning. Hunter et al. (1987) used a model to simulate movement of surgical patients in a facility. Levy et al. (1989) developed a simulation model using SIMAN to assist in the design of a new outpatient service center. Wilt and Goddin (1989) simulated staffing needs and the flow of work in an outpatient diagnostic center. Lowery and Martin (1993) used a simulation model in a critical care environment. Cirillo and Wise (1996) used simulation models to test the impact of changes in a radiology department. Schroyer (1997) used a simulation model to plan an ambulatory surgery facility. Benneyan (1997) conducted a simulation study of a pediatric clinic to reduce patient wait during a visit to the clinic.

7. APPLICATION OF STATISTICAL METHODS

Several statistical methods have been used in the analysis and improvement of health care systems. Variability is the fact of life in any kind of data collected in health care, and statistical methods are the tools needed to understand this data. In this section, some common examples of the use of statistical analysis and modeling in health care will be presented.

As stated above, use of queuing and simulation models requires collection of data regarding the probability distribution of interarrival times for customers and service times. Use of a specific queuing model requires that the assumptions regarding the probability distributions in the model are valid. Industrial engineers must be able to verify that the collected data fit the assumed probability distribution. Similarly, simulation models need the data regarding various service times and other probabilistic elements of the model. Statistical methods have also been used to study and manage variability in demand for services (Sahney 1982).

7.1. Use of Regression Models

Regression models can be used to predict important response variables as a function of variables that could be easily measured or tracked. Kachhal and Schramm (1995) used regression modeling to predict the number of primary care visits per year for a patient based upon patient's age and sex and a measure of health status. They used ambulatory diagnostic groups (ADGs) encountered by a patient during a year as a measure of health status of the patient. All the independent variables were treated as 0–1 variables. The sex variable was 0 for males and 1 for females. The age of the patient was included in the model by creating ten 0–1 variables based on specific age groups. The model was able to explain 75% of the variability in the response variable. Similar models have been used to predict health care expenses from patient characteristics.

7.2. Determination of Sample Size

Industrial engineers frequently encounter situations in health care systems where they need to determine the appropriate amount of data needed to estimate the parameters of interest to a desired level of accuracy. In health care systems, work-sampling studies are frequently done to answer questions

such as ''What percentage of a nurse's time is spent on direct patient care?'' or ''What fraction of a clinic service representative's time is spent on various activities such as answering phones, checking-in the patients, looking for medical records, and the like?'' In work-sampling studies, the person being studied is observed a predetermined number of times at random time intervals. For each observation, the task being performed is recorded. The estimate of the fraction of time spent on an activity is obtained by dividing the number of occurrences of that activity by the total number of observations.

The number of observations needed for a work-sampling study can be calculated from the following formula:

$$N = \frac{Z^2 \times p(1 - p)}{I^2}$$

where N = number of observations
Z = normal probability distribution factor, based on confidence level
p = unknown fraction to be estimated
I = desired margin of error in estimation

It is common to use a 95% confidence level for which the value of Z in the equation is 1.96. The value of I needs to be selected based upon the situation. For example, if the fraction being estimated is in 0.4–0.6 range, a value of I as ± 0.02 may be acceptable, but ± 0.05 may be too high. The value of p to be used in the equation poses a problem because this is the unknown fraction one is attempting to estimate from the data. If, from past experience or from literature, an approximate value of p is known, it can be used in the calculation of N. Another approach is to use $p = 0.5$ because it results in the largest value of N for fixed values of Z and I. If the computed value of N is too large to observe due to time and cost constraints, the only choice is to tolerate a larger possible error or a lower level of confidence.

A similar formula is also available for determining the sample size in situations that require determination of actual time to perform a task. For example, for a staffing study in a call center, one may need to estimate average time needed to service a phone call.

7.3. Use of Control Charts

Control charts have been used in health care as visual tools to observe the performance of a process over a period of time and alert the managers when an investigation may be necessary to identify an external cause that may have affected the performance. Individual (X) and moving range (MR) charts have been used for measurement data such as patient wait time, turnaround time for a test, number of times an error is made during a day, and length of stay for a particular diagnostic related group (DRG). P-charts have been used for fractions or percentages. Examples include patient satisfaction data, percentage utilization of a resource, bed occupancy expressed as % of total beds, and fraction of patient transport requests handled within 15 minutes of request. Cumulative sum charts have been used to detect small but significant changes in the mean. Kachhal and Schramm (1995) describe a bed model where auto regressive integrated moving average was used on a control chart with economic control limits to manage bed capacity at a hospital.

8. APPLICATION OF OPTIMIZATION MODELS

The best-known application of optimization models has been in the context of nurse scheduling. Warner (1976) formulated the problem of determining the optimal nurse schedule as a two-phase multiple-choice programming problem and solved it using a modified version of Balintfy's algorithm. In his formulation, the objective is the determination of the schedule that maximizes an expression representing the quality of the schedules, quantifying the degree to which the nurses like the schedules they would work. The solution is determined subject to the constraints that the minimum coverage requirement for each shift and for each skill level be met. The popular ANSOS nurse-scheduling software uses this model. Warner et al. (1990) discuss automated nurse scheduling software.

Trivedi (1976) studied the problem of the reallocation of nursing resources at the beginning of each shift. He developed a mathematical model that minimizes the total severity index for the hospital, which is a measure of the need for an additional staff member by skill level. The model was solved using a branch-and-bound algorithm to determine the optimal assignment of nurses by skill level to various inpatient units.

Fries and Marathe (1981) used mathematical models to determine the optimal variable-sized multiple-block appointment system. Calichman (1990) used a linear programming model to balance the bed demand among various surgical services.

9. APPLICATION OF QUALITY-IMPROVEMENT TOOLS

The concepts of quality control, quality improvement, and quality management in the United States largely evolved from the efforts of Dr. W. Edward Deming, Dr. Joseph Juran, and Philip Crosby. Manufacturing industries were first to apply these concepts to achieve significant improvements in the quality of manufactured goods while reducing costs. During the late 1980s, the health care industry started using some of these methods to improve quality of health care delivery and reduce costs. Many hospitals started continuous quality improvement (CQI) and total quality management (TQM) programs. Sahney et al. (1989) summarize 10 common points from the quality philosophies of Deming, Juran, and Crosby and conclude that they can be applied to any industry, including the health care industry, to improve quality.

Continuous quality improvement focuses on improvement of various processes in a health care organization. It starts with identifying the customers and their needs for each of the processes. The objective is to improve the processes to meet the needs of the customers. All the changes are data driven. Key quality characteristics are identified and measured to track improvements. The physicians and hospital employees are trained in quality concepts and tools for improvement. Some of these tools are the Pareto chart, the cause–effect (or fishbone) diagram, flowcharts, run charts, and control charts. These tools assist in the documentation, analysis, and improvement of processes. Sahney and Warden (1991), and Gaucher and Coffey (1993) give a good overview of the application of CQI approach in health care. A popular CQI methodology is FOCUS-PDCA. Griffith et al. (1995) give a description of this methodology.

Another term in the quality improvement effort that has gained popularity during the late 1990s is *process reengineering.* While the CQI approach looks at making incremental improvements in the processes, reengineering efforts look at radical redesign of systems and processes to achieve major improvements in the cost and quality of services (Hammer and Champy 1995). Kralovec (1993) provides a good introduction to applying reengineering techniques to health care. The proceedings of the Quest for Quality and Productivity in Health Services Conferences that have been held each year since 1989 provide numerous examples of the application of total quality management, CQI, and reengineering methods in health care systems.

10. APPLICATION OF INFORMATION SYSTEMS/DECISION SUPPORT TOOLS

Many projects conducted by industrial engineers in health care deal with the use of information systems to improve quality and performance. There is a need to take a team approach in information system-related projects. A project team is needed that has individuals from management engineering and information services as well as the user department. The role of an industrial engineer on this team is to first interview the client department to determine the user requirements. The requirements are then used in the request for proposal (RFP) process to obtain proposals from vendors of information systems. Subsequently, the evaluation of proposals is also done on the basis of meeting these requirements as well as other factors. Industrial engineers are also used in the implementation phase to redesign the manual processes in the client department because these processes usually require major changes after the implementation of an information system. Kachhal and Koch (1989) report on the development of user requirements for a management information system for an operating room and the evaluation of the systems available in the market in meeting these requirements.

Decision support systems (DSS) have become a standard component of hospital information systems. They allow managers to look at financial data on a product line basis. A product line is a collection of one or more diagnostic related groups (DRGs). DSS are able to integrate various sources of data and give managers the capability for ad hoc reporting, building models to project revenues and costs, analyzing various reimbursement scenarios, and the like. The *Journal of the Society for Health Systems* (1991) published an issue with focus on decision support systems that presents a good overview of DSS in health care.

The other type of DSS used in health care are the clinical decision support systems (CDSS), which use a set of clinical findings such as signs, symptoms, laboratory data, and past history to assist the care provider by producing a ranked list of possible diagnoses. Some CDSS act as alerting systems by triggering an alert when an abnormal condition is recognized. Another set of these systems act as critiquing systems by responding to an order for a medical intervention by a care provider. Several systems that detect drug allergies and drug interactions fall into this category. Another use of CDSS is in consulting systems that react to a request for assistance from a physician or a nurse to provide suggestions about diagnoses or concerning what steps to take next. The application of CDSS in implementing clinical practice guidelines has been a popular use of these systems. Doller (1999) provides a current status of the use of these systems as medical expert systems in health care industry. The author predicts that the major use of CDSS in future will be in implementing clinical

guidelines and allowing nonphysicians to handle routine care while directing the attention of true medical experts to cases that are not routine.

While some industrial engineers may be involved in the development of home-grown DSS or CDSS, the role of other industrial engineers is still in the evaluation and cost–benefit analysis of the standard systems available in the market.

11. APPLICATION OF OTHER INDUSTRIAL ENGINEERING TECHNIQUES

The application of other industrial engineering techniques such as forecasting, inventory control, materials management, facilities planning, economic analysis, and cost control is also common in health care systems. Examples of many of these applications are available in the proceedings of the annual Quest for Productivity and Productivity Conferences of the Society for Health Systems and the Healthcare Information and Management Systems Society Conferences. See also *Journal of the Society for Health Systems* (1992a), and Sahney (1993) on the use of industrial engineering tools in health care.

12. FUTURE TRENDS

Most healthcare systems around the country are facing serious financial problems due to the reductions in Medicare and Medicaid reimbursements. Health maintenance organizations (HMOs) have also reduced payments to health systems for services due to reductions in health care premiums forced by competition from other HMOs and by employers looking for cost reductions in their own organizations. Health care institutions are looking for ways to reduce costs while maintaining or improving quality. Industrial engineers are being asked to conduct benchmarking studies to identify areas where costs are higher than the norm and need reduction.

The financial problems are also leading to mergers and takeovers of financially troubled hospitals by health care systems in better financial health. Industrial engineers are being asked to work with individuals from finance on projects related to mergers and consolidation of services to evaluate the financial impact of alternative courses of action.

Many health care systems have undertaken TQM programs that include training of managers and supervisors in quality improvement tools such as flowcharts, cause–effect diagrams, run charts, and control charts. Quality improvement teams (QITs) consisting of employees from the departments in which the process resides are now conducting many of the studies previously conducted by industrial engineers. Industrial engineers are being asked to serve on these teams as facilitators or in staff capacity to conduct quantitative analysis of the alternatives.

Although simulation tools have been available to health care systems for decades, it is only recently that simulation models have been increasingly used as tools to model real systems to predict the impact of various policies and resource levels. Administrators and department managers are aware of the capabilities of these models and are requesting the use of simulation models to make sound decisions. The availability of reasonably priced, user-friendly simulation packages has increased the use of simulation modeling. The same is true for advance statistical tools. With the availability of user-friendly statistical software, more sophisticated statistical models are being built to guide in decision making.

Another area gaining attention is supply chain management. As health care systems are looking for ways to reduce costs without impacting the quality of patient care, procurement of supplies has stood out as an area where substantial reductions can be achieved through supply chain management. Some hospitals are having some of their supplies shipped directly from manufacturers to the user departments, bypassing all the intermediate suppliers and distributors. Other hospitals have eliminated their warehouses and distribution centers, giving the responsibility for daily deliveries and restocking of departments to external vendors. Industrial engineers are evaluating the alternative courses of action in supply chain management.

Industrial engineers are also working for consulting companies contracted by health care systems to assist them out of financial problems. The use of sophisticated industrial engineering tools in health care still lags behind the use in manufacturing industry. Over the next decade, it is expected that the use of these tools will become more prevalent in health care.

CHAPTER 28

Industrial Engineering Applications in Financial Asset Management

R. McFall Lamm, Jr.
Deutsche Bank

1. INTRODUCTION

Over the last decade, the challenges faced by asset managers have become significantly more complex. The array of investment choices has expanded tremendously in response to globalization and financial engineering. New products are now available such as collateralized debt, insurance-linked securities, and exotic structured products. At the same time, the need for investment planning has shifted more to individuals as companies and public entities relinquish responsibility for retirement programs.

Because of this incredible change in the investment world, institutions such as pension plan administrators, endowments, foundations, and asset managers are under greater pressure than ever to produce higher portfolio returns. This is the genesis for embracing new assets, which hopefully will

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

generate superior investment performance than plain vanilla portfolios of stocks and bonds. Better returns reduce the need for future cash injections to fund obligations.

Unfortunately, market risks have increased as the array of available investment instruments has broadened. For example, the Mexican peso crisis in 1994, the Asian currency debacle and recession beginning in 1997, the Russian debt default and the unprecedented hedge fund bail-out coordinated by the Federal Reserve Bank in 1998, and a 30% drop in the price of technology shares early in 2000 all had major repercussions for financial markets. Where is an investor to find solace in such an unfriendly and disturbing environment?

The obvious answer to heightened complexity and uncertainty lies in utilizing financial engineering techniques to manage asset portfolios. This chapter reviews the current state of the art from a practitioner's perspective. The prime focus is on mean-variance optimization techniques, which remain the principal application tool. The key message is that while the methods employed by today's specialists are not especially onerous mathematically or computationally, there are major issues in problem formulation and structure. It is in this arena that imagination and inventiveness take center stage.

2. THE ASSET-MANAGEMENT PROBLEM

The job of investment managers is to create portfolios of assets that maximize investment returns consistent with risk tolerance. In the past, this required simply selecting a blend of stocks, bonds, and cash that matched the client's needs. Asset managers typically recommended portfolios heavily weighted in stocks for aggressive investors desiring to build wealth. They proffered portfolios overweight in bonds and cash for conservative investors bent on wealth preservation. Aggressive stock-heavy portfolios would be expected to yield higher returns over time but with considerable fluctuations in value. Concentrated cash and bond portfolios would be less volatile, thus preserving capital, but produce a lower return.

2.1. Origins

Until recently, a casual rule-of-thumb approach sufficed and was deemed adequate to produce reasonable performance for investors. For example, a portfolio consisting of 65% equities and 35% bonds generated returns and risk similar to a 75% equities and 25% bonds portfolio. However, following the inflation trough in the 1990s, bond returns declined and investors with low equity exposure suffered. In addition, those investors ignoring alternative assets such as hedge funds and venture capital found themselves with lagging performance and greater portfolio volatility.

Studies have consistently shown that selection of the asset mix is the most important determinant of investment performance. Early influential research by Brinson et al. (1986, 1991) and a more recent update by Ibbotson and Kaplan (1999) indicate that asset allocation explains up to 90% of portfolio returns. Security selection and other factors explain the remainder. Consequently, the asset blend is the key intellectual challenge for investment managers and should receive the most attention. Traditional rules of thumb no longer work in a dynamic world with many choices and unexpected risks.

2.2. Problem Structure and Overview

Markowitz was the first to propose an explicit quantification of the asset-allocation problem (Markowitz 1959). Three categorical inputs are required: the expected return for each asset in the portfolio, the risk or variance of each asset's return, and the correlation between asset returns. The objective is to select the optimal weights for each asset that maximizes total portfolio return for a given level of portfolio risk. The set of optimum portfolios over the risk spectrum traces out what is called the efficient frontier.

This approach, usually referred to as mean-variance (MV) analysis, lies at the heart of modern portfolio theory. The technique is now mainstream, regularly taught in investment strategy courses. A massive literature exists exploring the methodology, its intricacies, and variations. "Black box" MV optimization programs now reside on the desks of thousands of brokers, financial advisors, and research staff employed by major financial institutions.

The principal advantage of MV analysis is that it establishes portfolio construction as a process that explicitly incorporates risk in a probabilistic framework. In this way, the approach acknowledges that asset returns are uncertain and requires that precise estimates of uncertainty be incorporated in the problem specification.

On the surface, MV analysis is not especially difficult to implement. For example, it is very easy to guess at future stock and bond returns and use historical variances and correlations to produce an optimum portfolio. It is not so simple to create a multidimensional portfolio consisting of multiple equity and fixed income instruments combined with alternative assets such as private equity, venture capital, hedge funds, and other wonders. Sophisticated applications require a lot of groundwork, creativity, and rigor.

2.3. Implementation

Because the vast majority of MV users are neophytes who are not fully aware of its subtleties, nuances, and limitations, they are sometimes dismayed by the results obtained from MV optimization programs. The reason is that achieving sensible outcomes is highly dependent on quality input. Very often the return, risk, and correlations injected into MV models are empirically and theoretically inconsistent. This generates fallacious and highly distorted portfolios, leading many novices to reject the approach as capricious and unrealistic.

Mean-variance analysis must be integrated with a specific investment process if the results are to be useful. The steps required include:

1. Specifying the investment alternatives to be considered
2. Accurately forecasting expected asset returns, variances, and correlations
3. Executing the optimization
4. Choosing the appropriate implementation vehicles that deliver the performance characteristics embedded in the analysis

Optimization results must be carefully reviewed to ensure that assumptions satisfy consistency requirements and examined for solution sensitivity to changes in inputs.

3. AN ILLUSTRATION

3.1. The Efficient Frontier

To illustrate the essence of the asset-allocation problem, I begin with a simple example that includes the following assets: U.S. stocks, international stocks, U.S. bonds, international bonds, and cash. This constitutes a broad asset mix typical of that used by many professional managers. Expected returns are 11.0%, 12.6%, 6.0%, 6.9%, and 5.0%, respectively. The expected standard deviations (risk) of these returns are 12.5%, 14.7%, 4.3%, 7.8%, and 0.0%. Note that the standard deviation of cash returns is zero because this asset is presumed to consist of riskless U.S. Treasury securities. The correlation matrix for asset returns is:

$$\mathbf{R} = \begin{vmatrix} 1.0 & 0.55 & 0.30 & 0.00 & 0.00 \\ & 1.0 & 0.10 & 0.30 & 0.00 \\ & & 1.0 & 0.30 & 0.00 \\ & & & 1.0 & 0.00 \\ & & & & 1.0 \end{vmatrix}$$

Optimum portfolios are obtained by selecting the asset weights that maximize portfolio return for a specific portfolio risk. The problem constraints are that (1) the portfolio return is a linear combination of the separate asset returns, (2) portfolio variance is a quadratic combination of weights, asset risks, and asset correlations, and (3) all weights are positive and sum to one.

The results of producing MV portfolios are presented in Table 1. The corresponding efficient frontier is shown in Figure 1. The allocations obtained are typical for analyses of this type. That is, to obtain higher portfolio returns, the investor must take on more risk. This is accomplished by weighting equities more heavily. The most conservative portfolios have both low returns and low risk. They consist primarily of cash and bonds. For moderate levels of risk, investors should blend stocks and bonds together in more equal proportions. In addition, note that the most risky portfolios skew to higher weights for international equities, which are more risky than U.S. stocks.

It should be obvious that the production of MV portfolios is not extraordinarily input intensive. Efficient frontiers for five asset portfolios require only five predicted returns, five standard deviations, and a five-by-five symmetrical matrix of correlation coefficients. Yet the process yields indispensable information that allows investors to select suitable portfolios.

3.2. Investor Risk Preferences

Once the efficient frontier is established, the issue of investor risk preferences must be addressed. Individuals exhibit markedly different attitudes towards risk. Some are extremely risk averse, tolerating nothing but near certainty in life. Others relish risk taking. Most are somewhere between these two extremes.

Risk attitudes depend on personality, life experience, wealth, and other socioeconomic factors. By default, extremely risk-averse investors are not interested in building wealth via asset accumulation, because they are unwilling to tolerate the risk necessary to obtain high returns. The opposite is true for adventurous souls ready to gamble for large payoffs. In this regard, ''old-money'' investors

TABLE 1 Selected Optimal Mean-Variance Portfolios

Return	Risk	Sharpe Ratio[a]	U.S. Stocks	International Stocks	U.S. Bonds	International Bonds	Cash
			Portfolio Allocation				
12.6%	15.0%	0.84	—	100%	—	—	—
12.5%	14.0%	0.89	9%	91%	—	—	—
12.2%	13.0%	0.94	25%	75%	—	—	—
11.8%	12.0%	0.99	43%	55%	—	2%	—
11.3%	11.0%	1.03	42%	48%	—	10%	—
10.8%	10.0%	1.08	40%	40%	—	20%	—
10.3%	9.0%	1.14	37%	34%	6%	23%	—
9.7%	8.0%	1.21	32%	29%	17%	22%	—
9.1%	7.0%	1.30	27%	25%	19%	19%	9%

Source: Results of optimization analysis.
[a]The Sharpe ratio is the portfolio return less the risk-free Treasury rate divided by portfolio risk.

are usually more risk averse than ''new-money'' investors. They require portfolios heavily weighted in conservative assets. New-money investors are comfortable with inherently risky equities (Figure 2). Age often plays an important role. Older investors are commonly more risk averse because they are either retired or close to retirement and dissaving (Figure 3).

How does one ascertain risk tolerance to guarantee a relevant portfolio is matched to the investor's needs? There are a number of ways. One is to estimate the risk-aversion parameter based on the investor's response to a battery of questions designed to trace out their return preferences with different payoff probabilities.

Some financial managers simply use personal knowledge of the investor to deduce risk tolerance. For example, if an investor with a $10 million portfolio is distraught if the portfolio's value plunges 20% in a year, he or she is not a candidate for an all-equity portfolio. Yet another approach used by some managers is to work backwards and determine the risk necessary for the investor to reach specific wealth-accumulation goals.

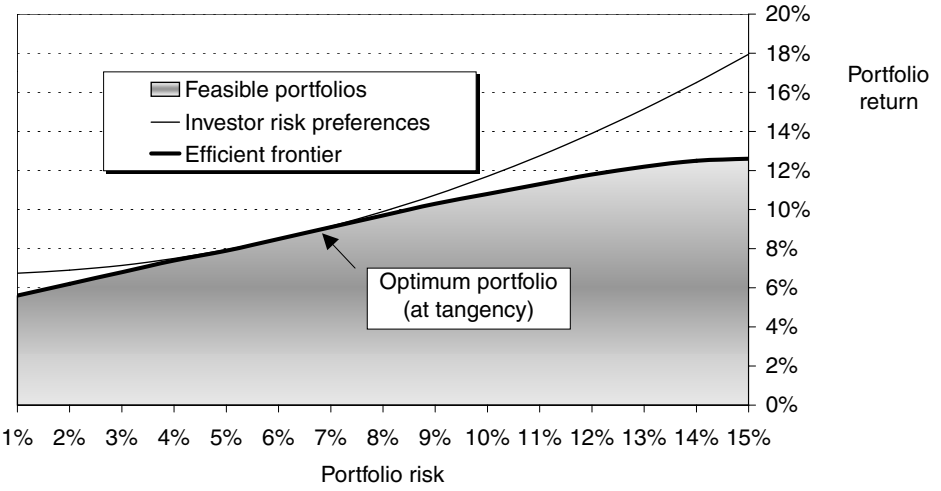

Figure 1 The Efficient Frontier and Investor Risk Preferences.

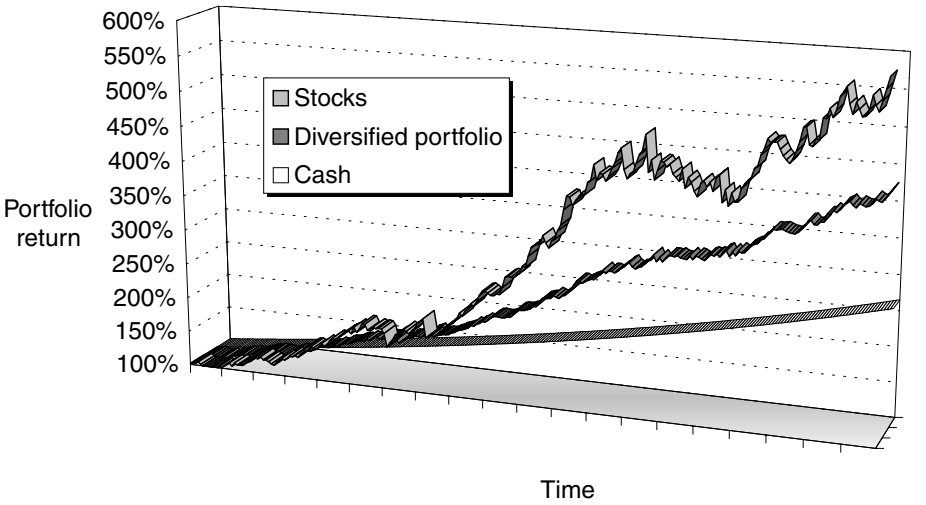

Figure 2 Wealth Creation vs. Wealth Preservation.

4. THE OPTIMIZATION PROBLEM

The specific mathematical formulation for the standard MV problem is straightforward:

$$\max \mathrm{U}(\mathbf{w}) = (r - \lambda\sigma^2) \quad \text{subject to} \tag{1}$$

$$r = \mathbf{w}^{\mathrm{T}}\mathbf{r} \tag{2}$$

$$\sigma = \mathbf{w}^{\mathrm{T}}\mathbf{S}^{\mathrm{T}}\mathbf{R}\mathbf{S}\mathbf{w} \tag{3}$$

$$\text{colsum } \mathbf{w} = 1 \tag{4}$$

$$w_j \geq 0 \tag{5}$$

where $\mathbf{w} = [w_1\ w_2 \ldots w_J]^{\mathrm{T}}$ = the portfolio weights for each asset
$\mathbf{r} = [r_1\ r_2 \ldots r_J]^{\mathrm{T}}$ = the return vector
$\mathbf{S}$ = the risk matrix with diagonal standard deviations $s_1\ s_2 \ldots s_J$
$\mathbf{R}$ = the $J \times J$ asset correlation matrix
λ = the investor's risk-aversion parameter

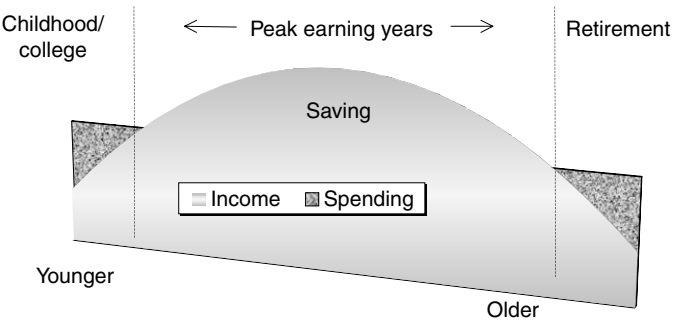

Figure 3 The Investor's Life Cycle.

Equation (1) incorporates the investor's attitude to risk via the objective function U. Equation (2) represents the portfolio return. Equation (3) is portfolio risk. Constraint (4) requires that the portfolio weights sum to 100%, while constraint (5) requires that weights be positive. This latter restriction can be dropped if short selling is allowed, but this is not usually the case for most investors.

This formulation is a standard quadratic programming problem for which an analytical solution exists from the corresponding Kuhn–Tucker conditions. Different versions of the objective function are sometimes used, but the quadratic version is appealing theoretically because it allows investor preferences to be convex.

The set of efficient portfolios can be produced more simply by solving

$$\max r = \mathbf{w}^{\mathrm{T}}\mathbf{r} \text{ subject to } \sigma = \mathbf{w}^{\mathrm{T}}\mathbf{S}^{\mathrm{T}}\mathbf{RSw}, \text{ colsum } \mathbf{w} = 1, w_j \geq 0 \text{ for target } \sigma \tag{6}$$

or alternatively,

$$\max \sigma = \mathbf{w}^{\mathrm{T}}\mathbf{S}^{\mathrm{T}}\mathbf{RSw} \text{ subject to } r = \mathbf{w}^{\mathrm{T}}\mathbf{r}, \text{ colsum } \mathbf{w} = 1, w_j \geq 0 \text{ for target } r \tag{7}$$

A vast array of alternative specifications is also possible. Practitioners often employ additional inequality constraints on portfolio weights, limiting them to maximums, minimums, or linear combinations. For example, total equity exposure may be restricted to a percentage of the portfolio or cash to a minimum required level. Another common variation is to add inequality constraints to force solutions close to benchmarks. This minimizes the risk of underperforming.

With respect to computation, for limited numbers of assets (small J), solutions are easily obtained (although not necessarily efficiently) using standard spreadsheet optimizers. This works for the vast majority of allocation problems because most applications typically include no more than a dozen assets. More specialized optimizers are sometimes necessary when there are many assets. For example, if MV is applied to select a stock portfolio, there may be hundreds of securities used as admissible ''assets.''

5. CAVEATS

5.1. Shortcomings of Mean-Variance Analysis

One must be cognizant that the MV approach has several important shortcomings that limit its effectiveness. First, model solutions are sometimes very sensitive to changes in the inputs. Second, the number of assets that can be included is generally bounded. Otherwise, collinearity problems can result that produce unstable allocations and extreme asset switching in the optimal portfolios. Third, the asset allocation is only as good as forecasts of prospective returns, risk, and correlation. Inaccurate forecasts produce very poorly performing portfolios. The first two limitations can be addressed through skillful model specification. The third requires that one have superlative forecasting ability.

A common mistake committed by naive users of MV analysis is to use recent returns, risk, and correlation as predictors of the future. Portfolios produced using such linear extrapolation methods normally exhibit poor performance. Table 2 shows historical returns and risk for various asset classes over the last decade. A variety of extraneous market developments, shocks, and one-time events produced these results. Rest assured that future time paths will not closely resemble those of the 1990s. For this reason, while one cannot ignore history, extending past performance into the future is a poor technique.

5.2. Dangers of Extrapolating from History

As an example of the extrapolation fallacy, consider portfolio performance over the last two decades. If one constructed an efficient portfolio in 1990 based on the 1980s history, large allocations would have been made to international equities. This is primarily due to the fact that Japanese stocks produced the best returns in the world up to 1989. Yet in the 1990s, Japanese equities fell by more than 50% from their 1989 peak, and the best asset allocation would have been to U.S. equities. Using the 1980s history to construct MV portfolios would have produced dismal portfolio returns (Table 3).

Empirical work by Chopra and Ziembra (1993) demonstrated that the most critical aspect of constructing optimal portfolios is the return forecast. For this reason, a shortcut employed by some practitioners is to concentrate on the return forecast and use historical risk and correlation to construct optimum portfolios. This may prove satisfactory because correlations and risk are more stable than returns and are therefore more easily predicted. However, this line of attack may be ineffective if return forecasts substantially deviate from history and are combined with historical risk and correlations. In this case, the optimal allocations can skew overwhelmingly to the high return assets

Whatever method is used to obtain forecasts, once the optimum portfolio is determined, the manager can momentarily relax and wait. Of course, actual outcomes will seldom match expectations.

TABLE 2 Annual Returns and Risk for Various Assets, 1990–99

Group	Asset	Return	Volatility	Sharpe Ratio
Equity	Large caps	17.7%	13.4%	0.94

No investment manager possesses perfect foresight. Errors in forecasting returns, risk, and correlation will produce errors in portfolio composition. Obviously, managers with the best forecasting ability will reap superior results.

5.3. Asset Selection

If a manager does not forecast extremely well, it is possible to produce superior investment performance via asset selection. That is, choosing an exceptional array of candidate assets, can enhance portfolio returns due to diversification benefits that other managers miss.

For example, consider a simple portfolio of U.S. equities and bonds. Normally managers with the best forecasts will achieve better performance than other managers investing in the same assets. But another manager, who may not forecast U.S. equity and bond returns extremely well, can outperform by allocating funds to assets such as international equities and bonds. These assets possess different returns, risks, and correlations with each other and U.S. assets. Their inclusion shifts the efficient frontier upward beyond that resulting when only U.S. stocks and bonds are considered.

TABLE 3 Optimum Portfolios: The 1980s vs. the 1990s

		Asset				Portfolio	
Period	Measure	S&P	International Stocks	Bonds	Cash	Return	Risk
1980s	Weight	15%	47%	34%	4%		
	Returns	18%	22%	12%	9%	17.4%

	Risk	14%	18%	4%	0%		10.5%
1980s portfolio performance in 1990s:						8.9%	10.8%

Source: Deutsche Bank.

The primary distinction between asset selection and asset allocation is that the thought processes differ. In asset selection, a manager focuses on defining the candidate universe broadly. In asset allocation, assets are typically viewed as given and the effort is on forecast accuracy.

A deep knowledge of markets and investment possibilities is necessary to identify the broadest possible asset universe. A manager who incorporates new assets with enticing features has a larger information set than a manager laboring in a narrowly defined world. This is why astute investment managers are constantly searching for new assets—their goal is to gain an edge over competitors by shifting the efficient frontier outward (Figure 4). Neglecting the opportunity to employ an ubiquitous asset domain is a common failure of beginners who rely on black box MV solutions they do not fully understand.

6. NEW ASSET CLASSES

A virtually endless stream of new investment products is paraded forth by financial service companies each year. Although promoted as innovative with superlative benefits, in reality most such creations are often narrowly focused with high risk or are reconfigured and redundant transformations of assets already available. Sorting through the muck and discovering innovative products that shift the efficient frontier outward is not an easy task

6.1. Desirable Asset Characteristics

In general, new assets that effectively shift the efficient frontier outward must possess differential return and risk profiles, and have low correlation with the existing assets in the portfolio. Incorporating an asset that has similar returns and risk and is collinear with an asset already in the portfolio is duplicative. One needs only one of the two.

Differential returns, risk, and correlation are not enough, however. A new asset that has a lower return and significantly higher volatility will not likely enter optimal portfolios even if it has a low correlation with existing assets. In contrast, a new asset with a higher return, lower risk, and modest correlation with existing assets will virtually always enter at least some of the optimal portfolios on the efficient frontier.

In decades past, adding real estate, commodities, and gold to stock and bond portfolios produced the desired advantages. Low returns for these assets in the 1980s and subsequent years led to their eventual purging from most portfolios by the mid-1990s. They were replaced with assets such as international stocks and bonds, emerging market securities, and high-yield debt.

Today, most managers employ multiple equity classes in their portfolios to achieve asset diversification. They usually include U.S. as well as international and emerging market stocks. Some managers split the U.S. equities category into large, midsized, and small capitalization securities, or alternatively into growth and value stocks. Some managers use microcap stocks. The fixed-income assets commonly used include U.S. bonds, international bonds, high-yield debt, and emerging market debt. Some managers further break U.S. bonds into short, medium, and long-duration "buckets." A

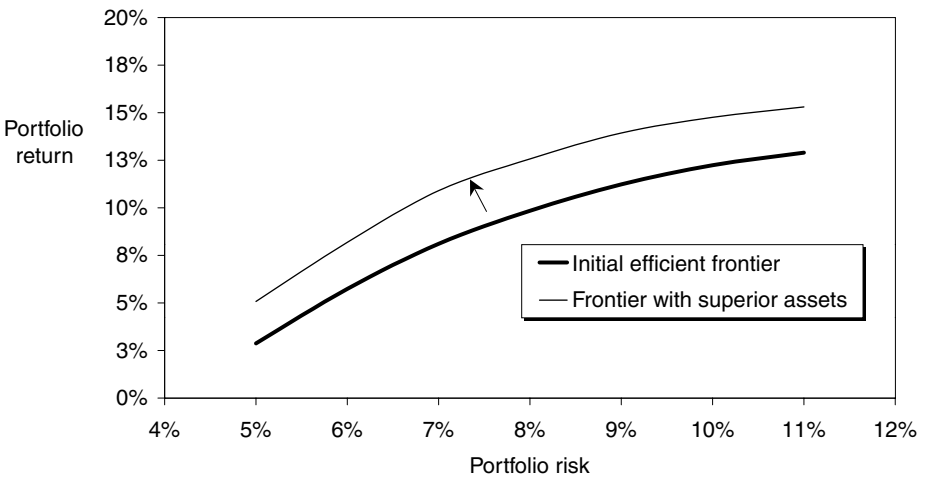

Figure 4 Improving Investment Performance via Asset Selection.

few investment managers retain real estate as an investable asset, while a smaller minority includes commodities as an inflation hedge.

One problem is that the correlation between different equity and fixed income subcategories is fairly high. Thus, the advantages gained from dividing equities and fixed income into components are not that great. In fact, cross-market correlation has increased recently due to globalization. For example, the performance of large, small, and midcap equities, as well as that of international equities, now moves much more in parallel than in the past.

Where are the new opportunities to improve portfolio performance by creatively expanding the investable asset domain? There are several assets that are now increasingly accepted and utilized in portfolios. The most important are hedge funds, private equity, and venture capital. Other new assets have shown the ability to improve portfolio performance but for various reasons have not yet made the leap to widespread recognition. These include inflation-protected securities and insurance-linked products.

6.2. Hedge Funds

Over the last several years, hedge funds have garnered tremendous attention as an attractive addition to classic stock and bond portfolios. A virtual avalanche of published MV studies indicates that hedge funds extend the efficient frontier. Examples include research by Agarwal and Naik (2000), Lamm and Ghaleb-Harter (2000b), Lamm (1999a), Purcell and Crowley (1999), Edwards and Lieu (1999), and Schneeweis and Spurgin (1999). Other work supporting the inclusion of hedge funds in portfolios was done by Tremont Partners and TASS Investment Research (1999), Goldman Sachs and Financial Risk Management (1999), Yago et al. (1999), Schneeweis and Spurgin (1998), and Fung and Hseih (1997). The general conclusions are that substantial hedge fund allocations are appropriate, even for conservative investors.

All of these studies presume that hedge fund exposure is accomplished via broad-based portfolios. That is, like equities, hedge fund investments need to be spread across a variety of managers using different investment strategies. This means at least a dozen or more. Investing in only one hedge fund is an extremely risky proposition, much like investing in only one stock.

The primary advantage of hedge fund portfolios is that they have provided double-digit returns going back to the 1980s with very low risk. Indeed, hedge fund portfolio volatility is close to that of bonds. With much higher returns and low correlation compared with traditional asset classes, they exhibit the necessary characteristics required to enhance overall portfolio performance.

Hedge funds are private partnerships and are less regulated than stocks. For this reason, a strict due diligence process is essential to safeguard against the rare occasion when unscrupulous managers surface. Because most investors cannot or do not want to perform comprehensive evaluations of each hedge fund, funds of hedge funds are increasingly used as implementation vehicles. Large investment banks or financial institutions usually sponsor these funds. They have professional staffs capable of performing a laborious investigative and review process.

Table 4 reproduces the results of a MV optimization by Lamm and Ghaleb-Harter to assess the impact of adding hedge funds to portfolios of traditional assets. Results are given for a conservative range of prospective hedge fund returns varying from 6.5–10.5%. The volatility of the hedge fund portfolio is close to 4%, not much different from history. The assumed correlation with stocks and bonds is 0.3, also close to historical experience. The other assumptions are similar to those presented in the Section 3 example.

The key findings are that (1) hedge funds primarily substitute for bonds and (2) substantial allocations are appropriate for practically all investors, even conservative ones. This is true even if relatively low hedge fund returns are assumed. The conclusion that hedge funds are suitable for conservative investors may be counterintuitive to many readers, who likely perceive hedge funds as very risky investments. However, this result is now strongly supported by MV analysis and occurs primarily because hedge fund managers practice diverse investment strategies that are independent of directional moves in stocks and bonds. These strategies include merger and acquisition arbitrage, yield curve arbitrage, convertible securities arbitrage, and market-neutral strategies in which long positions in equities are offset by short positions.

In response to recent MV studies, there has been a strong inflow of capital into hedge funds. Even some normally risk-averse institutions such as pension funds are now making substantial allocations to hedge funds. Swensen (2000) maintains that a significant allocation to hedge funds as well as other illiquid assets is one of the reasons for substantial outperformance by leading university endowment funds over the last decade.

6.3. Private Equity and Venture Capital

As in the case of hedge funds, managers are increasingly investing in private equity to improve portfolio efficiency. Although there is much less conclusive research on private equity and investing, the recent performance record of such investments is strong.

TABLE 4 Optimum Portfolios with Hedge Funds and Conventional Assets

Hedge Fund Return	Total Portfolio		Allocation					
			Equities		Bonds		Hedge Funds	Cash

Source: Lamm and Ghaleb-Harter 2000b.

There are varying definitions of private equity, but in general it consists of investments made by partnerships in venture capital (VC) leveraged buyout (LBO) and mezzanine finance funds. The investor usually agrees to commit a minimum of at least $1 million and often significantly more. The managing partner then draws against commitments as investment opportunities arise.

In LBO deals, the managing partner aggregates investor funds, borrows additional money, and purchases the stock of publicly traded companies, taking them private. The targeted companies are then restructured by selling off noncore holdings, combined with similar operating units from other companies, and costs reduced. Often existing management is replaced with better-qualified and experienced experts. After several years, the new company is presumably operating more profitably and is sold back to the public. Investors receive the returns on the portfolio of deals completed over the partnership's life.

The major issue with private equity is that the lock-up period is often as long as a decade. There is no liquidity if investors want to exit. Also, because the minimum investment is very high, only high-net-worth individuals and institutions can participate. In addition, investments are often concentrated in only a few deals, so that returns from different LBO funds can vary immensely. Efforts have been made to neutralize the overconcentration issue with institutions offering funds of private equity funds operated by different managing partners.

VC funds are virtually identical in structure to LBO funds except that the partnership invests in start-up companies. These partnerships profit when the start-up firm goes public via an initial public offering (IPO). The partnership often sells its shares during the IPO but may hold longer if the company's prospects are especially bright. VC funds received extraordinary attention in 1999 during the internet stock frenzy. During this period, many VC funds realized incredible returns practically overnight as intense public demand developed for dot-com IPOs and prices were bid up speculatively.

Because LBO and VC funds are illiquid, they are not typically included in MV portfolio optimizations. The reason is primarily time consistency of asset characteristics. That is, the risk associated with LBOs and VC funds is multiyear in nature. It cannot be equated directly with the risk of stocks,

bonds, and hedge funds, for which there is ample liquidity. A less egregious comparison requires multiyear return, risk, and correlation calculations.

6.4. Inflation-Protected Securities

Treasury inflation-protected securities (TIPs) are one of the most innovative financial products to appear in recent years. They pay a real coupon, plus the return on the Consumer Price Index (CPI). Thus, they automatically protect investors 100% against rising inflation, a property no other security possesses. Further, in a rising inflation environment, returns on TIPs are negatively correlated with those of bonds and other assets whose prices tend to decline when inflation rises.

In an MV study of combining TIPs with conventional assets, Lamm (1998a, b) finds that an overweighting in these securities vs. traditional bonds is appropriate only when inflation is expected to rise. He suggests a 50/50 weighting vs. traditional bonds when inflation direction is uncertain and underweighting when inflation is expected to fall.

In years past, some investment managers touted gold, commodities, or real estate as inflation hedges. The availability of TIPs neutralizes arguments made in favor of these ''real'' assets because their correlation with inflation is less than perfect. TIPs provide a direct one-to-one hedge against rising inflation.

Despite the attractive characteristics of TIPs, they have met with limited market acceptance. This is a consequence partly of a lack of awareness but also because TIPs significantly underperformed conventional Treasury securities as inflation declined immediately after their introduction in 1997. However, for the first time in years, inflation is now rising and TIPs have substantially outperformed Treasuries over the last year. This will likely change investor attitudes and lead to greater acceptance of the asset class.

6.5. Other Assets

Another new asset proposed for inclusion in portfolios is insurance-linked products such as catastrophe bonds. These securities were evaluated in MV studies done by Lamm (1998b,1999b). They are issued by insurance companies as a way of protecting against heavy losses that arise as a consequence of hurricanes or earthquakes. The investor receives a large payoff if the specified catastrophe does not occur or a low return if they do. Because payoffs are linked to acts of nature, the correlation of insurance-linked securities with other assets is close to zero. Unfortunately, the market for insurance-linked securities has failed to develop sufficient liquidity to make them broadly accessible to investors.

Another asset occasionally employed by investment managers is currency. While currencies meet liquidity criteria, their expected returns are fairly low. In addition, exposure to foreign stocks and bonds contains implicit currency risk. For this reason, currencies are not widely viewed as a distinct standalone asset. Even managers that do allocate to currencies tend to view positions more as short-term and tactical in nature.

Finally, there are a number of structured derivative products often marketed as new asset classes. Such products are usually perturbations of existing assets. For example, enhanced index products are typically a weighted combination of exposure to a specific equities or bond class, augmented with exposure to a particular hedge fund strategy. Similarly, yield-enhanced cash substitutes with principal guarantee features are composed of zero coupon Treasuries with the residual cash invested in options or other derivatives. Such products are part hedge fund and part primary asset from an allocation perspective and are better viewed as implementation vehicles rather than incorporated explicitly in the asset allocation.

7. THE FORECASTING PROBLEM

Beyond asset selection, the key to successful investment performance via MV asset allocation depends largely on the accuracy of return, risk, and correlation forecasts. These forecasts may be subjective or quantitative. A subjective or purely judgmental approach allows one the luxury of considering any number of factors that can influence returns. The disadvantage of pure judgment is that it is sometimes nebulous, not always easily explained, and may sometimes be theoretically inconsistent with macroeconomic constraints.

Model forecasts are rigorous and explicit. They derive straightforwardly from a particular variable set. Most quantitative approaches to forecasting are based on time series methods, explored in great depth in the finance literature over the years. Beckers (1996) provides a good review of such methods used to forecast returns, while Alexander (1996) surveys risk and correlation forecasting. In addition, Lummer et al. (1994) describe an extrapolative method as a basis for long-term asset allocation. An alternative to pure time series is causal models. For example, Connor (1996) explored macroeconomic factor models to explain equity returns. Lamm (2000) proposes a modified bivariate Garch model as one way of improving MV forecast accuracy.

In the case of a two-asset stock and bond portfolio, the modified Garch model proposed by Lamm is simply:

$$r_{1t} = \varphi_{11} + \varphi_{12} r_{1,t-1} + \Sigma \gamma_k x_{k,t-1} + \varepsilon_{1t} \quad (8)$$

$$r_{2t} = \varphi_{21} + \varphi_{22} r_{2,t-1} + \Sigma \gamma_k x_{k,t-1} + \varepsilon_{2t} \quad (9)$$

$$\sigma^2_{1t} = \alpha_{10} + \alpha_{11} \varepsilon^2_{1,t-1} + \beta_{11} \sigma^2_{1,t-1} \quad (10)$$

$$\sigma^2_{2t} = \alpha_{20} + \alpha_{21} \varepsilon^2_{2,t-1} + \beta_{21} \sigma^2_{2,t-1} \quad (11)$$

$$\sigma_{12t} = \alpha_{30} + \alpha_{31} \varepsilon_{1,t-1} \varepsilon_{2,t-1} + \beta_{31} \sigma_{12,t-1} \quad (12)$$

where r_{it} = the returns on equities and bonds, respectively
σ^2_{it} = the corresponding variances
ε_{it} = residuals
σ_{12t} = the covariance between stocks and bonds
x_k = exogenous factors (e.g., inflation, industrial production, corporate earnings, and interest rates) that determine market returns

The other symbols are estimated parameters. The first two equations predict returns, while the second two forecast associated risk. The correlation between stocks and bonds in any period is simply $\rho = \sigma_{12t} / \sigma_{1t} \sigma_{2t}$, which is derived from the last three equations. This model postulates that when extraneous changes occur that are not reflected in economic variables, the resulting prediction errors push up risk and reduce correlation—exactly the pattern observed in response to market shocks through time.

Lamm reports that augmenting Garch with exogenous variables significantly improves forecast accuracy. These findings have important implications for portfolio management. Critically, augmented Garch provides a more logical and systematic basis for reallocation decisions through the economic cycle (Figure 5) and changing inflation scenarios, which shift efficient frontiers (Figure 6). The augmented Garch process also allows one to distinguish economic influences from purely unexpected shocks, which are often event driven. A pure time series approach provides no such delineation.

If one desires to focus only on return forecasting, a useful approach is vector autoregression (VAR). Although largely atheoretic, except regarding system specification, such models have been shown to have superior predictive capability. In particular, VAR forecasts are more accurate the longer the periodicity of the data. For example, monthly VAR models typically explain 5–10% of the variation in returns, while annual VAR models often explain 90% or more. Quarterly forecasting models produce results in between. VAR models thus provide a reasonably good method for annual asset allocation while providing only a slight edge for monthly allocation.

VAR models are fairly simple and are specified as:

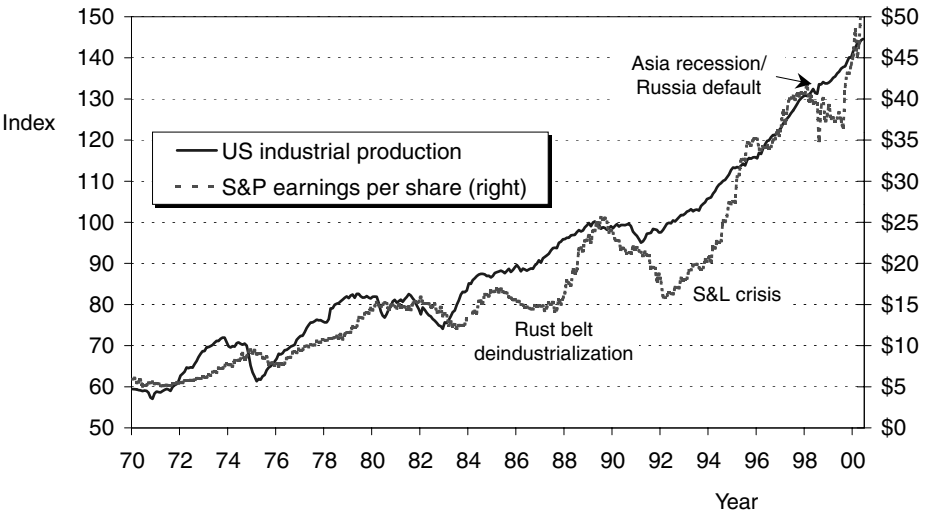

Figure 5 Corporate Earnings and Stock Prices Follow Economic Growth Cycles.

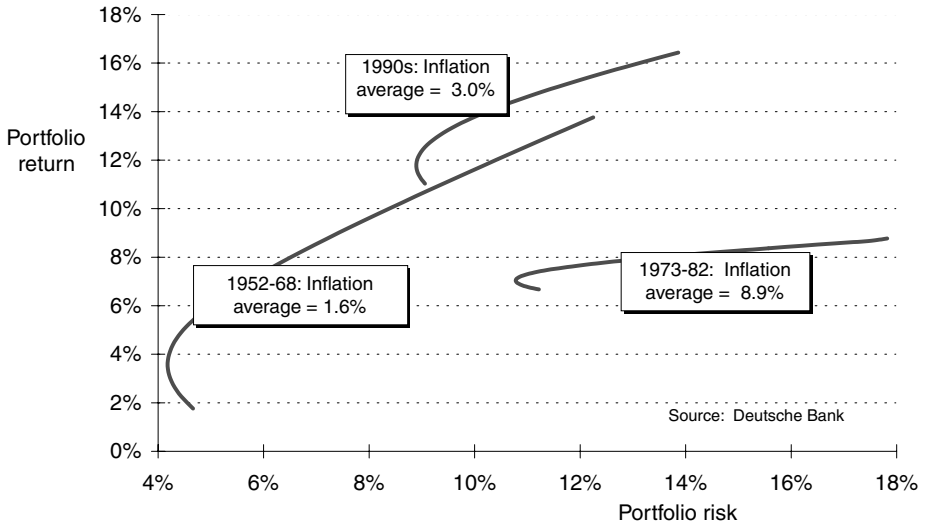

Figure 6 Efficient Frontiers in Different Macroeconomic Environments.

$$\mathbf{y}_t = \mathbf{A}L(\mathbf{y}_{t-1}) + \mathbf{e}_t \tag{13}$$

where $\mathbf{y}_t$ = the vector of system variables (including returns) that are to be predicted
$L(\ldots)$ = the lag operator
$\mathbf{e}_t$ = a vector of errors
$\mathbf{A}$ = the parameter matrix.

If some of the system variables are policy variables (such as Federal Reserve interest rate targets), they can be endogenized for making forecasts and evaluating scenarios. The forecasting system then becomes:

$$\mathbf{z}_{t+1} = \mathbf{B}L(\mathbf{z}_t) + \mathbf{C}L(\mathbf{x}_t) \tag{14}$$

where $\mathbf{z}$ contains the system variables to be forecast from $\mathbf{y} = [\mathbf{z}|\mathbf{x}]^{\mathrm{T}}$
$\mathbf{x}$ contains the expected policy values
$\mathbf{B}$ and $\mathbf{C}$ are the relevant coefficient submatrices contained in $\mathbf{A}$

8. ENGINEERING CLIENT-TAILORED SOLUTIONS: APPLYING PORTFOLIO RESTRICTIONS

The discussion so far has focused on asset allocation as generally applicable to a broad cross-section of investors. In reality, the vast majority of individual investors face special restrictions that limit their flexibility to implement optimal portfolios. For example, many investors hold real estate, concentrated stock holdings, VC or LBO partnerships, restricted stock, or incentive stock options that for various reasons cannot be sold. For these investors, standard MV optimization is still appropriate and they are well advised to target the prescribed optimum portfolio. They should then utilize derivative products such as swaps to achieve a synthetic replication.

Synthetic rebalancing cannot always be done, however. This is likely to be the case for illiquid assets and those with legal covenants limiting transfer. For example, an investor may own a partnership or hold a concentrated stock position in a trust whose position cannot be swapped away. In these situations, MV optimization must be amended to include these assets with their weights restricted to the prescribed levels. The returns, risk, and correlation forecasts for the restricted assets must then be incorporated explicitly in the analysis to take account of their interaction with other assets. The resulting constrained optimum portfolios will comprise a second-best efficient frontier but may not be too far off the unconstrained version.

An interesting problem arises when investors own contingent assets. For example, incentive stock options have no liquid market value if they are not yet exercisable, but they are nonetheless worth

something to the investor. Because banks will not lend against such options and owners cannot realize value until exercise, it can be argued that they should be excluded from asset allocation, at least until the asset can be sold and income received. Proceeds should then be invested consistent with the investor's MV portfolio. An alternative is to probabilistically discount the potential value of the option to the present and include the delta-adjusted stock position in the analysis. To be complete, the analysis must also discount the value of other contingent assets such as income flow after taxes and living expenses.

9. TAXATION

Taxes are largely immaterial for pension funds, foundations, endowments, and offshore investors because of their exempt status. Mean-variance asset allocation can be applied directly for these investors as already described. However, for domestic investors, taxes are a critical issue that must be considered in modeling investment choices.

9.1. Tax-Efficient Optimization

Interest, dividends, and short-term capital gains are taxed at ''ordinary'' income rates in the United States. The combined federal, state, and local marginal tax rate on such income approaches 50% in some jurisdictions. In contrast, long-term capital gains are taxed at a maximum of 20%, which can be postponed until realization upon sale. For this reason, equities are tax advantaged compared with bonds and investments that deliver ordinary income.

In an unadulterated world, MV analysis would simply be applied to after-tax return, risk, and correlations to produce tax-efficient portfolios. Regrettably, tax law is complex and there are a variety of alternative tax structures for holding financial assets. In addition, there are tax-free versions of some instruments such as municipal bonds. Further complicating the analysis is the fact that one must know the split between ordinary income and long-term gains to forecast MV model inputs. This muddles what would otherwise be a fairly straightforward portfolio-allocation problem and requires that tax structure subtleties be built into the MV framework to perform tax-efficient portfolio optimization.

9.2. Alternative Tax Structures

As one might imagine, modeling the features of the tax system is not a trivial exercise. Each structure available to investors possesses its own unique advantages and disadvantages. For example, one can obtain equity exposure in a number of ways. Stocks can be purchased outright and held. Such a ''buy-and-hold'' strategy has the advantage that gains may be realized at the investor's discretion and the lower capital gains rate applied.

Alternatively, investors may obtain equity exposure by purchasing mutual funds. Mutual fund managers tend to trade their portfolios aggressively, realizing substantially more short-term and long-term gains than may be tax efficient. These gains are distributed annually, forcing investors to pay taxes at higher rates and sacrificing some of the benefits of tax deferral. If portfolio trading produces higher returns than a simple buy-and-hold strategy, such turnover may be justified. But this is not necessarily the case.

A third option for equity exposure is to purchase stocks via retirement fund structures using pretax contributions. Tax vehicles such as 401k, IRA, Keogh, and deferred compensation programs fall in this category. The major benefit of this approach is that it allows a larger initial investment to compound. However, upon withdrawal, returns are taxed at ordinary income tax rates.

A fourth alternative for achieving equity exposure is through annuity contracts offered by insurance companies. These are often referred to as wrappers. This structure allows investors to purchase equity mutual funds with after-tax dollars and pay no taxes until distribution. Thus, gains are sheltered. Even so, all income above basis is taxed at ordinary rates upon distribution. Investors receive deferral benefits but lose the advantage of paying lower rates on returns arising from long-term capital gains.

Although I have described four alternative tax vehicles for equity exposure, the same general conclusions apply for other assets. The one difference is that consideration of ordinary vs. capital gains differentials must explicitly be considered for each type of asset. Table 5 summarizes the tax treatment of investment income through currently available tax structures.

9.3. Results of Tax-Efficient MV Optimizations

Another perplexing feature of the tax system is that after-tax returns are affected by the length of the holding period. For example, it is well known that the advantage of owning equities directly increases the longer is the holding period. This is because deferring capital gains produces benefits via tax-free compounding (Figure 7). Similarly, assets in insurance wrappers must be held over very long periods before the positive effects of tax-free compounding offset the potential negatives of converting long-term gains to ordinary tax rates.

TABLE 5 Alternative Tax Structures for Asset Holding

Structure	Annual Flow Taxation: Dividends and Interest	Annual Flow Taxation: Capital Gains	Annual Pre-Tax Return	Annualized After-Tax Return
Direct ownership	Ordinary rates	Deferred	$b_t = d_t + (r_T)^{1/T} - 1$	$\tau d_t + [\kappa(r_T)^{1/T} - 1]$
Mutual fund	Ordinary rates	Paid as gains realized	$f_t = d_t + r_t$	$\tau d_t + [\tau\alpha + \kappa(1 - \alpha)]r_t$
Retirement fund structure	Deferred	Deferred	$s_t = (2 - \tau)f_t$ or $s_t = (2 - \tau)b_t$	$(2 - \tau)\tau(d_t + r_t)$
Wrapper	Deferred	Deferred	$w_t = d_t + r_t$	$\tau(d_t + r_t)$

Source: Lamm and Ghaleb-Harter 2000c.
d_t = dividend return, r_T = gain from period 0 to T equal to $(p_T - p_0)/p_0$; r_t = gain from prior period, τ = one minus ordinary income tax rate, κ = one minus capital gains tax rate, α = percentage of gains that are short term, and T = investment horizon.

When it comes to applying the MV approach to taxable investing, the methodology is the same as that used for tax-free portfolios, except that four different after-tax return streams, risk measures, and four-square correlations are required for each asset. Table 6 compares the pre-tax and after-tax returns for assets typically considered in taxable portfolio allocation studies.

A complete review of after-tax-efficient frontiers would be beyond the scope of this chapter. However, there are four general conclusions. First, a basic conclusion of most after-tax allocation studies is that investors are well advised to hold the maximum possible portion of their investable wealth in tax-deferred vehicles such as 401k programs and deferred compensation plans. The 401k structure is particularly attractive because employers often match employee contributions.

Second, after maximizing contributions to tax-deferred vehicles, investors should utilize buy-and-hold strategies for equities and hold municipal bonds as the appropriate fixed income investment. Third, hedge funds enter most optimal allocations directly even though as much as 75% of the income is taxed at ordinary rates. Optimal allocations to hedge funds are lower than for tax-exempt investors, however. Fourth, for long horizons of at least a decade and more, wrapped assets often enter optimum portfolios, particularly for hedge funds.

Figure 7 The Benefit of Deferring Capital Gains Taxes.

TABLE 6 After-Tax Returns

Asset	Pre-Tax Return	5-Year Horizon Buy/Hold	5-Year Horizon Fund	Wrap	10-Year Horizon Buy/Hold	10-Year Horizon Fund	Wrap	20-Year Horizon Buy/Hold	20-Year Horizon Fund	Wrap
U.S. stocks	11.5%	8.6%	7.8%	5.9%	9.0%	7.8%	6.6%	9.6%	7.8%	7.6%
International stocks	13.1%	9.8%	8.8%	6.9%	10.3%	8.8%	7.8%	11.0%	8.8%	9.1%
U.S. bonds	6.5%	3.5%	3.5%	2.7%	3.5%	3.5%	3.0%	3.5%	3.5%	3.4%
International bonds	7.4%	4.0%	4.0%	3.3%	4.0%	4.0%	3.6%	4.0%	4.0%	4.1%
Muni bonds	5.0%	5.0%	5.0%	5.0%	5.0%	5.0%	5.0%	5.0%	5.0%	5.0%
REITs	8.25%	4.8%	4.8%	4.1%	4.8%	4.8%	4.5%	4.8%	4.8%	5.3%
Hedge funds	10.5%	6.2%	6.2%	5.2%	6.2%	6.2%	5.8%	6.2%	6.2%	6.8%
Cash	5.5%	3.0%	3.0%	2.1%	3.0%	3.0%	2.3%	3.0%	3.0%	2.6%
TE cash	3.2%	3.2%	3.2%	3.2%	3.2%	3.2%	3.2%	3.2%	3.2%	3.2%

Source: Lamm and Ghaleb-Harter 2000c.
Ordinary tax rates are assumed to be 46% (state and federal). Incremental costs of 1% annually are deducted for the wrap structure.

These generalizations presume investors are in the top marginal tax bracket (federal, state, and local) both at the beginning of the horizon and at the end. The extent to which investors move into lower brackets via diminished post-retirement income or by migrating to lower tax jurisdictions make the benefits of deferral even greater.

10. TIME HORIZON

Beyond the taxation issue, a key component of MV problem specification is properly defining the horizon over which the optimization is applied. In particular, risk and correlation can differ significantly, depending on the time frame considered. For example, equities are much less risky over five-year horizons than over one year (Figure 8). This has led some analysts to argue for larger equity allocations for long-term investors because stock risk declines relative to bonds over lengthy horizons.

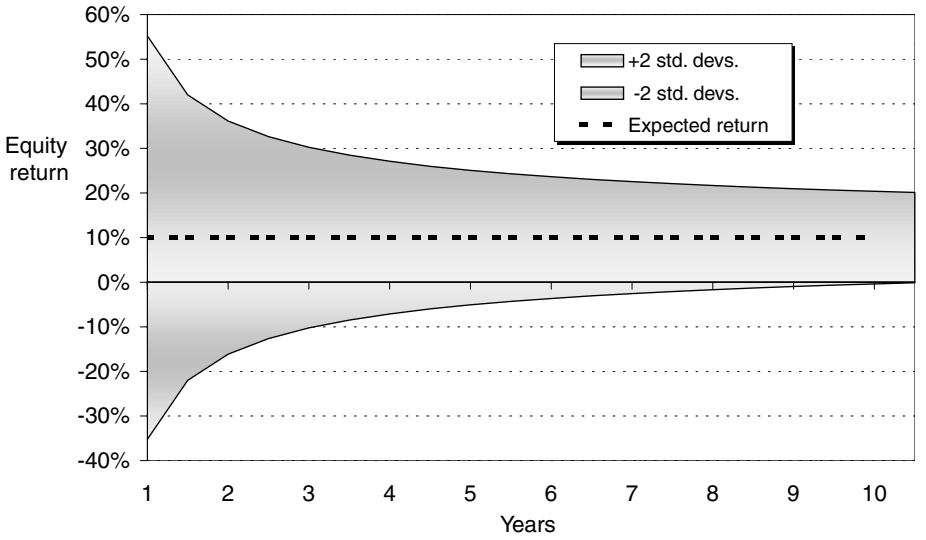

Figure 8 Equity Risk Is Lower over Long Time Horizons.

This issue is especially pertinent if illiquid assets such as private equity are to be included in the portfolio. Using annual volatility for private equity makes no sense—10-year risk must be considered.

In general, the longer the time horizon, the lower the risk for assets that appear to be risky when evaluated based on short-term data. As a consequence, long-horizon investors will allocate more to assets such as stocks and private equity. The reason for this is that annual risk is related to risk over other intervals by the identity $\sigma_a = \sigma_T T^{1/2}$, where T is the periodicity of the data. Note that T = 4, 12, or 52 for quarterly, monthly, and weekly data and T = 1/2, 1/5, or 1/10 for 2-, 5-, and 10-year intervals. Thus, assets with high annual risk have exponentially declining risk over lengthy time intervals. This is why long-horizon portfolios often have relatively small allocations to fixed-income instruments and higher allocations to what are perceived as riskier assets (Figure 9). Some managers go as far as to suggest that a long-horizon investor hold 100% equities if they desire liquidity and the ability to exit portfolios at a time of their choosing.

11. EXTENSIONS AND NEW FRONTIERS

There are numerous extensions of the basic MV model beyond those already described. For example, by dropping the constraint that portfolio weights be positive, the model can be used to ascertain short and long positions that should be held for various assets. Similarly, incorporating borrowing rates allows MV models to be used to design optimal leverageable portfolios. Furthermore, the MV approach can be applied to specific asset classes to build portfolios of individual securities such as equities or bonds. Beyond this, MV analysis has even broader strategic uses. For example, it can be applied by corporations to design portfolios of businesses.

One additional application of MV analysis is to use the technique to reengineer implied market returns. This requires the problem be reformulated to select a set of returns given asset weights, risk, and correlations. The weights are derived from current market capitalizations for equities, bonds, and other assets. The presumption is that today's market values reflect the collective portfolio optimizations of all investors. Thus, the set of returns that minimizes risk is the market's forecast of future expected returns. This information can be compared with the user's own views as a reliability check. If the user's views differ significantly, they may need to be modified. Otherwise the user can establish the portfolio positions reflecting his or her outlook under the premise his or her forecasts are superior.

Other variants of MV optimization have been proposed to address some of its shortcomings. For example, MV analysis presumes normal distributions for asset returns. In actuality, financial asset return distributions sometimes possess "fat tails." Alternative distributions can be used. In addition, the MV definition of risk as the standard deviation of returns is arbitrary. Why not define risk as first- or third-order deviation instead of second? Why not use absolute or downside deviation?

Recently, Duarte (1999) has suggested that value-at-risk approaches be used to derive efficient frontiers. This approach differs from MV analysis in that it uses Monte Carlo simulation to determine the dollar value of the portfolio that is at risk with a particular degree of statistical confidence. That

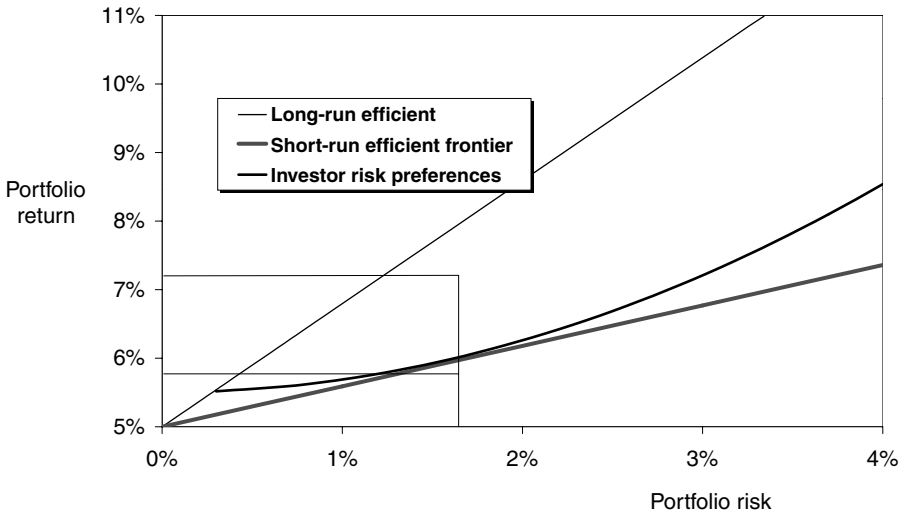

Figure 9 Long-Run vs. Short-Run Time Horizons.

is, a $10 million portfolio might be found to have a value at risk on a specific day of $1.1 million with 95% confidence. This means the value of the portfolio would be expected to fall more than this only 5% of the time. Changing the composition of the portfolio allows a value-at-risk efficient frontier to be traced out.

Duarte also proposes a generalized approach to asset allocation that includes mean semi-variance, mean absolute deviation, MV, and value-at-risk as special cases. While cleverly broad, Duarte's method relies on simulation techniques and is computationally burdensome. In addition, because simulation approaches do not have explicit analytical solutions, the technique loses some of the precision of MV analysis. For example, one can examine solution sensitivities from the second-order conditions of MV problems, but this is not so easy with the simulation. It remains to be seen whether simulation approaches receive widespread acceptance for solving portfolio problems. Nonetheless, simulation techniques offer tremendous potential for future applications.

12. COMBINING MEAN-VARIANCE ANALYSIS WITH OTHER TECHNIQUES—CONSTRUCTING OPTIMAL HEDGE FUND PORTFOLIOS

Because of the difficulty of identifying new assets that shift the efficient frontier upward, some investment managers have taken to creating their own. These assets are often ''bottoms-up'' constructions that in aggregate possess the desired return, risk, and correlation characteristics

In the case of funds of hedge funds, the current industry practice is simply to assemble judgmentally a montage consisting of well-known managers with established track records. Although some effort is expended towards obtaining diversification, a quantitative approach is seldom employed. As a consequence, most portfolios of hedge funds exhibit positive correlation with other asset classes such as stocks. This became obvious in 1998 when many hedge fund portfolios produced negative performance at the same time equity prices fell following the Russian debt default.

Lamm and Ghaleb-Harter (2000a) have proposed a methodology for constructing portfolios of hedge funds that have zero correlation with other asset classes. Their approach brings more rigor to the design of hedge fund portfolios by using an MV optimization format under the constraint that aggregate correlation with traditional assets is zero.

The steps in this process are as follows. First, hedge fund returns are decomposed into two components using a reformulation of Sharpe's (1992) style analysis. Specifically:

$$h_j = \alpha_j + \Sigma\beta_{jk} r_k \qquad j = 1, \ldots, J;\ k = 1, \ldots, K \tag{15}$$

where h_j = the return for the jth hedge fund in a portfolio of J funds
α_j = the skill performance of the fund
β_{jk} = the exposure of the fund to the kth ''traditional'' asset class
r_k = the traditional asset return

Time subscripts, which apply to h_j and r_k, are dropped.

Equation (15) can be written more simply as:

$$\mathbf{h} = \mathbf{a} + \mathbf{Br} \tag{16}$$

where $\mathbf{h} = [h_1\ h_2 \ldots h_J]^{\mathrm{T}}$
$\mathbf{a} = [\alpha_1\ \alpha_2 \ldots \alpha_J]^{\mathrm{T}}$
$\mathbf{r} = [r_1\ r_2 \ldots r_k]^{\mathrm{T}}$

and the asset exposure matrix is:

$$\mathbf{B} = \begin{bmatrix} \beta_{11} & \beta_{12} & \ldots & \beta_{1K} \\ \beta_{21} & \beta_{22} & \ldots & \beta_{2K} \\ \vdots & \vdots & \ldots & \vdots \\ \beta_{J1} & \beta_{J2} & \ldots & \beta_{JK} \end{bmatrix} \tag{17}$$

The return for the hedge fund portfolio is:

$$h = \mathbf{w}^{\mathrm{T}}\mathbf{h} = \mathbf{w}^{\mathrm{T}}(\mathbf{a} + \mathbf{Br}) \tag{18}$$

where $\mathbf{w} = [w_1\ w_2 \ldots w_J]^{\mathrm{T}}$ are the portfolio weights assigned to each hedge fund.

The variance of the hedge fund portfolio is:

$$\sigma = \mathbf{w}^{\mathrm{T}}\mathbf{S}^{\mathrm{T}}\mathbf{RSw} \tag{19}$$

where $\mathbf{S}$ = the risk matrix with diagonal standard deviations $s_1\ s_2\ \ldots\ s_J$
$\mathbf{R}$ = the $J \times J$ hedge fund correlation matrix.

To select the optimum MV hedge fund portfolio that produces the highest return with a target zero beta exposure to other assets, the problem is to:

$$\max\ \mathrm{U}(\mathbf{w}) = (h - \lambda\sigma^2) \quad \text{subject to} \tag{20}$$

$$h = \mathbf{w}^{\mathrm{T}}(\mathbf{a} + \mathbf{Br}) \tag{21}$$

$$\sigma = \mathbf{w}^{\mathrm{T}}\mathbf{S}^{\mathrm{T}}\mathbf{RSw} \tag{22}$$

$$\text{colsum } \mathbf{w}^{\mathrm{T}}\mathbf{B} = \mathbf{0} \tag{23}$$

$$\text{colsum } \mathbf{w} = 1 \tag{24}$$

$$w_j \geq 0 \tag{25}$$

$$w_j \leq 1/n \tag{26}$$

where $1/n$ = the maximum weight allowed for any hedge fund
λ = the risk aversion parameter.

This is the same as the standard MV model except the portfolio return takes a more complex form (21) and an additional constraint (23) is added that forces net exposure to traditional assets to zero. Also, constraint (26) forces sufficient diversification in the number of hedge funds.

Obtaining a feasible solution for this problem requires a diverse range of beta exposures across the set of hedge funds considered for inclusion. For example, if all equity betas for admissible hedge funds are greater than zero, a feasible solution is impossible to attain. Fortunately, this problem is alleviated by the availability of hundreds of hedge funds in which to invest.

A significant amount of additional information is required to solve this problem compared to that needed for most MV optimizations. Not only are individual hedge fund returns, risk, and correlations necessary, but returns must also be decomposed into skill and style components. This requires a series of regressions that link each hedge fund's return to those of traditional assets. If 200 hedge funds are candidates, then the same number of regressions is necessary to estimate the α and β parameters.

Table 7 presents optimum hedge fund portfolios that maximize returns for given risk levels while constraining beta exposure to traditional assets to zero. The optimization results are shown for (1) no constraints; (2) restricting net portfolio beta exposure to traditional assets to zero; (3) restricting the weight on any hedge fund to a maximum of 10% to assure adequate diversification; and (4) imposing the maximum weight constraint and the requirement that net beta exposure equals zero. Alternatives are derived for hedge fund portfolios with 3% and 4% risk.

Adding more constraints shifts the hedge fund efficient frontier backward as one progressively tightens restrictions. For example, with total portfolio risk set at 3%, hedge fund portfolio returns fall from 27.4% to 24.4% when zero beta exposure to traditional assets is required. Returns decline to 23.0% when hedge fund weights are restricted to no more than 10%. And returns decrease to 20.4% when net beta exposure is forced to zero and hedge fund weights can be no more than 10%.

13. CONCLUSION

This chapter has presented a brief introduction to asset management, focusing on primary applications. The basic analytical tool for portfolio analysis has been and remains MV analysis and variants of the technique. Mean-variance analysis is intellectually deep, has an intuitive theoretical foundation, and is mathematically efficient. Virtually all asset-management problems are solved using the approach or modified versions of it.

The MV methodology is not without shortcomings. It must be used cautiously with great care paid to problem formulation. The optimum portfolios it produces are only as good as the forecasts used in their derivation and the asset universe from which the solutions are derived. Mean-variance analysis without a concerted effort directed to forecasting and asset selection is not likely to add significant value to the quality of portfolio decisions and may even produce worse results than would otherwise be the case.

While MV analysis still represents the current paradigm, other approaches to portfolio optimization exist and may eventually displace it. Value-at-risk simulation methodologies may ultimately prove more than tangential. Even so, for many practitioners there is still a long way to go before forecasting techniques, asset identification, and time horizon considerations are satisfactorily inte-

grated with core MV applications. Greater rewards are likely to come from efforts in this direction rather than from devising new methodologies that will also require accurate forecasting and asset selection in order to be successful.

CHAPTER 29

Industrial Engineering Applications in Retailing

Edited by Gavriel Salvendy

1. HOW BOB GOT HIS BOOK

Bob decides that he needs a copy of Gordon MacKenzie's *Orbiting the Giant Hairball,* published in 1996 by Penguin Books. He gets in his car and drives to the local book superstore. After unsuccessfully searching in the superstore for the book, then someone to ask about the book, Bob gets a Starbucks and goes to the smaller chain bookstore in the nearby mall. As it turns out, this store does not have the book either, but the employee says he thinks they can get it for him—but cannot tell him for sure when. Frustrated with both stores, yet very satisfied with the Starbucks, he drives home.

At home, Bob decides that he will check Amazon.com. Within two clicks, he finds that *Orbiting* can be sent within 24 hours and at 30% off the price at the superstore. Bob also sees that it has a five-star rating and is one of the most popular purchases at Nike and Ernst & Young (not bad company, he thinks). Finally, he reads a review from a reader that says the following, ''Here is the passage that was on his funeral leaflet (it seems that Mr. McKenzie has recently died): 'You have a masterpiece inside you, too, you know. One unlike any that has ever been created, or ever will be. And remember: If you go to your grave without painting your masterpiece, it will not get painted. No one else can paint it. Only you.' '' Taken by this statement, Bob decides the book may be better than he heard and orders five copies (one to keep and four to give away). He clicks and within 30 minutes receives an e-mail notification that the order was received. The next day he receives an e-mail notification that the order was shipped. In three days, he receives the package from Amazon. That night he reads the book, finds it to be a great book on leadership, and orders 20 more from Amazon to give out as Christmas gifts. Thinking about the experience, Bob concludes that there may be no reason to ever go to a book store again (except for the Starbucks).

Superstore bookstores stock many single copies of books that sell infrequently and multiple copies of books that sell quickly. They have a sophisticated sales/inventory system so books can be replaced rather quickly from regional distribution centers. Each of the superstores has 130,000 different books, about 10 checkout lines, and a staff of about 20 working in the stores at any one time. When Bob went to purchase *Orbiting* and it was not there, there was no system or person who was able to tell Bob if they could get it to him in a reasonable amount of time. It seems that this superstore doesn't care that Bob did not get his book. These stores are profitable carrying a large inventory with many popular books. The lifetime value of Bob's business does not seem to be important to them.

When Bob goes to Amazon.com, he is welcomed as a regular client and asked if he wants to see some recommendations. (Most of the time he clicks ''yes'' and purchases a book or two he had not heard of, maybe a new book from an author he likes, and maybe a CD that he did not know about.) This time he simply typed in the name of the book he wanted and clicked on a button at the bottom of the page that tells Amazon.com how Bob wants to pay for the book and where to ship it based upon his previous orders. Amazon then assigned the order to one of its seven U.S. distribution centers (five have opened in 1999—Amazon has 3 million square feet of floor space) that had the book. A red light on a shelf where the book was stored automatically goes off. Workers move from bulb to bulb, retrieving the items ordered then pressing a button to turn off the light. Computers determine which rows the workers go to. Bob's order is placed in a moving crate that contains any number of orders. The crate moves along at 2.9 ft per sec through 10 miles of conveyor. Machines and workers (all of whom get Amazon stock options by the way) scan the bar codes on the items at least 15 times. At the end of the trail, the bar-coded books get matched with the orders. Bob's book goes down a three-foot chute to a box with a bar code that identifies the order. The box is packed, weighed, and labeled before leaving the warehouse in a truck. One of Amazon's newest facilities, in McDonough, Georgia, can ship as many as 200,000 boxes a day. One to seven days later, Bob is another one of over 13 million customers satisfied with Amazon.

The moral of the story—Bob really didn't care if the companies cared or what they had to go through to get the book to him. HE JUST WANTED THE BOOK.

2. INTRODUCTION TO RETAIL LOGISTICS

If your business has all the time in the world, no sales or profit pressures, and a strong competitive advantage in the marketplace, then you do not have to be concerned about the efficiency and effectiveness of your supply chain management. This is not the world of retailing, where margins are thin and competition plentiful (and aggressive).

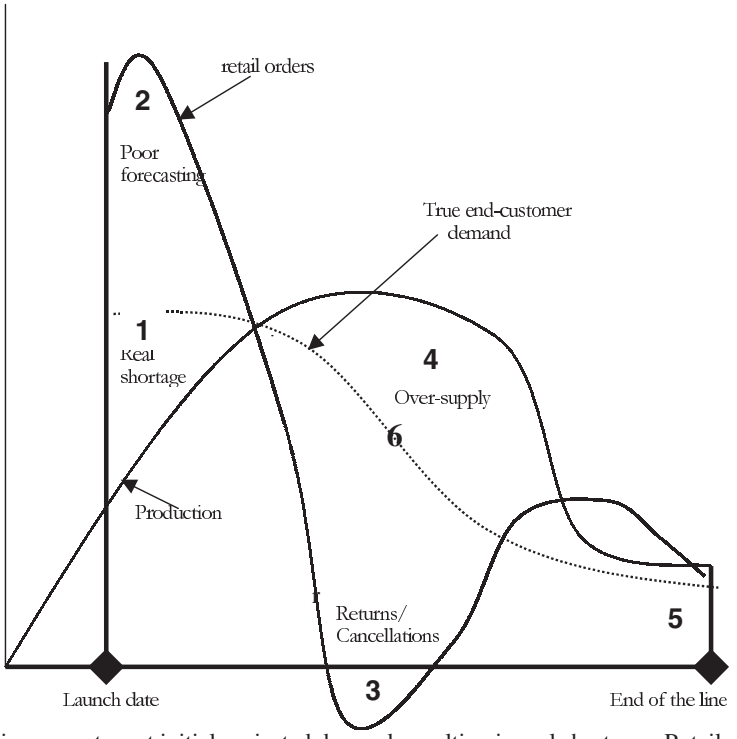
2.1. The Retail Supply Chain

By and large, consumers don't know (or really care) how the product made it to the retail shelf (or to their door). They do care that retailers have the right products, in the right sizes, in the right colors, at the right prices, where and when they want it. The business challenge for retailers is to manage the thousands of paths that exist between raw material to putting the product on the shelf, from the small one-store operation to the 2600+ store chain Wal-Mart.

The retailer's role is to manage these complex relationships and make it possible for the consumer to make a choice easily among the many thousands of vendors and manufacturers creating products that consumers would want. By reducing the complexity of finding and acquiring the right merchandise, retailers help deliver something of value to the consumer. The goal of the retail supply chain should be to minimize expense and time between the manufacturer and the consumer so that consumers find what they want at a competitive price. Customer relationships are only developed by designing product paths that deliver what the customer wants, when they want it, at the price they want it. This is what shareholders pay the executives to do. Executives who do not marshal the supply chain well will have a business that will underperform (see Figure 1).

2.2. Strategic Advantages through Retail Supply Chain Management

Today an executive whose goal is not lowering costs is not shepherding the resources of the company well. Procurement, distribution, and storing accounts for about 55% of all costs. By contrast, labor



1. Production cannot meet initial projected demand, resulting in real shortages. Retailers frustrated because they cannot get the merchandise they want. Consumers dissatisfied because they cannot find what they want.
2. Retailers overorder in an attempt to meet demand and stock their shelves. Retailers are angry at manufacturer and lose confidence.
3. As supply catches up with demand, orders are cancelled or returned. Retailers lose money and lose customers.
4. Financial and production planning are not aligned with real demand; therefore production continues. Overproduction means manufacturers lose money.
5. As demand declines, all parties attempt to drain inventory to prevent writedown
6. Supply and demand match closely. Everyone maximizes profit.

Figure 1 Supply–Demand Misalignment. (From J. Gattorna, Ed., *Strategic Supply Chain Alignment: Best Practice in Supply Chain Management.* Reprinted by permission of the publisher, Gower Publishing, UK.)

accounts for 6%. Thus, leveraging cost savings on supply chain issues creates a greater return than almost any other single category. A 5% savings in supply chain expense adds almost 3% to net profits (a 5% labor savings adds less than 0.3%). To achieve the bottom-line impact of a 5% supply chain saving, you would have to cut personnel costs by 46%. According to a study by Computer Sciences Corporation and *Consumer Goods Manufacturer Magazine,* almost 75% of executives responding to their survey said that reducing supply chain costs was one of the most significant market forces driving their companies and that integrating systems with their customers (e.g., retailers) was a top information system concern (57%) (see Figure 2).

How could such a large area be almost invisible? Quite simply, lack of interest, knowledge, and the clear priorities of sales and marketing drive it into invisibility. The issues in the supply chain seem almost coincidental to the business. It is clear that many senior executives don't quite understand the nature, scope, and bottom-line impact of their supply chain.

But the issue is not simply cost savings. The real benefits of supply chain management come when the retailer develops relationships with suppliers that add value for customers. Wal-Mart is the number one retailer in the world—$160 billion in sales in 1999. Its advantage in the marketplace is based on its ability to give customers what they want at the lowest price every day. The reason for its success is not really its outstanding customer service (although customer service doesn't hurt). The reason is that it manages it supply chain better than any other retailer does. Wal-Mart dictates to vendors the manner and costs by which goods will be delivered to its distribution centers and stores. Wal-Mart's ability to track and know what consumers buy, and its control over the process, result in over 50% of all Wal-Mart products on the shelves and out the door before it has to pay for them. Its efforts to increase this to 100% of all products sold will lead Wal-Mart's dominance into the 21st century. Wal-Mart's ability to manage its supply chain allows it to have the lowest cost structure in the industry, allowing lower prices and maximizing profitability.

2.3. What Is Supply Chain Management?

Supply chain management goes beyond mere transportation, logistics, warehousing, and distribution. It is a relationship among manufacturers, suppliers, vendors, retailers, and customers working together to provide a product that the customer wants at a price that the customer is willing to pay. The "extended enterprise" makes optimal use of shared resources to achieve greater operating efficiency than any could achieve alone. The resulting product is the highest quality, lowest cost, fastest delivery, and maximal customer satisfaction.

The best retailers are focusing on the complete supply chain, developing and maximizing whatever partnerships can exist to get what customers want, before they know they want it (Kuglin 1998). The new terms going into the 2000s are *quick response, category management, continuous replenishment,*

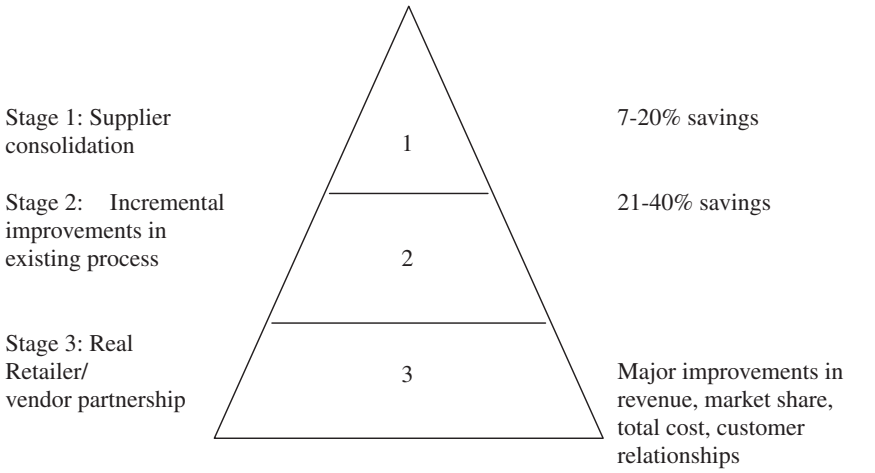


Figure 2 Supply Management Benefits. (Adapted from *The Executive's Guide to Supply Chain Management Strategies,* Copyright © 1998 David Riggs and Sharon Robbins. supply chain partnerships, efficient consumer response, flow-through merchandising (*cross-docking*), and *enterprise resource planning.*

2.4. A Short History of Supply Chain Management

In the beginning, it was sufficient for the owner/proprietor simply to order the products he or she thought the customer would want, and these would be delivered to the store. As business got more complex (and larger), the need arose for a division of labor in which a separate expert department/function was born for the major areas of the business. One part of the organization and set of people was empowered to order, track, plan, negotiate, and develop contacts. The greater the size of the retailer, the greater the number of buying functions—accessories, socks, underwear, coats sportswear, petites, men's wear, furnishings. Each department worthy of its name had an "expert" buyer and assistant buyer. Each buyer reported to a divisional merchandise manager (DMM). Each DMM reported to a general merchandise manager (GMM), and the GMM reported to a senior vice president.

Small retailers have direct store deliveries from the manufacturer or middleman. Larger retailers have centralization of storing, transporting, and distributing from regional distribution facilities (distribution). Technology development over the past 15 years has focused on more efficient and faster ways to get "stuff" into the regional distribution facilities and out to the stores or end user. Success was measured in the number of days or hours it took merchandise to hit the distribution center from the manufacturer or supplier and go out the distribution door. The end result of these developments is the situation today (Fernie 1990; Riggs and Robbins 1998):

- Many small transactions and high transaction costs
- Multiple suppliers delivering similar goods with the same specification but little price competition
- Very low levels of leveraging purchasing or achieving economies of scale
- Too many experts and executives focusing time and effort on very narrow areas that frequently have nothing to do with the core competency of the business, essentially wasting time that could be otherwise be devoted to improving the business's competitive advantage
- Little time for strategy because the experts are involved in daily transactions

2.5. The Current State of Supply Chain Management

We have seen what was. Now here is what some retailers have achieved. Expected demand for a product is forecasted (forecasts can be updated as changes in demand reflect change is needed). Stock levels are constantly monitored. The frequency of production and shipment is based on the difference between demand and on-hand goods. When stock falls below some number, the product is ordered by electronic data interchange (EDI). There is immediate electronic acknowledgment with a promised delivery date and mode of shipping. The mode will be automatically selected by comparing the current level of inventory and demand. When the product is shipped, it is bar coded and a packing skip is EDIed to the company. When the products arrive, bar codes are matched to the order. Any discrepancies are handled electronically. The product is cross-shipped, inventoried, picked, and entered into the purchaser's inventory electronically and is immediately available. Store shipment goes out according to store inventory levels and cost considerations.

There are a number of state-of-the-art processes and technologies at work here. Forecasting and monitoring is used to minimize inventory levels while maintaining very high levels of in-stock positions for the consumer. Money is saved by reducing the inventory at each distribution center. Inventory can be assessed at any of the distribution centers. Almost all handling and clerical labor is eliminated and greater accuracy is achieved. Lower handling costs per unit translate into savings and efficiency. Finally, if you don't have excessive inventory in the stores, it may be possible to raise the percentage of goods sold prior to the need to pay for them. This reduction of cash to cash cycle time is a major benefit of supply chain management.

3. RETAIL SUPPLY CHAIN COMPONENTS

Retail supply chains are different than other industry models. Many of the components of the supply chain are the same: product sourcing, inbound transportation, processing, location and storage of inventory, outbound transportation, company operations, and information. However, retailers are at the end of the chain, just before the products touch the consumer. As a result, the retailer is at the end of the cumulative efficiencies and deficiencies of all the chain partners. It may be that retail supply chains are just a bit more complex. Imagine the thousands of vendors, each with their own ideas and operations, all moving with a thousand different retailers' set of unique requirements and multiply this by the 90,000+ different stock keeping units (SKUs) in the typical large discount store.

3.1. Product Selection and Sourcing

Retailers must establish competence in selecting products that consumers want. The retailer must discern the needs and wants of its consumers and translate that into category assortments. Sourcing describes the manner in which the retailer forms relationships with manufacturers or vendors in order to deliver the products at the right time. Guess wrong and the retailer suffers a season of lower sales and profitability (e.g., short skirts when long is in). Guess right and the retailer becomes a hero.

Retailers have two broad choices as they strategize sourcing. With branded merchandise, the retailer selects manufacturers who have established some image equity with the consumer. The supply chain is simplified for the retailer, for all it has to do is inform the manufacturer how much and when it wants to get the ''stuff'' to the store. With private-label merchandise, the retailer must manage the whole process, from design to material to manufacturing to shipping, all the way to selling, and advertising the brand equity. Retailers choose to develop private-label merchandise because of the market advantage that this strategy allows. First, there is added profit margin. Retailers can make greater profit margins, even though private label goods are generally priced lower than manufacturer brands. Second, with private labels, retailers have the ability to develop products that are unique in the marketplace because the consumer can get the private label only at that retailer.

3.2. Inbound Transportation

The issues here revolve around getting the merchandise to the retailer's warehouse and distribution centers in the quickest time, minimizing the handling. The faster goods can be at the distribution center, the faster the speed to market.

3.3. Processing of Retail Goods

All products require some type of value-added service to make it ready for the shelf. Ten years ago, retailers received the merchandise in centralized warehouses and the warehouses tagged and priced the products before the products left for the stores. Today, retailers are forcing manufacturers to deliver the items already tagged and priced. Indeed, the greater the ability of the manufacturer to create shelf-ready merchandise, the greater the retailer's ability to develop just-in-time strategies for merchandise replenishment. Manufacturers with the ability to meet country-specific requirements for labeling and presentation will have a better chance of biting off a piece of the global marketplace.

3.4. Warehouse Management Technologies

Warehousing is a critical part of retail success and can add value as a crucial link between supply and demand. The key issues in warehousing are efficient handling, inventory management, product flow, transportation, and delivery.

Let us follow merchandise as it comes into the warehouse. Systems are needed to plan the breakdown of merchandise into manageable orders. Weight, size, and shipping dates need to be scheduled. Dock area management facilitates the loading and unloading of product. There is a need to make certain that products coming in match what was ordered. Discrepancies with merchandise not caught here will cause problems as the merchandise flows through the retail organization. The second significant function of the warehouse system is ''put away'' and replenishment. Inventory that will not be cross-docked has to be stored and available for retrieval. Merchandise that has been stored will need to be found and shipped out to stores that need it. In modern warehouses, this function is highly computerized, with automated picking tools and belts. In less sophisticated facilities, a lot is still done slowly and by hand. Finally, the warehouse system must pack the items and make certain accurate paperwork and order consolidation occur.

Given the complexity of the warehouse, it is easy to see how systems and technologies can be of considerable benefit. An effective warehouse-management system saves labor costs, improves inventory management by reducing inaccuracies, speeds delivery of merchandise to store or consumer, and enhances cross-docking management.

3.5. Distribution

Distribution is the set of activities involved in storing and transporting goods and services. The goal has been to achieve the fastest throughput of merchandise at a distribution center with minimal cost. These efforts are measured by internal standards with very little involvement by manufacturers/vendors and consumers. The service standards are typically set by pursuing efficiencies, not necessarily making sure that consumers have what they want, when and how they want it.

3.6. Outbound Transportation

Moving the correct quantity and type of merchandise to stores or direct to the consumer can create great economies, flexibility, and control. Inefficient transportation can be disastrous. Systems that do

not get the correct merchandise to the proper stores during a selling season or when an advertising campaign is scheduled (e.g., winter goods three weeks after the consumer starts shopping for winter clothing) face very poor sales. The effect is more than simply the store not selling a particular piece of merchandise. Each time the consumer does not find what he or she wants, the customer's chance of shopping at a competitor increases.

The diversity of merchandise and the number of stores create several important challenges for retailers. How do you transport merchandise to reach all the stores efficiently at the lowest cost and time? How do you fill the trucks to maximize space in the trucks? Differences in demand and geographic concerns make empty trucks very expensive.

Every day, merchandise moves into the city from a variety of vendors to a variety of stores. Yet for most stores, full truckloads have not been purchased. Third-party distributors that combine loads from different vendors to different merchants allow economies of scale to develop but nothing like the advantage of a large store that receives and buys full truckloads many times a week. The delivery expense to cost is a significant one for retailers. It cuts into the profit and makes prices for the smaller retailer less competitive.

Getting the goods from point A to point B is neither simple nor pedestrian. Tomorrow's business leaders will see this as part of the seamless experience leading to short lead times and reliable service at the lowest price. It has recently been estimated that the cost of transporting goods is 50% of the total supply chain costs. Significant improvements in the movement of goods have been advanced by improvements in software that aid in planning transportation, vehicle routing and scheduling, delivering tracking and execution, and managing the enterprise.

Cross-docking of merchandise occurs when the delivery of product to the distribution center is put directly into the trucks heading for the stores. For cross-docking to work well, suppliers and retailers must have fully integrated information systems. For example, Federal Express manages the complex task of getting all the component parts to Dell at the same time so that a particular Dell Computer order can be manufactured without Dell having to have inventories on hand.

3.7. Outsourcing

Many retailers make use of third-party logistics in the form of warehouse management, shipment consolidation, information systems, and fleet management. Outsourcing allows a retail management to focus on core competencies of purchasing, merchandising, and selling.

3.8. Storage

Consumers buy merchandise that is available—on the shelf—not merchandise in some backroom storage area. Storage costs money (which must be added to the price that consumers pay). Not every retailer is Wal-Mart, which claims to be able to restock products in any of its 2600+ stores within 24 hours. As a result, Wal-Mart stores can have minimal storage areas and maximal selling areas with shelves that always have the merchandise. Just-in-time, quick response, and vendor-managed inventory hold the promise that less merchandise will have to be stored at the local level because systems will dictate that manufacturers or central storage facilities will fill shelves with product as the product starts to decline. Most retailers must still carry inventory so that they may achieve a responsible level of service for the consumer. As a result, compared to Wal-Mart, they have fewer products to sell, more out-of-stock positions, greater consumer frustration, and greater cost structure because they have more nonproductive space used for storing inventory.

The Internet is increasing the pressure on retailers to have better in-stock positions. The only real sustainable competitive advantage that retailers have right now over the Internet is their ability to get product in consumers' hands immediately. If the consumer cannot find what he or she wants in the stores, and its takes just as long for the store to order the merchandise and get it to the customer, the customer might just take advantage of the Internet. Because information and pricing are more transparent on the Internet, if stores do not have the product, the competitive advantage goes to the Internet. This is assuming that the Internet has the same product available at a lower price. The consumer can use a shopping agent like My Simon (www.mysimon.com) to compare all the prices for a particular product on the Internet and choose the lowest price.

As this chapter was being written (December 1999), Toys "R" Us reported very significant problems in getting Internet orders delivered to consumers. Not only will this impact their bottom line in cancelled orders (all customers who were promised delivery that now could not be met were offered cancellation), but all affected customers received a certificate worth $100 on their next Toys "R" Us purchase. This will cost Toys "R" Us millions of dollars which would have gone directly toward their bottom line. More importantly, we cannot estimate the number of customers who will never go to a Toys "R" Us website again.

Internet retailers understand this, and independent or third-party businesses are offering almost immediate delivery in major metropolitan areas. If this is successful, Internet retailers will be removing one of the only barriers and will be competing head-on with store retailers. This suggests

large multibrand/manufacturer warehousing in central urban locations with technology and systems to support it.

Storage is also a major issue for Internet retailers. While Internet retailers have a competitive financial advantage because they do not have to support stores on their balance sheets, they still have to maintain extensive storage and distribution facilities. Their efficiency in building and maintaining and efficiently running these massive facilities will actually determine their success to a greater extent than any other single factor.

3.8.1. Inventory Management

The goal of managing inventory is to have what customers want in the right styles, colors, and prices, while holding costs down. The cost of maintaining inventory is from 25% to 40% of the value of the inventory. Too much inventory and you are not profitable. Not enough inventory and you miss sales and increase the likelihood that consumers will shop in other places. Money tied up in inventory that is not selling takes up money that could be profitably invested in inventory that would be selling. Because of inefficiencies in the supply chain, retailers often have more products in inventory than required by demand.

Vendor-managed inventory (VMI) means that the retailer shifts to the manufacturer the role of counting and replenishing dwindling stocks. Many vendors believe that this is simply an effort by retailers to reduce retailer costs by making the vendor pick up the tab for work the retailer used to do. VMI is most common in large mass merchandisers and in grocery stores. VMI helps reduce stock outs, a benefit to the vendor because when the item is out, consumers may try and switch to a competing brand.

3.8.2. Store Operations

Merchandise is not cost neutral when it arrives in the stores. The expense associated with unloading, unpacking, and storing the merchandise is considerable. Retailers have aggressively tried to minimize the amount of effort required once the merchandise enters the back room. Five years ago, it was common for central distribution facilities to receive the merchandise, unpack it, tag or bar code it, repack it, and ship to stores. Larger retailers have tried to shift many of these functions back up the supply chain to the manufacturer and demand that merchandise be priced, tagged, and packed for individual stores. However, not all suppliers are advanced enough to accomplish these simple tasks. For example, 20% of Saks' 12,000 suppliers are unable to accomplish these back room functions. In about 25% of these cases, the ability of Saks' to process products is hindered.

Retailers also have costs and problems of matching supply to demand across the chain. Adherence to a customer-satisfaction goal may require retailers to ship merchandise from store to store to meet different demands. This reshipping is quite expensive and inefficient. Systems and technologies that better predict what is needed, when, in what size and color, and in what quantity is essential for progress on this issue.

3.8.3 Customer Support Logistics

This refers to the support of customer service operations. Services that require logistical foundations include service parts management (parts shipment and inventories), service management (equipment, technology, scheduling involved in servicing and repairing products), and customer contact management (problem resolution, contact management, training). For example, a large Japanese consumer electronics company believed its products to be of superior quality. As a result, they saw no need to inventory parts in the United States. When product repairs were needed, they had to ship the required parts to the United States. Not only was this expensive, but consumer satisfaction was low with the repair process and the electronics manufacturer. The low satisfaction had an impact on repurchase of the product in that product category and other product categories carrying that brand name.

4. STRATEGIC OBJECTIVES FOR RETAIL SUPPLY CHAIN MANAGEMENT

4.1. Improved Forecasting Ability

Collaborative forecasting and replenishment is the term used to represent the joint partnership between retailers and vendors/manufacturers to exchange information and synchronize the demand and supply. With improved forecasting, the amount of material and inventory that vendors, manufacturers, and retailers have to have in hand is reduced. Most forecasting, if it is done (much more likely in larger retails), is done separately. It is only within the past five years that retailers have discovered the value or implemented any joint forecasting partnerships (e.g., Procter & Gamble and Wal-Mart. P&G maintains an office in Bentonville, Arkansas, where Wal-Mart world headquarters is located, to serve this important partnership).

Supply chain management advances rest firmly on the flow of information. Overwhelming paper flow, separate computer systems and databases, and nonnetworked computer systems are unacceptable in the supply chain era. Linking computers on a single platform of information with fast access to all information needed to make decisions fosters enterprise-wide solutions that make up supply chain management.

The success of the Procter & Gamble/Wal-Mart relationship has been looked to as the model for what will be happening in retailing over the next 10 years. It has also served as the model that P&G will be using with its business partners to grow and prosper. Since supply chain management procedures were implemented, market share for P&G went from 24.5% in 1992 to 28% in 1997, while net margin increased from 6.4% to 9.5% (Drayer 1999).

Typically it is the retailer that develops a forecast and hands it to the vendor/manufacturer. Trusting mutually beneficial relationships are not the operational reality between retailers and vendors/manufacturers (see Figure 3). Even greater efficiency will be achieved when multiple retailers in a geographic region combine their information seamlessly with multiple vendors/manufacturers to allow the most efficient delivery and manufacturing of product. Why should Procter & Gamble plan and ship with Wal-Mart, then do it again with Target, with K-Mart, and with the hundreds of smaller retailers in the area, when if they did it together, the costs would be lower for all?

4.2. Faster and More Accurate Replenishment

Direct product replenishment offers to increase the efficiency and effectiveness of retail operations. According to a Coopers & Lybrand study (1996), direct replenishment improves retail operations by allowing:

- Integration of suppliers with mission and function of store
- More reliable operations
- Synchronized production with need
- Cross-docking and associated savings and efficiencies
- Continuous replenishment and fewer out-of-stock positions
- Automated store ordering and more attention and money available for more important areas of the business

Retailers would need fewer people to be experts in a product area. Fewer mistakes would be made. Markdowns (need to sell inventory that did not or would not sell) would be minimized making margin enhancement possible. Goods would reach the consumer faster. Less inventory storage would be needed. There would be lower distribution expenses since much of the inventory would be stored at the manufacturer until needed.

Since inventory is a retailer's number one asset, making that asset more productive feeds the bottom line directly. Continuous and time-minimal replenishment schemes are easier with basic everyday items that move through the store quickly. Grocery stores have widely implemented electronic data system techniques to maximize the efficient replenishment of fast-moving merchandise.

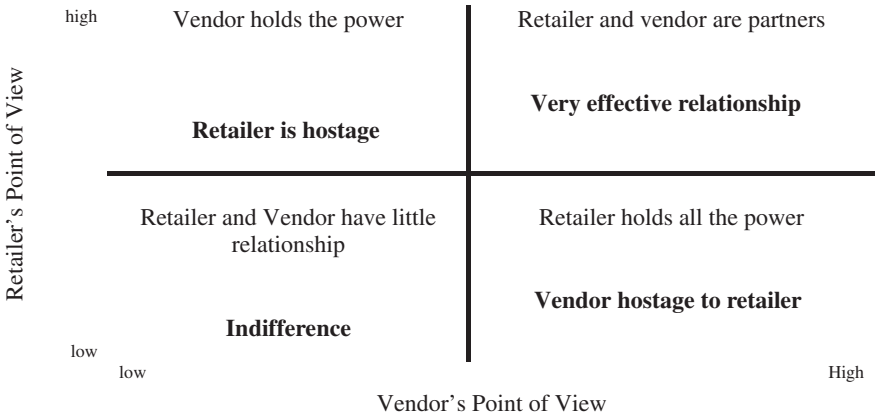

Figure 3 Retailer/Vendor Affairs in the Retail Supply Chain.

Other retailers are just beginning to learn how to use point-of-sale information to minimize quantities of merchandise stored (needed to buffer poor forecasting and slow replenishment). Ernst & Young estimates that savings in inventory management would give the economy a $35 billion boost.

4.3. Flexible Channel Capability

The emerging e-commerce pressures are forcing retailers to build supply chain flexibility. Getting merchandise to the consumer outside of the store chain while maintaining the stores (frequently called a clicks-and-mortar strategy) forces retailers to understand how to deliver items directly to the consumer as well as to the consumer from the stores. Federated Department Stores (parent company of such retailers as Macy's and Bloomingdales) realized the different nature of e-commerce and purchased one of the better mail-order fulfillment houses (Fingerhut) to build the expertise for their emerging e-commerce initiatives. Retailers who have the flexibility to provide multiple access points (stores, catalog, Internet) will be better positioned for success than solely store-based or Internet-based retailers. Petsmart will deliver Internet-ordered goods from their local stores. They have an Internet distribution system built into their already vast network of stores.

5. THE EMERGING PARADIGM FOR RETAIL SUPPLY CHAINS

Up to this point, retail supply chains have largely generated greater profit margins through driving out inefficiencies. For example, retailers have pushed the function of maintaining an inventory back onto the vendor or middleman. Vendors, in turn, have required lower prices and faster deliveries from their suppliers. This type of approach has been effective, but for many supply chains there is precious little fat still left to cut out of the system. To reach the next level of efficiency, productivity, and profitability, a new perspective on what retail competition means will have to be adopted.

5.1. Relationships/Alliances/Partnerships

Perhaps the factor that will have the greatest impact on supply chain management issues is not a technology or a system but a way of thinking. The gap between winning and losing retail organizations in the last decade was defined by their ability to manage the supply chain better than the competition: squeaking out margins and profits from cost savings and efficiencies in the supply chain. The winners in the 21st century will be those retailers who structure, organize, coordinate, and manage partnerships between manufacturers and stores to meet better, faster, and more closely the needs of the consumer. A survey of U.S. companies by Forrester Research shows that 50% of companies share inventory data with supply chain partners. Only 30% share demand histories and forecasts. It is this latter category that holds the greatest promise for all chain partners . . . and U.S. business has a long way to go.

The commoditization of products and services dictates that the real competition will come from organizations that will compete as configurations of partnerships. These partnerships allow greater probabilities of stores having the right item, at the right price, in the right size, in the right color, JUST before the customer wants it. Moreover, supply chain partnerships mean that retailers can spend less of their time and effort in accomplishing this portion of their operation, freeing time, energy, people, and financial resources for developing and maintaining customer relationships. According to Lewis (1995), these partnerships allow:

- Ongoing cost reductions
- Quality improvements
- Faster design cycle times
- Increased operating flexibility
- More value to the customer's customer
- More powerful competitive strategies

A partnership starts with a discussion based on "You are important to us and we are important to you. Now how can we do this better so we can both make more money." To be successful in this new paradigm will require skills that have not been well developed as yet.

5.2. Integrated Forecasting, Planning, and Execution

Multiple forecasts for the same line of business within the organization are common (if any planning is even done). The gap between what is planned and what actually happens represents lost profits and lost opportunities. The new paradigm for retail supply chain management begins with an accurate view of customer demand. That demand drives planning for inventory, production, and distribution within some understood error parameters. Consumers will never be completely predictable. At the same time, prediction is bounded by limitations in our statistical and modeling sciences. We can

predict only as well as our tools allow us. Computer advances will allow easier and affordable management of millions of data points so that demand can be measured. Effective demand management represents an untapped and significant opportunity for most if not all retailers. Effective demand modeling allows greater forecast accuracy, increases supply chain effectiveness, reduces costs, and improves service levels, and all reflect greater profit. The result—lower inventories, higher service levels, better product availability, reduced costs, satisfied customers, and more time available to respond to other areas of the organization.

5.3. Statistical Techniques

Understandable, usable, and affordable software to accommodate millions and millions of individual consumer purchases has only recently become available. But that is only part of the equation. It is still unusual to find company executives who understand the capability and use of these sophisticated software packages. Of equal importance is the need to have a uniform database representing the forecasting target. Typically, different data needed to accomplish accurate forecasting resides in isolated silos of databases that cannot talk to each other.

In addition to decisions regarding the supply chain, these tools would:

- Provide the CEO with an important strategic view of the business
- Provide opportunities for cost savings
- Aid in developing long-range strategic plans
- Assist in resource allocation
- Identify inadequate areas in existing management and operations

5.4. The Role of Senior Management

Logistic, warehouse, and other supply chain management efficiency can result from a piecemeal decision-making process. But true partnerships must flow from a strategic alignment with the mission and values of the organization. Wal-Mart's industry-leading supply chain operation did not result from chance but from Sam Walton's understanding of the business and a strategic view that saw that investments in state-of-the-art technology and systems will pay off handsomely in the future. For most companies, the appointment of a supply chain czar is needed to push supply chain management through the organization.

5.5. Information Technology

No advances in supply chain management can occur without a layer of middleware. Information and its collection, management, availability, and use serve as the foundation for all advances in supply chain management. Sustained success of retailers comes from an understanding of how information technology (IT) creates competitive advantage. Prepackaged enterprise-wide IT solutions are available, but they make it difficult to be different. Unique and strategic IT enterprise-wide solutions are difficult to integrate and implement.

The IT system should allow new and better customer–vendor relations, provide new insights into a company's consumers and markets, maximally exploit efficiencies in the supply chain, transform product development and delivery, increase the capability to make real-time decisions, increase planning ability, manage increasingly complex national and global markets, and eliminate traditional and costly processes.

6. RETAILER OPPORTUNITIES ON THE HORIZON

6.1. The Global Marketplace

The globalization of retailing presents a host of problems and opportunities for retailing. The ability of companies to meet cultural needs, transport goods and services across boundaries (sometimes oceans), while controlling costs and maintaining efficiencies is not clear . . . yet. Some companies may have already met this challenge. Dell Computers' direct-to-customer model is a global reality. Since a Dell computer is manufactured only when it is ordered, it does not matter to Dell if the computer is selected by a consumer sitting in Peoria, Illinois, or Kuala Lumpur, Malaysia. The computers are built and the appropriate shipping is arranged from the closest facility. Trained technicians answer technical and support questions over the phone and can be anywhere in the world (questions are also answered from a central website).

6.2. E-commerce: The Virtual Retailer

Fifty years ago, catalog shopping was deemed the beginning of the end of store retailing, in much the same way that e-commerce is proclaimed to spell the beginning of the end for store retailing

today. Offering products and services directly to the consumer who has money but little time is nothing new. The e-commerce alternative is simply another way for consumers to get what they want, when they want it. The e-commerce alternative is not a threat to the existence of retailing but is a challenge to supply chain management of the store-based retailer.

The promise of direct to consumer retailing is clear—fast, individualized, convenient delivery of what the customer wants. The reality is less clear. Few if any direct to consumer e-commerce initiatives have proven successful . . . yet. The reason is simple. The Internet is an easy way to sell but a lousy way to distribute. Everything purchased on the Internet has a price to which a shipping charge must be added as well as the time to deliver it. The Internet's ability to provide immediate purchase gratification is limited.

It is interesting to note when we review e-commerce discussions that it is as if home delivery were a new concept discovered by these Internet pioneers. In fact, home delivery has been a burgeoning trend in many industries—furniture, appliances, video, Chinese food, pizza, and now the grocery business. A study by Anderson Consulting predicted that delivery can capture 12% of the U.S. grocery business, about $85 billion. But even in this area of e-commerce there is plenty of need for, and money for, the store-based retailer. And it is still not clear whether grocery e-retailers will be able to make a profit in the near future. Peapod is the most successful example of this business model in groceries. The company started in 1989 in a suburb of Chicago, went online in 1990, and now has over 40,000 products available for delivery in eight metropolitan areas. The company delivers what is ordered at a prearranged time. Revenues for 1999 were estimated to be $70 million. However, Peapod has yet to show a profit.

6.2.1. Scope of E-commerce

Toyota is considering a direct electronic channel where customers submit their specifications, as well as financing information, via the Internet (or 800 number). Toyota would respond within the first 24 hours after researching their supply chain and retail distribution with the closest matches and estimated delivery time.

Cisco, Autodesk, Intel, Dell, and Gateway all allow their customers to access inventory and order information from the Internet. They can place and track orders without any human intervention (hence lower costs).

Anderson Windows has supplied point-of-sale kiosks to its retailers. Consumer and retailers design the windows, get order quotes, and place orders at the same time. The system shows customers what they have designed and links the retailers to the supply chain and distributors.

Levi's stores have a minimal inventory, but with a computer model, they measure the consumer at the key design points of their personal fit jeans. The measurements are transmitted to the production facility and a personal pair of jeans is mailed to the consumer within nine days. Consumers are willing to pay slightly more for the perfect pair of jeans. The customer simply cannot buy jeans that fit as well at any other retailer. The customer can now call Levi's from any place in the world and a custom-fit pair of jeans will be shipped.

Grainger is not the business you might think of when you think of an e-business. Since 1927, Grainger has sold industrial supplies (motors, cleaners, lightbulbs) through a 7-lb thick read catalog and 500 stores. It has made a spectacular transition to the Web. Its advertising says it all: "The Red Book [its catalog] has .com of age." They further say, "Our award winning web site (www.grainger.com) carries over 560,000 products online, 24 hours a day, 7 days a week. Our powerful search engine finds exactly what you want. Fast. And you can take advantage of your company's specific pricing." In 1998, its Internet sales were $13.5 million. In 1999, they were $100 million. Only Cisco, Dell, Amazon, and IBM have a larger sales volume. Grainger builds online customized catalogs for the many businesses that negotiate selling prices. When the customer write his or her own order, there are fewer errors made than with placing the order by calling the 800 number. The site tells customers whether the product is in stock at a local store that will deliver it the same day (or overnight) without the overnight shipping fee. The cost of selling a product is a fraction of what the costs are in other areas of Grainger's business, allowing greater discounts and greater profits. To encourage sales, account managers encourage their accounts to order on the Internet, and the salespeople will still get commission on their accounts, even when products are ordered from the website.

One of the biggest problems that retailers face in Internet retailing is the ability of manufacturers to go directly to the consumer. Why pay for a GE microwave from an appliance store on the Web when you can buy it from GEs website (probably for less money). What is particularly interesting about Grainger is that by selling a wide variety of manufactured products, it gives the customer a side-by-side comparison of all available brands when the customer is searching. The customer can buy all the brands he or she wants conveniently and easily instead of having to go to each manufacturer's website and buy separately.

6.2.2. The Internet Mindset

Yes, the Internet will spur many direct-to-consumer businesses. Yes, the Internet will allow existing retailers to expand their markets and provide a new channel for their existing companies. And yes, the Internet will allow retailers to develop efficiencies of time and money with their vendors and manufacturers. But more importantly, the Internet will force retail leaders to develop an Internet frame of mind that will allow challenges to the way business is being done at all levels in all ways. The advances that will come from this change of mindset cannot be predicted but can be expected.

6.3. One to One Marketing

A company's success at individualized product offerings means greater market penetration, greater market share, greater share of the consumer's wallet, and improved satisfaction as customers get exactly what they want instead of settling for what the retailer has. Mass customization/one to one marketing is the real final frontier for retailers. Responsive manufacturing, IT, and efficient replenishment systems allow Levi's to offer the consumer a pair of jeans made to his or her exact specifications.

Here we have a vision of the ultimate supply chain management. Customers have exactly what they want. A long-term relationship is established so that the customer has no reason to desert to a competitor. Because a customer is getting a unique product made just for him or her, a competitor cannot steal that customer simply by offering price inducement. The jeans are not manufactured until they are needed, and a third party delivers the product. The very issues that supply chain management has been concerned with are reduced and eliminated by one to one marketing.

6.4. The Product Comes Back: Reverse Logistics

If the supply chain is relatively invisible, the reverse supply chain (getting back to the manufacturer products that need repair or replacement) is practically ethereal. However, the costs of getting products back through these reverse channels makes process and management issues extremely important to retailers. According to the National Retail Federation, the average return rate from products bought in specialty stores is 10%, and in department stores, 12%. Catalogs have a return rate three times higher. Early indications are that Internet purchases are twice that. Reverse logistics is maximizing the value from returned products and materials.

Frequently, the products/material put into the reverse supply chain can be refurbished or remanufactured. Xerox reports that recovering and remanufacturing saves over $200 million annually, which can then be passed along to customers in lower prices or shareholders in higher earnings and profits. A product returned for repair can either be replaced (and the product broken down and its parts used in other manufacturing) or repaired. Repaired or returned products that cannot be sold as new can be resold, frequently as refurbished, using parts from other returned products. Unfortunately, retailers and manufacturers have made poor use of the strategic information available in returned products to change and improve design. Mostly the repairs are made or the broken product sits in a warehouse. The information about your product and the company sits useless.

A growing area of concern is how to conscientiously dispose of products or their components. Black & Decker avoided significant landfill costs and made money by selling recyclable commodities. When there are no alternatives except disposal, the product or material needs to be appropriately scrapped. In an era of environmental concern (which will continue to grow and drive marketplace decisions), companies should take proactive action to develop environmentally sound landfill or incineration programs. Not only will this allow favorable consumer reactions, but it may forestall government regulation and control.

7. THE FUTURE FOR SUPPLY CHAIN MANAGEMENT

The logic of supply chain management is compelling. Its benefits are well understood. The trend toward supply chain management is clear. Companies are excelling in parts of the equation.

As retailing moves into the 21st century, more retailers will be adopting the following lessons from supply chain management as we see it today:

- Advances in and use of IT to drive supply chain decisions. Large integrated stock-replenishment systems will control the storage and movement of large numbers of different goods into the stores.
- A restructuring of existing distribution facilities and strategic placement and development of new distribution facilities to reduce inventory and move the inventory more efficiently.
- Greater and more effective adoption of quick response. More frequent delivery of less. Greater use of cross-docking so that merchandise hits the docks of the distribution centers and is immediately loaded into destination trucks. EDI and POS electronics will track what is selling and transmit directly to distribution center to plan shipment.

- Greater diffusion of efficient consumer response, defining a process of close collaboration of retailer and manufacturer/supplier to coordinate activities to achieve maximal efficiency and better service levels for the ultimate customer.

7.1. Conclusions

It is easy to see how retailing will need to improve the front-end selling and merchandising function through stores, catalogs, television, and the Internet. What is not so clear to an outsider is that the real difference to retail success and bottom-line earnings and profits will not be in the store or on the Internet but in the middle. The invisible chain between manufacturer and consumer will be where the most significant competitive advantages will take place.

According to Gattorna (1998), the major improvements in the supply chain, over the next 10 years will include:

- Whole industries will rethink their sales and marketing channels, and these new channels to customers will require newly reengineered processes and technologies, in turn demanding significant changes at all levels.
- Leading companies will recognize the close relationship between customer relationship management and the supply chain; taken together, these two will open up new avenues for shaping trading terms from both supplier and reseller/customer perspectives.
- A much more aggressive search for additional organization design options for supply chains in particular industries will eliminate polarized thinking in terms of insourcing or outsourcing, opening the way to new solutions and combinations along this continuum.
- The best supply chains will have fully integrated enterprise systems and indeed will go beyond transactional information and decision-support systems to knowledge management. In turn, this will affect organization design and lead to improved coordination (rather than ''control'').
- Companies looking to embrace supply chain regimes at the global level will require a much better understanding of country cultures as a necessary ingredient for success.
- Strategic sourcing approaches at the supply end, and mass customization approaches at the consumption end, are likely to be fertile areas for relatively quick large-scale benefits.
- Reverse logistics will loom large on the agenda, with issues such as extending product usage life cycles, product-recovery processes, and bidirectional logistics channels coming to the fore in the search for new competitive dimensions.
- Organizations other than product companies will begin to recognize the huge untapped potential that the application of logistics and supply chain principles to their businesses will release, such as telecommunications, utilities, health care, education, entertainment, and financial services.

On the one hand, supply chain management is not hard. Any business can get anything to stores. Any store or e-retailer can get merchandise to consumers. What is hard is achieving an efficiency and effectiveness that maximizes a retailer's competitive advantage in the marketplace. Until we develop the *Star Trek* process of transportation, where we can dematerialize and materialize objects at command (now that's a one to one deliver system of the future), supply chain issues will be a leading-edge practice for the company and the driver for corporate strategy. Collaborative planning forecasting replenishing (CPFR) will be the strategy of the next decade in retailing. The bottom line is, of course, profits and shareholder value (Anderson and Lee 1999; Quinn 1999). Incremental improvements in the supply chain have a greater impact on profits than incremental improvements in other areas. Technology and the Web will be driving the most innovative changes and applications in retail supply chain management in the next 10 years, and this will drive retail performance and excellence.

CHAPTER 30

Industrial Engineering Applications in Transportation

Chryssi Malandraki
David Zaret
Juan R. Perez
Chuck Holland
United Parcel Service

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. OVERVIEW

Transportation and distribution play a critical role in the successful planning and implementation of today's supply chains. Although many view the transportation of goods as a non-value-added activity, effective transportation planning and execution will not only enhance a company's productivity but will also increase customer satisfaction and quality.

In this chapter, we will explore the factors that impact the transportation of goods and the different tools and techniques that the industrial engineer can apply in the development of effective transportation networks and systems to reduce or minimize costs, improve cycle time, and reduce service failures. A similar but inherently different aspect of transportation is that of transporting people. Although this chapter is concerned with the transportation of goods, the industrial engineer also plays an important role in designing these types of systems.

Today's logistics activities are concerned with the movement of goods, funds, and information. Information technology has now become an integral component of any transportation system. Technology is being used for scheduling and creating complex delivery and pickup routes and also for providing customers with up-to-the-minute information on the status of their shipments. The industrial engineer will not only aid in the development of efficient delivery routes and schedules, but will also help in the design of state-of-the-art transportation information systems.

2. INTRODUCTION

Transport is the process of transferring or conveying something from one place to another. Transportation is the process of transporting. The transportation of people, goods, funds, and information plays a key role in any economy, and the industrial engineer can play a key role in properly balancing the parameters and constraints that affect the effectiveness and efficiency of transportation systems.

This chapter will cover certain applications of industrial engineering in transportation. The emphasis is placed on the movement of goods. However, the methodologies described in the chapter can be applied to a variety of transportation problems.

Transportation plays a critical role in today's increasingly small world. Economies, businesses, and personal travel are, in one word, global. Information on the status of the items or persons being moved is as crucial as the movement itself. Confirmation of delivery in a timely, electronic form is often as important as on-time, damage-free, value-priced arrival.

The industrial engineer can apply a variety of mathematical and engineering tools and techniques in the planning and management of effective transportation networks and systems in order to reduce or minimize costs, improve cycle time, reduce service failures, and so on. The industrial engineer plays a critical role in the development of efficient delivery routes, schedules, and plans and also helps in the design and implementation of transportation information systems.

3. TRANSPORTATION AND INDUSTRIAL ENGINEERING

3.1 Transportation as a System

Designing a transportation system means, in most cases, the design of multiple integrated systems—systems to move goods or people, systems to move information about goods or people, and systems

to move funds associated with goods or people. Within each of these three types of systems there may be multiple subsystems.

Today, in the package delivery business, transportation companies offer several types of services in which the primary distinction is the time it takes to move the package from its point of origin to its final destination. Services range from same-day or next-day delivery to multi-week delivery, utilizing different transportation modes such as airplanes, trucks, railcars, boats, and even bicycles. The packages may all originate at the same location (e.g., shipper) going to the same destination, or each package in a shipment may have a different destination. In either case, the transportation systems must be capable of supporting a variety of service offerings, depending on the customer's needs. The success of such systems is measured by the systems' effectiveness in meeting the promised service guarantees.

In air travel, the service offerings vary from first class to coach travel. Dividing the aircraft into separate travel compartments allows multiple systems to utilize the same asset, route, flight crew, and schedule to offer variations in service. Therefore, the air travel industry must also utilize multiple integrated systems when designing the processes to facilitate the movement of people.

Providing information about the goods or people being moved also involves the implementation and use of multiple integrated systems. Many customers today provide information about shipments to the carrier at the time of shipment or earlier. This information is introduced into multiple systems for a variety of uses. The shipper has information about the shipment: its contents, the carrier, the mode of transportation, the expected date of arrival, the value of the shipment, shipping charges, and so on. The carrier and shipper can, through integrated systems, track the status of the shipment as it moves to its final destination. Upon delivery, the carrier can provide proof of delivery proactively or upon request. The receiver can be prealerted of the upcoming shipment, its contents, and the expected date and time of arrival. For international shipments, information can be sent to customs before the item is moved to the customs site. The movement and timely availability of all this information increase the efficiency of the modern supply chain.

As with the movement of goods, people, or information, the transfer of funds makes use of integrated systems. The electronic billing of the carrier's charges to the shipper is integrated with the system providing information about the shipment itself. The payment and transfer of funds to the carrier can be initiated by the pickup or the delivery or through periodic billing cycles. Payments upon delivery for the contents of the shipment can be handled electronically and triggered by the electronic transmission of the signature at delivery.

In designing a transportation system, it is crucial to facilitate the integration of the multiple systems needed for the movement of the goods, people, information, and funds. Industrial engineers are often the catalysts in facilitating such integration.

4. THE PARAMETERS AND FUNCTIONS ASSOCIATED WITH TRANSPORTATION

There are two basic parameters that affect the design of freight transportation processes: the territory to be covered and the frequency with which the transportation events occur. These parameters are not static. Demand (e.g., number of shipments per week or day) fluctuations make these parameters dynamic in nature. Demand in transportation is often seasonal. The Thanksgiving holiday in the United States is one of the highest demand days for air travel. The Saturday prior to Mother's Day usually presents a substantial increase in package delivery volume compared to other Saturdays. Demand can vary by time of day or day of the week. Traffic volume in a major city varies greatly between Monday morning at 7:30 am and Thursday morning at 3:00 am. The transportation system must be designed to handle these variations in demand effectively.

It is important to note that what drives demand in the private freight transportation sector is cost and quality of service. The design (planning), execution, and measurement of the transportation system have an impact on the cost and quality of the transportation process. The better the costs and quality of service, the greater the demand and therefore, the greater the need to alter the service territory and the frequency of service.

Transportation planning, execution, and measurement are the fundamental functions associated with transportation and are integral to the success of the transportation system.

Planning is needed across all areas of the transportation system. Planning the overall distribution network, regional (e.g., certain geography) planning, and site (e.g., local) planning are crucial. Asset planning, including buildings and facilities, vehicles, aircraft, trailers, and materials-handling equipment, is also required. Demand variations drive decisions for asset quantity and capacity. The use of owned vehicles supplemented by leased vehicles during peak (high-demand) times is an example of the decisions that need to be made during the planning process. The impact of demand on scheduling, vehicle routing, and dispatching drives labor and asset needs. Labor can often be the largest component of cost in the transportation industry. The transportation planning activity is charged with developing plans that, while minimizing costs, meet all service requirements.

The execution of the plan is as important as the planning of the transportation process itself. An excellent plan properly executed results in lower costs and higher quality of service. This in turn drives demand and therefore the need for new plans.

Finally, the proper measurement of the effectiveness of the transportation system, in real time, offers a mechanism by which transportation managers, supply chain specialists, and industrial engineers can constantly reduce costs and improve service. With new technologies such as wireless communication, global positioning systems (GPS), and performance-monitoring technology, measurement systems allow the users to improve transportation processes as needed.

5. THE ROLE OF THE INDUSTRIAL ENGINEER IN TRANSPORTATION PLANNING AND TRANSPORTATION OPERATIONS

The role of the industrial engineer in the transportation industry is primarily to aid the organization in providing a high level of service at a competitive price. The industrial engineer has the skills necessary to assist in many areas that impact the effectiveness of the transportation system:

- *Work measurement and methods analysis:* Labor is a large component of the total cost of service in the transportation industry. The pilot, driver, captain, or engineer literally controls the ''container'' of goods or people in transit. The design of effective work methods and the development of the appropriate work measurement offer tools that aid management in the control and execution of transportation processes and provide a mechanism by which the performance of the system can be measured. Methods design and work measurement are often used to develop comprehensive work scheduling and vehicle routing systems aimed at reducing costs and meeting all service commitments.
- *Facility design and location:* The determination of the number of facilities required to move materials and finished goods from one point to another, their capacity, and their location is often considered one of the traditional roles of the industrial engineer. The use of single (e.g., decentralized) vs. regional distribution center locations and the determination of the territory served by a local terminal are part of the transportation system design process. In addition, industrial engineers will often aid in the decision process to determine whether a facility should be automated or be built using manual sorting systems.
- *System design:* The integration of the components of the transportation process into a highly efficient system also involves the industrial engineer.
- *Equipment:* Requirements, design and selection of trucks, trailers, containers, aircraft, scanners, communication devices, materials-handling systems, etc. are tasks undertaken by the industrial engineer.
- *Facility layout:* The industrial engineer is often responsible for the design of facility layouts that will offer the most effective arrangement of the physical components and materials-handling equipment inside distribution centers and delivery terminals.
- *Asset utilization and control:* The design of systems and procedures to balance and manage the number of trucks, trailers, containers, aircraft, scanners, communication devices, and materials-handling systems required to facilitate the transportation processes is one more area requiring the attention of the industrial engineer.
- *Measurement systems:* Industrial engineers also participate in the development of effective transportation performance measures, including customer satisfaction, cost, and plan accuracy.

As indicated by this list, the industrial engineer adds great value to the transportation industry. Industrial engineering principles are highly applicable in this complex industry. Industrial engineers continue to serve as key members of the teams responsible for the design and integration of systems to facilitate the movement of goods, people, funds, and information in this increasingly competitive industry.

6. TRANSPORTATION AND THE SUPPLY CHAIN

Supply chain management is a comprehensive concept capturing objectives of functional integration and strategic deployment as a single managerial process. Figure 1 depicts the supply chain structure.

This structure has been in place for decades. Even when the manufacturing activity takes place in minutes, the final delivery of a product may take days, weeks, or months, depending on the efficiency of the supply chain. The operating objectives of a supply chain are to maximize response, minimize variance, minimize inventory, maximize consolidation, maintain high levels of quality, and provide life-cycle support.

Transportation is part of the physical distribution. The physical distribution components include transportation, warehousing, order processing, facility structure, and inventory. The major change in

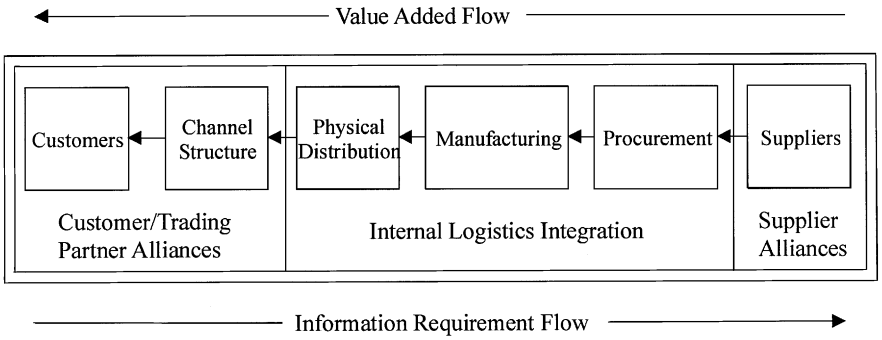

Figure 1 The Supply Chain Structure.

the supply chain in the last decade is information. It is information that allows transportation planners to reduce the costs in the supply chain in today's highly competitive environment. The integrated freight transportation systems that facilitate the movement of goods, information, and funds can target all areas of the supply chain. Every segment of the supply chain has a transportation need.

In an organization, transportation requirements may cover a wide range of territory and frequency characteristics. Decisions are usually made on the basis of cost as long as customer requirements are met. When making decisions that affect the organization's supply chain, it is important not to look at transportation alone or as an independent activity. Instead, transportation should be viewed in the context of the entire supply chain in order to make the most effective decisions (Figure 2).

The remainder of this chapter examines industrial engineering applications in transportation. We concentrate our attention in the transportation of goods. However, the techniques reviewed in the following sections can be applied to a variety of transportation problems. We do not provide a complete survey; instead, we present several representative applications in some detail.

7. TRANSPORTING GOODS

7.1. Cost, Time, and Quality Optimization in Transportation

In the transportation of goods, we often develop models that minimize total cost while maintaining acceptable levels of service. This cost may be a combination of the cost of operating a vehicle (fuel, maintenance, depreciation, etc.), the labor cost of the operator of the vehicle (driver, pilot, etc.), and possibly other fixed costs. In the transportation of small packages or less-than-truckload shipments, sorting cost is also considered, representing the cost of sorting and handling the packages to consolidate shipments. Cost may be considered indirectly, as in the case of minimizing empty vehicles or maximizing the load factor.

The time needed for transporting goods is another very important factor. Instead of minimizing general cost, transportation time may be minimized directly when time constraints are very tight or when the computation of cost is dominated by the labor cost. Whether the transportation time is

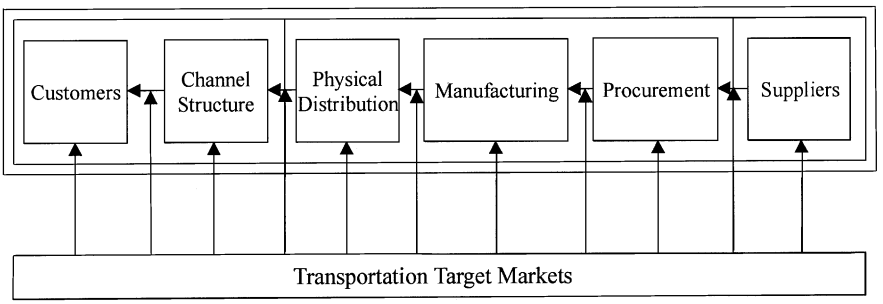

Figure 2 Transportation Target Markets in the Supply Chain.

minimized directly or not, the model may include time constraints (e.g., time windows, total time of a driver's route) or the time element may be incorporated in the input data of the model (e.g., included in the underlying network).

There is a tradeoff between transportation cost and transportation time. In the last decades, shorter product cycles in manufacturing and notions like just-in-time inventory have resulted in an increasing demand for smaller transportation times at higher prices and higher transportation cost. The small-package transportation industry has responded with many ''premium'' services that guarantee short transportation times. Even when the transportation time is not guaranteed, it represents a primary element of quality of service along with other considerations such as minimization of lost and damaged goods, which are often handled indirectly or are external to the cost optimization models.

7.2. Integrating Customer Needs in Transportation Planning

Although we often try to minimize cost in transportation planning, what we really want to achieve is maximization of profit (revenue minus cost). Cost minimization assumes that demand is external to the model and unaffected by the solution obtained. Demand remains at assumed levels only if the obtained solution satisfies customer requirements and customer needs are integrated into the transportation planning process.

Excluding price and transportation time, many customer needs are not easily incorporated into a mathematical model. They may be included in the input data (e.g., different types of service offered) or considered when alternative solutions obtained by optimization are evaluated. Flexibility, a good set of transportation options, and good communication are of primary importance to customers, permitting them to effectively plan their own operations, pickups, and deliveries.

7.3. Forecasting in Transportation Planning

The development of effective transportation plans is highly dependent on our ability to forecast demand. Demand, in the case of the transportation of goods, refers to the expected number of shipments, the number of packages associated with a shipment, and the frequency with which such shipments occur. When developing transportation routes and driver schedules, demand levels are used as input and therefore need to be forecasted. Changes in demand can occur randomly or can follow seasonal patterns. In either case, if an accurate forecast is not produced, the transportation planning effort will yield less accurate results. These results have implications in the design of facilities (e.g., capacity), the acquisition of assets (e.g., delivery vehicles), and in the development of staffing plans (e.g., labor requirements). It is important to note that several factors affect demand in the transportation industry. Business cycles, business models, economic growth, the performance of the shipper's business, competition, advertising, sales, quality, cost, and reputation all have a direct impact on the demand for transportation services.

When developing a forecast, the planner must address some basic questions:

1. Does a relationship exist between the past and the future?
2. What will the forecast be used for?
3. What system is the forecast going to be applied to?
4. What is the size of the problem being addressed?
5. What are the units of measure?
6. Is the forecast for short-range, long-range, or medium-range planning purposes?

Once these questions have been addressed, the steps shown in Figure 3 guide the planner towards the development of a forecasting model that can be used in generating the forecast to support the transportation planning process.

Depending on the type of the transportation problem being solved (e.g., local pickup and delivery operations, large-scale network planning), the user may select different forecasting techniques and planning horizons. For long-range network planning in which the planner is determining the location of future distribution centers, long-range forecasts are required. Sales studies, demographic changes, and economic forecasts aid in the development of such forecasts. When developing aggregate plans in order to determine future staffing needs and potential facility expansion requirements, the planner develops medium-range forecasts covering planning horizons that range from one or two quarters to a year. Known techniques such as time series analysis and regression are usually applied to historical demand information to develop the forecast. Finally, in order to develop weekly and daily schedules and routes to satisfy demand in local pickup and delivery operations, the planner may develop daily, weekly, or monthly forecasts (short-range forecasts). Because demand fluctuations can have a direct impact on the effectiveness of pickup and delivery routes, the use of up-to-date information from shippers is critical. Techniques such as exponential smoothing and trend extrapolation facilitate this type of forecasting.

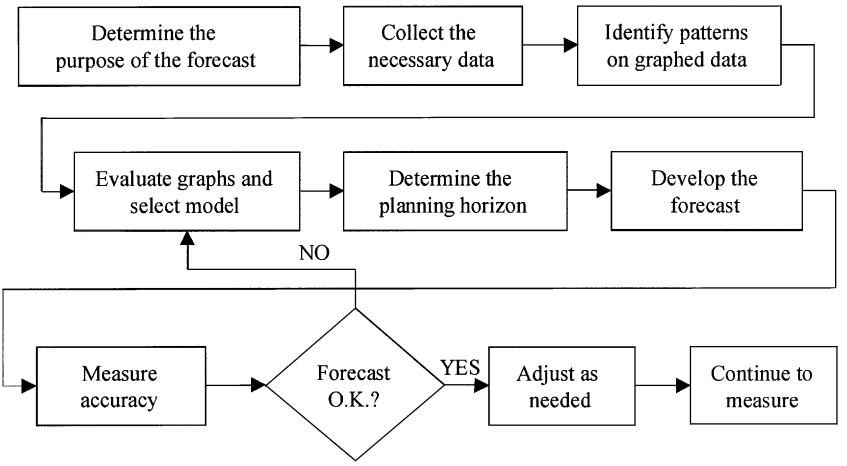

Figure 3 Steps in Forecasting.

Forecasting is often considered an art. Because the inputs to any forecasting model are mostly historical and based on experience, the accuracy of such forecasts is based on the model selected and the frequency with which it is updated. Forecasting models are usually grouped into two categories: subjective and objective.

Subjective forecasting models are based on judgement and experience. Several techniques exist that attempt to make use of the "expert" 's knowledge to develop a forecast. These techniques include the Delphi method, jury of executives, and the use of sales force intelligence to develop the forecast.

Objective forecasting models are also known as quantitative models. The selection of a quantitative model is dependent on the pattern to be projected and the problem being addressed. There are two types of quantitative forecasting models: time series and explanatory models. In time series models, time is the independent variable and past relationships between time and demand are used to estimate what the demand will be in the future. Explanatory models, on the other hand, use other independent variables instead of or in addition to time. The variables used in the forecasting model are those that have shown a consistent relationship with demand.

When evaluating the impact of seasonal variability on the forecast, the planner has several indicators that can be used to refine the forecast. Leading and lagging economic indicators of the general business cycles can aid the forecaster in the refinement of plans. The Department of Commerce creates an index of well-known economic indicators. This index can be effectively applied to medium- and long-range forecasts to anticipate demand in the transportation of goods.

Several correlation coefficients can be calculated to determine how closely the forecasts correlate with actual demand. The sample mean forecast error (e.g., the square root of the sum of the squared forecast errors), which provides an approximation of the average forecast error of the forecasting model, can also be used. Choosing the best forecast technique requires an understanding of the particular forecasting problem and the characteristics of the available data. Ultimately, the planner's ability to use past and current information to forecast stops, delivery volume, and other key inputs to the transportation planning process will determine the quality and accuracy of the transportation plans developed. With changes in technology and with the increased availability and sharing of information between companies, we expect substantial improvements in the way forecasting is done in the transportation industry.

8. PICKUP AND DELIVERY

8.1. Pickup-and-Delivery Operations

Daily operations in parcel delivery include local pickup and delivery. Terminal facilities are assigned to service areas so that every package that has an origin or destination in the service area is handled through the assigned terminal. Each workday, a fleet of vehicles leaves a terminal (depot) carrying packages to be delivered to customers and returns carrying packages that have been picked up from customers. Most deliveries occur before the pickups, which take place late in the day. Each customer stop (either delivery or pickup) is characterized by a time window during which service must begin.

These windows are usually one-sided: a delivery must occur before a given time and a pickup after a given time. Some windows, though, may be wide open (e.g., a delivery must occur by the end of the workday) and other windows may be two-sided (a pickup must occur before an early closing time). Vehicle capacities are not a limitation in this problem; therefore, the fleet of vehicles may be considered homogenous if the difference in type of vehicle does not have a significant effect on cost. Maximum on-road time for the workday is an important limitation, where on-road time is defined as the total elapsed time from the moment a vehicle leaves the depot until it returns to the depot. The importance of on-road time derives from the fact that often drivers are paid overtime for hours of work beyond a certain length (e.g., 8 hours), and work rules prohibit work days beyond a certain length (e.g., 10 hours).

Efficient distribution implies good asset utilization. The primary assets in this problem are vehicles and drivers. Minimization of the number of drivers and of the total cost of the routes are frequently used objectives. Efficiency needs to be achieved while level of service is maintained; that is, service is provided to all customers in such a way as to satisfy all time-window constraints. This problem has a very short-term planning horizon. Since customer stops may differ from day to day and all the stops are known only a few hours before the actual pickup-and-delivery operation, the problem needs to be solved a few hours before implementation.

8.2. Modeling

The pickup-and-delivery problem can be modeled as a variation of the vehicle routing problem with time windows (VRPTW) and a single depot. Inputs for the VRPTW include matrices that specify the distance and travel time between every pair of customers (including the depot); service time and time window for each customer; maximum (or specified) number of drivers; starting time of the workday; and maximum on-road time of the workday. The maximum on-road time of the workday can be implemented as a time window on the depot, so that the pickup and delivery problem described above can be considered as a traveling salesman problem with time windows and multiple routes (m-TSPTW). However, the term *VRPTW* will be used in this section for this uncapacitated pickup-and-delivery problem.

Distances and travel times can be derived from the longitude and latitude of the customers and depot, assuming specific speed functions. Alternatively, distances and travel times can be obtained from an actual street network; this latter method provides greater accuracy. Longitude and latitude values are relatively easy to obtain; it is often considerably more difficult to acquire data for a street network.

The objective in the VRPTW is to minimize the number of drivers and/or minimize the total cost of the routes while satisfying all constraints. Cost is a function of total distance and on-road time. The output is a set of routes, each of which specifies a sequence of customers and starts and ends at the depot. Because of the short-term planning horizon, the drivers need to be notified for work before the problem is solved. In many cases, therefore, the number of drivers may be estimated and assumed given; the objective then becomes to minimize total cost.

The number of drivers is unlikely to be changed daily. However, the transportation of small packages is characterized by seasonality of demand. In the United States, demand increases by 40–50% during the months before Christmas. A pickup-and-delivery model can be used to obtain the minimum number of additional drivers that must be used to maintain level of service when demand increases.

The VRPTW is an extension of the traveling salesman problem with time windows (TSPTW), which in turn is an extension of the classical traveling salesman problem (TSP). The TSP and its variants have been studied extensively, and many algorithms have been developed based on different methodologies (Lawler et al. 1985). The TSP is NP-complete (Garey and Johnson 1979) and therefore is presumably intractable. For this reason, it is prohibitively expensive to solve large instances of the TSP optimally. Because the TSPTW (and the VRPTW with a maximum number of available drivers) are extensions of the TSP, these problems are NP-complete as well. In fact, for the TSPTW and VRPTW, not only is the problem of finding an optimal solution NP-complete; so is the problem of even finding a feasible solution (a solution that satisfies all time window constraints) (Savelsbergh 1985). For more on time constrained routing and scheduling problems, see Desrosiers et al. (1995).

Existing exact algorithms for the VRPTW have been reported to solve problems with up to 100 stops. However, the problems encountered in parcel delivery are often substantially larger than this. Moreover, these problems need to be solved quickly because of the short-term planning horizon. For these reasons, much of the work in this area has focused on the development of heuristic algorithms—algorithms that attempt to find good solutions instead of optimal solutions.

Heuristic algorithms for the TSPTW and VRPTW are divided into two general categories: route-construction heuristics and route-improvement heuristics. The first type of heuristic constructs a set of routes for a given set of customers. The second type of heuristic starts from an existing feasible solution (set of routes), and attempts to improve this solution. Composite procedures employ both

types of heuristic, either by first constructing routes heuristically and then improving them or by applying route-improvement procedures to partially constructed routes at selected intervals during the route-construction process itself. Route-construction and route-improvement heuristics are discussed in more detail below.

8.3. Heuristic Construction Algorithms

There are two general strategies that a route-construction algorithm for the VRPTW can adopt. The first strategy is ''cluster first, route second,'' which first assigns stops to drivers, and then constructs a sequence for the stops assigned to each driver. The second strategy carries out the clustering and sequencing in parallel.

Because clustering is based primarily on purely spatial criteria, the cluster-first, route-second strategy is often more appropriate for the vehicle routing problem (VRP), where time windows are not present than for the VRPTW. However, cluster-first strategies can play a useful role in some instances of the VRPTW, as will be discussed later.

For now, we will confine our attention to algorithms that carry out clustering and sequencing in parallel. Within this general class of algorithms, there is a further distinction between sequential heuristics, which construct one route at a time until all customers are routed, and parallel heuristics, which construct multiple routes simultaneously. In each case, one proceeds by inserting one stop at a time into the emerging route or routes; the choice of which stop to insert and where to insert it are based on heuristic cost measures. Recent work suggests that parallel heuristics are more successful (Potvin and Rousseau 1993), in large part because they are less myopic than sequential approaches in deciding customer-routing assignments.

In the following discussion, we focus on heuristic insertion algorithms for the VRPTW. Solomon (1987) was the first to generalize a number of VRP route-construction heuristics to the VRPTW, and the heuristic insertion framework he developed has been adopted by a number of other researchers. Solomon himself used this framework as the basis for a sequential algorithm. In what follows, we briefly describe Solomon's sequential algorithm and then turn to extensions of the generic framework to parallel algorithms.

8.4. A Sequential Route-Construction Heuristic

This heuristic builds routes one at a time. As presented by Solomon (1987), sequential route construction proceeds as follows:

1. Select a ''seed'' for a new route.
2. If not all stops have been routed, select an unrouted stop and a position on the current route that have the best insertion cost. If a feasible insertion exists, make the insertion, else go to step 1.

In step 1, the heuristic selects the first stop of a new route (seed). There are various strategies for selecting a seed. One approach is to select the stop that is farthest from the depot; another is to select the stop that is most urgent in the sense that its time window has the earliest upper bound. In step 2, the heuristic determines the unrouted stop to be inserted next and the position at which it is to be inserted on the partially constructed route. In order to make this determination, it is necessary to compute, for each unrouted stop, the cost of every possible insertion point on the route.

Solomon introduced the following framework for defining insertion cost metrics. Let $(s_0, s_1, \ldots, s_m)$ be the current partial route, with s_0 and s_m representing the depot. For an unrouted stop u, $c_1(s_i, u, s_j)$ represents the cost of inserting u between consecutive stops s_i and s_j. If the insertion is not feasible, the cost is infinite. For a given unrouted stop u, the best insertion point $(i(u), j(u))$ is the one for which

$$c_1(i(u), u, j(u)) = \min_{p=1,\ldots,m} [c_1(s_{p-1}, u, s_p)]$$

The next stop to be inserted into the route is the one for which

$$c_1(i(u^*), u^*, j(u^*)) = \min_u [c_1(i(u), u, j(u))]$$

Stop u^* is then inserted in the route between $i(u^*)$ and $j(u^*)$. Possible definitions for the cost function c_1 are considered later.

8.5. A Parallel Route-Construction Heuristic

A parallel route-construction heuristic that extends Solomon's sequential algorithm is presented next; the presentation is based on ideas presented by Potvin and Rousseau (1993, 1995) and Russell (1995).

1. Run the sequential algorithm to obtain an estimate of the number of routes k. We can also retain the k seeds obtained by the sequential algorithm. Alternatively, once one has obtained an estimate of the number of routes, one can use some other heuristic to generate the seeds. A representative method is the seed-point-generation procedure of Fisher and Jaikumar (1981). The result of this process is a set of k routes that start from the depot, visit their respective seeds, and return to the depot.
2. If there are no unrouted stops, the procedure terminates. Otherwise, for each unrouted stop u and each partially constructed route $r = (s_0, \ldots, s_m)$, find the optimal insertion point $(p_r(u), q_r(u))$ for which

$$c_1(p_r(u), u, q_r(u)) = \min_{j=1,\ldots,m} [c_1(s_{j-1}, u, s_j)]$$

for some cost function c_1. For each unrouted u, its optimal insertion point $(p(u), q(u))$ is taken to be the best of its route-specific insertion points:

$$c_1(p(u), u, q(u)) = \min_r [c_1(p_r(u), u, q_r(u))]$$

Select for actual insertion the node u^* for which

$$c_2(p(u^*), u^*, q(u^*)) = \text{optimal}_u [c_2(p(u), u, q(u)]$$

for some cost function c_2 that may (but need not) be identical to c_1. If a feasible insertion exists, insert the stop u^* at its optimal insertion point and repeat step 2. Otherwise, go to step 3.
3. Increase the number of routes by one and go to step 2.

Possible definitions for c_1 and c_2 are presented below; again, the presentation here follows that of Potvin and Rousseau (1993).

We can measure the desirability of inserting u between i and j as a weighted combination of the increase in travel time and cost that would result from this insertion. Thus, let

d_{ij} = cost from stop i to stop j
$d(i,u,j) = d_{iu} + d_{uj} - d_{ij}$
e_j = current service start time at j
$e_{u,j}$ = new service start time at j, given that u is now on the route
$t(i,u,j) = e_{u,j} - e_j$

Then a possible measure of the cost associated with the proposed insertion is given by

$$c_1(i,u,j) = \alpha_1 d(i,u,j) + \alpha_2 t(i,u,j) \tag{1}$$

where α_1 and α_2 are constants satisfying

$$\alpha_1 + \alpha_2 = 1$$
$$\alpha_1, \alpha_2 \geq 0$$

One way of defining the measure c_2 is simply by setting $c_2 = c_1$. In this case, the optimal c_2-value is a minimum. An alternative approach is to define c_2 as a "maximum regret" measure.

A regret measure is a kind of "look-ahead" heuristic: it helps select the next move in a search procedure by heuristically quantifying the negative consequences that would ensue, if a given move were not selected. In the context of vehicle routing, a simple regret measure for selecting the next customer to be routed might proceed as follows. For each unrouted customer, the "regret" is the difference between the cost of the best feasible insertion point and the cost of the second-best insertion point; the next customer to be added to a route is one whose regret measure is maximal. But this is still a relatively shortsighted approach. One obtains better results by summing the differences between the best alternative and *all* other alternatives (Potvin and Rousseau 1993; Kontoravdis and Bard 1995). The regret measure that results from this idea has the form

$$c_2(u) = \Sigma_{r \neq r^*} [c_1(p_r(u), u, q_r(u)) - c_1(p_{r^*}(u), u, q_{r^*}(u))] \tag{2}$$

Underlying the use of this regret measure is a notion of urgency: the regret measure for a stop u is likely to be high if u has relatively few feasible or low-cost insertion points available. We would like

to route such a u relatively early to prevent its few good insertion points from being taken by other customers.

8.6. A Numerical Example

We illustrate the route-construction process by considering an instance of the VRPTW with 18 stops, together with the depot (node 0). Table 1 displays the time matrix for this problem, and Table 2 the time windows. All times are listed in hundredths of an hour; for example, 9:45 is represented as 975. The starting time from the depot is 875 for all drivers. Three routes are to be generated, using as seeds nodes 18, 6, and 4.

The parallel route-construction procedure initializes each route by inserting its seed node. Hence, this process creates the three one-stop routes, (0–18–0), (0–6–0), and (0–4–0). Next, for each un-

17	875	1200
18	875	1300

routed node, the best feasible insertion cost for each of the three current routes is computed from formula (1), where $\alpha_1 = 0$, $\alpha_2 = 1$, and time is used as the cost measure. This computation obtains for node 1 the best insertion costs (55 63 53) for the three routes. Hence, the best feasible insertion of node 1 is into route 3 ($r^* = 3$ in formula (2)). The regret measure for node 1 using formula (2) is calculated as follows:

$$c_2(1) = 55 - 53 + 63 - 53 + 53 - 53 = 12$$

The regret measures for the remaining unrouted nodes are computed similarly. The regret values for each node are shown in the following array, where x indicates a node that has already been included in a route.

$$\text{Regrets} = (12\ 16\ 52\ x\ 100\ x\ 3\ 23\ 96\ 29\ 86\ 21\ 31\ 1\ 24\ 50\ 48\ x)$$

At each iteration of the procedure, the next stop to be inserted into a route is a stop with the maximal regret measure. In the present case, node 5 has the maximal regret. Hence, the procedure inserts node 5 into its best feasible insertion point (first stop after the depot on route 1). After node 5 is inserted, the three routes under construction become (0–5–18–0), (0–6–0), and (0–4–0). The algorithm repeats this process until all nodes have been inserted.

The three routes returned by the procedure are shown in Table 3 and Figure 4.

8.7. Infeasible Problems

One of the inputs to a typical instance of the VRPTW is the maximum number of drivers available. In the case where the time windows are relatively tight, an algorithm may not be able to find a feasible solution (i.e., a solution in which all time windows are satisfied). The way one proceeds in this case depends on the nature of the application. In some applications, where there is a service guarantee and the same penalty applies no matter how close to meeting the service commitment a late delivery happens to be, we wish to minimize the number of missed time windows. In other applications, where the penalty is proportional to the lateness of a delivery, we wish to minimize,

over all stops, the total time by which the upper bounds of the time windows of stops are missed. In either case, we can still apply the heuristic insertion framework described above by adding an appropriate penalty function to the standard heuristic cost functions.

8.8. Work Breaks

The algorithms presented thus far provide a framework for solving a variety of routing and scheduling problems. However, the specific algorithms we have considered are applicable directly only to a small range of problems; they generally have to be extended in some way in order to deal with real-world applications. One important extension arises in routing applications in which the driver spends an entire day on the road. For such applications, we must take into account the necessity of scheduling lunch and other breaks in order to satisfy work rules and other constraints. Taking these factors into account complicates an already difficult problem.

We can characterize a break by specifying the following values: earliest start time for the break, latest start time for the break, and duration of the break. For example, we might specify that we are to include a 50-minute lunch break that begins any time between 11 am and 1 pm.

To accommodate breaks within the heuristic insertion framework, the most natural way to proceed is to represent the breaks themselves as nodes. Note that a break does come with a natural time window (earliest and latest start times) and an analogue of service time (duration of break). The one crucial missing item is location. In some cases, the location of breaks may be specified as part of the input to the algorithm. In general, however, the algorithm will have to select a location for each break, based on the locations of the nodes that represent actual stops.

For example, suppose we wish to schedule a break after stop a but before stop c. According to the heuristic insertion framework, this is just the problem of inserting the break node b between nodes a and c. One possible approach is simply to assign a's location to b. In this case, we calculate the arrival time at c as follows. Let $[e_x, l_x]$ be the time window for a given stop x, svcTime_x the service time at x, and t_{xy} the travel time from x to y. If x has been assigned to a route, we let arrival_x be the arrival time of the driver at location x. Then the time at which service begins at stop x is given by

$$\text{startTime}_x = \max(\text{arrival}_x, e_x)$$

In the case being considered here, where break node b is inserted between stops a and c, we have

$$\text{startTime}_c = \text{startTime}_a + \text{svcTime}_a + \text{svcTime}_b + t_{ac}$$

Recall that svcTime_b is just the duration of the break.

This is the basic picture, but there is at least one complication that we have to take into account. Suppose, as before, that we wish to insert break node b between a and c. Suppose also that the travel time from a to c is 30 minutes, that service is completed at a at 10:45, and that the time window for b is [11:00, 1:00]. Then, according to the simple scheme just described, we would have to wait for 15 minutes at location a before starting lunch at a!

To avoid this sort of awkward behavior, we would actually insert b at the first point on segment (a, c) such that there is no waiting time at b. If there is no such point, then we conclude that no lunch break can be inserted between stops a and c. For example, in the scenario just described, we would insert b halfway between a and c.

When a break has been fully represented this way as a node with time window, location, and service time, it is treated just like any other node within the heuristic insertion framework.

8.9. Route-Improvement Heuristics

Heuristic route-improvement procedures play a fundamental role in vehicle routing algorithms. Such procedures take as input a feasible solution consisting of a route or set of routes and seek to transform this initial solution into a lower-cost feasible solution.

One of the most successful route-improvement strategies has involved the use of edge-exchange heuristics. The edge-exchange technique was introduced by Lin and Kernighan (1973) as a local search strategy in the context of the conventional traveling salesman problem, but it has since been applied to a variety of related problems, including the vehicle routing problem.

For an individual route, a k-exchange involves replacing k edges currently on the route by k other edges. For example, a 2-exchange involves replacing two edges (say $(i, i + 1)$ and $(j, j + 1)$) by two other edges $((i, j)$ and $(i + 1, j + 1))$. Usually, all the available k-exchanges are examined and the best one is implemented. This is repeated as long as an improved solution is obtained. Since there are $\binom{n}{k}$ subsets of k edges in a cycle of n edges, the computational complexity of the edge-exchange method increases rapidly with k. Even one k-exchange requires $O(n^k)$ time, so attention is usually confined to the cases $k = 2$ and $k = 3$.

The idea of an edge exchange can be extended in a straightforward way to the case of pairs of routes. In this case, one exchanges entire paths between routes, where a path consists of a sequence of one or more nodes. For example, let $\text{routeA} = (a_1, a_2, \ldots, a_k)$, $\text{routeB} = (b_1, b_2, \ldots, b_n)$. Then, after exchanging paths between the two routes, the routes that result would be of the form, $\text{routeA} = (a_1, \ldots, a_i, b_{j+1}, \ldots, b_{j+r}, a_m, \ldots, a_k)$, and similarly for routeB.

As mentioned, the goal of a route-improvement heuristic is to reduce routing costs; typically this means that we wish to minimize route duration. However, when we are dealing with time windows, we must also verify that any proposed exchange retains time window feasibility. Techniques for efficient incorporation of time window constraints into edge-exchange improvement methods were developed by Savelsbergh (1985, 1990, 1992); see also Solomon et al. (1988).

The most recent work on route improvement has focused on the development of metaheuristics, which are heuristic strategies for guiding the behavior of more conventional search techniques, with a view towards avoiding local optima and thereby achieving higher-quality solutions. Metaheuristic techniques include tabu search, genetic algorithms, simulated annealing, and greedy randomized adaptive search (Glover 1989, 1990; Kontoravdis and Bard 1995; Potvin et al. 1996; Rochat and Taillard 1995; Taillard et al. 1997; Thangiah et al. 1995).

To illustrate the pertinent concepts, we focus here on tabu search. Tabu search helps overcome the problem of local optimality, which often arises when traditional deterministic optimization heuristics are applied. The problem of local optimality arises in the following way. A wide range of optimization techniques consists of a sequence of moves that lead from one trial solution to another. For example, in a vehicle-routing algorithm, a trial solution consists of a route for each vehicle; and a "move," in the route-improvement phase, might consist of some sort of interroute exchange. A deterministic algorithm of this general type selects a move that will most improve the current solution. Thus, such a procedure "climbs a hill" through the space of solutions until it cannot find a move that will improve the current solution any further. Unfortunately, while a solution discovered with this sort of hill-climbing approach cannot be improved through any local move, it may not represent a global optimum.

Tabu search provides a technique for exploring the solution space beyond points where traditional approaches become trapped at a local optimum. Tabu search does not supplant these traditional approaches. Instead, it is designed as a higher-level strategy that guides their application.

In its most basic form, the tabu method involves classifying certain moves as forbidden (or "tabu"); in particular, a move to any of the most recently generated solutions is classified as tabu.

(When we speak of ''moves'' here, we mean moves generated by some traditional search method such as edge exchange.) The tabu algorithm then selects the best move from the set of moves not classified as tabu, in order to drive the search into new regions. No concern is given to the fact that the best available moves may not improve the current solution. In particular, because a recently achieved local optimum will be classified as tabu, the method can drive the search down the hill away from this local optimum. The hope is that the expanded search will lead to an improved final solution. There is no guarantee that an improved solution will be found, but variations on the method just described have achieved considerable success and have become increasingly popular.

What has been described here is a very simple tabu search framework, which performs ''bookkeeping'' operations to ensure that the algorithm does not return to recently explored solutions. More sophisticated metaheuristic strategies more explicitly guide the direction of the search itself.

8.10. Preassigned Routes and Preassigned Territories

The heuristic route-construction methods described thus far are designed to minimize route cost while satisfying time window and other constraints. Route cost is typically a function of total on-road time and distance. In an approach to routing that seeks only to minimize travel time and distance, one typically follows a reoptimization strategy. That is, one is faced each day by a new problem, defined by the set of customers who actually require service that day; and one solves that problem by applying a heuristic route-construction algorithm. Because there is no concept, in such algorithms, of geographical area or regularity of service, the solution for one day will be independent of the solution for another. While these solutions may be very efficient from the standpoint of total cost and travel time, they may not be satisfactory for some applications. The reason for this shortcoming is that in some applications, there may be additional, hidden costs that the reoptimization strategy fails to take into account.

One such cost involves driver knowledge of the area in which he or she is providing service. A driver who is familiar with the road network and traffic conditions in his service area is likely to be more efficient than a driver for whom the delivery area is relatively new. A second, related cost involves the development of business relationships. For many service providers, an important goal is to achieve regularity and personalization of service by having the same driver visit a particular customer every time that customer requires service.

These considerations suggest that for some applications, it may be desirable to maintain some consistency from one day to the next in assigning customers to drivers. In this case, we need to devise some alternative to the reoptimization strategy.

One way of devising such an alternative is to interpret our problem as a probabilistic vehicle routing problem (PVRP) (Jaillet and Odoni 1988). According to this interpretation, we are given a service region and the set of all potential customers in that region. On a given day, only a subset of the customers will actually need service and the exact customer set for a given day cannot be predicted. However, we are also given a probability distribution, based on historical data, over the set of potential customers. The probability assigned to a potential customer represents the probability that that customer will require service on any given day.

One way of defining an objective function for this problem is provided by the a priori optimization strategy investigated by Jaillet (1988) and Bertsimas et al. (1990). In order to develop the ideas underlying this strategy, it is helpful to focus on the TSP. In the conventional TSP, we are given a complete graph $G = (V,E)$ and wish to find a lowest-cost tour that visits every node in V. We obtain the probabilistic TSP (PTSP) by supposing that, on any given day, the traveling salesman may have to visit only some subset S of the nodes in V. The probability that any v in V is present (must be visited) in a given problem instance is given by a probability function p over V. We identify a problem instance with the subset S of nodes that are present in that instance. Thus there are 2^n possible instances of the PTSP on G, where $n = |V|$.

According to the a priori optimization strategy, one finds a priori a tour through all n nodes of G. For any given instance of the problem, the $k \leq n$ nodes that are actually present are visited in the same order as they appear in the a priori tour; the $(n - k)$ missing nodes are simply skipped.

A natural measure of effectiveness for the a priori strategy is given by the notion of minimum length in the expected value sense. Thus, let τ be the a priori tour, and let L_τ be the length of τ. If the problem instance S occurs with probability $p(S)$ and requires covering a total length $L_\tau(S)$ according to the a priori tour, then it will receive a weight of $p(S)L_\tau(S)$ in the computation of expected length. Therefore, according to this construal of the PTSP, the objective is to find an a priori tour τ_0 through the n nodes of G, which minimizes the quantity

$$E[L_\tau] = \Sigma_{S \subseteq V}\, p(S)L_\tau(S)$$

We extend this model to the VRP by requiring that an a priori tour be constructed for each driver in

such a way that all potential customers are assigned to some driver. Note that a set of a priori tours of this sort does provide the kind of regularity of service described above.

At first glance, the task of calculating $E[L_\tau]$ for a given a priori tour τ may appear problematic because the summation is over all 2^n subsets of V. However, Jaillet derived an efficient closed-form expression for $E[L_\tau]$, which requires only $O(n^2)$ time to compute (see discussion in Jaillet 1988).

Of course, being able to calculate $E[L_\tau]$ efficiently for a given a priori tour is very different from actually finding a tour that minimizes $E[L_\tau]$. Because the PTSP is at least as hard as the TSP, there is little hope of developing exact optimization methods that could solve more than modestly sized instances of the problem. Consequently, one must employ heuristics in order to develop practically viable PTSP algorithms. However, it has proven difficult to develop effective heuristic approaches to the PTSP, at least in part because the class of optimal solutions to the PTSP has properties very different from those associated with the conventional (Euclidean) TSP. For example, one of the fundamental properties of the Euclidean TSP is that an optimal solution cannot intersect itself; this property follows directly from the triangle inequality. In contrast, an optimal solution for the PTSP *can* intersect itself, even when the triangle inequality is satisfied (systematic treatments of the differences between the TSP and PTSP are presented by Jaillet [1988] and Jaillet and Odoni [1988]). One consequence of the fact that the PTSP has features very different from the TSP is that, in general, we cannot expect heuristic approaches designed specifically for the TSP to be extended successfully to the PTSP. In general, therefore, entirely new solution approaches are needed. One of the few promising approaches to the PTSP that has been discussed in the literature is based on the idea of "spacefilling curves" (Bartholdi and Platzman 1988). But the probabilistic versions of the TSP and VRP remain very much under the heading of research topics.

The problem becomes even more difficult when we turn to probabilistic versions of the VRPTW. For this problem, presumably, the a priori strategy would involve multiple objectives; in addition to minimizing the expected length of the a priori tour, we would also want to minimize the expected number of missed time windows. But it is difficult even to formulate this problem properly, much less solve it.

For this reason, when time windows are involved, we try in actual applications to capture some subset of the key features of the problem. In this case, instead of trying to construct a priori tours of the kind just described, we simply try to construct a solution in which a large percentage of repeat customers is handled by the same driver and each driver is relatively familiar with most of the territory to which he or she is assigned.

One way of achieving such a solution is to partition the service area into geographical regions and then always assign the same driver to the same region. In operational terms, a solution of this sort is one in which drivers have well-defined territories: a driver travels from the depot to his or her service area, carries out his or her work there, and then returns to the depot. This picture is to be contrasted with the one that emerges from the heuristic insertion framework, which usually results in routes that form a petal structure: in general, it creates routes in the form of intersecting loops, in which stops appear in a roughly uniform way.

To construct a solution in which drivers are assigned to territories in this way, it is appropriate to adopt the cluster-first, route-second strategy mentioned earlier. Thus, we proceed by first assigning stops to drivers, thereby partitioning the service area. We then construct a sequence for the stops assigned to each driver. This strategy represents a departure from the heuristic insertion framework, according to which clustering and routing proceed in parallel.

One way of implementing a cluster-first strategy is as follows. Suppose that, on a given day, we wish to construct k routes. We can proceed by (heuristically) solving a k-median problem (Daskin 1995); we then carry out the initial clustering by assigning each stop to its closest median. Having created the clusters, we then construct a route for each cluster individually by solving the resulting TSPTW. Unfortunately, it is often impossible to construct a feasible route for each cluster. When feasible routes cannot be constructed, we have to shift stops between clusters in such a way as to achieve feasibility while maintaining well-defined territories as much as possible.

If we begin by solving a new k-median problem each day, then we may succeed in producing well-defined territories for drivers; but we are unlikely to achieve consistency from one day to the next in assigning customers to drivers. A natural way of extending this approach to achieve consistency is to take historical information into account. Thus, we can solve a weighted k-median problem over the set of all locations that have required service over a specified number of past days, where the weight of a location is proportional to the number of times it has actually required service. We would then consistently use these medians as the basis for clustering. There may well be days in which the initial clusters thus constructed are significantly unbalanced with respect to numbers of customers per driver; in this case, we have to shift stops between clusters, as described above.

Whether the procedure just outlined can be applied successfully in the presence of time windows depends in part on the nature of those time windows. For some applications, time windows are one-sided, and there are only a few different service levels: for example, delivery by 9:00 am for express packages, delivery by 11:00 am for priority packages, and so on. For such applications, it is plausible

to suppose that the sort of strategy just described, which emphasizes the spatial aspects of the problem, can be implemented successfully. If, on the other hand, there is a variety of different, overlapping, two-sided time windows, then we are faced with what is really a three-dimensional problem, with time as the third dimension. In such a case, where the temporal aspect of the problem predominates, the prospects for a successful cluster-first strategy of the type described here are considerably less promising.

An alternative heuristic strategy is to employ a sweep method for clustering, introduced by Gillet and Miller (1974); see also Fisher and Jaikumar (1981) and Hall et al. (1994). According to this strategy, one begins by dividing the service area into annuli centered at the depot, using some heuristic method for determining the radius of each annulus. For each annulus, one then sorts the set of customers by increasing polar angle and then builds routes sequentially, inserting stops in order into the current route.

As in the *k*-median method, the prospects for successful application, in the presence of time windows, of what is essentially a spatial method depend on the nature of those time windows. Again as in the *k*-median method, one would have to take historical data into account in order to achieve assignments of customers to drivers that are reasonably consistent over time.

8.11. Implementation Issues

It is evident, on the basis of the discussion in this section, that for vehicle-routing applications one may require a suite of algorithms, each of which best serves a somewhat different objective. Furthermore, to make the best use of these algorithms, it is important that the actual user be specially trained for the application.

Accuracy of the input data is very important in this problem (and in optimization problems in general). Because the objective is to minimize cost, the model is very sensitive to data that affect cost calculations. Because traffic conditions change with the time of day, weather conditions, and so on, travel times are generally estimated even when the best data are available. When longitude and latitude values are used as the basis for travel time estimates, a further loss of accuracy results. This indicates that the extra cost of getting provably optimal solutions may not be justified, and also that effort needs to be made to develop methodologies that are robust with respect to data inaccuracies. One must certainly take into account the possibility of such inaccuracies when one reports the output routes. It is especially important to do so if the intention is to provide precise directions to drivers who are inexperienced in their assigned areas. Obvious inaccuracies may generate distrust for the model by the users.

The pickup-and-delivery problem discussed in this section is static in the sense that all demand is known before any service begins. But one can also consider real time dispatching problems, in which demand is generated in real time and routing decisions are made after the driver has left the depot. Advances in communications technology make it feasible to implement real-time systems of this sort. They also make feasible the implementation of hybrid systems, in which drivers are given predetermined routes but these routes may be modified dynamically as new demand arises during the workday. Dynamic problems of this sort will require new algorithmic techniques to supplement those presented in this section.

9. LARGE-SCALE TRANSPORTATION NETWORK PLANNING

9.1. Line-Haul Movement of Packages

During the pickup and delivery operation of a parcel delivery company, packages are picked up and brought to a local terminal, as discussed in Section 8. These packages are sometimes transported to their destination terminal directly and delivered to the customers. In most cases, however, packages go though a series of transfer terminals where they get sorted and consolidated. Transportation between terminals is achieved using several modes of transportation. The most prevalent modes on the ground are highway and rail, using a fleet of tractors and trailers of different types. A fleet of aircraft is used for transporting by air.

A transfer terminal often shares the same building with one or more local terminals. Several sorting operations may be run daily in a transfer terminal and are repeated every day of the work week at the same times. A large transfer terminal may have four sorting operations at different times of the day or night. Packages get unloaded, sorted, and reloaded on trailers. Several types of trailers may be used with different capacities and other characteristics. One or more trailers are attached to a tractor and depart for the next terminal on their route. This may be another transfer terminal or their destination terminal, or a rail yard for the trailers to be loaded and transported by rail, or an air terminal, if the packages have to be transported by air. In this section, we will examine a model that determines the routes of packages from their origin to their destination terminals and the equipment used to transport them, only for packages that travel on the ground using two modes, highway or rail.

Package handling and transporting between terminals represents a large part of the operating costs for a package transportation company. A good operating plan that minimizes cost and/or improves service is crucial for efficient operations. In recent years, many new products and services have been introduced in response to customer demand. These changes as well as the changes in package volume require additions and modifications to the underlying transportation network to maintain its efficiency. A planning system that can evaluate alternatives in terms of their handling and transporting costs and their impact on current operations is very important. There is a tradeoff between the number of sorting operations a package goes through and the time needed to reach its destination. More sorting operations increase the handling cost, decrease the transportation cost because they consolidate loads better, but also increase the total time needed until a package is delivered to the customer. All these factors need to be taken into account in the design of a transportation network for routing packages.

9.2. A Network-Optimization Problem

The network-optimization problem for transporting packages on the ground can be defined as follows. Determine the routes of packages, mode of transportation (highway or rail), and types of equipment to minimize handling and transportation costs while the following constraints are met: service requirements are respected, the capacities of sorting operations are not surpassed, no sorting operation is underutilized, the number of doors of each facility available for loading trailers is considered, trailers balance by building, and all the packages to the same destination are routed along the same path.

To maintain level of service, packages must be transported between particular origin/destination (OD) pairs in a given time. The capacity of a sorting operation cannot be surpassed but also, if the number of packages through a sorting operation falls below a given value, the sorting operation needs to be closed down. The number of loading doors of each facility represents the maximum number of trailers that can be loaded simultaneously during a sorting operation. Note that two or more of the trailers loaded simultaneously may be going to the same terminal next on their route.

Trailers need to balance by building daily. This means that the trailers of each type that go into a building must also leave the building during the daily cycle. Balancing is achieved by introducing empty trailers into the system. There are several types of trailers that are used, with different capacities. Some types can be used both on highway and rail. Trailers can also be rented from the railroads, and these trailers may not need to balance. Each tractor can pull one, two, and, on rare occasions, three trailers, depending on the trailer types and highway restrictions. At a terminal, tractor–trailer combinations are broken up, the trailers unloaded, the packages sorted, the trailers loaded again, and the tractor and trailers reassembled to form new combinations. There is no constraint on the number of trailers of any type that are used.

An important operational constraint is that all the packages to the same destination must be routed along the same path. This implies that all packages with the same destination terminal follow the same path from the terminal where they first meet to their destination. This constraint results from the fact that sorting is done by destination. If sorting became totally automated, this constraint might be modified.

A network-optimization model can be used as a long-term planning tool. It can evaluate alternatives for locating new building facilities, opening or closing sorting operations, and changing an operating plan when new products are introduced or the number of packages in the system changes. Because any such changes require retraining of the people who manually sort the packages, the routing network in parcel delivery is not changed often or extensively. For a network-optimization model to be used as an intermediate-term planning tool to modify the actual routing network, the model needs to obtain incremental changes, that is, to obtain solutions as close as possible to the current operations.

9.3. Modeling

The network-optimization problem is formulated on a network consisting of nodes that represent sorting operations and directed links that represent movement of packages from one sorting operation to another. Both the highway and rail modes are represented by one link if the same time is needed to traverse the link by either mode. If a different time is needed by each mode, two different links are used, each representing one mode. In the latter case, all the packages need to travel by only one mode even if both modes are feasible so that all the packages that start together arrive at the same time to their destination. It is assumed that every day is repeated unchanged without any distortion of the pattern because of weekends. Since a sorting operation is repeated every day at the same time, one node represents a sorting operation for as many days as necessary for a complete cycle of operations to occur in the system. To avoid any confusion, we will use in the description of the network design problem the terms *origin* and *destination* or *OD pair* to refer to the origin and destination nodes of a package; we will use the terms *initial* and *final* nodes to refer to the origin and destination nodes of a directed link.

Each node is characterized by a daily starting and ending time of the sorting operation, a sorting capacity, a sorting cost, and the number of loading doors available. Each link is characterized by a travel time and distance between its initial and final nodes and the types of combinations that are permitted on the link with their costs and capacities. The combinations representing both highway and rail are associated with the same link when the travel time is the same for highway and rail. If the travel time is different and the link represents a particular mode, only the combinations of this mode are associated with the link. In addition, for each OD pair, the number of packages that need to be transported is given as well as the maximum time permitted from the moment a package starts at its origin until it reaches its destination.

A network-optimization system that solves the problem presented above utilizes large amounts of data and must have a reliable data interface in addition to the solver. The data interface extracts, verifies, and validates the data needed for the problem corresponding to the particular geographical area applicable to the problem. It then generates the network and, after the solver is applied, produces reports of the results. The solver consists of optimization algorithms that obtain solutions of the problem.

The network described above can be very large. To facilitate the application of the optimization algorithms, the network size is reduced using various aggregation rules. OD pairs may be consolidated by building or destination group, and local terminals in the same building may be combined into one node. If all the possible connections between each pair of sorting operations are added, the network becomes very dense. For this reason, only links that are likely to be used in the solution are included (e.g., direct links between sorting operations that are farther apart than a given distance are omitted).

The network design problem is formulated below as a mixed-integer programming problem (MIP) (Nemhauser and Wolsey 1988). A graph $G(N,E)$ is given with N a set of nodes and E a set of directed links. A node represents a sorting operation for each consecutive day of a whole cycle of operations. A directed link (i,j) represents the movement of packages from sorting operation i (initial node of the link) to sorting operation j (final node of the link). Because of the presence of two different links that are used in parallel between the same sorting operations representing two different modes with different travel times, link (i,j) may not be unique. To simplify the presentation, however, we disregard the presence of parallel links. The formulation can be easily extended to include this case because at most one of such parallel links can be used in the solution. Additional notation is introduced next.

9.3.1. Notation

Parameters

A = set of OD pairs = $\{(k,l) \mid k \in N$ is the origin and $l \in N$ is the destination, $k \neq l\}$
M = set of all trailer-combination types (a trailer combination consists of a tractor and one or more trailers)
M_{ij} = set of trailer-combination types of link $(i,j) \in E$; $M_{ij} \subseteq M$
Q = set of trailer types
F = set of trailer types that must balance (rented rail trailers may not need to balance); $F \subseteq Q$
B = $\{B_k \mid B_k$ is a building; $B_k \subseteq N\}$; $j \in B_k$ means that sorting operation $j \in N$ resides in building B_k
c_{ijm} = cost of moving trailer-combination type $m \in M_{ij}$ on link $(i,j) \in E$
d_{ikl} = cost of handling all the packages of OD pair $(k,l) \in A$ through node $i \in N$
k_q = capacity of trailer type $q \in Q$ in number of average-size packages
δ_{qm} = number of single trailers of type $q \in Q$ in trailer-combination type $m \in M$
h_{ij} = starting time of sorting operation j minus ending time of sorting operation i so that the packages sorted at $i \in N$ are transported on $(i,j) \in E$ and sorted next at $j \in N$
r_j = duration of sorting operation j
s_{kl} = starting time at origin $k \in N$ of the packages to be transported to destination $l \in N$
v_{kl} = number of average-size packages of OD pair $(k,l) \in A$
τ_{kl} = total time permitted for the packages of OD pair (k,l) to travel from k to l
u_i = capacity of sorting operation $i \in N$ (maximum number of packages that can go through node i)
g_i = minimum number of packages going through $i \in N$, if sorting operation i is open
f_i = maximum number of outgoing-trailer positions (loading doors) available at node $i \in N$
INF = a very large number

Decision variables

x_{ijm} = number of trailer combinations of type $m \in M_{ij}$ used on link $(i,j) \in E$
w_{ijq} = number of nonempty trailers of type $q \in Q$ on link $(i,j) \in E$
y_{ijkl} = 1 if link $(i,j) \in E$ is used to transport the packages of OD pair $(k,l) \in A$; 0 otherwise
z_i = 1 if sorting operation $i \in N$ is open; 0 otherwise
t_{ikl} = departure time of packages of OD pair $(k,l) \in A$ from node $i \in N$ (end time of sorting operation i).

The cost d_{jkl} is estimated as the average cost of a package through sorting operation $i \in N$ multiplied by the number of packages of OD pair $(k,l) \in A$. The cost c_{ijm} is estimated as a function of the distance of link $(i,j) \in E$, fuel prices, driver wages as well as depreciation and cost of the trailer-combination type $m \in M_{ij}$.

It is assumed that all the packages processed through a sorting operation are available at the beginning and leave at the end of the sorting operation. The time h_{ij} of link $(i,j) \in E$ is the difference between the starting time of the sorting operation j and the ending time of the sorting operation i with the appropriate time difference included for the packages to be transported on link (i,j) and be available at j on time. The time h_{ij} as defined above makes it unnecessary to consider the time windows of the sorting operations explicitly in the following formulation. The time h_{ij} is also equal to the travel time on link (i,j) plus the difference in time between the beginning of the sorting operation at j and the arrival of the packages at j, which corresponds to the wait time until the sorting operation j starts. The capacity of a sorting operation is represented by an upper bound that cannot be exceeded. A lower bound may also be used to force sorting operations to be closed if they are underutilized.

9.4. Network Design Formulation

$$\text{Min } Z(\mathbf{x},\mathbf{w},\mathbf{y},\mathbf{z},\mathbf{t}) = \Sigma_{j\in N} \Sigma_{(k,l)\in A} d_{jkl} \Sigma_{i\in N} y_{ijkl} + \Sigma_{(i,j)\in E} \Sigma_{m\in M_{ij}} c_{ijm} x_{ijm} \tag{3}$$

subject to

$$\Sigma_{j\in N} y_{ijkl} - \Sigma_{p\in N} y_{pikl} = b \qquad \forall\ (k,l) \in A,\ i \in N \tag{4}$$

where $b = 1$ for $i = k$; $b = -1$ for $i = l$; $b = 0$ otherwise

$$t_{jkl} - t_{ikl} - \text{INF}(y_{ijkl} - 1) \geq h_{ij} + r_j \qquad \forall\ i \in N,\ j \in N,\ (k,l) \in A \tag{5}$$

$$t_{kkl} = s_{kl} \qquad \forall\ (k,l) \in A \tag{6}$$

$$t_{lkl} \leq \tau_{kl} + s_{kl} + r_l \qquad \forall\ (k,l) \in A \tag{7}$$

$$\Sigma_{i\in N} \Sigma_{(k,l)\in A} v_{kl}\, y_{ijkl} \leq u_j \qquad \forall\ j \in N \tag{8}$$

$$\Sigma_{i\in N} \Sigma_{(k,l)\in A} v_{kl}\, y_{ijkl} - g_j\, z_j \geq 0 \quad \forall\ j \in N \tag{9}$$

$$\Sigma_{j\in B_k} \Sigma_{i\in N} \Sigma_{m\in M_{ij}} \delta_{qm}\, x_{ijm} - \Sigma_{j\in B_k} \Sigma_{p\in N} \Sigma_{m\in M_{ij}} \delta_{qm}\, x_{jpm} = 0 \qquad \forall\ B_k \in B,\ q \in F \tag{12}$$

$$\Sigma_{q\in Q} k_q\, w_{ijq} - \Sigma_{(k,l)\in A} v_{kl}\, y_{ijkl} \geq 0 \qquad \forall\ (i,j) \in E \tag{13}$$

$$\Sigma_{j\in N} \Sigma_{q\in Q} w_{ijq} \leq f_i \qquad \forall\ i \in N \tag{14}$$

$$\Sigma_{m\in M_{ij}} \delta_{qm}\, x_{ijm} - w_{ijq} \geq 0 \qquad \forall\ (i,j) \in E,\ q \in Q \tag{15}$$

$$x_{ijm} \geq 0 \text{ and integer} \qquad \forall\ i,j,m \tag{16}$$

$$w_{ijq} \geq 0 \text{ and integer} \qquad \forall\ i,j,q \tag{17}$$

$$y_{ijkl} = 0 \text{ or } 1 \qquad \forall i,j,k,l \tag{18}$$

$$z_i = 0 \text{ or } 1 \qquad \forall\ i \tag{19}$$

$$t_{jkl} \geq 0 \qquad \forall\ j,k,l \tag{20}$$

The objective function (3) minimizes the total cost of handling and transporting the packages of all the OD pairs. Constraints (4) are balancing constraints ensuring that the packages of an OD pair start from their origin, end at their destination, and, if they enter an intermediate node, also exit the node. Each constraint (5) computes the departure time of the packages of OD pair (k,l) from node j, using the departure time of the preceding node i. If link $(i,j) \in E$ is used to transport the packages of OD pair $(k,l) \in A$ ($y_{ijkl} = 1$), the constraint becomes $t_{jkl} - t_{ikl} \geq h_{ij} + r_j$. If link $(i,j) \in E$ is not used ($y_{ijkl} = 0$), the constraint is not binding. The starting time at each origin is set with constraints (6).

Constraints (7) ensure that the service requirements are met, that is, the movement of the packages of OD pair (k,l) from their origin k to their destination l takes no more than τ_{kl} time. These constraints also force constraints (5) to apply with equality if necessary.

Constraints (8) ensure that the capacities of the sorting operations are not violated, and constraints (9) prevent sorting operations that are open from being underutilized. Constraints (10) ensure that packages enter node j only if the sorting operation j is open. That is, if $y_{ijkl} = 1$ for any i, j, k, l then $z_j = 1$ from constraints (10). If $y_{ijkl} = 0$ for all i, j, k, l then $z_j = 0$ from constraints (9) and (10).

Constraints (11) ensure that all the packages going though sorting operation i and having the same destination l use the same network link to the next sorting operation on their path, that is, there are no split paths to the same destination. The only case that is permitted is $k \neq k', j = j'$. The case $k = k', j \neq j'$ is excluded by constraints (4) which ensure a unique path for each OD pair (k,l). The case $k \neq k', j \neq j'$ is excluded by constraints (11). Using $k < k'$ avoids repeating the constraints (11) twice.

Constraints (12) are balancing constraints ensuring that for each building B_k and for each trailer type $q \in F$ that must balance, the same number of trailers that enter building B_k also exit it. To achieve balancing of trailers, empty trailers may be introduced into the system by constraints (12). These constraints are more complicated than they would be if each trailer-combination type rather than each trailer type needed to balance. Constraints (13) are the volume constraints, ensuring that for each link (i,j) trailers with enough capacity are used to transport the number of packages on the link.

Constraints (14) ensure that the number of trailers that are filled during a sorting operation is no larger than the number of available loading doors. It is assumed that at most one trailer is filled from each door during a sorting operation. This is a good approximation although it may be conservative at times because occasionally it is possible to fill a trailer at a door and replace it with a new trailer during the same sorting operation. Constraints (15) ensure that the number of nonempty trailers of type $q \in Q$, on link $(i,j) \in E$ represented by w_{ijq} is no larger than the total number of trailers of type $q \in Q$ (empty and nonempty) forming the trailer combinations of type $m \in M_{ij}$ on link $(i,j) \in E$ represented by x_{ijm}. Note that w_{ijq} can have alternative solution values in the previous formulation apart from being exactly equal to the number of nonempty trailers. The value of w_{ijq} is always at least as large as the number of nonempty trailers from constraint (13). If empty trailers are introduced for balancing so that constraint (15) is not binding, w_{ijq} can have alternative solution values larger than the number of nonempty trailers, depending on how tight the corresponding constraint (14) is. Constraints (16) to (20) are the integrality and nonnegativity constraints.

For a large transportation company, the $G(N,E)$ network may have 40,000 links even when care is taken to keep it as sparse as possible. The number of binary variables y_{ijkl} of the above MIP formulation may be 14,000,000 or more. That is also the number of constraints (5), while the number of constraints (11) is much larger.

Formulation (3)–(20) is too large to be supplied to an MIP solver and solved directly. Instead, a heuristic solution for the network design problem can be obtained by solving sequentially two smaller problems that are embedded in formulation (3)–(20). These are the package-routing problem and the trailer-assignment problem. In the first step, the routes of the packages are obtained assuming a representative trailer type for highway and rail. This step produces the number of packages that are transported from the initial node to the final node of each link of the network. In the second step, given the number of packages and the types of permitted equipment on each link, the actual modes and trailer combinations that balance are obtained. These two problems are presented next.

9.5. Package-Routing Problem

The package-routing problem determines the routes of packages on the $G(N,E)$ network for each OD pair so that the service requirements are met, the capacities of the sorting operations are not exceeded, the sorting operations are not underutilized, the number of loading doors of the buildings is not exceeded, packages to a common destination are routed along the same path, trailers are not underutilized, and total cost is minimized. The package-routing problem does not determine the trailer combinations that are used, nor does it balance trailer types.

In the following, we still present a simplified formulation where we do not indicate mode, although we continue to use one link for both modes if the travel times are the same for both modes on the link and two different links if the travel times are different. We extract from formulation (3)–(20) constraints (4)–(8), (18), and (20), which involve only the y_{ijkl} and t_{jkl} variables, putting aside for the moment the constraints on the number of loading doors, underutilized sorting operations, split paths to common destination, and maximization of trailer utilization. Because of their very large number, constraints (11) are not included.

Because the objective function (3) involves variables other than y_{ijkl} and t_{jkl}, we replace it with a new objective function that uses an estimated cost parameter. First, we select a representative trailer-combination type for each mode and estimate the cost per package, per mode for each link by dividing

the combination cost on the link by the combination capacity. For links that share both modes, the smaller cost of the two modes is used. Using the cost per package, the following cost parameter is computed:

d_{ijkl} = cost of transporting all the packages of OD pair $(k,l) \in A$ on link $(i,j) \in E$

Using this new cost, the objective function (3) is replaced by the following approximation:

$$\text{Min } Z(\mathbf{y},\mathbf{t}) = \Sigma_{j\in N} \Sigma_{(k,l)\in A} d_{jkl} \Sigma_{i\in N} y_{ijkl} + \Sigma_{(i,j)\in E} \Sigma_{(k,l)\in A} d_{ijkl}\, y_{ijkl} \tag{21}$$

Objective function (21) can be simplified if we combine the transporting cost of all the packages of OD pair (k,l) along link (i,j) and their handling cost through sorting operation j in the following cost parameter:

c_{ijkl} = cost of transporting all the packages of OD pair $(k,l) \in A$ on link $(i,j) \in E$ and handling them through node $j \in N$

The objective function becomes

$$\text{Min } Z(\mathbf{y},\mathbf{t}) = \Sigma_{(i,j)\in E} \Sigma_{(k,l)\in A} c_{ijkl}\, y_{ijkl} \tag{22}$$

The MIP formulation (22), (4)–(8), (18), and (20) of the package-routing problem is still a very large problem and difficult to solve directly. If the complicating constraints (8) are removed, the problem is solved relatively easily. We take advantage of this characteristic by using a Lagrangian relaxation approach (Ahuja et al. 1993; Fisher 1985; Geoffrion 1974). This is combined with search heuristics that also implement the constraints that are completely omitted in the formulation, which are the constraints on the number of loading doors, the lower bound constraints on the capacity of each sorting operation that is open, the split paths constraints, and an additional lower bound constraint on the number of packages on any link $(i,j) \in E$ that is actually used. The last constraint forces more efficient trailer utilization by ensuring that no link carries too few packages, which would result in the use of trailers with very low load factors in the trailer-assignment step.

The following Lagrangian dual problem is obtained by dualizing constraints (8) using their non-negative Lagrange multipliers λ_j, $j \in N$.

9.6. Lagrangian Relaxation of the Package-Routing Problem

$$\begin{aligned}\text{Min } Z(\mathbf{y},\mathbf{t},\lambda) &= \Sigma_{(i,j)\in E} \Sigma_{(k,l)\in A} c_{ijkl}\, y_{ijkl} + \Sigma_{j\in N} \lambda_j (\Sigma_{i\in N} \Sigma_{(k,l)\in A} v_{kl}\, y_{ijkl} - u_j) \\ &= \Sigma_{(i,j)\in E} \Sigma_{(k,l)\in A} (c_{ijkl} + \lambda_j v_{kl})\, y_{ijkl} + \text{CONSTANT} \\ &= \Sigma_{(i,j)\in E} \Sigma_{(k,l)\in A} \bar{c}_{ijkl}\, y_{ijkl} + \text{CONSTANT}\end{aligned} \tag{23}$$

subject to

$$\Sigma_{j\in N} y_{ijkl} - \Sigma_{p\in N} y_{pikl} = b \qquad \forall\ (k,l) \in A,\ i \in N \tag{24}$$

where $b = 1$ for $i = k$; $b = -1$ for $i = l$; $b = 0$ otherwise

$$t_{jkl} - t_{ikl} - \text{INF}(y_{ijkl} - 1) \geq h_{ij} + r_j \qquad \forall\ i \in N,\ j \in N,\ (k,l) \in A \tag{25}$$

$$t_{kkl} = s_{kl} \quad \forall\ (k,l) \in A \tag{26}$$

$$t_{lkl} \leq \tau_{kl} + s_{kl} + r_l \quad \forall\ (k,l) \in A \tag{27}$$

$$y_{ijkl} = 0 \text{ or } 1 \qquad \forall\ i,j,k,l \tag{28}$$

$$t_{jkl} \geq 0 \quad \forall\ j,k,l \tag{29}$$

$$\lambda_j \geq 0 \qquad \forall\ j \tag{30}$$

The cost $\bar{c}_{ijkl} = c_{ijkl} + \lambda_j v_{kl}$ is the modified cost of transporting all the packages of OD pair $(k,l) \in$ A on link $(i,j) \in E$ and handling them through node $j \in N$, given the Lagrange multipliers λ_j, $j \in N$.

The Lagrangian dual problem (23)–(30) can be solved relatively easily because it decomposes into $|A|$ constrained shortest-path problems, one for each OD pair. A constrained shortest-path problem

finds a path from an origin $k \in N$ to a destination $l \in N$ with the smallest cost that has total time no greater than τ_{kl}. Although the constrained shortest-path problem is NP-complete, it can be used as part of an algorithm for the package-routing problem because there are several algorithms that solve large enough problems in good computer running times (Ahuja et al. 1993; Desrosiers et al. 1995).

A heuristic algorithm for the package-routing problem is presented next, based on the previous analysis. It is applied to the network described before that includes only one link between a pair of sorting operations representing the cheaper mode if the times h_{ij} for both modes are the same, and two links, one for each mode, if the times are different. A more detailed (but still high-level) description of each step follows the algorithm.

9.7. Package-Routing Heuristic Algorithm

1. Find the OD pairs that have a unique feasible path from their origin to their destination using a k-shortest path algorithm. Route all the packages with unique shortest paths along the obtained paths, remove them from the package-routing problem, and update all the parameters.
2. Solve a constrained shortest path for each OD pair using the costs $\bar{c}_{ijkl} = c_{ijkl} + \lambda_j v_{kl}$, where the Lagrange multipliers are set to zero for the first iteration.
3. Reroute packages to (i) eliminate split paths from each sorting operation to a common destination, (ii) eliminate split paths between different modes that have different times on links so that only one mode is used, (iii) enforce the capacity constraint, and (iv) enforce the constraint on the number of loading doors for each sorting operation.
4. If the solution can be improved and the limit on the number of Lagrangian iterations is not reached, compute new costs $\bar{c}_{ijkl}$ using subgradient optimization or some other methodology and go to step 2.
5. Reroute packages from underutilized links to consolidate loads while preserving solution feasibility.
6. Reroute packages to close the underutilized sorting operation that is permitted to be closed and realizes the most savings. If a sorting operation is closed, disable the node representing it and start over from step 2.

In step 1, a k-shortest path algorithm (Minieka 1978) for $k = 2$ is used to obtain all the OD pairs that have unique feasible paths. The packages of these OD pairs are routed along their single paths and removed from the problem, updating all the parameters.

Steps 2–4 implement the Lagrangian relaxation algorithm. In step 2, a constrained shortest-path problem is solved for each OD pair using the costs $\bar{c} = c_{ijkl} + \lambda_j v_{kl}$. For the first iteration, the original link costs are used that result from setting the Lagrange multipliers to zero.

Step 3 takes care of the split-paths, capacity, and loading-door constraints. Each node of the network is examined if it satisfies the split-paths constraints (11). If multiple paths to the same destination exist starting from the node, the best path is selected based on several criteria and all the packages from the node to the common destination are routed along this path. Also, if packages are split between two parallel links of different modes, they are rerouted along only one parallel link. Each node is also examined to find whether it satisfies the capacity constraints (8). For each node that surpasses the permitted capacity, OD pairs that use the node are selected according to several criteria and their packages are removed until the capacities are satisfied. The removed packages are routed again sequentially using the constrained shortest-path algorithm on a network where the nodes that have reached their capacities are disabled. The split-paths constraints and the capacity constraints are examined repeatedly until they are satisfied or the algorithm indicates that it cannot find a feasible solution. Finally, each node is examined if it satisfies constraint (14) on the number of loading doors. If a node is found that violates the door constraint, packages are rerouted to sequentially reduce the number of doors but keep the capacity and split constraints valid.

In step 4, if the solution can be improved and more Lagrangian iterations are permitted, new Lagrange multipliers are computed using subgradient optimization (Ahuja et al. 1993; Crowder 1976) or some other methodology. These are used to obtain new costs $\bar{c}_{ijkl}$ and a new Lagrangian iteration starts at step 2. No more details are given here about the Lagrangian relaxation or the subgradient optimization algorithm. A Lagrangian relaxation approach is used to solve the trailer-assignment problem and a more detailed description of this optimization procedure is given in that section. When the Lagrangian iterations are completed, the solution satisfies the split-paths, capacity, and door constraints. If at any point the heuristic cannot obtain a solution that satisfies a constraint, it stops and indicates that it cannot find a feasible solution.

In step 5, links are found that carry too few packages for a complete load and the packages are rerouted so that the capacity, split-paths, and door constraints continue to be satisfied. These con-

straints are included to improve the results of the trailer-assignment problem that is solved after the package-routing problem and that represents the true cost of a network design solution.

Finally, in step 6, underutilized sorting operations are examined to implement constraints (9). The packages of underutilized sorting operations are rerouted and the underutilized sorting operation for which the total cost of the solution decreases most is eliminated. The node representing the eliminated sorting operation is disabled and the algorithm starts over from step 2.

The routing decisions obtained by the package-routing heuristic algorithm outlined above are used as input in the trailer-assignment problem that is described next.

9.8. Trailer-Assignment Problem

Given the number of packages on each link obtained by solving the package-routing problem, the trailer-assignment problem determines the number and type of trailer combinations on each link of the network $G(N,E)$ that have enough combined capacity to transport all the packages on the link, balance by trailer type for each building, and have the least cost.

The trailer-assignment problem is described next. To solve the problem more efficiently, the network $G(N,E)$ can be modified into the network $G'(N',E')$ as follows. Each node $i \in N'$ represents a building, that is, all the nodes representing sorting operations in the same building are collapsed into one node. All the links that carry packages in the solution of the package-routing problem are included. Among the links in $G(N,E)$ that do not carry packages, only those that may be used to carry empty combinations for balancing are included so that $E' \subseteq E$. In particular, among parallel links between buildings that do not carry packages, only one is retained in G'. Still, the network G' generally has several parallel links between each pair of nodes, in which case link (i,j) is not unique. To avoid complicating the formulation and because it is easy to extend it to include parallel links, we will not include indexing to indicate parallel links, exactly as we did in formulation (3)–(20).

The trailer-assignment problem is formulated below on the network $G'(N',E')$ using constraints (12), (13), and (16) as well as the objective function (3) with some modifications.

9.9. Trailer-Assignment Formulation

$$\text{Min } Z(\mathbf{x}) = \Sigma_{(i,j)\in E'} \Sigma_{m\in M_{ij}} c_{ijm}\, x_{ijm} \tag{31}$$

subject to

$$\Sigma_{i\in N'} \Sigma_{m\in M_{ij}} \delta_{qm}\, x_{ijm} - \Sigma_{p\in N'} \Sigma_{m\in M_{ij}} \delta_{qm}\, x_{jpm} = 0 \qquad \forall\, j \in N',\, q \in F \tag{32}$$

$$\Sigma_{m\in M_{ij}} k_m\, x_{ijm} \geq \overline{v}_{ij} \qquad \forall\, (i,j) \in E' \tag{33}$$

$$x_{ijm} \geq 0 \text{ and integer} \qquad \forall\, i,j,m \tag{34}$$

Objective function (31) is the same as objective function (3). It does not include the first component because it is a constant since the values of the y_{ijkl} variables are known from the solution of the package-routing problem. Constraints (32) are the same as constraints (12) except that the summation over buildings is now unnecessary because a node represents a building. Constraints (33) are similar to constraints (13) where, as in the objective function, the number of packages, $\overline{v}_{ij}$, for all OD pairs on link (i,j) is now a constant. The variables w_{ijq} are not needed anymore and only the variables x_{ijm} are used, representing combinations with both full and empty trailers. So the trailer capacities k_q for $q \in Q$ are replaced by the trailer-combination capacities k_m for $m \in M_{ij}$.

The integer-programming (IP) problem (31)–(34) is still difficult to solve. If constraints (32) are removed, the problem without balancing is easy to solve because it breaks into many very small problems, one for each link. To take advantage of this characteristic, Lagrangian relaxation (Ahuja et al. 1993; Fisher 1985; Geoffrion 1974) is used to solve problem (31)–(34), dualizing the balancing constraints (32). A Lagrange multiplier λ_{jq}, unrestricted in sign, is used for each balancing constraint and the following Lagrangian dual problem is obtained.

$$\begin{aligned}
\text{Min } Z(\mathbf{x},\lambda) &= \Sigma_{(i,j)\in E'} \Sigma_{m\in M_{ij}} c_{ijm}\, x_{ijm} \\
&\quad + \Sigma_{j\in N'} \Sigma_{q\in F} \lambda_{jq} \left(\Sigma_{i\in N'} \Sigma_{m\in M_{ij}} \delta_{qm}\, x_{ijm} - \Sigma_{p\in N'} \Sigma_{m\in Mij} \delta_{qm}\, x_{jpm}\right) \\
&= \Sigma_{(i,j)\in E'} \Sigma_{m\in M_{ij}} \left(c_{ijm} + \Sigma_{q\in F} \delta_{qm} (\lambda_{jq} - \lambda_{iq})\right) x_{ijm} \\
&= \Sigma_{(i,j)\in E'} \Sigma_{m\in M_{ij}} \overline{c}_{ijm}\, x_{ijm}
\end{aligned} \tag{35}$$

subject to

$$\Sigma_{m\in M_{ij}} k_m\, x_{ijm} \geq \overline{v}_{ij} \qquad \forall\, (i,j) \in E' \tag{36}$$

$$x_{ijm} \geq 0 \text{ and integer} \qquad \forall\, i,j,m \tag{37}$$

where $\bar{c}_{ijm} = c_{ijm} + \Sigma_{q \in F}\ \delta_{qm}\ (\lambda_{jq} - \lambda_{iq})$ is the modified cost of moving trailer-combination type $m \in M_{ij}$ on link $(i,j) \in E'$ given the vector $\boldsymbol{\lambda}$.

Problem (35)–(37) decomposes into $|E'|$ subproblems, one for each link $(i,j) \in E'$. Each one of the subproblems is a kind of integer reverse knapsack problem, similar to the integer knapsack problem (Martello and Toth 1990; Nemhauser and Wolsey 1988; Chvátal 1983) and can be solved by similar algorithms. Each subproblem is very small, having $|M_{ij}|$ variables for link $(i,j) \in E'$. The solution obtained by solving the Lagrangian dual (i.e., all the reverse knapsack problems) does not necessarily balance trailer combinations at each node even for optimal $\boldsymbol{\lambda}$ and is not generally feasible for the original problem (31)–(34). A feasible solution is obtained heuristically by solving sequentially one minimum-cost-flow problem (Ahuja et al. 1993) for each trailer type that needs to balance. Balancing is achieved by adding empty trailers or replacing one trailer type with another one of larger capacity that is not yet balanced or does not need to balance.

A Lagrangian relaxation heuristic algorithm that solves the Lagrangian dual problem (35)–(37) is presented next. It uses subgradient optimization to compute the Lagrange multipliers $\boldsymbol{\lambda}$.

9.10. Lagrangian Relaxation Algorithm for the Trailer-Assignment Problem

1. Set the Lagrange multipliers $\boldsymbol{\lambda}$ to zero in the Lagrangian dual problem and initialize $\overline{Z}$ (upper bound, best known feasible solution of the original problem) to a high value.
2. Solve the Lagrangian dual problem with the latest values of $\boldsymbol{\lambda}$ (by solving a set of integer reverse knapsack problems) to obtain the optimal objective function value, $Z^*(\mathbf{x}^*, \boldsymbol{\lambda})$, for the given $\boldsymbol{\lambda}$.
3. Apply a heuristic approach to obtain a feasible solution of the problem and update $\overline{Z}$.
4. If the gap between $\overline{Z}$ and $Z^*(\mathbf{x}^*, \boldsymbol{\lambda})$ is small or some other criterion is satisfied (e.g., a set number of iterations is reached or no more improvement is expected), stop.
5. Compute new values of the Lagrange multipliers $\boldsymbol{\lambda}$ using subgradient optimization and go to step 2.

Step 3 above may be implemented only occasionally instead of at every iteration. Improvement heuristics can also be used to modify the solution in several ways. They can be used to combine single trailers into more efficient trailer combinations. They can also be used to find any cycles of trailer types that are either empty or can be replaced by trailer types that do not need to balance. If a whole cycle of trailers that results in improved cost is modified, balancing of trailers is maintained. Improvement heuristics can also be used to replace whole cycles of trailers of excess capacity with trailers of smaller capacity if the total cost is decreased.

A subgradient optimization algorithm (Ahuja et al. 1993; Crowder 1976) is used in step 5 to compute an improved Lagrange multiplier vector and is described below.

9.11. Subgradient Optimization Algorithm

Given an initial Lagrange multiplier vector $\boldsymbol{\lambda}^0$, the subgradient optimization algorithm generates a sequence of vectors $\boldsymbol{\lambda}^0, \boldsymbol{\lambda}^1, \boldsymbol{\lambda}^2, \ldots$ If $\boldsymbol{\lambda}^k$ is the Lagrange multiplier already obtained, $\boldsymbol{\lambda}^{k+1}$ is generated by the rule

$$t_k = \frac{\rho_k(\overline{Z} - Z^*(\mathbf{x}^*, \boldsymbol{\lambda}^k))}{\Sigma_j\ \Sigma_q\ (\Sigma_i\ \Sigma_m\ \delta_{qm}\ x^k_{ijm} - \Sigma_p\ \Sigma_m\ \delta_{qm} x^k_{jpm})^2} \tag{38}$$

$$\boldsymbol{\lambda}^{k+1}_{jq} = \lambda^k_{jq} + t_k\ (\Sigma_i\ \Sigma_m\ \delta_{qm}\ x^k_{ijm} - \Sigma_p\ \Sigma_m\ \delta_{qm}\ x^k_{jpm}) \qquad \forall\ j \in N',\ q \in F \tag{39}$$

where t_k is a positive scalar called the step size and ρ_k is a scalar that satisfies the condition $0 < \rho_k \leq 2$. The denominator of equation (38) is the square of the Euclidean norm of the subgradient vector corresponding to the optimal solution vector $\mathbf{x}^k$ of the relaxed problem at step k. Often a good rule for determining the sequence ρ_k is to set $\rho_0 = 2$ initially and then halve ρ_k whenever $Z^*(\mathbf{x}^*, \boldsymbol{\lambda}^k)$ has not increased in a specific number of iterations. The costs are calculated with the new values of $\boldsymbol{\lambda}$. If any negative costs are obtained, the value of ρ is halved and the values of $\boldsymbol{\lambda}$ recomputed until all the costs are nonnegative or ρ is too small to continue iterating.

A feasible solution is obtained in step 3, using a minimum-cost-flow algorithm (Ahuja et al. 1993) sequentially for each trailer type that needs to balance. First, for each building the excess or deficit of trailers of each type that has to balance is computed. Then a minimum-cost-flow algorithm is applied for each trailer type that obtains the optimal movements of trailers from each node of excess to each node of deficit. This may be the movement of a single empty trailer, the movement of an empty trailer that gets attached to an already used trailer to make up a permitted combination, or the

movement of an already used trailer replacing another trailer type of smaller or equal capacity that is not yet balanced or does not need to balance.

Lagrangian relaxation is often used within a branch-and-bound procedure. The exact branch-and-bound algorithm has large computational cost; also, the trailer-assignment problem is only part of a heuristic algorithm for the network design problem. For these reasons, the Lagrangian relaxation algorithm is applied only once, at the root of the branch-and-bound tree, to find a heuristic solution to the trailer-assignment problem.

9.12. Extensions of the Network-Design Problem

If the results of the network-design problem are intended not only for long-term planning but to actually modify the routing network, the solution must represent an incremental change from the currently used solution. Otherwise, any savings from an improved solution may be lost in modifying the sorting operations to accommodate the solution changes. To this end, both the package-routing and the trailer-assignment problem can be modified relatively easily to handle presetting some of the variables. For the package-routing problem, this means presetting whole or partial paths of specific OD pairs. A solution is obtained by preprocessing the input data to eliminate or modify OD pairs that are completely or partially preset and updating the input data. Similarly, for the trailer-assignment problem, particular combinations on links may be preset. After appropriate variables are fixed, the Lagrangian relaxation algorithm optimizes the remaining variables.

The network-design problem presented considers only packages moving on the ground and chooses only one transportation mode when travel times differ between sorting operations. The network-design problem can be extended to include all modes of transportation and all types of products with different levels of service requirements. Different modes may have different costs and travel times between sorting operations, permitting parallel use of modes with different travel times along the same routes. This extension complicates considerably an already difficult problem and is not described here any further.

10. DRIVER SCHEDULING

10.1. Tractor-Trailer-Driver Schedules

This section examines one approach for solving the tractor-trailer-driver-scheduling problem for a package-transportation company. Tractor-trailer combinations transport packages between terminals of a package-transportation company, as discussed in Section 9. This involves movement of both equipment and drivers. While balancing is the only constraint for equipment routing, the movement of drivers is more complex. The daily schedule of a tractor-trailer driver starts at his or her base location (domicile) where he or she returns at the end of his workday. A driver schedule consists of one or more legs.

A leg is the smallest piece of work for a driver and consists of driving a tractor-trailer combination from one terminal to another or repositioning trailers inside a terminal. Each leg is characterized by an origin terminal and a destination terminal, which may coincide. There is an earliest availability time at the origin terminal, a latest required arrival time at the destination terminal, and a travel time (or repositioning time) associated with a leg. A tractor-trailer combination that is driven from the origin terminal to the destination terminal of a leg must start no earlier than the earliest availability time at the origin and arrive at the destination no later than the latest required arrival time. At the destination terminal of a leg, a driver may drop his or her current tractor-trailer combination and pick up a new one to continue work on the next leg of his or her daily schedule, take a break, or finish work for the day.

In this section, we assume that the legs are already determined and given. We want to generate driver schedules by combining legs. An acceptable schedule must meet specific work rules, which specify the minimum number of hours that a driver must be paid for a day's work (usually 8 hours) and the maximum length of a workday (usually 10 hours). In addition, a driver must return to his or her domicile every day and a workday must incorporate breaks of specified duration at specified times. For example, a lunch break must last 1 hour and be scheduled between 11:00 am and 2:00 pm.

Another consideration in the generation of driver schedules is the availability of packages for sorting within a terminal. During a sorting operation, loads should arrive at such a rate that the facility is not kept idle. If packages arrive late, the facility will be underutilized during the early stages of sorting while the facility capacity may be surpassed later. For this reason, the duration of each sorting operation is divided into equal time intervals, say, half-hour intervals. Driver schedules need to be generated in such a way that volume availability is satisfied, that is, a minimum number of packages arrives at each sorting facility by the end of each time interval.

The driver-scheduling problem has a short or intermediate planning horizon. It is usually solved regularly once or twice a year and the obtained schedules are bid by the drivers, based on seniority.

The problem may also be solved if changes in volume occur that render the existing schedules inadequate. If decisions about driver schedules are made at the local level and the schedules are bid separately by region, the problem is solved locally in a decentralized fashion.

10.2. Driver-Scheduling Problem

The problem of generating driver schedules can be defined as follows. Given a set of legs with time windows and travel times, generate driver schedules that assign work to drivers so that all the loads are moved within their time windows, the total work assigned to each driver meets given work rules, volume availability meets or exceeds sorting capacities, and the total cost of the schedules is as low as possible.

The problem is defined on an underlying network. The terminals are represented by nodes of the network and each leg is represented by an arc connecting the terminal of origin to the terminal of destination. Time windows on the nodes correspond to the earliest departure and latest arrival times at the terminals.

The cost of a schedule is a combination of both time and distance in addition to fixed costs because it is computed based on driver wages, cost of fuel, and vehicle depreciation. Feasible schedules can be generated using deadheading—that is, a driver can drive a tractor without a trailer to reposition himself or herself for the next leg. Tractor-only movements are used sparingly in a good set of schedules.

The driver-scheduling problem is formulated mathematically as a set-partitioning problem, a special type of integer-programming (IP) problem (Nemhauser and Wolsey 1988; Bradley et al. 1977).

10.2.1 Notation

Parameters

J = set of schedules (columns)
I_{leg} = set of legs (rows)
I_{dom} = set of domiciles (rows)
I_{sort} = set of sort intervals (rows)
c_j = cost of column j
a_{ij} = 1 if column j contains leg i; 0 otherwise
b_{ij} = 1 if column j has $i \in I_{\text{dom}}$ as its domicile; 0 otherwise
k_i^{lo} = minimum number of times domicile i must be used
k_i^{hi} = maximum number of times domicile i can be used
g_{ij} = number of packages contributed by column j to sort interval i
u_i = minimum number of packages required for sort interval i

Decision variables

x_j = 1 if column j is selected; 0 otherwise

10.3. Set-Partitioning Formulation with Side Constraints

$$\text{Min } \Sigma_{j\in J}\, c_j\, x_j \tag{40}$$

subject to

$$\Sigma_{j\in J}\, a_{ij}\, x_j = 1 \qquad \forall \text{ leg } i \in I_{\text{leg}} \qquad \text{(set-partitioning constraints)} \tag{41}$$

$$\Sigma_{j\in J}\, b_{ij}\, x_j \geq k_i^{\text{lo}} \qquad \forall \text{ domicile } i \in I_{\text{dom}} \qquad \text{(lower-domicile constraints)} \tag{42}$$

$$\Sigma_{j\in J}\, b_{ij}\, x_j \leq k_i^{\text{hi}} \qquad \forall \text{ domicile } i \in I_{\text{dom}} \qquad \text{(upper-domicile constraints)} \tag{43}$$

$$\Sigma_{j\in J}\, g_{ij}\, x_j \geq u_i \qquad \forall \text{ sort interval } i \in I_{\text{sort}} \qquad \text{(volume-availability constraints)} \tag{44}$$

$$x_j = 0 \text{ or } 1 \qquad \forall \text{ schedule } j \in J \qquad \text{(binary constraints)} \tag{45}$$

The objective function (40) minimizes the total cost of schedules. Constraints (41) are the set-partitioning constraints ensuring that each leg (row) is used by only one schedule (column). Constraints (42) and (43) are the domicile constraints and ensure that the lower and upper bounds for the selection of domiciles are met. According to work rules, each particular terminal must be used as a domicile a number of times within a given range. Constraints (44) are the volume-availability constraints and ensure that the required volume of packages is available for each sort interval. Constraints (45) are the binary constraints.

The presented formulation is a set-partitioning problem with additional side constraints. For a freight transportation company with 10,000 tractors and 15,000 drivers in the continental United States, the problem formulated above is too large to be solved for the whole country. Often, however,

driver-scheduling decisions are made at the local level and the problem is broken naturally into smaller problems that are solved locally by each region.

It is sometimes difficult to obtain even a feasible solution of the IP problems formulated in (40)–(45). If the feasible region contains few feasible solutions or if there are errors in the data that make it difficult or impossible to find a feasible solution, the set-partitioning formulation (40)–(45) can be changed into a set-covering formulation (Nemhauser and Wolsey 1988; Bradley et al. 1977) with soft domicile and volume-availability constraints to help guide the cleaning of data and the solution process. Slack and surplus (auxiliary) variables are added to the equations and inequalities (41)–(45) and incorporated into the objective function (40) with very high costs. The following additional notation is introduced:

d_i = very high cost for auxiliary variable of row i.
s_i^+ = surplus variable for row i; if positive, it indicates the number of units that the original constraint is below its right-hand-side.
s_i^- = slack variable for row i; if positive, it indicates the number of units that the original constraint is above its right-hand-side.

10.4. Set-Covering Formulation with Soft Constraints

$$\text{Min } \Sigma_{j\in J}\, c_j\, x_j + \Sigma_{i\in I_{\text{leg}}} d_i s_i^- + \Sigma_{i\in I_{\text{dom}}} d_i s_i^+ + \Sigma_{i\in I_{\text{dom}}} d_i s_i^- + \Sigma_{i\in I_{\text{sort}}} d_i s_i^+ \tag{46}$$

subject to

$$\Sigma_{j\in J}\, a_{ij}\, x_j - s_i^- = 1 \qquad \forall \text{ leg } i \in I_{\text{leg}} \qquad \text{(set-covering constraints)} \tag{47}$$

$$\Sigma_{j\in J}\, b_{ij}\, x_j + s_i^+ \geq k_i^{\text{lo}} \qquad \forall \text{ domicile } i \in I_{\text{dom}} \qquad \text{(soft lower-domicile constraints)} \tag{48}$$

$$\Sigma_{j\in J}\, b_{ij}\, x_j - s_i^- \leq k_i^{\text{hi}} \qquad \forall \text{ domicile } i \in I_{\text{dom}} \qquad \text{(soft upper-domicile constraints)} \tag{49}$$

$$\Sigma_{j\in J}\, g_{ij}\, x_j + s_i^+ \geq u_i \qquad \forall \text{ sort interval } i \in I_{\text{sort}} \qquad \text{(soft volume-availability constraints)} \tag{50}$$

$$x_j = 0 \text{ or } 1 \qquad \forall \text{ schedule } j \in J \tag{51}$$

$$s_i^+ \geq 0 \qquad \forall \text{ row } i \tag{52}$$

$$s_i^- \geq 0 \qquad \forall \text{ row } i \tag{53}$$

The high value of the costs d_i of the slack and surplus variables prevents their inclusion in a solution with positive values, if this is possible. Constraints (47) resemble set-partitioning constraints but they can also be considered as set-covering constraints, that penalize overcoverage. If some slack or surplus variables have positive values in a solution, they may help identify reasons for not obtaining a true feasible solution or they may remain in the solution for as long as necessary in an iterative solution process that will be discussed later.

10.5. Column-Generation Methodology

Each one of the regional problem formulations of a large freight transportation company may have up to 2000 legs (2400 rows altogether) that can be combined into possibly billions of feasible schedules. Even if the binary constraints (51) are relaxed, it is impossible to solve the resulting linear program (LP) with all the columns included. Instead, a standard decomposition method for large LPs called column generation is used (Bradley et al. 1977; Chvátal, 1983).

When the binary constraints (51) are replaced with the following bounding constraints

$$0 \leq x_j \leq 1 \qquad \forall \text{ schedule } j \in J$$

a column generation approach refers to the resulting LP problem that includes all the possible columns as the master problem. The corresponding LP problem that includes only a subset of the columns is called the restricted master problem.

Solving the LP involves pricing out each column using the dual variables or shadow prices associated with the restricted master problem. Sometimes this pricing-out operation can be formulated as a known problem (e.g., a shortest-path problem) and is called a subproblem. The solution of the subproblem produces a column, not yet included in the restricted master problem, that prices out best. For a minimization problem, if the best new column obtained has negative reduced cost, its inclusion in the restricted master problem will improve the solution. Column generation iterates solving the subproblem, adding a new column with negative reduced costs to the restricted master problem, and solving the new restricted master problem until no more columns can be obtained with

negative reduced costs. At that point the master problem has been solved optimally since all billions of possible schedules have been examined implicitly.

When the generation of columns cannot be structured as a known optimization problem, they must be generated explicitly. Usually, this approach results in solving the master problem heuristically because optimality is guaranteed only if all the feasible columns are examined. The schedules for the set-partitioning or set-covering problems presented above are obtained explicitly. The nature of the breaks imposed by work rules, the possible existence of additional local work rules in some regions, the presence of legs that carry priority loads and need to be included as early as possible in a schedule, and other local characteristics make it very difficult to generate schedules by solving a structured subproblem.

The schedules obtained from the solution of the LP problem by column generation may be fractional and therefore unacceptable. To obtain feasible schedules, an IP problem needs to be solved. An iterative heuristic approach for solving the driver-scheduling problem is presented next.

10.6. Iterative Process for Solving the Driver-Scheduling Problem with Column Generation

1. Start with a feasible solution. Set up an LP that consists of the columns of the feasible solution.
2. Solve the LP (restricted master problem). If the LP cost is low enough or a given number of iterations is reached, go to step 4.
3. Using the LP shadow prices, generate up to a given number of good new schedules and add them to the LP. If the number of columns exceeds a given maximum, remove columns with the worst reduced costs. Go to step 2.
4. Solve the IP.

In step 1, the algorithm starts with a feasible solution, which can be obtained from the currently used set of schedules. These schedules are broken apart to obtain the set of legs for the problem. In step 2, an LP problem is solved that consists of the current set of schedules and shadow prices are obtained for the rows. In step 3, the algorithm generates more schedules with reduced costs less than a set value using the shadow prices. The new schedules are added to the LP, omitting duplicate schedules. Because the LP is a minimization problem, columns with negative reduced costs will reduce the objective function value. More than one column is added to the LP at each iteration. For this reason, columns with low positive reduced costs may also be accepted. Such columns are also valuable in solving the IP problem in step 4. If the total number of columns in the restricted master problem exceeds a preset maximum number, the columns with the worst (highest) reduced costs are deleted. Steps 2 and 3 are repeated until an LP cost is obtained that is below a preset cutoff value or until a given number of iterations is reached. The resulting IP problem is solved in step 4.

In actual applications, the IP problem at step 4 of the previous algorithm obtained from column generation turned out to be a very difficult problem to solve with existing IP solvers. There were several reasons for this difficulty. The optimal LP solution at the beginning of step 4 included too many fractions, the problem structure exhibited massive degeneracy, and there were too many alternative optimal solutions. It was even difficult for IP solvers to obtain feasible solutions for large problems. Because of these difficulties, the following heuristic approach has been used that combines column generation with solution of the IP problem.

10.7. Integrated Iterative Process for Solving the Driver-Scheduling Problem

1. Start with a feasible solution. Set up an LP that consists of the columns of the feasible solution.
2. Solve the LP (restricted master problem). If the LP cost is low enough or a given number of iterations is reached, go to step 4.
3. Using the LP shadow prices, generate up to a given number of good new schedules and add them to the LP. If the number of columns exceeds a given maximum, remove columns with the worst reduced costs. Go to step 2.
4. Select a small number of columns with the highest fractional values, say 8. Using their legs as seeds, generate a small number of additional schedules, say 300, add to the LP, and solve it.
5. Select a small number of the highest fractional schedules, say 8. Restrict them to be integers and solve the resulting mixed-integer-programming (MIP) problem. If all variables in the solution of the current restricted master problem are integral, stop. Otherwise, set the selected columns to their integer solution values permanently, update the formulation, and go to step 2.

Steps 1, 2, and 3 are the same as before. In step 4, a preset number of columns with the highest fractional values are selected. The actual number used is set by experimentation. The legs making up these columns are used as seeds to generate a small number of additional columns that are added to the LP. The LP is solved and a small number of columns with the highest fractional values are selected and restricted to be integral. The resulting MIP problem is solved to optimality using an MIP solver. If all the columns of the restricted master problem have integral values in the solution, the algorithm stops. If some fractional values are still present in the solution, the selected columns to be integral are set permanently to their integer solution values and eliminated from the formulation and the column-generation phase starts again. In applications, up to about 40,000 columns were included in the restricted master problem during the iterative solution process.

10.8. Generation of Schedules

Approaches for generating new schedules are discussed in this section. Several techniques can be used to obtain new schedules explicitly, guided by the LP shadow prices. Each leg is associated with a shadow price in the LP solution, which indicates how expensive it is to schedule this leg. The generation of schedules focuses on the expensive legs to provide more alternative schedules that include them and drive the LP cost down. New schedules improve the LP solution if they have negative reduced costs. Usually the cutoff value is set higher than zero to include schedules with low positive costs that may combine well with the rest of them because columns are not added one at a time to the LP.

New schedules are generated probabilistically. Each available leg is assigned a probability of selection proportional to its shadow price. The list of legs is then shuffled using the assigned probabilities of selection as weights.* This means that legs with high shadow prices are more likely to be at the top of the shuffled list. Each leg in the shuffled list is used as a seed sequentially to generate up to a given number of legs.

Starting with a seed, schedules are generated using three different approaches: one based on depth-first search (Aho et al. 1983), a second approach that generates a given number of schedules in parallel, and a third method that recombines existing schedules to produce new and better ones. The schedules are generated by limited complete enumeration, that is, all the schedules that can be generated starting with a particular seed are generated, limited by an upper bound when too many combinations exist. Tractor-only movements for repositioning drivers are also used in the generation of feasible schedules. A partial schedule is accepted only if a complete feasible schedule can be generated from it, including appropriate work breaks. When a maximum total number of columns is obtained, the process stops.

The depth-first-search approach starts with a seed and adds legs sequentially until a complete schedule is obtained. Then a new schedule is started using either the same seed or the next seed in the list. All the feasible successors of a leg are shuffled based on their shadow prices as weights and used to obtain the next leg of a partial schedule. The parallel approach generates several schedules simultaneously by adding each one of its feasible successors to the current partial schedule.

The recombination approach identifies feasible schedules that are generated by removing one or more consecutive legs from one feasible schedule and replacing them with one or more legs from another schedule. Cycles of leg exchanges are then identified that produce new schedules of lower costs. In actual applications, the recombination approach tends to produce columns that drive the iterative solution process much more quickly toward a good overall result than when only columns obtained by the other two approaches are included.

10.9. Beyond Algorithms

Good algorithms that capture well the complexities of real-world problems are a big step towards achieving efficiency using optimization techniques. They are rarely, however, sufficient by themselves. The perfect algorithm is useless if it is not actually used, if it not used properly, or if the solution is not implemented. This is particularly important in the transportation of goods, which is a labor-intensive industry, and where the implementation of an optimization system may involve and affect a large number of people.

Often, a big challenge, beyond the development of good algorithms, is defining the correct problem to solve, finding the necessary data, setting up tools to extract the needed data, correcting and validating the data, having the model used correctly, and obtaining acceptance of the model and its results. A successful, decentralized application needs the involvement of the users, who must be able and willing to use it correctly and apply the results.

*This is exactly like regular shuffling except for the probabilities of selection that are not uniform. An ordered list of legs is obtained by randomly selecting one leg at a time from an original list of legs, based on the weights.

To obtain good results using the algorithms described in this chapter, correct data need to be used. Obtaining good, correct data is often a difficult, expensive, and time-consuming task. Errors in the data need to be identified and corrected easily for the system to succeed. The driver-scheduling problem is especially sensitive to the values of the time windows and cost input. An interface needs to be available that handles the cleaning of the data as well as the generation of the input to the algorithms in an appropriate format and that after a solution is obtained produces useful reports.

If a computer system is put in place for the first time to replace a manual system, the data needs of the computer system may be much larger than those of the manual system. Most optimization models obtain solutions by comparing explicitly or implicitly large numbers of alternatives for which data must be available. Manual systems, on the other hand, often obtain a new solution by modifying an existing one, that is, they examine very few alternatives and need fewer input data. The difference in input data also means that input-data needs for solving an existing application often have to be redefined for computer models. If good input data cannot be obtained for the computer model, its use cannot be expected to improve results.

The algorithms described previously are used to solve difficult MIP problems. Large computers and expensive commercial LP and IP solvers need to be used, which are usually available only in centralized locations. The interface that cleans the data and obtains the input can be implemented locally when the driver-scheduling system is applied separately by region.

A system like the one described has been deployed successfully by United Parcel Service using two different platforms. The data preparation is implemented on local computers available at all company locations. The optimization algorithms are solved remotely on large computers at another location using the company's intranet. The fact that two different platforms are used is hidden from the users, who are informed by e-mail about the status of a submitted job at various stages and get all the reports on the intranet. This kind of application is now possible because of the increase in computer power that permits the solution of difficult optimization problems in reasonable time and because of the evolution of the Internet that provides the tools supporting a remote implementation.

To improve the probability of success, user training is very important for both actual use of the system and interpretation of results. Optimization systems sometimes do not include some difficult characteristics of a real-life problem. In cases like this, interpretation of results, modification of the solution, or simply selection among alternative solutions is very important. A pilot implementation is also very helpful.

An important element for the success of the system is the existence of appropriate support to the users in applying the system, interpreting the results, and making appropriate decisions. This is especially important when the system results differ from current practices and need to be understood and their validity accepted or when they need to be slightly modified. A team of experts in both the computer system and the operational problem that is solved, who are accepted by the users and speak the same business language, needs to be available to assist the users, especially when the system is first deployed.

The optimization model described minimizes total cost of schedules, which often results in a solution using fewer drivers than those used in the current solution. How such a solution is implemented depends on company–labor agreements, which may differ among companies and regions. In the short term, available drivers beyond the number needed by the solution may be put on an ''on-call'' list and asked to come to work only if another driver is sick or a particular need arises.

It is generally very important to get the final users involved early on in the development process. In this way, the developer makes sure that the correct problem is solved and user needs are met as much as possible. Including the user in the development process early on increases the probability of acceptance of the model.

For the implementation of results, one other very significant factor for success concerns the reward structure of a company. If an optimization model minimizes cost but the user is not rewarded directly for implementing a solution that minimizes cost, the solution results are unlikely to be used. If a model minimizes the number of drivers but the decision maker is not rewarded for using fewer drivers, he is unlikely to jeopardize the goodwill of the people working with him by making a big effort to change the status quo.

11. QUALITY IN TRANSPORTATION

Companies that specialize in the transportation of goods must manage their costs, growth, and quality in order to remain competitive. However, without the appropriate measures and the systems to support performance measurement, it is practically impossible to manage any transportation system. In measuring quality in the freight-transportation industry several questions arise. First, of course, is the definition of quality itself. In this industry, quality is viewed differently at different steps in the transportation process. Shippers have different requirements from those of the receivers. Different internal processes have different views of quality and its measurement. However, we can summarize these requirements into five categories:

1. *Damages:* Was the shipment damaged in the process?
2. *On-time performance:* Were all service guarantees met?
3. *Accuracy:* Was the shipment delivered to the correct destination?
4. *Shipment integrity:* Were all the items in a shipment delivered together?
5. *Information integrity:* Was the information associated with a shipment available at all times?

The primary objective of the transportation-planning activity is to design processes that maintain high levels of performance in all five categories. Let's explore these requirements further:

- *Damages:* Of all the quality factors discussed, damages are perhaps one of the most important indicators of quality in both the receiver's and the shipper's view. When the freight-transportation company damages the merchandise being moved, the shipper, the receiver, and the transportation company itself are affected. Costs associated with insurance, returns, product replacement, and lost productivity are all a result of damaged goods. All transportation processes must be designed to prevent damaging the goods. Usually, every step in the transportation process has procedures to measure the number of damages created in any period of time. These procedures are used to establish accountability practices and to identify process-improvement opportunities.
- *On-time performance:* Freight-transportation companies compete on the basis of service performance and cost. In order to support the needs of the complex supply chains that exist today, high levels of on-time delivery reliability are expected from the transportation company. Several external and internal factors can have a direct impact on on-time delivery performance. External factors such as weather, traffic conditions, and subcontractor labor relations can have a direct impact on the ability of the transportation company to meet service commitments. With proper planning, transportation companies manage to minimize the impact of some of these factors. On the other hand, the one internal factor that will always have a negative impact on on-time delivery is lack of planning or, quite simply, poor planning. If the organization is not prepared to handle seasonal variations in pickup and delivery volumes or does not have contingency plans to deal with unexpected events, on-time delivery performance will be affected.
- *Accuracy:* Delivering to the correct destination is expected every time for every shipment. However, there are instances in which the transportation system fails to satisfy this basic requirement. Two major causes contribute to this type of service failure: missing or incorrect information and inadequate planning. For example, when the wrong address is attached to a shipment, the probability of making delivery mistakes increases substantially. Today, transportation companies offer a variety of services aimed at providing continuous shipment tracking and improved information quality. As indicated before, labor is usually the highest cost variable in the profitability equation of a transportation company. Labor is also the primary driver of quality in these organizations. When companies fail to develop staffing and training plans properly, delivery accuracy and reliability will be impacted.
- *Shipment integrity:* Receivers expect to receive all the items (e.g., packages) in a shipment on the same day and at the same time. It is the responsibility of the freight-transportation company to maintain the integrity of all shipments. The transportation system must be capable of using shipment information in its different processes to ensure the integrity of every shipment.
- *Information integrity:* As indicated earlier in this chapter, the information about a shipment is as important, in today's supply chains, as the movement of the shipment itself. Since shipment information is offered to shippers and receivers as a value-added service, the effectiveness with which this information is provided to them must be monitored and measured. Systems to effectively capture, store, and provide shipment information are critical in today's freight transportation business models. The freight-transportation industry will continue to be an information-based industry. Therefore, maintaining high levels of information accuracy and integrity will continue to be an important measure of performance.

Now that some basic measures have been defined, let's look into the quality-improvement process. Like other industries, freight-transportation companies make use of well-established quality-improvement techniques. Without a clear understanding of the facts and figures that affect the quality of the services offered, management cannot control and improve the processes involved. Remember that there are four continuous phases in the quality improvement process: Plan, Do, Check, and Act. Together, these phases are known as the Deming circle. Transportation processes must be designed and performance targets must be defined. As activities are completed throughout the different processes, regular checks must take place as the processes are monitored and controlled. The information gathered from these checks must be used to improve the process continuously.

12. TECHNOLOGY

12.1. Vehicle Routing

For solving transportation problems, the use of computers plays an important role in the development of models, schedules, network plans, and delivery and pickup routes. As described in previous sections, the complexity and magnitude of the transportation problems discussed in this chapter require extensive computation times. Making transportation decisions is a complex process. Dispatch managers in package-delivery companies must assess a variety of factors before making dispatch decisions. Some of those factors were discussed in previous sections. They include vehicle capacity, time windows, demand fluctuations, labor productivity, and the dynamic changes in pickup and delivery characteristics of customers, geographies, and traffic conditions.

Vehicle-routing problems fall into one of three basic segments: routing of service vehicles, passenger vehicles, and freight vehicles (Hall and Partyka 1997). Service vehicles are used to support jobs in the field and are generally used by service technicians. In this type of problem, the primary constraints are service time, time windows, and travel time. Because there is no major variation in the merchandise carried by any given vehicle, capacity constraints are not included in the formulation of service routes. Passenger-transportation services such as bus service face an additional constraint: capacity. The size of the vehicle determines the number of passengers that can be safely carried from one point to another. Freight vehicles are also constrained by their capacity. When completing pickups, a vehicle may run out of capacity at a certain customer location. At this point, the dispatcher must either dispatch another vehicle to the customer's location to complete service or ask the current driver to return to the depot, obtain an empty vehicle, and return to the customer's location to complete the service. It is clear from this example that the decision made by the dispatcher can have different cost and service implications and may affect more than one customer. A few years ago, the only way to make these dispatch decisions effectively was through human knowledge and experience. The ability of the dispatcher to make numerous decisions based on a few pieces of information could make or break the dispatching process. Today, things have changed. With the increasing implementation of technologies such as the geographic information systems (GIS) and global-positioning systems (GPS), dispatchers have new tools that automate and improve the vehicle-routing process.

Routing pickup-and-delivery vehicles does not end with the development of routes prior to the drivers' departure from the depot. Once drivers have left the depot, in-vehicle communications and route-information systems offer mechanisms not only to improve their performance but to meet on-demand customer requests. When dispatchers have the ability to communicate routing instructions and customer requests to drivers in the field, the opportunities for improving the overall efficiency of a dispatch plan increase substantially. However, the initial development of an efficient and effective dispatch plan is still critical.

Several software vendors have developed vehicle-routing software. In 1997, Hall and Partyka surveyed several vendors in order to compare the characteristics of their respective software systems. Table 4 presents an extract of this survey. The complete survey appeared in the June 1997 issue of *OR/MS Today.*

12.2. Information Gathering and Shipment Tracking

As indicated earlier in this chapter, the information associated with the goods being moved is as important as the transportation process itself. Today, transportation companies use a variety of tools to track, manage, and control the movement of goods from pickup to delivery. In addition, sophisticated electronic devices are being used by drivers not only to record the status of deliveries and pickups, but also to keep track of vehicle usage, time cards, and sales information.

12.3. New Trends: Intelligent Transportation Systems (ITS)

The transportation community has turned to the deployment of intelligent transportation systems (ITS) to increase the efficiency of existing highway, transit, and rail systems. One of the key variables in the vehicle-routing models described above is travel time. With the use of information from ITS, dispatchers can make better decisions. The U.S. Department of Transportation (DOT) has indicated that "ITS uses advanced electronics and information technologies to improve the performance of vehicles, highways, and transit systems. ITS provides a variety of products and services in metropolitan and rural areas."

As ITS evolves from pure research, limited prototyping, and pilot projects into routine usage, decision makers at "the corporate, state, regional, and local levels seek reliable information about the contribution that ITS products can make toward meeting the demand for safe and efficient movement of people and goods." Literature indicates that substantial benefits have already been realized in areas such as accident reduction, travel-time savings, customer service, roadway capacity, emission reduction, fuel consumption, and vehicle stops. Greater benefits are predicted with more extensive

TABLE 4 Routing Software Survey

Product	Publisher	Solvable Problem Size			Routing			GIS Product Interface	Special Features
		Number of Stops	Number of Vehicles	Number of Terminals	Real-Time Routing	Daily Routing	Route Planning		
GeoRoute	Kositzky & Associates, Inc.	4600	512	256	N	Y	Y	GeoWhiz	GeoRoute works for local delivery as well as over-the-road applications. Options for multidepot and redisptach are available.
GeoRoute 5	GIRO Enterprises, Inc.	Unlimited	Unlimited	Unlimited	N	Y	Y	ArcInfo, MapInfo	Software supports both point-to-point and street-by-street operations, as well as mixed requirements.
Load Manager	Roadnet Technologies, Inc.	N/A	N/A	N/A	N	N	N		
LoadExpress Plus	Information Software, Inc.	Unlimited	500	Unlimited	N	Y	Y	Proprietary, can work with data from all GIS systems	LoadExpress is a simple, powerful, and flexible choice for building and optimizing routes, scheduling deliveries, and analyzing distirbution patterns.
Manugistics Routing & Scheduling	Manugistics, Inc.	Unlimited	Unlimited	Unlimited	Y	Y	Y	Xeta, Rockwell, Cadec, Autoroach	Resource management—allows management of driver, tractor and trailer schedules, provides information on equipment requirements.
OVERS	Bender Management Consultants	10,000	1000	100	Y	Y	Y	Map Objects	Can optimize routes across multiple time periods, respect space/time constraints, optimize number and location of terminals and service areas.
RIMMS	Lightstone Group, Inc.	Unlimited	Unlimited	Unlimited	Y	Y	Y	ESRI shape files	Configurable by users across multiple industries, including both scheduling model and screen cosmetics. Interfaces via ODBC drivers.

ROADNET 5000	Roadnet Technologies, Inc.	Unlimited	Unlimited	Unlimited	N	Y	N	GDT maps	
RoadShow for Windows	ROADSHOW International, Inc.	8000	Unlimited	Unlimited	Y	Y	Y	GDT, Etak, MapInfo and proprietary software	ROADSHOW calculates cost-effective solutions based on actual costs incorporating specific information supplied by the user.
RoutePro	CAPS LOGISTICS	HW-based	HW-based	HW-based	Y	Y	Y	Etak, Horizons Technology, GDT, PCMiler	Customizable through fourth-generation macro language and ability to call functions from other languages.
RouteSmart Neighborhood	RouteSmart Technologies	Unlimited	Unlimited	1+ Intermediates	N	N	Y	GIS Plus (DOS version), ArcInfo	Meter-reading system, handles walking, driving, and combination routes.
RouteSmart Point-to-Point	RouteSmart Technologies	Unlimited	Unlimited	1+ Intermediates	N	Y	Y	ArcView version 3.0	
Routronics 2000	Carrier Logistics	Unlimited	Unlimited	Unlimited	N	Y	N	MapInfo	Routronics 2000 has been developed as a complete customer-service routing and dispatch system with interfaces to wireless communications.
SHIPCONS II	Insight, Inc.	Unlimited	Unlimited	Unlimited	N	Y	Y	GDT, MapInfo, Etak	Cost-based, integer optimization; user-configurable screens; Ad Hoc Report Writer; Digital Geography; Shipment Rater for TL and LTL carriers.
Taylor II	F&H Simulations, Inc.	1000	100	1000	N	N	Y		2 and 3D animation; Windows 95 and Windows NT; design of experiments; curve fitting of raw data (advanced statistics module).
Territory Planner	Roadnet Technologies	Unlimited	Unlimited	Unlimited	N	N	Y	GDT maps	
TESYS	Inform Software Corporation	3000	1000	500	Y	Y	N	CDPD/GPS/RF	
TransCAD	Caliper Corporation	Unlimited	Unlimited	Unlimited	Y	Y	Y	Maptitude, GIST, can work with data from all GIS systems	Toolkit of OR methods including min-cost network flow, transportation problem, and various optimal location methods.

deployment of more mature products. Freight-transportation companies face new constraints and challenges not only in meeting service commitments but in remaining competitive and cost effective while meeting governmental regulations. The use of ITS offers new opportunities to use information in the development of routes and schedules.

The ITS program is sponsored by the DOT through the ITS Joint Program Office (JPO), the Federal Highway Administration (FHWA), and the Federal Transit Administration (FTA).

ITS, formerly known as the intelligent vehicle highway systems (IVHS), were created after the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991 was established. ISTEA helped authorize larger spending for transit improvement. In January 1996, then Secretary of Transportation Frederico Peña launched Operation TimeSaver, which seeks to install a metropolitan intelligent transportation infrastructure in 75 major U.S. cities by 2005 to electronically link the individual intelligent transportation systems, sharing data so that better travel decisions can be made.

A projected $400 billion will be invested in ITS by the year 2011. Approximately 80% of that investment will come from the private sector in the form of consumer products and services.

The DOT has defined the following as the components of the ITS infrastructure:

- *Transit fleet management:* enables more efficient transit operations, using enhanced passenger information, automated data and fare collection, vehicle diagnostic systems, and vehicle positioning systems
- *Traveler information:* linked information network of comprehensive transportation data that directly receives transit and roadway monitoring and detection information from a variety of sources
- *Electronic fare payment:* uses multiuse traveler debit or credit cards that eliminate the need for customers to provide exact fare (change) or any cash during a transaction
- *Traffic signal control:* monitors traffic volume and automatically adjusts the signal patterns to optimize traffic flow, including signal coordination and prioritization
- *Freeway management:* provides transportation managers the capability to monitor traffic and environmental conditions on the freeway system, identify flow impediments, implement control and management strategies, and disseminate critical information to travelers
- *Incident management:* quickly identifies and responds to incidents (crashes, breakdowns, cargo spills) that occur on area freeways or major arteries
- *Electronic toll collection:* uses driver-payment cards or vehicle tags to decrease delays and increase roadway throughput
- *Highway–rail intersection safety systems:* coordinates train movements with traffic signals at railroad grade crossings and alerts drivers with in-vehicle warning systems of approaching trains
- *Emergency response:* focuses on safety, including giving emergency response providers the ability to pinpoint quickly the exact location of an incident, locating the nearest emergency vehicle, providing exact routing to the scene, and communicating from the scene to the hospital

The use of information from all of these system components will enhance the planner's ability in designing efficient transportation networks and delivery routes. In addition, as this information is communicated to the drivers, they will also have the capability of making better decisions that will enhance customer satisfaction and reduce overall costs.

For additional information, visit the DOT's website on ITS: http://www.its.dot.gov/.

Acknowledgments

The authors wish to thank Professor Mark S. Daskin of Northwestern University and Professor Ching-Chung Kuo of Pennsylvania State University for their constructive comments. They also thank their colleagues Ranga Nuggehalli, Doug Mohr, Hla Hla Sein, Mark Davidson, and Tai Kim for their assistance. CHAPTER 31

Industrial Engineering Applications in Hotels and Restaurants

DOUGLAS C. NELSON
Purdue University

1. OVERVIEW

In many aspects, the hospitality industry, which includes hotels and restaurants, is just like most other industries. In fact, components such as the kitchen and the laundry can be viewed as small factories. Several aspects, however, distinguish the hospitality industry from other industries. These differences center on the industry's products. Two of the most important product characteristics are the direct link between production and delivery and the perishable nature of the product (Nebel 1991). Unlike those in many industries, most of the hospitality industry's products must be consumed when and where they are produced. Therefore, in order to be competitive, hotels and restaurants must be able to produce products efficiently when and where consumers want them. The necessary levels of efficiency can be achieved through the application of industrial engineering techniques and principles. This chapter covers some of the more important applications that help hotels and restaurants maintain their competitiveness.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

2. DEVELOPING EFFICIENT WORK ENVIRONMENTS FOR HOTELS AND RESTAURANTS

2.1. Overview

One area in which the application of industrial engineering techniques and principles has become increasingly important is improving worker efficiency. Between 1988 and 1997, the productivity, in output per hour, in food service kitchens decreased at an average annual rate of 0.6% per year (U.S. Bureau of the Census 1999).

Operators have tried many things in their attempts to slow and reverse this trend. Many operations have turned to technology and increased automation as a possible solution. While the incorporation of technology in the kitchen is important, Clark and Kirk (1997) failed to find a positive relationship between implementation of technology and productivity. Operations have also sought to improve productivity by purchasing labor in the form of convenience foods and increasing utilization of self-serve systems (Schechter 1997). Still other operations have sought to improve productivity though kitchen design. A study on trends in kitchen size, found that it has been steadily decreasing (Ghiselli et al. 1998). These smaller kitchens have reduced the distances workers must walk to prepare meals. If workers are walking less, they can become more productive (Liberson 1995). To develop smaller, more efficient kitchens, designers have used a variety of methods. One of the better ones is design by consensus (Avery 1985).

2.2. Design by Consensus

2.2.1. Overview

This technique uses the same standard relationship charts and diagrams as recommended for traditional design methods by some of the leading experts on food service layout and design (Almanza et al. 2000; Avery 1985; Kazarian 1989). However, there are major differences between design by consensus and some more traditional design methods. Traditional design methods have centered on management providing operational information to a kitchen design professional. The design professional takes that information and, based on experience and training, develops a layout for the facility. Design by consensus recognizes that workers who will be utilizing the facility have valuable information that can be used to improve the design. Design by consensus does not eliminate the need for the professional designer. Rather, it provides the designer with additional information that can lead to a more efficient, user-friendly design. Information is collected from workers by the use of relationship charts.

2.2.2. Relationship Charts

The first step to preparing a relationship chart is to identify all work centers in the facility. Once this has been accomplished, they are entered into a relationship chart as shown in Figure 1. The chart is now ready to distribute to the workers who will be using the facility. Along with the charts, the

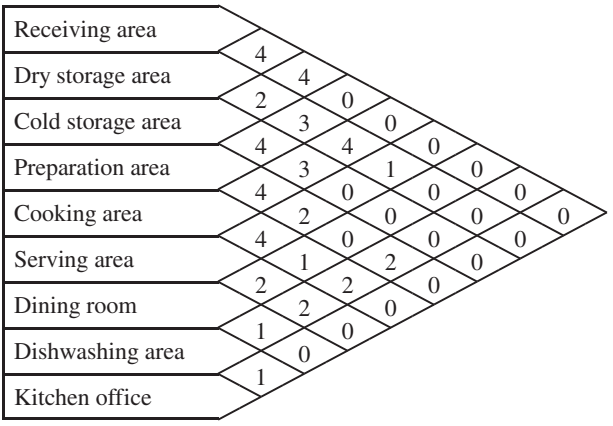

Figure 1 Relationship Chart for Work Centers within the Facility. (The ratings are anchored at 4, very important to be located close together, and 0, not important to be located close together.)

workers are provided instruction on how to complete the charts. They are instructed to rate the importance of placing each pair of work centers close together. The ratings can be on a seven-point scale, using numbers from zero to six (Kazarian 1989), or a five-point scale, using numbers from zero to four (Almanza et al. 2000; Avery 1985). While the seven-point scale allows for greater differentiation, the five-point scale is easier for nonprofessional designers to use. Because the workers are not professional designers, the five-point scale is often used.

The five-point scale is anchored at ''not important to be located close together'' (0) and ''very important to be located close together'' (4). To determine the level of importance, the workers must consider how often they move between the two work centers, the frequency, and other factors such as any load they will be carrying and time limitations to travel the distance between the work centers. Figure 1 shows an example of a completed relationship chart.

Once all workers have completed relationship charts, the charts are consolidated into a single chart. To ensure the lowest possible production costs, the highest-paid employees should engage in as little unproductive action as possible, such as walking between work centers. Therefore, when the charts are consolidated, weights are assigned to the different charts based on who submitted the chart. For example, the ratings of a relatively high-paid chef would be weighted higher than those of a lower-paid worker such as a dishwasher. This will lead to an arrangement that will help maximize the productivity of the highest-paid workers and as a result, lower production costs. Figure 2 shows an example of a consolidated relationship chart.

Once the consolidated relationship chart for the work centers has been completed, the designer can develop relationship charts for the equipment within the individual centers. As before, the first step is to determine all equipment that is to be located in the particular work center. The equipment is then listed on the relationship chart just as the work centers were listed on their relationship chart (Kazarian 1989).

While listing only equipment on the chart will help the designer determine the optimum layout for the particular work center, it ignores any relationships between equipment within the work center and other work centers. This is important because it is possible to have an efficient layout within a work center that is not the best layout for the facility. For example, Figure 2 shows that the most important links to the preparation work center are with the cooking work center, followed by the cold storage area and the serving area. If only the equipment is listed on the relationship diagram for the preparation area, then the designer will not know where in the preparation area the movement to the other work centers originates or terminates. Thus, while the layout developed for the preparation area might be the most efficient for that area, the designer has no way of knowing whether it is the optimum layout for the operation. To correct this deficiency, those work centers with the greatest link to the work center for which the relationship chart is being prepared should be included. As shown in Figure 3, the cooking, cold storage, and serving areas have been included in the relationship chart for the preparation area. It is important not to include more than the top two or three linked work centers in the chart. The addition of less important linked work centers to the chart will increase the complexity while adding very little useful information.

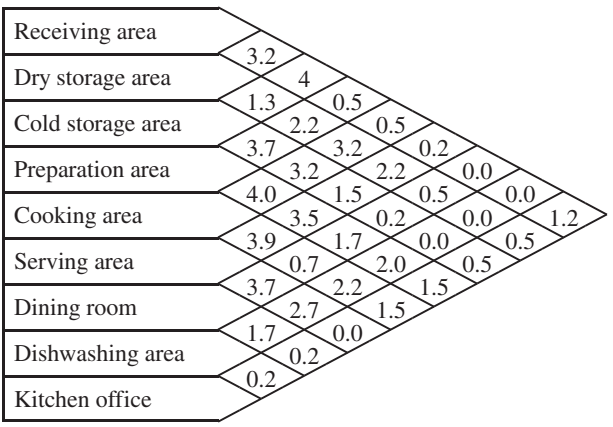

Figure 2 Relationship Chart for Consolidated Ratings for Work Centers within the Facility. (The ratings are anchored at 4, very important to be located close together, and 0, not important to be located close together.)

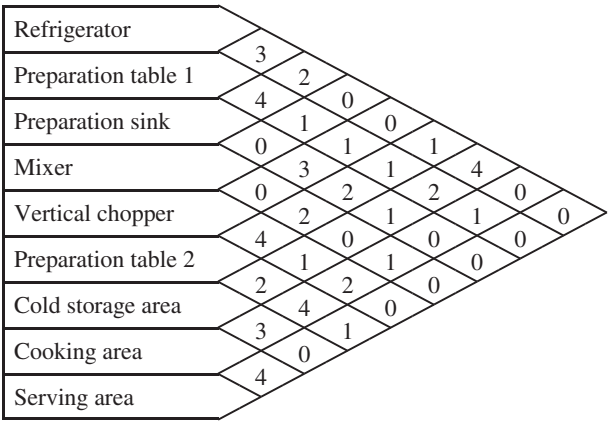

Figure 3 Relationship Chart for Equipment within the Preparation Work Center. (The ratings are anchored at 4, very important to be located close together, and 0, not important to be located close together.)

Using the information from Figure 3, the designer can easily see that the preparation area should be arranged so that preparation table 2 is located nearest the cooking area and the refrigerator is located nearest the cold storage area. The fact that there are no important links between the serving area and any of the equipment in the preparation area does not mean that the link between the two areas is not important, just that movement between the two areas is likely to be to or from any of the pieces of equipment in the work center.

While the consolidated relationship charts for the work centers within the facility and the equipment within the work centers provide valuable information, it is sometimes difficult to visualize the optimum layout in the numbers in the chart. This is particularly true if the relationship chart has a large number of work centers or pieces of equipment listed on it. Therefore, it is helpful to display the information in the form of a relationship diagram that highlights the most important links.

To prepare the information for use in the relationship diagrams, the numbers in the consolidated charts must be converted to whole numbers (Avery 1991). This is done by organizing the ratings for the individual links between work centers/equipment in descending order of importance. Only those links receiving a composite rating of 3.0 or higher are included in the ranking. The inclusion of less important links will clutter the relationship diagram and not provide the designer any additional information. Once the rank order of the importance of the links has been established, they are split into three or four groups based on the breaks in the data. Those links in the highest grouping are assigned an importance rank of four, those in the next highest grouping are assigned an importance rank of three, and so forth until the top four groupings have been assigned importance ranks. Table 1 shows the importance ranking for the work center links from Figure 2. The designer is now ready to prepare the relationship diagrams.

TABLE 1 Importance Rankings for the Top Links from Figure 2

Link	Consolidated Score	Importance Rank
Receiving and cold storage	4.0	4
Preparation and cooking	4.0	4
Cooking and serving	3.9	4
Cold storage and preparation	3.7	3
Serving and dining room	3.7	3
Preparation and serving	3.5	2
Receiving and dry storage	3.2	1
Dry storage and cooking	3.2	1
Cold storage and cooking	3.2	1

2.2.3. Relationship Diagrams

There are two different types of relationship diagrams: a bubble type and a layout type. The bubble type is done first. This relationship diagram, as shown in Figure 4, uses labeled circles connected by lines to help visualize the important links. The number of lines connecting the different circles corresponds to the importance rank of the links as determined in Table 1. The primary purpose of this type of relationship chart is to help determine which work center(s) should be centrally located, which can be done simply by counting the number of lines connected to the circle. The work center(s) with the greatest number of lines should be centrally located. For simpler drawings, this step can be eliminated, in which case the layout-type relationship chart is drawn directly from Table 1.

Once the work centers that must be centrally located have been determined, the layout-type relationship diagram is drawn. The work centers are drawn to scale inside the space that has been allocated for the operation. The first step in drawing this relationship diagram is to locate any work centers that are anchored to a specific part of the building. For example, the receiving area is generally located along an outside wall, out of public view. Once the centers that must be located in specific parts of the facility are drawn, the designer can begin inserting the remaining work centers, starting with those that must be centrally located. The last centers added to the layout are those centers with few, if any, links to the other work centers. At this point in the design process, the actual shape of each work center is not known. It is up to the designer to estimate the shape of each work center as it is drawn in the diagram. The result is that frequently the area for the last work center is not a functional shape, even though it is the correct size. For example, the remaining area for a 200-ft^2 office might be 2 ft wide and 100 ft long, or it could be split into two locations, neither of which would allow the construction of an acceptable office. If this happens, the layout-type relationship chart must be redrawn and the shapes and locations of some of the work centers modified to allow a functional office to be included. This process may need to be repeated several times to ensure that there is enough usable space for all work centers. An example of a completed layout-type relationship diagram is shown in Figure 5.

2.2.4. Designing for Supervision

Designing for ease of supervision as well as efficiency is one of the basic design principles (Birchfield 1988; Kazarian 1989). Relationship diagrams, however, do not take designing for supervision into account. For example, the location of kitchen office is essential for adequate supervision, but the information provided by the workers is not very helpful when it comes to locating the kitchen office. Because the office is not an area that workers visit frequently during production, it is likely to receive low importance ratings for being located near production areas, as can be clearly seen in Figures 1

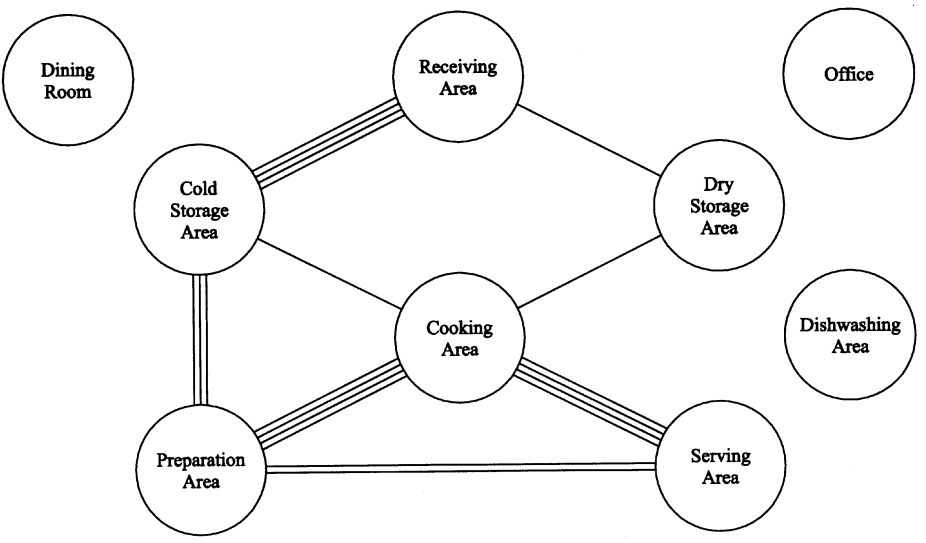

Figure 4 Bubble-Type Relationship Diagram Developed from the Information in Figure 3 and Table 1.

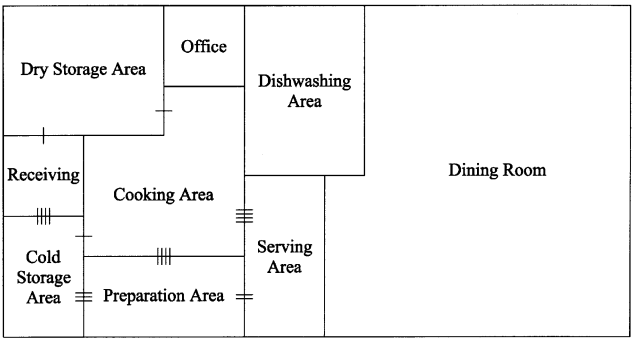

Figure 5 Layout-Type Relationship Diagram Developed from Figure 4.

and 2. Therefore, it is up to the designer to ensure that the kitchen office is properly placed to provide adequate supervision of the kitchen. The placement of the office is further complicated by other functions for which the office is used. Birchfield (1988) describes the need for the office to be accessible to customers needing to talk to management without having those customers walk through the kitchen to reach the office. Further, managers must also monitor the movement of food and supplies in and out of the building and storage areas. This places the office near the receiving area, which would cause problems for customers accessing the office. The final location of the office is often a compromise and depends on which function management views as its primary one.

2.2.5. Designing for Efficient Utility Use

Another important consideration when arranging the kitchen is efficient use of utilities. As with the office, the information provided by the relationship charts and diagrams will not adequately address this issue. Frequently, designing for efficient utility use conflicts with designing for maximum worker efficiency. Kazarian (1989) recommends that heating and cooling equipment be separated. While this is important for controlling energy use, it does not always provide for efficient production. Frequently, food is moved directly from a refrigerator to a piece of cooking equipment. Designing for efficient energy use would place the pieces of equipment some distance apart, while designing for efficient production would place them adjacent to each other. In this case, the designer must weigh the need for energy conservation against the need for worker efficiency and develop an arrangement that minimizes total production costs.

There are several other arrangement considerations that can help reduce energy consumption. One is locating steam- and hot water-generating equipment near the equipment that uses steam or hot water. Shortening the distance between the generation and use of steam or hot water will reduce energy loss from the pipes connecting the equipment. Another way to help reduce energy consumption is to consolidate as many pieces of heat-generating equipment under one exhaust hood as possible. This will reduce costs by reducing ventilation requirements. Finally, Avery (1985) recommends that compressors and condensers for large cooling equipment such as walk-in refrigerators and freezers be located so that the heat they generate can be easily exhausted, thereby reducing the cooling requirements for the kitchen. As with the example in the previous paragraph, arranging the kitchen to take advantage of these energy conservation techniques may conflict with arranging for maximum worker efficiency. It is up to the designer to develop a compromise arrangement that will minimize the total cost of operating the facility.

2.3. Evaluating the Efficiency of a Layout

2.3.1. Overview

Kazarian (1989) describes a cross-charting technique that uses distance, move, and travel charts to compare two or more layouts to determine which is the most efficient. This technique recognizes that if the time spent walking between equipment can be reduced, then the worker can spend more time being productive. Avery (1985) took the use of cross-charting one step further. He recognized that not all production workers are paid the same wage. It is possible to have an arrangement that is the most efficient based on total man-hours, but not the most efficient in total labor cost. Because of different training and skill requirements, it is possible for the highest-paid workers to make twice what the lowest-paid workers make. If the travel charts are adjusted for wages, then the comparison of arrangements is based on cost efficiency and not man-hour efficiency.

TABLE 2 Distance Chart[a]

	From				
To	Prep Table	Sink	Oven	Walk-in	Dishwasher
Prep table		2	3.5	8	11
Sink	2		3	6	10
Oven	3.5	3		6	18
Walk-in	8	6	6		18
Dishwasher	11	10	18	18	

[a]Distances are in meters.

2.3.2. Distance Charts

The first cross-chart that must be prepared is the distance chart. This chart contains the distance from each piece of equipment to all the other pieces of equipment in the work center. Table 2 shows an example of a completed distance chart. The pieces of equipment listed across the top of the chart are the starting points for the movements, and those listed down the side are the ending points. The order of the pieces of equipment in the list depends on the arrangement of the work center. Adjacent pieces of equipment should be listed next to each other in the chart. Listing the equipment in that order will make it easier to recognize ways to rearrange the work center so that it can be more productive. If the chart was prepared properly, then cells adjacent to the diagonal line will contain the smallest numbers and those farther away from the diagonal line will contain larger the numbers.

2.3.3. Move Charts

The move chart is a frequency chart that tracks the number of times a worker moves from one piece of equipment to another. Equipment is listed in these charts in the same order as in the distance chart. There are several ways to determine the frequencies of movement between the different pieces of equipment. The most accurate way is to observe the workers and record their movements. If this is not possible, a reasonable estimate can be developed using the menus and estimating the number of times workers will move between each pair of equipment. If the wages of the different classifications of workers using the facility are significantly different, then multiple move charts should be prepared, one for each classification. Table 3 shows examples of the move charts for two classifications of workers.

2.3.4. Travel Charts

After the distance and move charts are complete, they are used to generate travel charts. The individual cells in the travel charts are the products of the corresponding cells in the distance and move charts. The cells in the travel charts sum to the total distance traveled by the worker. Once the total distances traveled by each classification of workers are calculated, those numbers are weighted by

TABLE 3 Move Charts for Prep Cook and Dishwasher

To	Prep Table	Sink	Oven	Walk-in	Dishwasher
Prep table		0	0	0	60
Sink	0		0	0	0
Oven	0	0		0	0
Walk-in	0	0	0		0
Dishwasher	60	0	0	0	

their wages. Finally, a single sum is calculated for all the charts. That number can now be used to compare two or more arrangements. The arrangement that yields the smallest number is the most efficient in terms of labor costs. Table 4 show the travel charts for this example. The weighted sum for the prep cook's chart is 24,850 and the weighted sum of the dishwasher's chart is 9,240. Combining the two, the weighted sum for the operation is 34,090. The units are in currency times distance. The exact units used for currency and distances are not important, as long as they are consistent for each layout being evaluated.

2.3.5. Evaluating the Charts

The final step is to evaluate the charts to identify ways to improve the arrangement of equipment. There are basically two different ways to do this. One is to modify the arrangement, and the other is to modify the production procedures. For an efficient arrangement, the majority of the movement will be between adjacent equipment. Since the distance chart was set up so that adjacent equipment in the arrangement appeared in adjacent cells, the move chart can be used to identify problems with the arrangement. If the work center is properly arranged, the numbers in the cells along the diagonal line should be large and get progressively smaller the farther they are from the line. Rearranging the layout so that the largest numbers are adjacent to the line will improve the efficiency of the operation. In the prep cook's chart, one possible change in the arrangement that may reduce the total distance traveled is to move the walk-in closer to the sink than the oven is. The total number of moves between the prep table and the walk-in is 65 (45 from the walk-in to the sink and 20 from the sink to the walk-in), while the total number of moves between the walk-in and oven is only 20 (10 from the oven to the sink and 10 from the sink to the oven). Because moving one piece of equipment affects other pieces of equipment, the only way to be sure that the new arrangement is indeed better is to chart the new arrangement and compare the total weighted sums for both arrangements. When there is more than one travel chart because of different wage rates, both charts must be prepared for the new arrangement.

Be careful when making adjustments based on the move chart for the lowest-paid worker. While those adjustments may reduce the total man-hours need to perform the task, they may actually increase the total labor cost for the operation. For example, from the dishwasher's chart in Table 3, one possible change would be to move the dishwashing machine closer to the prep table. While this would reduce the travel of the lowest-paid worker, it may increase the travel of the highest-paid worker. Therefore, moving the dishwashing machine may increase labor dollars, making this an unwise adjustment to the arrangement.

Identifying procedural changes using these charts is not as straightforward as identifying arrangement changes. Basically, these charts can only be used to identify problems with procedures requiring further investigation. In the example in Table 3, there is a total of 100 trips to and from the dishwasher made by the prep cook and another 120 trips made by the dishwasher. The dishwasher's trips are all between the dishwasher and the prep table. This is an area requiring further investigation to see whether procedural changes are needed. The designer should seek to uncover the reason for the trips. It could be that the prep cook is bringing dirty dishes to the dishwasher and returning empty-handed and that the dishwasher is returning clean dishes to the prep table and returning empty-handed. If

TABLE 4 Travel Charts for Prep Cook and Dishwasher

Prep Cook	From				
To	Prep Table	Sink	Oven	Walk-in	Dishwasher
Prep table		80	140	120	385
Sink	60		30	270	150
Oven	140	30		60	0
Walk-in	320	120	60		0
Dishwasher	220	300	0	0	
Dishwasher	**From**				
To	Prep Table	Sink	Oven	Walk-in	Dishwasher
Prep table		0	0	0	660
Sink	0		0	0	0
Oven	0	0		0	0
Walk-in	0	0	0		0
Dishwasher	660	0	0	0	

this is the case, then the dishwasher may be able to drop off clean dishes and pick up the dirty dishes. Making this procedural change reduces the total trips between the two areas. Further savings are realized because all the trips are now made by the lowest-paid worker.

2.4. Kitchen Ergonomics

2.4.1. Overview

Another method that can be used to help improve the productivity in kitchens is the application of ergonomic principles. Commercial food preparation is a physically demanding occupation. Typically, employees must stand for long periods of time on hard surfaces. As their shifts proceed, workers often become fatigued and experience impaired perception and reduced physical performance, both of which will negatively impact their productivity (Almanza et al. 2000; Avery 1985). The application of sound ergonomic principles can delay the onset of fatigue, making the workers more productive over the course of the day. Something as simple as an incorrect table height can accelerate the onset of fatigue. If a worker is standing vertically, then between 20–27% of his or her energy expenditure can be used to perform work. If that same worker is stooping, then the percent of energy expenditure available to perform work drops to around 5% (Avery 1985). Providing workers the proper table height will allow them to have four to five times more energy to devote to production than they would have if they were stooping.

2.4.2. Table Heights

The correct table height depends on the type of work being performed and who is performing the work. For heavy work, the ideal height is the point where the wrist bends when the arms are hanging at the person's sides. This puts the table height for heavy work at 76–91 cm (34–36 in.), depending on the person (Almanza et al. 2000; Avery 1985). For lighter work, there seems to be some disagreement among the industry experts on what is the proper height in terms of body dimension. Katsigris and Thomas (1999) recommend that the surface height be 10 cm (4 in.) below the bend in the elbow. Avery (1985) recommends 2.5–7.6 cm (1 to 3 in.) below the bend in the elbow, and Kazarian (1989) recommends 7.6 cm (3 in.). Despite their differences on where the table should be located in reference to the worker, they all agree that the range is 94–99 cm (37–39 in.) for women and 99–104 cm (39–41 in.) for men.

The new smaller kitchens do not have enough room to have separate tables for different workers and different tasks. One way to overcome this problem and provide the optimum table height is to use adjustable tables. These are available, but their use is not yet widespread.

2.4.3. Heights of Other Equipment

While a significant amount of food preparation takes place at tables, it is also important that other kitchen equipment be at the proper height. Height is of particularly important for sinks, stacked equipment, storage equipment, and top-loading equipment. Most other equipment follows the same rules as tables when it comes to height.

According to Avery (1985), the height of the top of the sink should be 94–99 cm (37–39 in.) for women and 99–102 cm (39–40 in.) for men. The depth of the sink depends on its function. For standard sinks, the bottom of the sink should be at the tip of the worker's thumb when the arms are at the worker's sides. This places the bottom at approximately 69 cm (27 in.) for women and 74 cm (29 in.) for men. If the sink is to be used to soak pans, the bottom can be 15 cm (6 in.) lower, provided small items are not placed in the sink.

Avery (1985) also presents information on the importance of height for stacked items such as an oven. He recommends that deck ovens be stacked not more than two high and that the bottom oven be at least 51 cm (20 in.) off the ground. If three ovens are stacked and the first oven is at least 51 cm (20 in.) off the ground, there is a greater risk that workers will be burned trying to use the top oven. If the top oven is at an acceptable height, the bottom oven will be below 51 cm (20 in.), increasing the risk that a worker will be burned using that oven. Further, the worker will have to expend more energy stooping to place things in and remove them from the bottom oven. Stacking of other types of ovens is also not recommended. Conventional and convection ovens are too tall to stack without the risk of serious burns to those using them. It is far safer to put the oven on a stand so the opening is between the workers' waists and shoulders.

Restaurants often employ several different types of storage devices, from refrigeration and warming cabinets to plate and tray dollies to standard shelves. The proper height for storage of frequently used items is between the worker's waist and shoulders (Avery 1985). Placing items too high can lead to items being improperly placed on shelves, which can lead to falling objects and the related potential for damage and personal injury. Placing items too low forces workers to stoop, causing them to expend additional energy and putting a strain on their back muscles. In the process of designing small, efficient kitchens, designers have turned to undercounter storage units, such as

refrigerators. If the use of undercounter storage units is necessary, the designers should consider using drawers instead of reach-ins because they require less bending and stooping to access products. Finally, if plate and tray dollies are used, they should be self-leveling, meaning that as one plate or tray is removed, the load on the springs at the bottom of the stack decreases, decreasing the compression of the spring and raising the stack. This keeps the items within easy reach of the workers.

With top-loading pieces of equipment such as steam-jacketed kettles, pots and pans, and mixers, it is important for the user to be able to reach comfortably and safely over the rim. This helps prevent burns, spills, and similar accidents when workers are adding ingredients or stirring the mixture. Avery (1985) recommends a rim height of no greater than 97 cm (38 in.) for steam-jacketed kettles, whenever possible. Operations that use large kettles must exceed that height to ensure that the draw-off is high enough to allow a pan to be placed beneath it. The same height recommendations for steam-jacketed kettles also apply to other top-loading equipment, such as stock pots and mixers.

2.4.4. Workstation Dimensions

In addition to proper surface height being maintained, the length and width of the workstations must also be addressed to help workers be productive. For a standing worker, the workstation should be arranged so that the majority of the tasks can be performed in a 46-cm (18-in.) arc centered on the worker (Avery 1985). Supplies needed to perform the tasks can be stored just outside that arc. Since people tend to spread out to fill their environment, it is important that table size be restricted to ensure efficient production. Almanza et al. (2000) recommend limiting the table size for a single work to 61–76 cm (24–30 in.) wide and 1.22–1.83 m (4–6 ft) long. The width of the table can be increased to 91 cm (36 in.) if the back of the table will be used for storage and to 107 cm (42 in.) if two workers will be using opposite sides of the table. If the two workers will be working side by side, then the table length should be 2.44–3.05 m (6–8 ft).

3. CONTROLLING CAPITAL COSTS

3.1. Overview

As with any industry, controlling capital costs is an important ingredient in developing and maintaining a successful operation. Earlier sections presented information on controlling production costs by increasing worker productivity. Equally important is the need to control capital cost. While capital costs for restaurant and hotels may not be as large as for heavy industry, they are significant when compared to the revenue generated by the respective operations. Therefore, it is important that operations not waste money on capital expenditures. By using value engineering and life-cycle costing, operators are able to control costs by making better capital-expenditure decisions.

3.2. Value Engineering

In its simplest terms, value engineering is the process of reviewing purchase decisions to determine whether they are cost effective. Value engineering seeks to determine whether the value added to the operation by the purchase provides the greatest possible return or whether there is a more cost-effective way to accomplish the same thing. When performing value engineering, it is important to have a good understanding of the operation and its goals. More than one concept has been diminished or destroyed by the improper application of value engineering. Deleting the required equipment to produce a restaurant's signature item in an attempt to cut cost has been a contributing factor in more than one business failure (Foster 1998). Foster also points out that operators should avoid doing last-minute value engineering. Last-minute budget cutting does not allow for proper evaluation of the options and can lead to the cutting of necessary pieces of equipment or options that will have to be added later at an increased cost. The problem for kitchen equipment is further compounded by a lack of understanding of the reasons behind the relatively high costs of commercial food-service equipment. A microwave oven designed to meet the sanitation and operational requirements of a commercial kitchen can cost $2000 or more. If the kitchen designer does not start the value-engineering process early and demonstrate the need for each piece of equipment and option, these items are likely to be the prime targets of last-minute value engineering. Foster recommends that designers start their own value-engineering process at the beginning of the design process. They should describe each piece of equipment and each option, noting its importance to the successful operation of the business. It is also helpful to obtain multiple bids for each item.

3.3. Life-Cycle Costing

3.3.1. Overview

In evaluating the different pieces of equipment and options, it is important to consider more than just the initial cost. Purchasing a holding cabinet made of anodized aluminum instead of stainless steel can significantly reduce the purchase cost. However, aluminum cabinets are not as durable and

typically have shorter lives than stainless steel cabinets. Further, the salvage value of the steel cabinet is typically higher. If these other factors are not considered as part of the selection process, then the chance of selecting the most cost-efficient piece of equipment is greatly reduced (Borsenik and Stutts 1997). The challenge is to compare today's dollars with periodic payments and future dollars. Fortunately, relatively simple formulas can be used to bring all amounts back to present value so the different options can be properly evaluated.

3.3.2. Information to Be Included in Life-Cycle Costing

The process begins with collecting all pertinent information. The more information collected, the more accurate the prediction. Typically, information is collected on as many of the following items as are applicable.

1. *Initial costs:* This includes purchase price and installation costs.
2. *Periodic costs:* This includes energy usage, maintenance, supplies, and labor estimates. It can also include lease payments and service contracts.
3. *End of service costs/revenues:* This can be a revenue such as salvage or a cost such as a residual lease payment.
4. The organization's standard return on investment and anticipated inflation rate.

3.3.3. Converting Amounts to Present Value

The equation used to return all amounts to present value depends on when the amount is paid or received. First, it must be determined whether the amount is a cost or revenue. Since this is a costing method, costs are treated as positive numbers and revenues are treated as negative numbers. Once the sign of the amount has been determined, the next step is to determine whether it is a one-time payment/receipt or a periodic payment/receipt. Examples of one-time payments/receipts include purchase price, installation costs, and salvage value. Examples of periodic payments/receipts include rents, monthly charges such as energy cost, wages, and increased income directly attributed to using the equipment.

If the payment/receipt is a one-time event, then the next step is to determine when it occurs. If it occurs now, it is already in present value and no conversion is necessary. If, however, it occurs some time in the future, it must be converted to present value using the following equation from Newman (1980):

$$P = F(1 + i)^{-n} \tag{1}$$

where P = present value of the future amount (F)
i = interest rate
n = number of compounding periods

The length of the compounding periods must agree with the interest rate; that is, if the interest rate is an annual rate, the number of compounding periods must be expressed in years.

If the payment/receipt is periodic in nature, the following equation derived from information contained in Newman (1980) is used.

$$P = A(1 + i)^{-n} \frac{(1 - i)^n - (1 - \text{CPC})^n}{(i - \text{CPC})} \tag{2}$$

where A = periodic amount
CPC = compound price change or inflation rate

As before, the length of the compounding period must be the same for all terms. Equation (2) will work for all combinations of interest rate and CPC except those where the interest rate and CPC are equal. If the interest rate and the CPC are equal, Equation (2) is undefined. If this happens, the present value of the periodic amount can be found by multiplying the periodic amount by the number of compounding periods. Once all amounts have been converted to present value, the last step is to sum all payments/receipts. The equipment/option with the lowest sum is the most cost-effective alternative.

4. SUMMARY

The industrial engineering techniques discussed in this chapter are but a few of the techniques currently being used by hospitality operations. Successful food-service operations of the future will find ways to change the negative productivity trend that the industry has been experiencing for the last

20+ years. They will become more productive by making better use of existing resources and exploiting the benefits of new technology. The prudent application of the principles and techniques of industrial engineering will help make a positive productivity trend a reality.

1. INTRODUCTION

Most definitions of leadership reflect the assumption that it involves a social influence process whereby intentional influence is exerted by one person over other people to structure the activities and relationships in a group or organization (Yukl 1998). Leadership occurs when one group member modifies the motivation and competencies of others in the group (Bass 1990). Work motivation is the willingness of an individual to invest energy in productive activity. Thus, leadership and motivation are interwoven, inseparable concepts; a core outcome of effective leadership is a higher willingness on the part of the employees to invest energy in performing their tasks. A new genre of leadership and motivation theories has been shown to affect organizational effectiveness in ways that are quantitatively greater than, and qualitatively different from, the effects specified by previous theories (House and Shamir 1993; for a meta-analytic review see Lowe et al. 1996). These theories have led to new applications in human resource management. As shown in Figure 1, we first review the early vs. the most recent paradigms of leadership, namely the shift from transactional to transformational, charismatic, or visionary leadership. This shift is manifested by changes in the bases for work motivation from an emphasis on calculative, individualistic, extrinsic, short-term motivators toward more expressive, collectivistic, intrinsic, long-term motivators. Taken together, these new approches have been shown to positively impact organizational outcomes, including performance and employee development. The impact of the new leadership and motivation paradigm on organizational outcomes has implications for strategic human resource management, specifically recruiting, performance management, training and development, and compensation.

2. LEADERSHIP AND MOTIVATION

2.1. The Classic Paradigm of Leadership: A Transactional Approach

> I was his loyal friend, but no more. . . . I was so hurt when I discovered that in spite of my loyalty, he always preferred Arie Dery to me. I asked him: 'Bibi, why?' and he answered: "He brings me 10 seats in the parliament while you don't have such a bulk of voters behind you."
>
> —Itzhak Levi, former Minister of Education, on Benjamin Netanyahu, former Prime Minister of Israel

Many of the classic approaches to leadership concentrated on how to maintain or achieve results as expected or contracted between the leader and the employees. These transactional theories and practices viewed leadership in terms of contingent reinforcement, that is, as an exchange process in which employees are rewarded or avoid punishment for enhancing the accomplishment of agreed-upon objectives.

Figure 2 shows the process by which transactional leaders affect their employees' motivation and performance. Transactional leaders help employees recognize what the role and task requirements are to reach a desired outcome. The transactional leader helps clarify those requirements for employees, resulting in increased confidence that a certain level of effort will result in desired performance. By recognizing the needs of employees and clarifying how those needs can be met, the transactional leader enhances the employee's motivational level. In parallel, the transactional leader recognizes what the employee needs and clarifies for the employee how these needs will be fulfilled in exchange for the employee's satisfactory effort and performance. This makes the designated outcome of sufficient value to the employee to result in his or her effort to attain the outcome. The model is built upon the assumption that the employee has the capability to perform as required. Thus, the expected effort is translated into the expected performance (Bass 1985).

There is support in the literature for the effectiveness of transactional leadership. Using contingent reinforcement, leaders have been shown to increase employee performance and job satisfaction and to reduce job role uncertainty (Avolio and Bass 1988). For example, Bass and Avolio (1993) report results collected from 17 independent organizations indicating that the correlations between the contingent reward leadership style and employees' effectiveness and satisfaction typically ranged from 0.4 to 0.6, depending on whether it was promises or actual rewards. Similarly, Lowe et al. (1996), in their meta-analysis of 47 studies, report that the mean corrected correlation between contingent reward and effectiveness was 0.41.

Although potentially useful, transactional leadership has several serious limitations. First, the contingent rewarding, despite its popularity in organizations, appears underutilized. Time pressure, poor performance-appraisal systems, doubts about the fairness of the organizational reward system, or lack of managerial training cause employees not to see a direct relationship between how hard they work and the rewards they receive. Furthermore, reward is often given in the form of feedback from the superior, feedback that may also be counterproductive. What managers view as valued feedback is not always perceived as relevant by the employees and may be weighted less than feedback received from the job or coworkers. In addition, managers appear to avoid giving negative feedback to employees. They distort such feedback to protect employees from the truth. Second, transactional leadership may encourage a short-term approach toward attaining organizational objec-

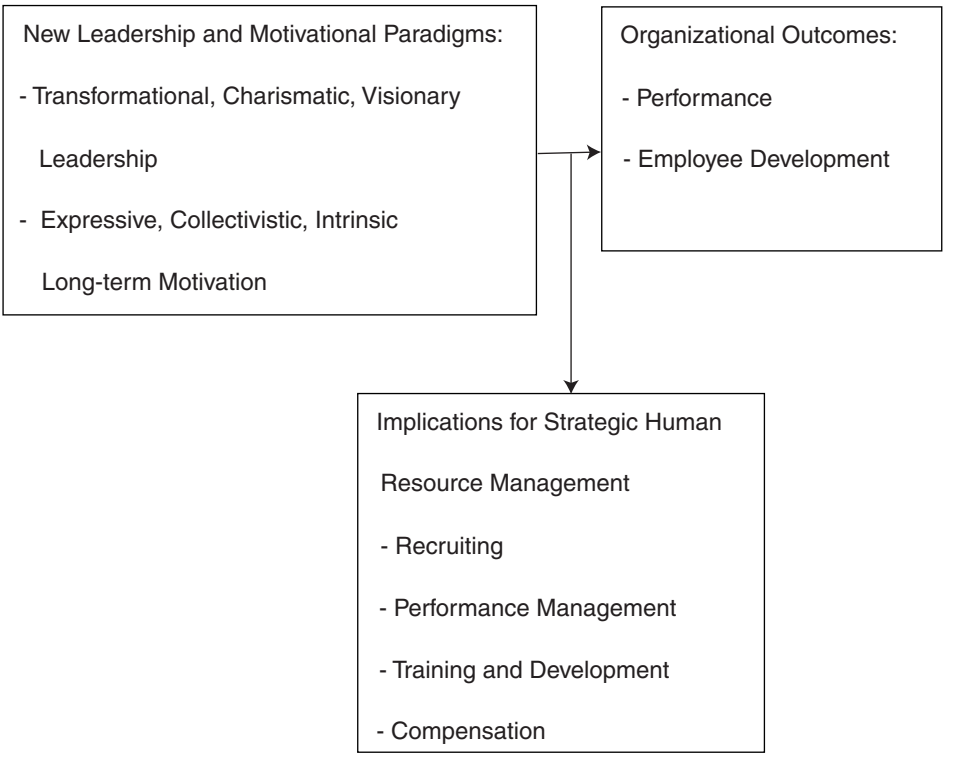

Figure 1 Linkages between Leadership and Motivational Paradigms, Organizational Outcomes, and Strategic Human Resource Management.

tives. A transactional leader who views leadership solely from a contingent reinforcement perspective may find that employees will circumvent a better way of doing things to maximize short-term gain to reach their goals in the most expeditious manner possible, regardless of the long-term implications. Third, employees do not always perceive contingent reinforcement as an effective motivator. The impact may be negative when the employees see contingent rewards given by the superior as manipulative (Avolio and Bass 1988).

Finally, one of the major criticisms directed toward this contract-based approach to leadership has been that it captures only a portion of the leader-follower relationships. Scholars like Hemphill (1960) and Stogdill (1963) (in Seltzer and Bass 1990) felt long ago that an expanded set of factors was necessary to fully describe what leaders do, especially leader–follower relationships that include motivation and performance that go beyond contracted performance. Bass and Avolio (1993) state that the ''transaction'' between a leader and a follower regarding the exchange of rewards for achieving agreed-upon goals cannot explain levels of effort and performance of followers who are inspired to the highest levels of achievement. There are many examples of leadership that do not conform to the ever-popular notion of a transaction between leader and follower. As Howell (1996) points out, the notion of leaders who manage meaning, infuse ideological values, construct lofty goals and visions, and inspire was missing entirely from the literature of leadership exchange. A new paradigm of leadership was needed to account for leaders who focus the attention of their employees on an idealized goal and inspire them to transcend themselves to achieve that goal. The actions of such leaders result in higher-order changes in employees and therefore in higher performance.

2.2. The New Paradigm of Leadership: A Transformational Approach

> Head in the clouds, feet on the ground, heart in the business.
>
> —Anita Roddick, founder of The Body Shop

Pat Summitt has been called the best basketball coach since the famed John Wooden. Just some

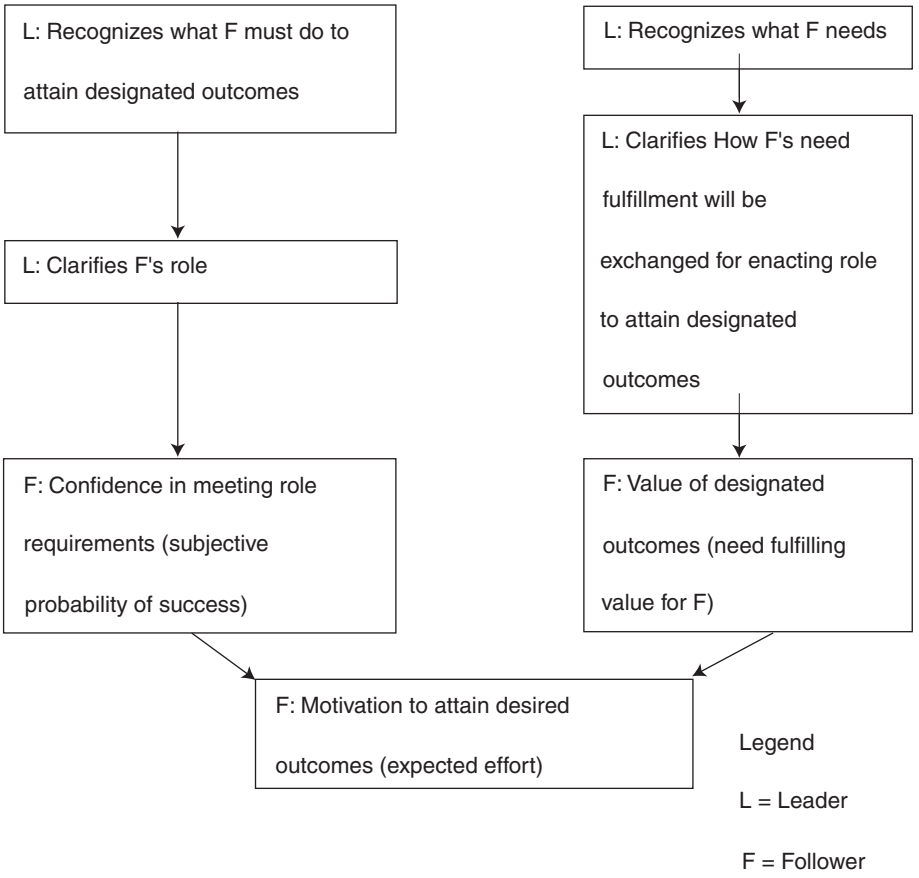

Figure 2 Transactional Leadership and Follower Motivation. (Adapted with the permission of The Free Press, a Division of Simon & Schuster, from *Leadership and Performance beyond Expectations,* by Bernard M. Bass, Copyright © 1985 by The Free Press.)

of her credentials include winning the first-ever Olympic gold medal in U.S. women's basketball history; six national championships; an .814 winning percentage, fifth among all coaches in college basketball history; and so many trips to basketball's Final Four that her record in all likelihood will never be equaled. Her 1997–1998 University of Tenessee team finished the regular season 30 and 0 and won its third consecutive national title. Beyond coaching records, however, what is Summitt like as a person? Among other things, when she walks into a room, her carriage is erect, her smile confident, her manner of speaking direct, and her gaze piercing. Her calendar documents her pressured schedule. But she is also a deeply caring person, appropriate for a farm daughter who grew up imitating her mother's selfless generosity in visiting the sick or taking a home-cooked dinner to anyone in need. Summitt clearly has many extraordinary qualities as a coach, but perhaps most striking is the nature of the relationship she develops with her players (Hughes et al. 1998). Pat Summitt does not rely only on her players' contracts to gain their highest levels of motivation and performance. The best transactional, contract-based leadership cannot assure such high performance on the part of the players. Summitt clearly has the additional qualities of what is referred to as transformational leadership.

Indeed, the past 15 years have seen some degree of convergence among organizational behavior scholars concerning a new genre of leadership theory, alternatively referred to as ''transformational,'' ''charismatic,'' and ''visionary.'' Transformational leaders do more with colleagues and followers than set up simple transactions or agreements (Avolio 1999). Transformational leadership theory explains the unique connection between the leader and his or her followers that accounts for extraordinary performance and accomplishments for the larger group, unit, and organization (Yammarino and Du-

binsky 1994), or, as stated by Boal and Bryson (1988, p. 11), transformational leaders ''lift ordinary people to extraordinary heights.'' Transformational leaders engage the ''full'' person with the purpose of developing followers into leaders (Burns 1978). In constrast to transactional leaders, who seek to satisfy the current needs of followers through transactions or exchanges via contingent reward behavior, transformational leaders (a) raise the follower level of awareness about the importance of achieving valued outcomes, a vision, and the required strategy; (b) get followers to transcend their own self-interests for the sake of the team, organization, or larger collectivity; and (c) expand the followers' portfolio of needs by raising their awareness to improve themselves and what they are attempting to accomplish. Transformational leaders encourage followers to develop and perform at levels above what they may have felt was possible, or beyond their own personal expectations (Bass and Avolio 1993).

Perhaps the major difference between the new paradigm of leadership and the earlier classic approaches mentioned above lies in the nature of the relationships that are built between leaders and employees, that is, the process by which the leaders energize the employees' effort to accomplish the goals, as well as in the type of goals set. According to the new genre of leadership theory, leaders transform the needs, values, preferences, and aspirations of the employees. The consequence of the leader's behaviors is emotional and motivational arousal of the employees, leading to self-reinforcement mechanisms that heighten their efforts and bring performance above and beyond the call of duty or contract (Avolio and Bass 1988; House and Shamir 1993).

2.3. Differences in the Motivational Basis for Work between the Classic and the New Leadership Paradigms

Individuals may approach social situations with a wide range of motivational orientations. The classic transactional and the new transformational paradigms of leadership differ in their assumptions about the core underlying bases for motivation to work. The main shifts in the motivational basis for work concentrate on three dimensions. The first deals with a transition from a calculative–rational toward an emotional–expressive motivation. The second concerns the shift from emphasizing individualistic-oriented motivation toward stressing the centrality of collectivistic-oriented motivation. The third dimension refers to the importance given to intrinsic motivators in addition to the traditional extrinsic incentives.

2.3.1. From a Calculative–Rational toward an Emotional–Expressive Motivation to Work

The transactional approach to leadership is rooted in behavioral and contingency theories. This transactional paradigm is manifested in the long fixation on the dimensions of consideration or people-orientation and initiating structure or task-orientation (review in Yukl 1998). Leadership behavior, as measured by the indexes of initiating structure and consideration, is largely oriented toward accomplishing the tasks at hand and maintaining good relationships with those working with the leader (Seltzer and Bass 1990). When the superior initiates structure, this enhances and reinforces the employees' expectancy that their efforts will succeed. Consideration by the superior is a desired benefit reinforcing employee performance (Bass 1985). This transactional approach was also carried into contingency theories such as the path–goal theory of leadership developed by House (1971). The path–goal theory took as its underlying axioms the propositions of Vroom's expectancy theory, which was the prevailing motivational theory at that time. According to expectancy theory, employees' efforts are seen to depend on their expectancy that their effort will result in their better performance, which in turn will result in valued outcomes for them (Yukl 1998). The path–goal theory to leadership asserted that ''the motivational function of the leader consists of increasing personal payoffs to subordinates for work-goal attainment and making the path to these payoffs easier travel by clarifying it, reducing roadblocks and pitfalls, and increasing the opportunities for personal satisfaction en route'' (House 1971, p. 324). The common denominator of the behavioral and contingency approaches to leadership is that the individual is assumed to be a rational maximizer of personal utility. They all explain work motivation in terms of a rational choice process in which a person decides how much effort to devote to the job at a given point of time. Written from a calculative-instrumental perspective, discussions and applications of work motivation have traditionally emphasized the reward structure, goal structure, and task design as the key factors in work motivation and deemphasized other sources of motivation. Classic theories assume that supervisors, managers, leaders, and their followers are able to calculate correctly or learn expected outcomes associated with the exercise of theoretically specified behaviors. These theories, then, make strong implicit rationality assumptions despite substantial empirical evidence that humans are subject to a myriad of cognitive biases and that emotions can be strong determinants of behavior (House 1995).

The new motivation and leadership paradigms recognize that not all of the relevant organizational behaviors can be explained on the basis of calculative considerations and that other considerations may enrich the explanation of human motivation (Shamir 1990). Transformational and charismatic leadership approaches assume that human beings are not only instrumental-calculative, pragmatic,

and goal-oriented but are also self-expressive of feelings, values, and self-concepts. We are motivated to do things because it makes sense to do them from a rational-instrumental point of view, but also because by doing so we can discharge moral obligations or because through such a contribution we can establish and affirm a cherished identity for ourselves. In other words, because it is useful, but also because it is right, or because it ''feels right.'' Making the assumption that humans are self-expressive enables us to account for behaviors that do not contribute to the individual self-interest, the most extreme of which is self-sacrifice (House and Shamir, 1993; Shamir 1990; Shamir et al. 1993). Huy (1999), in discussing the emotional dynamics of organizational change, refers to the emotional role of charismatic and transformational leaders. According to Huy, at the organizational level, the emotional dynamic of encouragement refers to the organization's ability to instill hope among its members. Organizational hope can be defined as the wish that our future work situation will be better than the present one. Transformational leaders emotionally inspire followers through communication of vivid images that give flesh to a captivating vision so as to motivate them to pursue ambitious goals. The most important work for top managers is managing ideology and not strategy making. Transformational leaders can shape an ideological setting that encourages enthusiasm, nurtures courage, reveals opportunities, and therefore brings new hope and life into their organizations.

Thus, classic leadership theories addressed the instrumental aspects of motivation, whereas the new paradigm emphasizes expressive aspects as well. Such emotional appeals can be demonstrated by the words of Anita Roddick, founder and CEO of The Body Shop:

> Most businesses focus all the time on profits, profits, profits . . . I have to say I think that is deeply boring. I want to create an electricity and passion that bond people to the company. You can educate people by their passions . . . You have to find ways to grab their imagination. You want them to feel that they are doing something important . . . I'd never get that kind of motivation if we were just selling shampoo and body lotion. (Conger and Kanungo 1998, pp. 173–174)

2.3.2. From an Individualistic-Oriented toward a Collectivistic-Oriented Motivation to Work

Nearly all classic models of motivation in organizational behavior, in addition to being calculative, are also hedonistic. These classic approaches regard most organizational behavior as hedonistic and treat altruistic, prosocial, or cooperative behavior as some kind of a deviation on the part of the organizational members. This trend may be traced in part to the influence of the neoclassical paradigm in economics and psychology, which is based on an individualistic model of humans. American psychology, from which our work motivation theories have stemmed, has strongly emphasized this individualistic perspective (Shamir 1990).

The recent recognition that not all relevant work behaviors can be explained in terms of hedonistic considerations has led to the current interest in prosocial organizational behaviors, those that are formed with the intent of helping others or promoting others' welfare. However, between totally selfish work behavior and pure altruistic behaviors, many organizationally relevant actions are probably performed both for a person's own sake and for the sake of a collectivity such as a team, department, or organization. Individuals may approach social situations with a wide range of motivational orientations that are neither purely individualistic (concerned only with one's satisfaction) nor purely altruistic (concerned only with maximizing the other's satisfaction). Deutsch (1973, in Shamir, 1990) uses the term *collectivistic* to refer to a motivational orientation that contains a concern with both one's own satisfaction and others' welfare.

The importance of discussing the linkages between individual motivations and collective actions stems from the increasing recognition of the importance of cooperative behaviors for organizational effectiveness. During the 1990s, hundreds of American companies (e.g., Motorola, Cummins Engine, Ford Motor Co.) reorganized around teams to leverage the knowledge of all employees. Now it appears that the concept is going global, and recent research conducted in Western Europe has supported the wisdom of teams. For example, the Ritz-Carlton Hotel Co. has created ''self-directed work teams'' with the goal of improving quality and reducing costs. In the hotel's Tysons Corner, Virginia, facility, a pilot site for the company's program, the use of these teams has led to a decrease in turnover from 56 to 35%. At a cost of $4,000 to $5,000 to train each new employee, the savings were significant. At Air Products, a chemical manufacturer, one cross-functional team, working with suppliers, saved $2.5 million in one year. OshKosh B'Gosh has combined the use of work teams and advanced equipment. The company has been able to increase productivity, speed, and flexibility at its U.S. manufacturing locations, enabling it to maintain 13 of its 14 facilities in the United States, which made one of the few children's garment manufacturers able to do so (Gibson et al. 2000). This shift in organizational structure calls for higher cooperation in group situations. Cooperation, defined as the willful contribution of personal effort to the completion of interdependent jobs, is essential whenever people must coordinate activities among differentiated tasks. Individualism is the condition in which personal interests are accorded greater importance than are the needs of groups.

Collectivism occurs when the demands and interests of groups take precedence over the desires and needs of individuals. Collectivists look out for the well being of the groups to which they belong, even if such actions sometimes require that personal interests be disregarded. A collectivistic, as opposed to an individualistic orientation should influence personal tendencies to cooperate in group situations (Wagner 1995).

A core component incorporated in the new paradigm of leadership is that transformational leaders affect employees to transcend their own self-interests for the sake of the team, organization, or larger collectivity (Bass and Avolio 1990; Burns 1978). The effects of charismatic and transformational leaders on followers' relationships with the collective are achieved through social identification, that is, the perception of oneness with, or belonging to, some human aggregate (Shamir 1990). People who identify with a group or organization take pride in being part of it and regard membership as one of their most important social identities. High social identification may be associated with a collectivistic orientation in the sense that the group member is willing to contribute to the group even in the lack of personal benefits, places the needs of the group above individual needs, and sacrifices self-interest for the sake of the group (Shamir 1990; Shamir et al. 1998). A charismatic or transformational leader can increase social identification by providing the group with a unique identity distinguishing it from other groups. This can be achieved by the skillful use of slogans, symbols (e.g., flags, emblems, uniforms), rituals (e.g., singing the organizational song), and ceremonials. In addition, transformational and charismatic leaders raise the salience of the collective identity in followers' self-concepts by emphasizing shared values, making references to the history of the group or organization, and telling stories about past successes, heroic deeds of members, and symbolic actions by founders, former leaders, and former members of the group (Shamir et al. 1993). Frequent references by the leader to the collective identity and presentation of goals and tasks as consistent with that identity further bind followers' self-concepts to the shared values and identities and increase their social identification (Shamir et al. 1998).

Collectivistic appeals are illustrated by comments from Mary Kay Ash to her sales force at the company's annual convention:

> There was, however, one band of people that the Romans never conquered. These people were the followers of the great teacher from Bethlehem. Historians have long since discovered that one of the reasons for the sturdiness of this folk was their habit of meeting together weekly. They shared their difficulties and they stood side by side. Does this remind you of something? The way we stand side by side and share our knowledge as well as our difficulties with each other at our weekly unit meetings? . . . What a wonderful circle of friends we have. Perhaps it is one of the greatest fringe benefits of our company.
>
> —(Conger and Kanungo 1998, p. 160)

By implication, Mary Kay is saying that collective unity can work miracles in overcoming any odds.

2.3.3. From Extrinsic toward Intrinsic Motivation to Work

A classic categorization for work motivation is the intrinsic–extrinsic dichotomy. Extrinsic needs demand gratification by rewards that are external to the job itself. Extrinsic motivation derives from needs for pay, praise from superiors and peers, status and advancement, or physically comfortable working conditions. Intrinsic needs are satisfied when the activities that comprise the job are themselves a source of gratification. The desire for variety, for meaning and hope, and for challenging one's intellect in novel ways are examples of intrinsic motivation. When one engages in some activity for no apparent external reward, intrinsic motivation is likely at work. There is evidence that extrinsic rewards can weaken intrinsic motivation and that intrinsic rewards can weaken extrinsic motivation. However, intrinsic job satisfaction cannot be bought with money. Regardless of how satisfactory the financial rewards may be, most individuals will still want intrinsic gratification. Money is an important motivator because it is instrumental for the gratification of many human needs. Fulfilling basic existence needs, social needs, and growth needs can be satisfied with money or with things money can buy. However, once these needs are met, new growth needs are likely to emerge that cannot be gratified with money. Pay, of course, never becomes redundant; rather, intrinsic motivators to ensure growth-stimulating challenges must supplement it (Eden and Globerson 1992).

Classic motivational and leadership theories have emphasized both extrinsic and intrinsic rewards. However, transformational leadership theory goes beyond the rewards-for-performance formula as the basis for work motivation and focuses on higher-order intrinsic motivators. The motivation for development and performance of employees working with a transformational leader is driven by internal and higher-order needs, in contrast to the external rewards that motivate employees of transactional leaders (Bass and Avolio 1990). The transformational leader gains heightened effort from employees as a consequence of their self-reinforcement from doing the task. To an extent, transformational leadership can be viewed as a special case of transactional leadership with respect to exchanging effort for rewards. In the case of transformational leadership, the rewarding is internal (Avolio and Bass 1988).

The intrinsic basis for motivation enhanced by transformational and charismatic leaders is emphasized in Shamir et al.'s (1993) self-concept theory. Self-concepts are composed, in part, of identities. The higher the salience of an identity within the self-concept, the greater its motivational significance. Charismatic leaders achieve their transformational effects through implicating the self-concept of followers by the following four core processes:

1. By increasing the intrinsic value of effort, that is, increasing followers' intrinsic motivation by emphasizing the symbolic and expressive aspects of the effort, the fact that the effort itself reflects important values.
2. By empowering the followers not only by raising their specific self-efficacy perceptions, but also by raising their generalized sense of self-esteem, self-worth, and collective efficacy.
3. By increasing the intrinsic value of goal accomplishment, that is, by presenting goals in terms of the value they represent. Doing so makes action oriented toward the accomplishment of these goals more meaningful to the follower in the sense of being consistent with his or her self-concept.
4. By increasing followers' personal or moral commitment. This kind of commitment is a motivational disposition to continue a relationship, role, or course of action and invest effort regardless of the balance of external costs and benefits and their immediate gratifying properties.

2.4. The Full Range Leadership Model: An Integrative Framework

Bass and Avolio (1994) propose an integrative framework that includes transformational, transactional, and nontransactional leadership. According to Bass and Avolio's ''full range leadership model,'' leadership behaviors form a continuum in terms of activity and effectiveness. Transformational leadership behaviors are at the higher end of the range and are described as more active–proactive and effective than either transactional or nontransactional leadership. Transformational leadership includes four components.

Charismatic leadership or idealized influence is defined with respect to both the leader's behavior and employee attributions about the leader. Idealized leaders consider the needs of others over their own personal needs, share risks with employees, are consistent and trustworthy rather than arbitrary, demonstrate high moral standards, avoid the use of power for personal gain, and set extremely challenging goals for themselves and their employees. Taken together, these behaviors make the leader a role model for his or her employees; the leader is admired, respected, trusted, and ultimately identified with over time. Jim Dawson, as the president of Zebco, the world's largest fishing tackle company, undertook a series of initiatives that would symbolically end the class differences between the workforce and management. Among other actions, he asked his management team to be role models in their own arrival times at work. One executive explained Dawson's thinking:

> What we realized was that it wasn't just Jim but we managers who had to make sure that people could see there were no double standards. As a manager, I often work long hours. . . Now the clerical and line staff don't see that we are here until 7 because they are here only until 4:45 p.m. As managers, we don't allow ourselves to use that as an excuse. . . Then it appears to the workforce that you have a double standard. An hourly person cannot come in at 7:05 a.m. He has got to be here at 7:00 a.m. So we have to be here at the same time.
>
> (Conger and Kanungo 1998, pp. 136–137)

Similarly, Lee Iacocca reduced his salary to $1 in his first year at Chrysler because he believed that leadership means personal example.

Inspirational motivation involves motivating employees by providing deeper meaning and challenges in their work. Such leaders energize their employees' desire to work cooperatively to contribute to the collective mission of their group. The motivational role of vision is achieved through the selection of goals meaningful to followers. For example, Mary Kay Ash articulates her company's mission as enhancing women's role in the world and empowering them to become more self-confident. This is a highly appealing message to an organization made up of women for whom selling Mary Kay Cosmetics may be their first working career. The importance of giving meaning to work is also illustrated in the speech of Orit Gadiesh, the vice chairman of Bain and Co., a well-known Boston management consulting firm. After a period of crisis, the financial picture of the company had turned around, but Gadiesh sensed that the organization had lost pride in itself. She chose the company's annual meeting in August 1992 to convey in words what she felt the organization had to realize, a ''pride turnaround.'' Gadiesh said, ''We've turned around financially, and we've turned around the business. . . . Now it's time to turn around what they [competitors] really fear, what they have always envied us for, what made them most uneasy—as crazy as this sounds. It's time to turn around our collective pride in what we do!'' (Conger and Kanungo 1998, p. 182).

Intellectual stimulation entails the leader's and the employees' questioning of assumptions, reframing problems, and thinking about concepts using novel approaches or techniques. For instance, Richard Branson, the charismatic British entrepreneur who built the diversified, multibillion dollar business of Virgin, sets an example of an innovative and unconventional approach to business. Time after time, Branson has found opportunities in established industries by going against conventions. One of his earliest successful initiatives was in discount stores. When approximately 20 years old, he observed that despite the abolition of a government policy allowing manufacturers and suppliers to ''recommend'' prices to retail outlets (which had ensured high prices for records), music records remained overpriced. He decided to challenge norms around pricing by offering records through the mail, discounting them some 15% from retail stores. When he entered the airline business in 1984, he distinguished himself from competitors in various ways from lower fares to in-flight masseurs, fashion shows to musicians, and motorcycle transportation to the London airport. Anita Roddick of The Body Shop also expresses a hard-line stance against the traditional practices of the cosmetics industry: ''It turned out that my instinctive trading values were dramatically opposed to the standard practices in the cosmetic industry. I look at what they are doing and walk in the opposite direction'' (Conger and Kanungo 1998, p. 185).

Individualized consideration represents the leader's effort to understand and appreciate the different needs and viewpoints of employees while attempting continuously to develop employee potential. A soldier in the Israel Defense Forces (IDF) describes his platoon leader's individualized treatment

> On the way back, there was a very steep slope. I finished it with no air in my lungs. We still had 400 meters to run. I was last and I couldn't walk anymore. Then, K., the platoon commander came and said ''run.'' I can't walk and he is talking to me about running. Ten meters before the end he said ''now sprint.'' I did it and got to the camp. I felt great. I felt I had done it. Suddenly I discovered that K. was able to get me to do things that I never thought I could do.
>
> (Landau and Zakay 1994, pp. 32–33)

Donald Burr, the former CEO of People Express Airlines, who was deeply interested in creating a humane organization and was guided by a fundamental belief in people, summarizes his view: ''The people dimension is the value added to the commodity. Many investors still don't fully appreciate this point'' (Conger and Kanungo 1998, p. 144).

Conversely, transactional leaders exert influence on employees by setting goals, clarifying desired outcomes, providing feedback, and exchanging rewards for accomplishments. Transactional leadership includes three components. With the *contingent reinforcement* style, the leader assigns or secures agreements on what needs to be done and promises or actually rewards others in exchange for satisfactorily carrying out the assignments. Alternatively, using the *management-by-exception—active* style, the leader arranges actively to monitor deviations from standards, mistakes, and errors in the employees' assignments and takes corrective action as necessary. With the *management-by-exception—passive* style, the leader waits for problems to emerge and then takes corrective action. Nontransactional leadership is represented by the *laissez-faire* style, in which the leader avoids intervention, transactions, agreements, or setting expectations with employees (Bass 1996; Bass and Avolio 1993).

One of the fundamental propositions in Bass and Avolio's model is that transformational leadership augments transactional leadership in predicting leader effectiveness. Transformational leadership cannot be effective if it stands alone. Supporting most transformational leaders is their ability to manage effectively, or transact with followers, the day-to-day mundane events that clog most leaders' agenda. Without transactional leadership skills, even the most awe-inspiring transformational leaders may fail to accomplish their intended missions (Avolio and Bass 1988). Indeed, several studies (Hater and Bass 1988; Howell and Frost 1989; Seltzer and Bass 1990) have confirmed this ''augmentation hypothesis'' and shown that transformational or charismatic leadership explained additional variance in leader effectiveness beyond either transactional leadership or leadership based on initiating structure and consideration. Sometimes, with highly transformational or charismatic leaders, there is a need to find a complementary top manager with a more transactional-instrumental orientation. For example, Colleen Barrett, the executive vice president of Southwest, is the managerial complement to Herb Kelleher's charismatic, loosely organized style. She is a stickler for detail and provides the organizational counterweight to Kelleher's sometimes chaotic style (Conger and Kanungo 1998).

Thus, according to the full range leadership model, every leader displays each style to some degree. Three-dimensional optimal and suboptimal profiles are shown in Figure 3. The depth *frequency* dimension represents how often a leader displays a style of leadership. The horizontal *active* dimension represents the assumptions of the model according to which the laissez-faire style is the most passive style, whereas transactional leadership incorporates more active styles and transformational leadership is proactive. The vertical *effectiveness* dimension is based on empirical results that

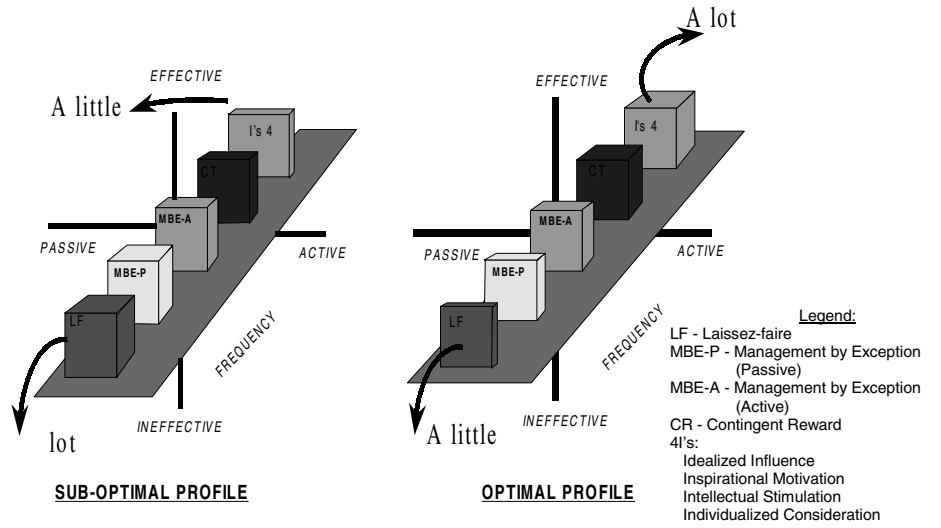

Figure 3 Full Range Leadership Model: Optimal and Suboptimal Profiles as Created by the Frequency of Displaying the Leadership Styles' Behaviors. (Adapted from B. J. Avolio, *Full Leadership Development: Building the Vital Forces in Organizations,* p. 53, copyright © 1999 by Sage Publications, Inc., reprinted by permission of Sage Publications, Inc.)

have shown active transactional and proactive transformational leadership to be far more effective than other styles of leadership. The frequency dimension manifests the difference between optimal and suboptimal profile. An optimal managerial profile is created by more frequent use of transformational and active transactional leadership styles along with less frequent use of passive transactional and laissez-faire leadership. The opposite directions of frequency create a suboptimal profile.

3. LEADERSHIP OUTCOMES

My message was, and will always be, "There are no limits to the maximum."
—T., an exemplary infantry platoon commander in the Israel Defense Forces

"Transformational leaders encourage follower to both *develop* and *perform* at levels above what they may have felt was possible, or beyond their own personal expectations" (Bass and Avolio 1990, p. 234, emphasis in original). Thus, achieving certain levels of performance as well as development become a targeted outcome. The linkages between transformational leadership, employee development, and performance are presented in Figure 4.

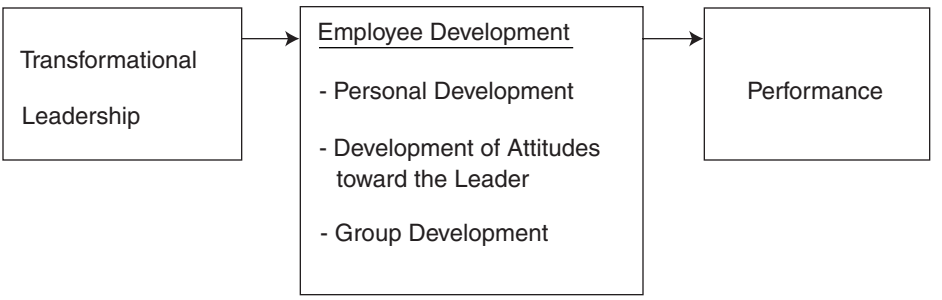

Figure 4 Linkages among Transformational Leadership, Employee Development, and Performance.

3.1. Performance

Numerous studies have examined the relationships between various components of the full range leadership model and performance outcomes. Overall, these studies confirmed the positive impact of transformational leadership on perceived effectiveness as well as on hard measures of performance.

The most commonly studied perceived outcomes were perceived effectiveness of the leader and the work unit, extra effort, and satisfaction with the leader. In the majority of the studies, both transformational/transactional leadership and the outcome variables were evaluated by the same source, usually the immediate followers. For example, Hater and Bass (1988) found positive high correlations between transformational leadership and perceived effectiveness and satisfaction, both rated by the leaders' immediate followers, whereas the correlations between the transactional factors and followers' ratings were low to moderate. Seltzer and Bass (1990) studied 138 followers and 55 managers and confirmed that transformational leadership adds to transactional leadership (as represented by the dimensions of initiating structure and consideration) in explaining the variance of followers' satisfaction and ratings of leader effectiveness. Several studies have expanded the spectrum of outcome variables. Thus, for example, Bycio et al. (1995) conducted a study among 1376 nurses who evaluated both their superior's leadership style and the outcome variables. They found that in addition to the strong positive relationships between transformational leadership and followers' extra effort, satisfaction with the leader, and perceived leader effectiveness, transformational leadership also had positive correlations with followers' organizational commitment and negative correlations with followers' intentions to leave the profession and the job. Podsakoff et al.'s (1990) study among 988 exempt employees of a large petrochemical company confirmed that ''core'' transformational leadership behaviors and individualized support had positive effects on followers' trust and satisfaction with the leader. Bass and Avolio (1993) summarize the findings of this type from studies conducted in industrial, military, educational, and religious organizations. The pattern of relationships was consistent across 17 independent samples and pointed to a clear hierarchy. The correlations with perceived effectiveness and satisfaction with the leader typically ranged from 0.60 to 0.80 for transformational leadership, from 0.40 to 0.60 for contingent reward, from -0.30 to 0.30 for management-by-exception, and from -0.30 to -0.60 for laissez-faire leadership.

Fewer studies have collected survey measures of both leadership and outcomes from multiple sources. In these studies, different sources subjectively evaluated transformational/transactional leadership and organizational outcomes. The most frequent additional source used was the evaluation of managers' performance by their superiors. For example, Keller (1992) studied 66 project groups containing professional employees from three industrial research and development organizations. He showed that transformational leadership, as rated by immediate followers, was more predictive of project quality, as evaluated by the management, in research vs. development teams. Yammarino and Dubinsky (1994) collected leadership and perceived effectiveness data from various sources, including 105 salespersons and their 33 sales supervisors, in a $1 billion multinational medical products firm. They confirmed an individual-level positive relationship between transformational leadership, as perceived by followers, and extra effort and perceived performance of followers, as perceived by their superiors.

A growing number of studies have examined the impact of transformational leadership on objective performance measures. For example, Onnen (1987, in Bass and Avolio 1993) reports that transformational leadership of Methodist ministers, as evaluated by their district members, was positively related to Sunday church attendance and to growth in church membership. Avolio et al. (1988) found that transformational leadership and active transactional leadership were positively related to financial measures and productivity among MBA students engaged in a complex, semester-long competitive business simulation. Bryant (1990, in Bass and Avolio 1993) confirms that nursing supervisors who were rated by their followers as more transformational managed units with lower turnover rates. Howell and Avolio (1993) found positive relationships between transformational leadership and objective unit performance over a one-year interval among managers representing the top four levels of management in a large Canadian financial institution. German bank unit performance over longer vs. shorter time periods was higher in banks led by leaders who were rated by their employees as more transformational (Geyer and Steyrer 1998 in Avolio 1999).

However, ''even when predictions regarding objective performance outcomes support the model, we are still faced with plausible alternative cause-and-effect relationships'' (Bass and Avolio 1993, p. 69). Therefore, to establish causal effects, several experiments (Barling et al. 1996; Crookall 1989; Dvir et al. in press; Howell and Frost 1989; Kirkpatrick and Locke 1996; Sosik et al. 1997) were conducted either in the field or in the laboratory. Overall, these experiments confirmed the causal impact of transformational or charismatic leadership on performance outcomes. Such an experimental design can confirm that the direction of causal flow is indeed from transformational leadership to the hypothesized performance outcomes as opposed to instances where enhanced follower performance cause the higher transformational leadership ratings. Howell and Frost (1989) found that experimentally induced charismatic leadership positively affected task performance, task adjustment, and ad-

justment to the leader and the group. Kirkpatrick and Locke (1996) manipulated three core components common to charismatic and transformational leadership in a laboratory simulation among 282 students. They found that a vision of high quality significantly affected several attitudes, such as trust in the leader, and congruence between participants' beliefs and values and those communicated through the vision. Vision implementation affected performance quality and quantity. Barling et al. (1996), in a field experiment among 20 branch managers in a large Canadian bank, confirmed the positive impact of transformational leadership training on employees' organizational commitment and on two aspects of branch-level financial performance. Dvir et al. (in press) conducted a longitudinal randomized field experiment among military leaders and their followers. They confirm the positive impact of transformational leadership, enhanced through a training intervention, on direct followers' personal development and on indirect followers' objective performance.

Two meta-analytic studies have been conducted recently. Lowe et al. (1996) found that significantly higher relationships were observed between transformational scales and effectiveness than between transactional scales and effectiveness across 47 samples. This pattern held up across two levels of leadership and with both hard (number of units) and soft (performance appraisals) measures of performance (see Figure 5). Coleman et al. (1995) found that, across 27 studies, the transformational leadership styles were more strongly related to performance than the transactional styles. The average relationship across studies for the transformational leadership factors and performance ranged from 0.45 to 0.60; for transactional leadership, 0.44; for management-by-exception—active, 0.22; for management-by-exception—passive, 0.13; and for laissez-faire, −0.28.

To sum up, there is sufficient empirical evidence to conclude that transformational leadership has a positive impact on both perceived and objective performance and that this impact is stronger than the effects of transactional leadership.

3.2. Employee Development

Rather than solely focusing on the exchange with an eye toward performance, transformational leaders concentrate on developing employees to their full potential. Indeed, one of the most prominent aspects of transformational leadership compared to transactional leadership concerns employee developmental processes (Avolio and Gibbons 1988). The transformational leader evaluates the potential of all employees in terms of their being able to fulfill current commitments and future positions with even greater responsibilities. As a result, employees are expected to be more prepared to take on the responsibilities of the leader's position, and to be "transformed," as Burns (1978) originally argued, from followers into leaders. In contrast, working with the transactional leader, employees are expected to achieve agreed upon objectives but are not expected to undergo a developmental process whereby they will assume greater responsibility for developing and leading themselves and others. Follower

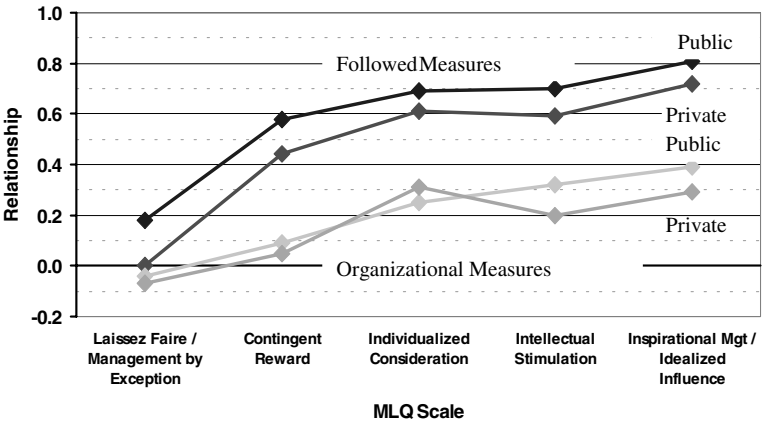

Figure 5 The Relationships between the Full Range Leadership Model's Styles and Leader Effectiveness in Public and Private Organizations in Lowe et al.'s (1996) Meta-analysis of 47 Samples. (MLQ = multifactor leadership questionnaire, which measures transformational, transactional, and nontransactional leadership; Relationship = correlations between leadership style and leader effectiveness; Follower measures = subordinate perceptions of leader effectiveness; organizational measures = quasi-institutional measures of leader effectiveness including both hard measures [e.g., profit] and soft measures [e.g., supervisory performance appraisals].)

developmental variables were classified here into the three broad categories of personal development, development of attitudes toward the leader, and group development.

3.2.1. Employee Personal Development

Most general references in the literature to follower development actually refer to an intrapersonal, developmental change that followers of transformational leaders presumably undergo; the leader transforms followers by serving as a coach, a teacher, and a mentor. Dvir et al. (in press) propose a conceptual framework for examining developmental aspects of transformational leadership theory on the basis of the sporadic theoretical discussions and empirical examinations in the literature. Their framework for follower personal development includes the three domains of motivation, morality, and empowerment. Dvir et al. found evidence of the impact of transformational leaders upon their direct followers' development in at least one measure of each category.

Motivation The emphasis in transformational leadership theory on employee motivational development can be traced back to Burns's (1978) references to two continuums of follower development. The first dealt with motivation and was based on Maslow's (1954) hierarchy of needs. Maslow conceived a hierarchy of human needs according to the following order: physiological, security, social, self-esteem, and self-actualization needs. Self-actualization, the realization of one's potential to become what one has the capacity to become, is at the highest level of need. According to Maslow, only upon satisfaction of the lower level needs does the motivation to satisfy a higher level need arise, and self-actualization needs are infinite. Burns (1978) proposes that transforming compared to transactional leaders motivate followers to achieve the highest possible level of need satisfaction such that the primary motive becomes the desire to satisfy *self-actualization needs* rather than lower needs. Based on Burns, Bass (1985, 1996) suggests that transformational leaders elevate the level of needs along Maslow's hierarchy or expand the employees' portfolio of needs. Unlike transactional leaders, who concentrate on fulfilling current employee needs, transformational leaders arouse needs that may have lain dormant.

Another motivational aspect associated with transformational leadership is the emphasis on employees' *extra effort*. Bass (1985) originally posited extra effort as a manifestation of employee motivation. He claimed that employees' extra efforts show how highly a leader motivates them to perform beyond expectations. Thus, it can be concluded that the emphasis on satisfying self-actualization needs reflects the type of need underlying the employees' motivation, whereas extra effort reflects the level of their motivation. Shamir et al. (1993), in discussing the motivational effects of charismatic leadership, propose that charismatic leaders increase employee effort by increasing the intrinsic value of their efforts through links to valued aspects of the employee's self-concept. Forming these linkages to the employee's self-concept helps to harness the motivational forces of self-expression, self-consistency, self-esteem, and self-worth. Extra effort is one of the most widely confirmed correlates of transformational leadership. Dvir et al. (in press) conducted a randomized field experiment in a military organization and confirmed the positive impact of transformational leadership, enhanced through training, on direct followers' perceived extra effort.

Morality Burns's (1978) second developmental continuum relates to the employees' moral development, based on Kohlberg's (1973) theory. Burns summarizes that "transforming leadership ultimately becomes moral in that it raises the level of human conduct and ethical aspiration of both leader and led, and thus it has a transforming effect on both" (p. 20). Bass (1985) purposely omitted the moral element from his original theory, apart from emphasizing the importance of collective interests. Recent articles have decried the omission of the moral element from transformational and charismatic leadership theories, and have called for its inclusion as part of the developmental process undergone by employees of transformational leaders. Bass (1996) came to agree with Burns that to be transformational, a leader must be morally uplifting. One of the difficulties in applying this part of the theory is that, according to Kohlberg, moving from one moral stage to the next may take years, a time span too long to wait for results to appear in typical leadership studies. Therefore, moral development in the short-term can be represented by the employees' *internalization of organizational moral values* (Dvir et al. in press).

The transition from a desire to satisfy solely personal interests to a desire to satisfy the broader collective interests is part of moral development, according to Kohlberg (1973). Bass (1985) places special emphasis on this aspect of moral development and suggests that transformational leaders get their employees to transcend their own self-interest for the sake of the team or organization. In Shamir's (1991) self-concept theory, the *collectivistic orientation* of the employees is one of the central transformational effects of charismatic leaders. Dvir et al. (in press) confirm the causal impact of transformational leaders on their direct followers' collectivistic orientation.

Empowerment Transformational leadership theory, in contrast to early charismatic leadership theories (e.g., House 1977), never assumed that leadership relationships are based on regression or weakness on the part of the employees. On the contrary, transformational leadership theory has

consistently emphasized employees' development toward autonomy and empowerment over automatic followership. Neocharismatic leadership theories have ceased conceptualizing the employees as weak (House 1995; Shamir 1991).

The literature has referred to critical-independent thinking as one of the essential empowerment-related processes undergone by employees of transformational leaders. Bass and Avolio (1990) state that transformational leaders enhance employees' capacities to think on their own, develop new ideas, and question operating rules and systems that no longer serve the organization's purpose or mission. Avolio and Gibbons (1988) posit that a primary goal of transformational leadership is to develop employee self-management and self-development. Shamir's (1991) self-concept theory emphasized the transformational effects of charismatic leaders on employee autonomy, independence, and empowerment. A critical-independent employee as an outcome of transformational leadership also accords Kelley's (1992) conceptualization regarding styles of followership perceived within organizations as good followership. Kelley's respondents described the best followers as those who ''think for themselves,'' ''give constructive criticism,'' ''are their own person,'' and ''are innovative and creative.'' The worst followers were characterized as ''must be told what to do'' and ''don't think.'' In between were the typical followers who ''take direction'' and ''don't challenge the leader or group.'' Although Kelley labels this dimension critical-independent thinking, he actually refers to thinking and action, or in his words, ''to become a full contributor, you need to cultivate independent, critical thinking and develop the courage to *exercise* it'' (p. 114, emphasis added). Thus, it is more appropriate to label this developmental outcome of transformational leadership *critical-independent approach*. Howell and Avolio (1989) confirm the hypothesized relationships between transformational leadership and employee innovation, risk-taking, and creativity among Canadian executives. Dvir et al. (in press) found a positive effect of transformational leadership on direct followers' critical-independent approach toward the self, peers, superiors, and the organizational system.

Kelley's (1992) review of best, worst, and typical follower characteristics reveals a second dimension, namely active engagement in the task. The best followers ''take initiative,'' ''participate actively,'' ''are self-starters,'' and ''go above and beyond the job.'' The worst ones are ''passive,'' ''lazy,'' ''need prodding,'' and ''dodge responsibility.'' The typical followers basically ''shift with the wind.'' Active engagement in the task involves the investment of energy into the followership role, usually toward a mutually shared dream or goal. Thus, *active engagement in the task* is defined as the energy invested in the employee role as expressed by high levels of activity, initiative, and responsibility taken by the employee, and is expected to be positively affected by transformational leadership.

Transformational and charismatic leadership theorists have emphasized the impact of the leader on employees' self-perceptions. Shamir et al. (1993) specify increased employee self-efficacy as one of the transformational effects of charismatic leaders. According to Conger and Kanungo (1988), self-efficacy can be tied to charismatic leadership through empowerment. Avolio and Gibbons (1988, p. 298) stated that ''a significant part of developing or transforming followers is developing their feelings of self-efficacy.'' Eden (1988) argues about the difference between general and specific self-efficacy (GSE and SSE, respectively). GSE is relatively a stable trait and is resistant to change, whereas SSE represents a more labile state. Direct followers of transformational leaders were found to have higher levels of SSE (Dvir et al. in press). Based on the importance given to self-efficacy as an empowerment-related outcome of transformational and charismatic leadership, we posited *specific self-efficacy* as a malleable developmental outcome that is enhanced among employees of transformational leaders.

3.2.2. Development of Employee Attitudes toward the Leader

According to Yukl (1998), transformational leaders influence followers by arousing strong emotions and identification with the leader. The notion of follower development going in the direction of strong emotional attachment or favorable attitudes toward the leader is deeply rooted in charismatic and transformational leadership theory. For example, House (1977) asserts that followers in charismatic relationships feel affection toward the leader. According to Conger and Kanungo (1987), charismatic leaders are more likable and honorable than noncharismatic leaders. Shamir et al. (1993) suggest that personal commitment to the leader is part of the transformational effects of charismatic leaders. Favorable attitudes toward the leader have been the most commonly studied outcomes of transformational leadership. There is a considerable amount of evidence to conclude that transformational leadership enhances employees' *satisfaction with the leader* and *perceived effectiveness of the leader* (Bass and Avolio 1990).

The full range leadership model (Avolio and Bass 1988) suggests that having a shared sense of purpose and common norms between follower and leader should assist transformational leaders in successfully completing and communicating their mission. Furthermore, if norms are not common to both leader and follower, then the first step toward transforming followers may involve the leader's unfreezing followers' attitudes and values and then gaining conformity with his or her own value

system. Many writers have emphasized the importance of the similarity between leaders and followers. For example, House and Baetz (1979, in Conger and Kanungo 1987) postulate that the followers of charismatic leaders are characterized by the similarity of their beliefs to those of the leader. The self-concept theory (Shamir 1991; Shamir et al. 1993) posits that the values and identities of followers within charismatic relationships are congruent with the leaders' vision. According to this theory, one of the two classes of charismatic leaders' behaviors is frame alignment, which refers to the linkage of follower and leader interpretive orientations so that the followers' interests, values, and beliefs and the leaders' activities, goals, and ideology become congruent and complementary. Some level of demonstrated and moral superiority is likely to be necessary for the leader to become a representative character, but the leader should also emphasize his or her similarity to the followers on certain dimensions. The main processes of psychological attachment through which the leader's behaviors of frame alignment influence their followers in the charismatic relationships are personal identification and value internalization. Personal identification refers to the followers' desire to emulate or vicariously gain the qualities of the leader. Such identification increases with the extent to which the leader represents desirable identities, values, and attributes in his or her behaviors. Value internalization refers to the incorporation of the leader's or group's values within the self as guiding principles. The self-concept theory stresses that personal identification is consistent with the theory, but a stronger emphasis is put on value internalization.

Several empirical studies have been conducted on the relationships between *leader–follower similarity or value congruence* and various outcome variables. Turban and Jones (1988) found that superior–follower similarity was related to followers' perceived performance. Megalino et al. (1989) showed that workers were more satisfied and committed when their values were congruent with the values of their superior. Enz (1988) found that perceived value congruity between department members and top managers, examined from the perspectives of both groups, accounted for unique variance in departmental power. Kirkpatrick and Locke (1996) found in a laboratory experiment that articulation of a vision emphasizing quality by the leader positively affected the followers' perceived congruence with the beliefs and values communicated through the vision.

3.2.3. Employee Group Development

Several models have explicitly considered leadership to be one determinant of team effectiveness. In addition, recent references to transformational and charismatic leadership have begun to emphasize the importance of group-level outcomes (Avolio 1999; Shamir et al. 1998). For example, Guzzo et al. (1993) suggest that transactional leadership might have indirect effects on group potency and effectiveness, whereas transformational leadership has both indirect and direct effects. Klein and House (1995) recently extended charismatic theory to the group level by conceiving groups as constellations of dyadic relationships. In their extension, groups and organizations vary along the dimension of homogeneity or heterogeneity of group members' charismatic relationships with the leader. Shamir (1990) suggests that leaders can enhance collectivistic motivation, that is, the individual contributions to collective work efforts, through calculative considerations, the internalization of values and personal norms, or the maintenance and affirmation of relevant identities. In his self-concept theory, Shamir (1991) posits collectivistic orientation as an important transformational effect on followers of charismatic leaders. In spite of the emphasis on follower group development in recent frameworks of transformational leadership, very few empirical investigations have connected transformational and transactional leader behaviors and group-level outcomes. Sivasubramaniam et al. (1997, in Avolio 1999) found that transformational leadership directly predicted the performance of work groups while also predicting performance indirectly through levels of group potency. In a longitudinal laboratory experiment, Sosik et al. (1997) largely confirm that transformational leadership affected group potency and group effectiveness more strongly than transactional leadership. Shamir et al. (1998) confirm that the leaders' emphasis on the collective identity of the unit was associated with the strength of the unit culture, as expressed in the existence of unique symbols and artifacts, and with unit viability as reflected by its discipline, morale, and cooperation. More research is needed on the effects of transformational leaders on follower group development.

4. IMPLICATIONS FOR STRATEGIC HUMAN RESOURCE MANAGEMENT

This section will introduce central implications of the implementation of the new genre of leadership theories in organizations. Our goal is to focus on the implications of leadership research in the framework of the major functions of human resource management (HRM). As with other aspects of organizational behavior, leadership and motivation research has contributed to the development of sophisticated HRM tools and techniques that have been shown to improve organizational effectiveness (e.g., Jackson and Schuler 1995). The major functions of HRM, discussed below, are recruiting, performance appraisal, training, and compensation. For each function, we provide a background based on a strategic approach to HRM. We then describe the utility of the above research findings, regarding leadership and motivation, to strategic HRM and provide examples.

4.1. A Strategic Approach to Human Resource Management

As traditional sources of competitive advantage, such as technology and economies of scale, provide less competitive leverage now than in the past, core capabilities and competence, derived from how people are managed have become more important. A strategic perspective of human resource management is critical for creating and sustaining human resource-based competitive advantage (Sivasubramaniam and Ratnam 1998). A strategic approach to HRM implies a focus on ''planned HRM deployments and activities intended to enable the form to achieve its goals'' (Wright and McMahan 1992, p. 298). Strategic HRM involves designing and implementing a set of internally consistent policies and practices that ensure that a firm's human capital (employees' collective knowledge, skills, and abilities) contributes to the achievement of its business objectives. Internal consistency is achieved by creating vertical and horizontal fit. Vertical fit involves the alignment of HRM practices and strategic management, and horizontal fit refers to the alignment of the different HRM functions (Wright and Snell 1998).

Strategic HRM is concerned with recognizing the impact of the outside environment, competition, and labor markets, emphasizes choice and decision making, and has a long-term focus integrated in the overall corporate strategy. For instance, companies like General Motors that emphasize a retrenchment or cost reduction strategy will have an HRM strategy of wage reduction and job redesign, while the growth corporate strategy of Intel requires that it will aggressively recruit new employees and rise wages (Anthony et al. 1998). Similarly, cost-reduction policies may require that leaders emphasize equity and contingent reward, while growth strategy should enhance transformational leadership. Cost-reduction and growth strategies, as well as other strategies, have clear implications for how companies should recruit employees, evaluate their performance, and design training and compensation systems.

Considerable evidence has shown the performance implications of HRM. These studies indicate that high-performing systems are characterized by careful selection, focus on a broad range of skills, employ multisource appraisals focused on employee development, employ teams as a fundamental building block of the organization's work systems, provide facilitative supervision, include human resource considerations in strategic decision making, and link rewards to performance that focuses the employees on the long-term goals of the firm. These findings have been fairly consistent across industries and cultures (Sivasubramaniam and Ratnam 1998).

4.2. Recruiting: From Hiring to Socialization

Recruiting, the process by which organizations locate and attract individuals to fill job vacancies, should be matched with company strategy and values as well as with external concerns, such as the state of the labor market. Recruiting includes both pre- and post-hiring goals. Among the pre-hiring goals are attracting large pools of well-qualified applicants. Post-hiring goals include socializing employees to be high performers and creating a climate to motivate them to stay with the organization (Fisher et al. 1996). Another major decision in the recruiting philosophy of a firm is whether to rely on hiring outside candidates or to promote from within the organization.

The above decisions and goals have implications for how organizations can benefit from recent research on leadership and motivation. Organizations that recruit from their internal labor market and accept candidates for long-term employment may seek candidates with leadership skills who can be potential managers. Such organization may use mentoring programs as a way of enhancing employee socialization. Other organizations may benefit from using leadership skills as part of the selection procedures they employ, though the use of leadership characteristics as a criterion for selection is highly controversial (e.g., Lowery 1995).

4.2.1. Implications for Selection

While good leadership qualities could be a criterion for selecting employees at all levels, if used at all, it is more common in managerial selection. Managerial selection is a particularly difficult task because there are many different ways to be a successful manager. Managing requires a wide range of skills, one of which could be leadership. Leadership effectiveness was found to relate to common selection criteria, such as practical intelligence, reasoning, creativity, and achievement motivation (Mumford et al. 1993). However, many HRM professionals are reluctant to use leadership as a criterion for selection, citing reasons, such as lack of definition, complexity of the construct, and difficulty in validating selection tools (Lowery 1995). These challenges pose a threat to the validity of the selection process. An invalid selection system may be illegal, as well as strategically harmful for the organization. Consequently, our discussion of leadership as a selection tool is mainly exploratory.

The most common use of leadership criteria in selection is as part of an assessment center (e.g., Russell 1990). Assessment centers are work samples of the job for which candidates are selected (mostly candidates for managerial positions). They can last from one day to one week and have multiple means of assessment, multiple candidates, and multiple assessors. Assessment centers are

considered relatively valid predictors of both short- and long-term success in managerial positions (e.g., Russell 1987).

Many assessment centers include leadership evaluation in the form of leaderless group discussions, where candidates are evaluated on small-group management activities (Lowery 1995). In the simple form of leaderless group discussion, the initially leaderless group is assigned a problem to discuss to reach a group decision. Assessors judge who emerges as a leader, initiatives displayed by each participant, and other aspects of interpersonal performance (Bass 1990). Assessors are required to identify behaviors, such as gatekeeping, facilitate support, and evaluate the candidate's ability to accomplish the ''tasks.'' Although assessment centers are generally more suitable for evaluating candidates for promotion, they are also used with candidates for entry (Lowery 1995). In Lowery's review of the applicability of measuring leadership in an assessment center, he argues that we still do not know how to assess leadership as an independent performance dimension in assessment centers.

Recognizing the limitations of assessment centers, Russell (1990) suggested using biodata to select top corporate leaders. According to Kunhert and Lewis (1987), biodata captures early life events, which are hypothesized to impact leadership performance in adulthood. They argued that transformational leaders derive meaning from personal experience in a significantly different way than transactional leaders based on early development. Identifying the life experiences that lead to the development of transformational leaders may contribute to selecting such leaders based on their biodata reports. Indeed, Russell (1990) obtained correlations between prior life experiences and contribution to fiscal performance of candidates for top managerial positions at a Fortune 50 firm. According to Russell, transformational leadership measures may be a good source of anecdotal behavioral examples that correlate with biodata and can serve as tools for executive selection.

More recent attempts to utilize findings from the new genre of leadership theory in selection use both biodata and assessment center procedures. Avolio and colleagues from South Africa have developed a preliminary tool to assess the leadership potential of candidates to the South African police force. This tool is based on the multifactor leadership questionnaire (MLQ) developed by Bass and Avolio (1996) to measure the full range leadership styles. The assessment center also includes a biodata survey that has been used in previous research (Avolio 1994). Similarly, researchers from the Center for Creative Leadership examined the process of executive selection and identified that success in the top three jobs in large organizations was predicted mostly by ''relationships with subordinates'' and ''expressed affection'' (Kouzes 1999).

The above are examples of early application of the new genre of leadership theory in selection. However, since selection procedures require serious legal considerations, the application of findings from recent research to selection is relatively slow. However, recent leadership approaches may provide insights for other recruiting-related functions, such as mentoring.

4.2.2. Implications for Mentoring and Socialization

A strategic HRM approach requires that the staffing process not end once applicants are hired or promoted. To retain and maximize human resources, organizations must emphasize socializing newly hired/promoted employees. A thorough and systematic approach to socializing new employees is necessary if they are to become effective workers. Good socialization is essential to ensure employee understanding of the company's mission and vision. It includes a realistic job preview (RJP) that allows the creation of appropriate expectations for the job (Breaugh 1983). RJP includes presenting realistic information about job demands, the organization's expectations, and the work environment. At a later stage, when employees begin to feel part of the organization, a mentoring program, in which an established worker serves as an adviser to the new employee, may help in the socialization process. Mentoring programs are especially necessary in environments of high turnover, such as high technology (Messmer 1998).

Mentoring programs have both short- and long-term benefits. In addition to developing the skills, knowledge, and leadership abilities of new and seasoned professionals, these programs strengthen employee commitment (Messmer 1998). Mentoring programs have been successful in developing new talent, as well as recruiting junior level staff and bringing them up to speed on policies and procedures. Mentors provide more than company orientation; they become trusted advisors on issues ranging from career development to corporate culture. At a time when many executives are managing information instead of people, mentoring may offer a welcome opportunity to maintain the kinds of critical interpersonal skills that can further a manager's career. Although the mentors in most mentoring programs are not the supervisors of the mentees, the characteristics of good mentors are very similar to the characteristics of good leaders, especially transformational leaders (Bass 1985).

Bass (1985) argues that effective transformational leaders emphasize individualized consideration that involves the leader's service as a counselor for their proteges. Such leaders have more knowledge and experience and the required status to develop their proteges. Johnson (1980) found that two thirds of 122 recently promoted employees had mentors. Bass (1985) claims that since mentors are seen as

authorities in the system, their reassurance helps mentees be more ready, willing and able to cooperate in joint efforts. Moreover, mentoring is an efficient method for leadership development because followers are more likely to model their leadership style on that of their mentor, as compared with a manager who is not seen as a mentor (Weiss 1978). To be effective, mentors need to be successful, competent, and considerate (Bass 1985). Companies like Bank of America and Pricewaterhouse-Coopers' employ mentoring mostly to increase retention. In competitive labor markets, such as the high-technology industry, increasing retention is a major HR goal. In PricewaterhouseCoopers', mentoring has led to an increase in female retention (Messmer 1998). Clearly, transformational leadership, and individualized consideration in particular, can provide a strategic advantage to organizations that employ mentoring programs.

The development of mentoring programs should include a review of needs for mentoring, a buy-in from senior management, and constant updating of all managers involved with the mentee. Such programs should also include a selection of mentors based on the above principles, a careful match of participants, and company events to demonstrate the importance of the mentoring program for the organization (Messmer 1998). Top managers, such as the long-time CEO of the Baton Rouge Refinery of Exxon, are seen as more effective if they develop their followers. In the case of Exxon, these followers were later promoted more than their mentor.

We chose to demonstrate the contribution of effective leadership to recruiting using the examples of selection and mentoring. However, leadership and motivation are important parts of other recruiting processes, such as in interviewer skills and assessment of candidates' motivation. We chose those aspects that we feel benefit especially from the new genre of leadership theories. We continue to use this approach with the HRM function of performance management.

4.3. From Performance Appraisal to Performance Management

Performance appraisal is the process by which an employee's contribution to the organization during a specific period of time is assessed. Performance feedback provides the employees with information on how well they performed. If used inappropriately, performance appraisal can be disastrous and lead to a decrease in employee motivation and performance. Performance appraisal has a significant strategic role in HRM. It provides strategic advantage by allowing the organization to monitor both its individual employees and the extent to which organizational goals are met. From a strategic HRM perspective, performance appraisal involves more than assessment or measurement. Rather, it is a method for performance management, including defining performance, measuring it, and providing feedback and coaching to employees (Fisher et al. 1996). In sum, performance management has three major strategic functions. First, it signals to employees which behaviors are consistent with organizational strategy. Second, if used appropriately, it is a useful method for organizational assessment. Finally, it is a feedback mechanism that promotes employee development. The movement from a focus on appraisal to performance management allows for better application of the new genre of leadership and motivation theory.

While the traditional performance-appraisal systems emphasized uniform, control-oriented, narrow-focus appraisal procedures that involved supervisory input alone, strategic performance management emphasizes customization, multipurpose, and multiple raters, focusing on development rather than past performance. Similarly, whereas traditional approaches to leadership and motivation (e.g., House 1971) emphasized control and exchange based on extrinsic motivators, more recent approaches emphasize development and influence through intrinsic motivators (e.g., Bass 1985; Shamir et al. 1993). Indeed, even during the 1980s and the beginning of the 1990s, employees and managers viewed performance appraisal negatively. Longnecker and Gioia (1996, in Vicere and Fulmer 1996) found that out of 400 managers, only one quarter were satisfied with appraisal systems and the higher a manager rose in the organization, the less likely he or she was to receive quality feedback. Nevertheless, they indicated that when used as a strategic tool for executives, systematic feedback was crucial for them. Many of them were also willing to be evaluated personally. According to Vicere and Fulmer (1996), performance-management processes are highly linked with leadership development. We chose to focus on the contributions of leadership research to two aspects of performance management: feedback from multiple raters (360°) and alignment of strategic goals.

4.3.1. Implications for Feedback

As we mentioned above, strategic performance-management systems involve more than the traditional supervisory evaluation. Current appraisal systems often include peer ratings, follower ratings, and self-ratings. Each source seems to contribute differently and their combination (a 360° approach) is used mainly for developmental reasons (Waldman et al. 1998). About 12% of American organizations are using full 360° programs for reasons such as management development, employee involvement, communication, and culture change (Waldman et al. 1998). Advocates of 360° systems believe that they contribute to leadership development by allowing managers to compare their self-perceptions with those of their employees (Yammarino and Atwater 1997).

The gaps between self and other ratings were found to predict the perceived performance of the leader. Agreement between self and other reports on *high* ratings predicted high performance (Yammarino and Atwater 1997). Gaps between self and other ratings may also relate to the leadership style of the targeted manager. Transformational executives who had ratings congruent with those of their followers were seen as highly considerate, emphasized meetings with their employees, and associated individual employee goals with organizational goals.

Nontransformational leaders, who had little congruence with their followers' ratings, were seen as detached and as having little or no impact (Berson and Avolio 1999). These findings may contribute to a better understanding of the gaps between raters and provide insight into the type of training and development that can be given to managers following performance appraisal. This is especially important given recent criticism of the use of 360° in performance management. Waldman et al. (1998) argued that 360° feedback, in addition to being a high cost, has become a fad rather than a systematically and appropriately used tool. Rather, 360° systems should be tailored to organizational needs.

4.3.2. Implications for Alignment and Signaling of Strategic Goals

A major strategic advantage of performance management is that it is a method by which managers signal to employees the mission of the unit or the organization. Managers can use performance management to align their employees' behaviors with organizational goals or strategy. Employees want to be rewarded and will engage in behaviors that their supervisors emphasize. We expect transactional leaders to use performance appraisal as a mechanism of contingent reward (Bass 1985; Bass and Avolio 1994). Such leaders will mostly benefit from performance appraisal in the short term. In order to achieve a long-term alignment with organizational goals, supervisors need to have followers who identify with them. Transformational or charismatic leaders may be able to use performance management to align followers with organizational goals and inspire and motivate them to achieve these goals. These leaders will be better communicators of organizational goals. Indeed, effective appraisal depends on the supervisor's ability to communicate organizational goals.

In a study of a large telecommunication company, Berson and Avolio (2000) found that employees of transformational leaders viewed their managers as more open and informal and as better conveyers and receivers of information than employees of nontransformational leaders. Moreover, employees of effective communicators were more aware of strategic organizational goals than employees who reported to less effective communicators. These findings hint that supervisors who are transformational leaders will be able to utilize performance-management systems to communicate strategic goals more effectively than transactional supervisors for whom performance management may serve as a contract with employees. In addition to better communication of organizational goals, charismatic leaders may also use performance-management systems to sense the environment. Such leaders can use performance management to assess the capabilities of the organization and determine quality goals (Conger and Kanungo 1998).

In summary, evidence from studies in the new genre of leadership theories offers insights regarding the strong impact of transformational or charismatic leaders on their followers. We believe that performance management is an excellent tool for such leaders to communicate strategic goals and sense followers' needs for personal development.

4.4. From Training to Development

With the rapid developments in technology and the changing nature of jobs, the provision of training and development exercises has become a major strategic objective for the organization. Organizations provide training for many reasons, from orientation to the organization and improving performance on the job to preparation for future promotion. Like other HRM functions, training should be aligned with the strategic goals of the organization. Organizations that rely on a highly committed, stable workforce will have to invest more in individuals than will organizations that employ unskilled temporary employees (Fisher et al. 1996).

When a company changes strategy, as Xerox did when it became "the Document Company," it begins intensive training to equip employees with the new skills. Xerox spent $7 million on developing a training center. In a world of networking and alliances between organizations, Xerox needs this center not only to train its employees but to train suppliers, customers, and other constituencies. Xerox, like other employers, has a long-term perspective on its workforce and is using training to increase employee retention. More and more professionals seek jobs that will provide them with the opportunity for professional development. Many engineers who work in high-technology industries have multiple job opportunities and are constantly in the job market (Messmer 1998). Consequently, organizations that wish to decrease turnover move from emphasizing short-term training for specific purposes to long-term development.

We believe that the shift to development calls for more leadership of the new genre type. While the short-term emphasis on training, where employees are trained to learn a new skill that they need for their current task or job, required mainly task-oriented transactional leadership, the move to long-

term development entails transformational leadership. The need for more transformational or charismatic leaders in organizations is a consequence of several trends that reflect the shift from training to development. First, in addition to sending employee to off-the-job training workshops, more companies emphasize individual coaching. Coaching, like other types of on-the-job training, ensures maximized transfer between what was learned in the training and the actual job (Ford 1997). On-the-job training also allows for maximum trainee motivation because trainees see this type of training as highly relevant.

Second, as managerial jobs become more complex, there is an increased need for managerial training. Most typologies of managerial tasks emphasize that managers need to have leadership skills. Specifically, skills such as providing feedback, communication, motivation, aligning individual goals with organizational goals, and having good relationships with colleagues and followers should be the focus of development (Kraut et al. 1989).

Finally, as discussed above regarding socializing employees, coaching and mentoring programs have become more popular, sometimes as spontaneous mentor–protégé relationship and sometimes as an organized mentoring program (Messmer 1998).

These shifts in training, together with the emphasis on long-term development, highlight the importance of developing transformational leadership in the organization. Transformational leaders develop significant relationships with their followers and thus have a chance to be seen as coaches and to provide practical on-the-job training. These leaders are also intellectually stimulating and can constantly challenge employees and develop them. Personal development involves individualized consideration, another major style of transformational leaders. More specifically, individualized consideration consists of mentoring (Bass 1985).

Furthermore, both intellectual stimulation and individualized consideration can be cultivated and nurtured not only at the individual level but also at the team and organizational levels (Avolio and Bass 1995). Organizations can create cultures that encourage coaching and development while providing consideration and recognition of individual needs. Paul Galvin, a CEO of Motorola, created a culture, based on his leadership style, where risk-taking is advocated and seen as the most secure approach (Avolio 1999). Employees are encouraged to be creative and develop new products.

Intellectually stimulating leaders also empower their followers (Bass 1985). Empowerment is an effective method of training because employees learn more tasks and are responsible for problem solving. It is especially important in innovative environments where employees have to learn to take risks. Organizations that employ empowering techniques try to applaud both successful and unsuccessful risk-taking behavior. For example, Lockheed Martin takes a team approach to empowerment. Employees who have knowledge regarding an aspect of a project are encouraged to speak up (Wolff 1997, in Anthony et al. 1998). In this way, employees get to experience managerial roles.

Several studies using the transformational leadership paradigm have demonstrated the relationships between transformational leadership and empowerment. Masi (1994, in Avolio 1999) reported positive correlations between transformational leadership and empowering organizational culture norms. Moreover, transformational leadership at the top may filter to lower levels of the organization. Bass and Avolio (1994) suggested the ''falling dominoes effect,'' where leaders who report to transformational leaders tend to be transformational as well. Bryce (1988, in Avolio 1999) found support for this effect in a study of Japanese senior company leaders. Finally, Spreitzer and Jansaz (1998, in Avolio 1999) found that empowered managers are seen as more intellectually stimulating and charismatic than nonempowered managers. These findings demonstrate that by being transformational, executives can create a culture that facilitates professional development for their employees. Even when their managers are empowered by other managers, followers seem to attribute charisma and intellectual stimulation to the empowered leader.

In addition to the contribution of transformational leaders to employee and managerial development, organizations can use transformational leadership as a model for training leadership. There seems to be agreement that leadership is to some extent innate but to some extent trainable (e.g., Avolio 1999). From the models of the new genre of leadership, training using the full range leadership model has been the most extensive. Crookall (1989) compared the effectiveness of training Canadian prison shop supervisors in transformational leadership and in situational leadership using a control group that did not receive any training. Crookall concluded that the transformational leadership workshop had a significant positive impact on two of the four performance measures subjectively evaluated by superiors, and the situational leadership training had significant positive influence on one of the four subjective performance measures. There was no change in the perceived performance of the untrained group. In addition, a significant positive impact was found in both training groups on turnover, work habits, and managers' evaluations regarding the personal growth of prisoners. Significant improvement regarding respect for superiors, professional skills, and good citizenship as evaluated by the manager, were found only for the transformational leadership workshop.

A more recent study (Barling et al. 1996) demonstrated that bank branch managers who received transformational leadership training had a more positive impact on follower commitment and unit financial performance than did those who did not receive training. Finally, Dvir et al. (in press)

conducted a comprehensive randomized field experiment comparing the impact of military leaders who received training in transformational leadership vs. leaders who participated in an eclectic leadership training program. Indirect followers of leaders who participated in the transformational training demonstrated superior performance on a battery of objective measures. Direct followers of leaders who got the transformational training showed higher levels of personal development over time. The above findings, together with the extensive training conducted with the transformational leadership model in a wide range of organizations (Avolio 1999), suggest that organizations can benefit from the advantages of the new-genre leaders by training managers at all levels to become transformational (Bass 1990).

4.5. Compensation: From Transactional to Intrinsic Reward Systems

We conclude our discussion of HRM functions with compensation systems. Our goal is to demonstrate that although compensation systems seem to be a classic example of contractual or transactional conduct between employees and the organization, transformational leaders can utilize this strong rewarding agent to motivate employees to perform beyond expectations (Bass 1985).

Organizations expect employees to provide their services and in return to be compensated. Compensation exists to help employees fulfill their own needs. Consequently, classic compensation systems are based on pure exchange or contractual relationships between employees and the organization. In effect, innovative organizations use compensation systems as a strategic tool. Compensation, like performance-management systems, can help signal to employees the major objectives of the organization (e.g., customer focus), to attract and retain employees, encourage skill development, motivate employees to perform effectively, and help shape organizational culture (Fisher et al. 1996). Compensation is considered the most important HRM function and is seen as crucial by all employees. It includes different aspects of pay and benefits. Although compensation systems are supposed to motivate employees, there is high variability in their effectiveness.

HRM professionals and researchers have been using motivation theory to examine compensation systems. Most of these theories view compensation as a transaction and its components as extrinsic motivators. However, these theories tend to explain why employees do not just work for money (Fisher et al. 1996). For example, according to equity theory, individuals determine whether they are being fairly treated by comparing their input/outcome ratio to the input/outcome ratio of someone else. However, individuals may be motivated to work by factors beyond the direct input/output ratio of their peers. For example, the success of the software company SAS, which is growing at an annual rate of more than 25%, cannot be explained using equity models. Although most software companies pay their employees with bonuses and stock options, SAS offers an intellectually rewarding environment and a family corporate culture. SAS has a 4% turnover rate and is the largest privately owned software company (Pfeffer 1998). According to equity theory, there is little equity between SAS employees and other software employees in similar positions. However, based on turnover rates, it seems that SAS employees are quite motivated. Theories that make motivation contingent on compensation are, according to Pfeffer (1998), a myth that has little or no supporting evidence.

The intellectually engaging work and friendly environment as well as the ability to work using state-of-the-art technology (Pfeffer 1998) that SAS provides its employees can explain their extra effort according to the new genre of leadership theories. SAS employees and other employees do indeed expect monetary rewards, but their extra effort relates to intrinsic factors such as leadership and organizational culture. As Bass and Avolio (1994) suggest, this is an example of how transformational leadership augments transactional or contingent reward behaviors.

Transformational leaders have employees who trust them and are committed to work for more then short-term goals. Transactional leaders, who rely on contingent reward and management by exception, teach employees that they should work only when rewarded or when they are closely monitored. Such leaders signal to their followers that they do not trust them. Consequently, these employees will be less motivated than employees who feel that their supervisors do trust them. Indeed, companies like Southwest Airlines recognize these issues and highlight managing through trust and respect rather than exceptional compensation packages (Bass 1985; Pfeffer 1998).

Moreover, transformational leaders provide a personal example to employees. Executives who get paid over 80 times more than their employees do not signal to employees that pay is motivating. For example, Whole Food Markets pays nobody in the company more than 8 times the average company salary. Similarly, when the CEO of Southwest Airlines asked pilots to freeze their salaries for another year, he froze his own salary for four years. On the other hand, paying executives bonuses when employees are being laid off, as was done by GM in the 1980s, sends the wrong message to employees (Pfeffer 1998). Motivating employees using compensation has to be aligned with other organizational practices, including exemplification of top managers. By providing an example, executives send a message that they share a common fate and that the organization emphasizes a culture of cooperation and teamwork rather than competition.

Compensation systems often highlight individual incentives (Fisher et al. 1996). Among these incentives are commissions, bonuses, and merit pay. Although these methods lead to employee satisfaction, they have little relationship with organizational outcomes that can be measured only at the unit or the organizational levels. Indeed, when organizations want to encourage teamwork, rewarding individuals may be extremely harmful. They end up with a compensation system that undermines teamwork and focuses on short-term goals. Such compensation systems send a mixed message to employees regarding organizational goals. As the director of corporate industrial relations at Xerox said, "if managers seeking to improve performance or solve organizational problems use compensation as the only lever, they will get two results: nothing will happen, and they will spend a lot of money. That's because people want more out of their jobs than just money" (Pfeffer 1998). Transformational leaders appeal to collective needs of employees and help align their individual goals with organizational goals (Shamir et al. 1993). Organizations need to emphasize collective rewards, such as profit-sharing and gain-sharing plans, where employees share organizational gains. These methods may motivate teamwork to a certain extent, but effective teamwork will still depend on leaders and the culture or environment that they create. Rather, transformational leaders may be able to use compensation and its components to signal what is important and thus shape company culture.

In summary, the traditional notion that compensation systems are effective motivators is based on a transactional contractual approach to employee–management relations. More recent approaches to compensation emphasize rewarding at least at the team if not the organizational level and posit that monetary rewards should accompany intrinsic rewards, such as trust and recognition. These recent approaches also emphasize decentralizing pay decisions (Gomez-Mejia et al. 1998). We argue here that these new compensation procedures can be better applied by transformational or charismatic leaders. Applying the full range leadership model, we argue that such leaders may also exhibit contingent reward and management by exception to support the basic compensation contract. However, aligned with transformational leadership, the above compensation procedures can lead to maximum motivation.

4.6. Involvement-Transformational vs. Inducement-Transactional HRM Systems: An Integrative Framework

One common characteristic of most extant research is the use of the "parts view" of HRM. Typically, researchers identify dimensions of HRM to identify the dimensions that were significantly related to performance. New approaches to HRM argue that to be considered strategic, the set of practices should be part of a system, interrelated, interdependent, and mutually reinforcing. HRM systems are best viewed as configurations, systems of mutually reinforcing and interdependent set of practices that provide the overarching framework for strategic actions. The configurational approach to HRM has gained support in recent empirical studies (review in Sivasubramaniam and Ratnam 1998). Dyer and Holder (1988) have proposed three clusters of human resource strategies, labeled inducement, investment, and involvement.

Inducement human resource strategy is based on the concept of motivation through rewards and punishment. Companies following this philosophy tend to emphasize pay and benefits, perquisites, or assignment to nontraditional work environments as inducement to perform and remain with the firm. In addition, such firms demand high levels of reliable role behaviors, define jobs narrowly, hire on the basis of meeting minimum qualifications, and provide directive supervision. The inducement strategy is most closely linked to transactional leadership (Kroeck 1994).

Investment human resource strategy is built around extensive training and development. Companies adhering to this strategy place a premium on the long-range education of employees and expect employees to exercise a fair amount of initiative and creativity in carrying out their tasks. Dominant corporate values are personal growth, respect, equity, justice, and security, not autonomy and empowerment. Due to the developmental aspects of this strategy, some (e.g., Kroeck 1994) link it to the individualized consideration style in the full range leadership model. However, because this strategy often takes on a paternalistic approach to management, and because of the lack of emphasis on autonomy and empowerment, core elements in the relationships between transformational leaders and their followers, we will refer to this strategy as paternalistic.

Involvement human resource strategy is built around creating a very high level of employee commitment. Employees are motivated by the stimulus of autonomy, responsibility, and variety and of being able to see their contribution to the final product or service. The employees at these companies are expected to exercise considerable initiative and creativity as well as display a high degree of flexibility to adapt to rapid change. Team-based work systems are the building blocks of the organization, and supervision is facilitative and minimal. The involvement strategy calls for all four styles of transformational leadership (Kroeck 1994).

It was found that in general, firms following an involvement strategy outperformed firms pursuing inducement strategy. For example, Sivasubramaniam, et al. (1997, in Avolio 1999) conducted a study among 50 Indian firms and found higher correlations between involvement-transformational human

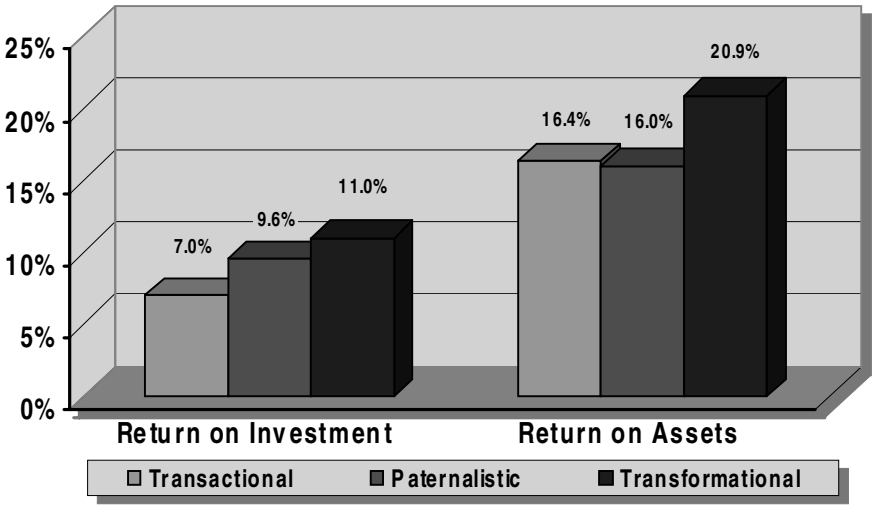

Figure 6 Relationships between Type of Human Resource Management System and Financial Performance among 50 Indian Firms According to Sivasubramaniam, et al.'s (1997) Findings.

resource strategy and the firm's return on investment and return on assets compared to the inducement-transactional and investment-paternalistic strategies (see Figure 6). Sivasubramaniam and Ratnam (1998) found that firms pursuing an involvement-transformational human resource strategy outperformed the other firms in actual accounting returns. Specifically, adopting an involvement human resource strategy translated into nearly a 4.5% edge in return on investment. For a typical firm in this study, this would mean an additional profit of nearly $400,000 per year, a sustainable advantage accrued due to superior human resource practices. It should be noted that these results were obtained after controlling for past year's profitability and hence cannot be dismissed as possibly due to profitable firms having the resources to invest in innovative human resource practices. These firms also reported lower levels of employee turnover as compared to their closest competitors, as well as superior human resource performance. In contrast, inducement-transactional type firms outperformed other firms in labor productivity because their primary focus is on efficiency.

5. CONCLUSION

An overwhelming body of evidence supports the notion that transformational leadership exists at many hierarchical levels, in a variety of organizational settings, and across many cultures. This new genre of leadership theories holds different assumptions on human motivation than traditional leadership theories. The emphasis has shifted from calculative, individualistic, short-term, extrinsic motivation to work toward more expressive, collectivistic, long-term, intrinsic motivators. Numerous studies have supported the greater effectiveness of transformational leadership compared to transactional and nontransactional leadership in enhancing employees' development and performance.

The advantages of transformational leadership have contributed to practical applications in the major HRM functions. Beginning with recruiting, transformational leaders emphasize long-term socialization rather than focusing on hiring alone. Moreover, the commitment of such leaders to employee growth transcends performance appraisal to become developmentally oriented performance-management systems. Furthermore, such systems can be used as a basis for programs that view employee skills and potential contribution rather than training for specific tasks. Finally, while transactional leaders rely mostly on monetary rewards that build contractual relations with employees, transformational leaders augment these rewards with intrinsic motivators that lead to building a highly committed workforce.

As the market conditions get tougher and competitors attempt to duplicate every single source of advantage, what may be sustainable and inimitable by competition is the human resource-based advantage (Sivasubramaniam and Ratnam 1998). Therefore, an integrated, interdependent, and mutually reinforcing HRM system that represents the new leadership and motivational paradigms may contribute to organizational effectiveness.

CHAPTER 33
Job and Team Design

GINA J. MEDSKER
Human Resources Research Organization

MICHAEL A. CAMPION
Purdue University

1. INTRODUCTION

1.1. Job Design

Job design is one of those aspects of managing organizations that is so commonplace that it often goes unnoticed. Most people realize the importance of job design when an organization is being built and production processes are being developed. Some even recognize the importance of job design when changes are taking place in organizational structures and processes. However, few people realize that job design may be affected when organizations grow, retrench, or reorganize, when managers use their discretion in the assignment of miscellaneous tasks on a day-to-day basis, or when the people in the jobs or their managers change. Fewer yet realize that job design change can be used as an intervention to enhance important organizational goals.

Many different aspects of an organization influence job design, including an organization's structure, technology, processes, and environment. A discussion of these influences is beyond the scope of this chapter, but they are dealt with in other sources (e.g., Davis 1982; Davis and Wacker 1982). These influences impose constraints on how jobs are designed. However, considerable discretion often exists in the design of jobs in many organizational situations. The job (defined as a set of tasks performed by a worker) is a convenient unit of analysis in developing new organizations or changing existing ones.

Several distinctions are useful to clarify the terminology in this chapter. One distinction is between a task and a job. A task is a set of actions performed by a worker who transforms inputs into outputs through the use of tools, equipment, or work aids. The actions of the task may be physical, mental, or interpersonal. On the other hand, a job is an aggregation of tasks assigned to a worker (Gael 1983; U.S. Department of Labor 1972). When the same set of tasks is performed by more than one worker, those workers are said to have the same job.

It is often useful to distinguish among positions, jobs, and occupations. A position is the set of tasks performed by one worker (e.g., the specific industrial engineering position held by employee X). A job is a set of similar positions (e.g., the industrial engineering positions in manufacturing in a particular company). The tasks performed in a given position are usually a combination of tasks that are common to all workers in that job and of tasks that are unique to that position. The unique tasks are sometimes a function of organizational requirements (e.g., different product or equipment) and sometimes a function of the disposition of the particular worker (e.g., different strengths or interests). An occupation is a collection of similar jobs (e.g., all industrial engineering jobs across companies). Job design usually focuses, by definition, on the job level. Differences in design between positions are assumed to be small and are often ignored. This may not be the case in all situations, however. And there can be great differences in design across jobs within an occupation.

Among the most prolific writers on job design in the industrial engineering literature over the last 35 years has been Louis Davis and his associates (Davis 1957; Davis et al. 1955; Davis and Taylor 1979; Davis and Valfer 1965; Davis and Wacker 1982, 1987). As he and his colleagues point out, many of the personnel and productivity problems in industry may be the direct result of the design of jobs. Job design can have a strong influence on a broad range of important efficiency and human resource outcomes:

- Productivity
- Quality
- Job satisfaction
- Training time
- Intrinsic work motivation
- Staffing
- Error rates
- Accident rates
- Mental fatigue
- Physical fatigue
- Stress
- Mental ability requirements
- Physical ability requirements
- Job involvement
- Absenteeism
- Medical incidents
- Turnover
- Compensation rates

As indicated by many of these outcomes, job-design decisions can influence other human resource systems. For example, training programs may need to be developed, revised, or eliminated. Hiring standards may need to be developed or changed. Compensation levels may need to be increased or decreased. Performance appraisal can be affected due to changed responsibilities. Promotion, transfer, and other employee-movement systems may also be influenced. Thus, aspects of many human resource programs may be dictated by initial job-design decisions or may need to be reconsidered following job redesign. In fact, human resource outcomes may constitute the goals of the design or redesign project. Research supporting these outcomes is referenced below during the description of the approaches.

Unfortunately, many people mistakenly view the design of jobs as technologically determined, fixed, and inalterable. However, job designs are actually social inventions that reflect the values of the era in which they were constructed. These values include the economic goal of minimizing immediate costs (Davis et al. 1955; Taylor 1979) and the theories of human motivation that inspire work designers (Steers and Mowday 1977; Warr and Wall 1975). These values, and the designs they influence, are not immutable but subject to change and modification (Campion and Thayer 1985).

The question is, what is the best way to design a job? In fact, there is no single best way. There are actually several major approaches to job design. Each derives from a different discipline and reflects different theoretical orientations and values. This chapter describes the various approaches and their advantages and disadvantages. It highlights the trade-offs and compromises that must be made in choosing among these approaches. This chapter provides tools and procedures for developing and assessing jobs in all varieties of organizations.

1.2. Team Design

This chapter also compares the design of jobs for individuals working independently to the design of work for teams of individuals working interdependently. The major approaches to job design usually focus on designing jobs for individual workers. In recent years, design of work around groups or teams, rather than at the level of the individual worker, has become more popular (Goodman et al. 1987; Guzzo and Shea 1992; Hollenbeck et al. 1995; Tannenbaum et al. 1996). New manufacturing systems and advancements in understanding of team processes have encouraged the use of team approaches (Gallagher and Knight 1986; Majchrzak 1988).

In designing jobs for teams, one assigns a task or set of tasks to a group of workers rather than to an individual. The team is then considered to be the primary unit of performance. Objectives and rewards focus on team, rather than individual, behavior. Team members may be performing the same tasks simultaneously or they may break tasks into subtasks to be performed by different team members. Subtasks may be assigned on the basis of expertise or interest, or team members may rotate from one subtask to another to provide variety and cross-train members to increase their breadth of skills and flexibility (Campion et al. 1994).

The size, complexity, or skill requirements of some tasks seem to naturally fit team job design, but in many cases there may be a considerable degree of choice regarding whether to design work around individuals or teams. In such situations, job designers should consider the advantages and disadvantages of the different design approaches in light of the organization's goals, policies, technologies, and constraints (Campion et al. 1993, 1996). The relative advantages and disadvantages of designing work for individuals and for teams are discussed in this chapter, and advice for implementing and evaluating the different work-design approaches is presented.

2. JOB DESIGN

This chapter is based on an interdisciplinary perspective on job design. That is, several approaches to job design are considered, regardless of the scientific disciplines from which they came. Interdisciplinary research on job design has shown that several different approaches to job design exist; that each is oriented toward a particular subset of outcomes for organizations and employees; that each has costs as well as benefits; and that trade-offs are required when designing jobs in most practical situations (Campion 1988, 1989; Campion and Berger 1990; Campion and McClelland 1991, 1993; Campion and Thayer 1985). The four major approaches to job design are reviewed below in terms of their historical development, design recommendations, and benefits and costs. Table 1 summarizes the approaches, while Table 2 provides detail on specific recommendations.

2.1. Mechanistic Job Design

2.1.1. Historical Background

The historical roots of job design can be traced back to the concept of the division of labor, which was very important to early thinking on the economies of manufacturing (Babbage 1835; Smith 1981). The division of labor led to job designs characterized by specialization and simplification. Jobs designed in this fashion had many advantages, including reduced learning time, reduced time

TABLE 1 Interdisciplinary Approaches to Job Design and Human Resource Benefits and Costs

APPROACH/Discipline Base (example references)	Illustrative Recommendations	Illustrative Benefits	Illustrative Costs
MECHANISTIC/Classic Industrial Engineering (Gilbreth 1911; Niebel 1988; Taylor 1911)	Increase specialization simplification repetition automation Decrease spare time	Decrease in training staffing difficulty making errors mental overload and fatigue mental skills and abilities compensation	Increase in absenteeism boredom Decrease in satisfaction motivation
MOTIVATIONAL/Organizational Psychology (Hackman and Oldham 1980; Herzberg 1966)	Increase variety autonomy significance skill usage participation feedback recognition growth achievement	Increase in satisfaction motivation involvement performance customer service catching errors Decrease in absenteeism turnover	Increase in training time/cost staffing difficulty making errors mental overload stress mental skills and abilities compensation
PERCEPTUAL-MOTOR/Experimental Psychology, Human Factors (Salvendy 1987; Sanders and McCormick 1987)	Increase lighting quality display and control quality user-friendly equipment Decrease information-processing requirements	Decrease in making errors accidents mental overload stress training time/cost staffing difficulty compensation mental skills and abilities	Increase in boredom Decrease in satisfaction
BIOLOGICAL/Physiology, Biomechanics, Ergonomics (Astrand and Rodahl 1977; Grandjean, 1980; Tichauer, 1978)	Increase seating comfort postural comfort Decrease strength requirements endurance requirements environmental stressors	Decrease in physical abilities physical fatigue aches and pains medical incidents	Increase in financial cost inactivity

Advantages and disadvantages are based on findings in previous interdisciplinary research (Campion 1988, 1989; Campion and Berger 1990; Campion and McClelland 1991, 1993; Campion and Thayer 1985).

TABLE 2 Multimethod Job Design Questionnaire (MJDQ)

(Specific Recommendations from Each Job Design Approach)

Instructions: Indicate the extent to which each statement is descriptive of the job, using the scale below. Circle answers to the right of each statement. Scores for each approach are calculated by averaging applicable items.

Please use the following scale:
(5) Strongly agree
(4) Agree
(3) Neither agree nor disagree
(2) Disagree
(1) Strongly disagree
( ) Leave blank if do not know or not applicable

Mechanistic Approach					
1. *Job specialization:* The job is highly specialized in terms of purpose, tasks, or activities.	1	2	3	4	5
2. *Specialization of tools and procedures:* The tools, procedures, materials, etc. used on this job are highly specialized in terms of purpose.	1	2	3	4	5
3. *Task simplification:* The tasks are simple and uncomplicated.	1	2	3	4	5
4. *Single activities:* The job requires you to do only one task or activity at a time.	1	2	3	4	5
5. *Skill simplification:* The job requires relatively little skill and training time.	1	2	3	4	5
6. *Repetition:* The job requires performing the same activity(s) repeatedly.	1	2	3	4	5
7. *Spare time:* There is very little spare time between activities on this job.	1	2	3	4	5
8. *Automation:* Many of the activities of this job are automated or assisted by automation.	1	2	3	4	5
Motivational Approach					
9. *Autonomy:* The job allows freedom, independence, or discretion in work scheduling, sequence, methods, procedures, quality control, or other decision making.	1	2	3	4	5
10. *Intrinsic job feedback:* The work activities themselves provide direct and clear information as to the effectiveness (e.g., quality and quantity) of job performance.	1	2	3	4	5
11. *Extrinsic job feedback:* Other people in the organization, such as managers and coworkers, provide information as to the effectiveness (e.g., quality and quantity) of job performance.	1	2	3	4	5
12. *Social interaction:* The job provides for positive social interaction such as team work or coworker assistance.	1	2	3	4	5
13. *Task/goal clarity:* The job duties, requirements, and goals are clear and specific.	1	2	3	4	5
14. *Task variety:* The job has a variety of duties, tasks, and activities.	1	2	3	4	5
15. *Task identity:* The job requires completion of a whole and identifiable piece of work. It gives you a chance to do an entire piece of work from beginning to end.	1	2	3	4	5
16. *Ability/skill-level requirements:* The job requires a high level of knowledge, skills, and abilities.	1	2	3	4	5
17. *Ability/skill variety:* The job requires a variety of knowledge, skills, and abilities.	1	2	3	4	5
18. *Task significance:* The job is significant and important compared with other jobs in the organization.	1	2	3	4	5
19. *Growth/learning:* The job allows opportunities for learning and growth in competence and proficiency.	1	2	3	4	5
20. *Promotion:* There are opportunities for advancement to higher level jobs.	1	2	3	4	5
21. *Achievement:* The job provides for feelings of achievement and task accomplishment.	1	2	3	4	5
22. *Participation:* The job allows participation in work-related decision making.	1	2	3	4	5
23. *Communication:* The job has access to relevant communication channels and information flows.	1	2	3	4	5

TABLE 2 (*Continued*)

24. *Pay adequacy:* The pay on this job is adequate compared with the job requirements and with the pay in similar jobs.	1	2	3	4	5
25. *Recognition:* The job provides acknowledgement and recognition from others.	1	2	3	4	5
26. *Job security:* People on this job have high job security.	1	2	3	4	5
Perceptual/Motor Approach					
27. *Lighting:* The lighting in the workplace is adequate and free from glare.	1	2	3	4	5
28. *Displays:* The displays, gauges, meters, and computerized equipment on this job are easy to read and understand.	1	2	3	4	5
29. *Programs:* The programs in the computerized equipment on this job are easy to learn and use.	1	2	3	4	5
30. *Other equipment:* The other equipment (all types) used on this job is easy to learn and use.	1	2	3	4	5
31. *Printed job materials:* The printed materials used on this job are easy to read and interpret.	1	2	3	4	5
32. *Workplace layout:* The workplace is laid out such that you can see and hear well to perform the job.	1	2	3	4	5
33. *Information-input requirements:* The amount of information you must attend to in order to perform this job is fairly minimal.	1	2	3	4	5
34. *Information-output requirements:* The amount of information you must output on this job, in terms of both action and communication, is fairly minimal.	1	2	3	4	5
35. *Information-processing requirements:* The amount of information you must process, in terms of thinking and problem solving, is fairly minimal.	1	2	3	4	5
36. *Memory requirements:* The amount of information you must remember on this job is fairly minimal.	1	2	3	4	5
37. *Stress:* There is relatively little stress on this job.	1	2	3	4	5
Biological Approach					
38. *Strength:* The job requires fairly little muscular strength.	1	2	3	4	5
39. *Lifting:* The job requires fairly little lifting, and/or the lifting is of very light weights.	1	2	3	4	5
40. *Endurance:* The job requires fairly little muscular endurance.	1	2	3	4	5
41. *Seating:* The seating arrangements on the job are adequate (e.g., ample opportunities to sit, comfortable chairs, good postural support, etc.).	1	2	3	4	5
42. *Size differences:* The workplace allows for all size differences between people in terms of clearance, reach, eye height, leg room, etc.	1	2	3	4	5
43. *Wrist movement:* The job allows the wrists to remain straight without excessive movement.	1	2	3	4	5
44. *Noise:* The workplace is free from excessive noise.	1	2	3	4	5
45. *Climate:* The climate at the workplace is comfortable in terms of temperature and humidity, and it is free of excessive dust and fumes.	1	2	3	4	5
46. *Work breaks:* There is adequate time for work breaks given the demands of the job.	1	2	3	4	5
47. *Shift work:* The job does not require shift work or excessive overtime.	1	2	3	4	5
For jobs with little physical activity due to single workstation add:					
48. *Exercise opportunities:* During the day, there are enough opportunities to get up from the workstation and walk around.	1	2	3	4	5
49. *Constraint:* While at the workstation, the worker is not constrained to a single position.	1	2	3	4	5
50. *Furniture:* At the workstation, the worker can adjust or arrange the furniture to be comfortable (e.g., adequate legroom, footrests if needed, proper keyboard or work surface height, etc.).	1	2	3	4	5

Adapted from Campion et al. (1993). See reference and related research (Campion et al. 1996) for reliability and validity information. Scores for each preference/tolerance are calculated by averaging applicable items.

for changing tasks or tools, increased proficiency from the repetition of the same tasks, and the development of special-purpose tools and equipment.

A very influential person for this early perspective on job design was Frederick Taylor (Taylor 1911; Hammond 1971), who expounded the principles of scientific management, which encouraged the study of jobs to determine the "one best way" to perform each task. Movements of skilled workers were studied using a stopwatch and simple analysis. The best and quickest methods and tools were selected, and all workers were trained to perform the job in the same manner. Standards were developed, and incentive pay was tied to the standard performance levels. Gilbreth was also a key founder of this job-design approach (Gilbreth 1911). Through the use of time and motion study, he tried to eliminate wasted movements in work by the appropriate design of equipment and placement of tools and materials.

Surveys of industrial job designers indicate that this mechanistic approach to job design, characterized by specialization, simplification, and time study, was the prevailing practice throughout the last century (Davis et al. 1955; Davis and Valfer 1965). These characteristics are also the primary focus of many modern-day writers on job-design (Barnes 1980; Niebel 1988; Mundel 1985; also see Chapter 38). The discipline base is indicated as "classic" industrial engineering in Table 1. Modern-day industrial engineers may practice a variety of approaches to job design, however.

2.1.2. Design Recommendations

Table 2 provides a brief list of statements that describe the essential recommendations of the mechanistic approach. In essence, jobs should be studied to determine the most efficient work methods and techniques. The total work in an area (e.g., department) should be broken down into highly specialized jobs that are assigned to different employees. The tasks should be simplified so that skill requirements are minimized. There should also be repetition in order to gain improvement from practice. Idle time should be minimized. Finally, activities should be automated or assisted by automation to the extent possible and economically feasible.

2.1.3. Advantages and Disadvantages

The goal of this approach is to maximize efficiency, in terms of both productivity and the utilization of human resources. Table 1 summarizes some of the human resource advantages and disadvantages that have been observed in previous research. Jobs designed according to the mechanistic approach are easier and less expensive to staff. Training times are reduced. Compensation requirements may be less because skill and responsibility are reduced. And because mental demands are less, errors may be less common.

The mechanistic approach also has disadvantages. Too much of the mechanistic approach may result in jobs that are so simple and routine that employees experience less job satisfaction and motivation. Overly mechanistic work can lead to health problems from the physical wear that can result from highly repetitive and machine-paced work.

2.2. Motivational Job Design

2.2.1. Historical Background

Encouraged by the human relations movement of the 1930s (Mayo 1933; Hoppock 1935), people began to point out the unintended drawbacks of the overapplication of the mechanistic design philosophy in terms of worker attitudes and health (Argyris 1964; Blauner 1964; Likert 1961). Overly specialized and simplified jobs were found to lead to dissatisfaction (Caplan et al. 1975; Karasek 1979; Kornhauser 1965; Shepard 1970) and to adverse physiological consequences for workers (Frankenhaeuser 1977; Johansson et al. 1978). Jobs on assembly lines and other machine-paced work were especially troublesome in this regard (Salvendy and Smith 1981; Walker and Guest 1952). These trends led to an increasing awareness of the psychological needs of employees.

The first efforts to enhance the meaningfulness of jobs simply involved the exact opposite of specialization. It was recommended that tasks be added to jobs, either at the same level of responsibility (i.e., job enlargement) or at a higher level (i.e., job enrichment) (Ford 1969; Herzberg 1966). This job-design trend expanded into a pursuit of identifying and validating the characteristics of jobs that make them motivating and satisfying (Griffin 1982; Hackman and Lawler 1971; Hackman and Oldham 1980; Turner and Lawrence 1965). This approach to job design considers the psychological theories of work motivation (Mitchell 1976; Steers and Mowday 1977; Vroom 1964), thus this "motivational" approach to job design draws primarily from organizational psychology as a discipline base.

A related trend following later in time but somewhat comparable in content is the sociotechnical approach (Cherns 1976; Emory and Trist 1960; Rousseau 1977). It focuses not only on the work, but also on the technology itself. Interest is less on the job per se and more on roles and systems. The goal, and key concept, is the joint optimization of both the social and technical systems. Although

this approach differs somewhat in that it also gives consideration to the technical system, it is similar in that it draws on the same psychological job characteristics that affect satisfaction and motivation.

2.2.2. Design Recommendations

Table 2 provides a list of statements that describe the recommendations from the motivational approach. It suggests that jobs should allow the worker some autonomy to make decisions about how and when tasks are to be done. The worker should feel that the work is important to the overall mission of the organization or department. This is often done by allowing the worker to perform a larger unit of work or to perform an entire piece of work from beginning to end. Feedback on job performance should be given to the worker from the task itself, as well as from the supervisor and others. The worker should be able to use a variety of skills and have opportunities to learn new skills and personally grow on the job. Aside from these characteristics that make jobs meaningful from a task-oriented perspective, this approach also considers the social or people-interaction aspects of the job. That is, jobs should have opportunities for participation, communication, and recognition. Finally, other human resource systems should contribute to the motivating atmosphere, such as adequate pay, promotion, and job-security systems.

2.2.3. Advantages and Disadvantages

The goal of this approach is to enhance the psychological meaningfulness of the jobs, thus influencing a variety of attitudinal and behavioral outcomes. Table 1 summarizes some of the human resource benefits and costs from previous research. Jobs designed according to the motivational approach have more satisfied, motivated, and involved employees. Furthermore, job performance may be higher and absenteeism lower. Customer service may even be improved, in part because employees may take more pride in the work, and in part because employees can catch their own errors by performing a larger part of the work.

In terms of disadvantages, jobs that are too high on the motivational approach may have longer training times and be more difficult and expensive to staff because of their greater skill and ability requirements. Higher skill and responsibility may in turn require higher compensation. Overly motivating jobs may be so stimulating that workers become predisposed to mental overload, fatigue, errors, and occupational stress.

2.3. Perceptual/Motor Job Design

2.3.1. Historical Background

This approach draws on a scientific discipline that goes by many names, including human factors, human factors engineering, human engineering, man–machine systems engineering, and engineering psychology. As a field, it developed from a number of other disciplines, primarily experimental psychology, but also industrial engineering (Meister 1971; Meister and Rabideau 1965). Within experimental psychology, job-design recommendations draw heavily from knowledge of human skilled performance (Welford 1976) and the analysis of humans as information processors (Fogel 1976). The main concern of this approach is with the efficient and safe utilization of humans in human–machine systems, with emphasis on the selection, design, and arrangement of system components so as to take account of both people's capabilities and limitations (Pearson 1971). It is more concerned with equipment than is the motivational approach and more concerned with people's abilities than is the mechanistic approach.

The perceptual/motor approach received public attention through the Three Mile Island incident, after which it was concluded that the control room-operator job in the nuclear power plant may have created too many demands on the operator in an emergency situation, thus creating a predisposition to errors of judgment (Campion and Thayer 1987). Federal government regulations issued since that time require that nuclear power plants consider the ''human factors'' in their design (NRC 1981). The primary emphasis suggested by the title of these regulations is on perceptual and motor abilities of people. This approach is the most prolific with respect to recommendations for proper job design, with the availability of many handbooks giving specific advice for all types of equipment, facilities, and layouts (Salvendy 1987; Sanders and McCormick 1987; Van Cott and Kinkade 1972; Woodson 1981).

2.3.2. Design Recommendations

Table 2 provides a list of statements describing some of the most important recommendations of the perceptual/motor approach. They refer either to equipment and environments on the one hand or information processing requirements on the other. Their thrust is to take into consideration the mental capabilities and limitations of people, such that the attention and concentration requirements of the job do not exceed the abilities of the least-capable potential worker. The focus is on the limits of the least-capable worker because this approach is concerned with the effectiveness of the total system,

which is no better than its weakest link. Jobs should be designed to limit the amount of information workers must pay attention to, remember, and think about. Lighting levels should be appropriate, displays and controls should be logical and clear, workplaces should be well laid out and safe, and equipment should be easy to use (i.e., user friendly).

2.3.3. Advantages and Disadvantages

The goals of this approach are to enhance the reliability and safety of the system and to gain positive user reactions. Table 1 summarizes some of the human resource advantages and disadvantages found in previous research. Jobs designed according to the perceptual/motor approach have lower likelihoods of errors and accidents. Employees may be less stressed and mentally fatigued because of the reduced mental demands of the job. Like the mechanistic approach, it reduces the mental ability requirements of the job. Thus, it may also enhance some human resource efficiencies, such as reduced training times and staffing difficulties.

On the other hand, costs to the perceptual/motor approach may result if it is excessively applied. In particular, less satisfaction, less motivation, and more boredom may result because the jobs provide inadequate mental stimulation. This problem is exacerbated by the fact that the least-capable potential workerplaces the limits on the mental requirements of the job.

2.4. Biological Job Design

2.4.1. Historical Background

This approach and the perceptual/motor approach share a joint concern for proper person–machine fit. The primary difference is that this approach is more oriented toward biological considerations of job design and stems from such disciplines as work physiology (Astrand and Rodahl 1977), biomechanics (i.e., the study of body movements) (Tichaeur 1978), and anthropometry (i.e., the study of body sizes) (Hertzberg 1972). Like the perceptual/motor approach, the biological approach is concerned with the design of equipment and workplaces as well as the design of tasks (Grandjean 1980).

2.4.2. Design Recommendations

Table 2 provides a list of important recommendations from the biological approach. This approach tries to design jobs to reduce physical demands, and especially to avoid exceeding people's physical capabilities and limitations. Jobs should not have excessive strength and lifting requirements, and again the capabilities of the least-physically able potential worker set the maximum level. Chairs should be designed so that good postural support is provided. Excessive wrist movement should be reduced by redesigning tasks and equipment. Noise, temperature, and atmosphere should be controlled within reasonable limits. Proper work/rest schedules should be provided so that employees can recuperate from the physical demands of the job.

2.4.3. Advantages and Disadvantages

The goals of this approach are to maintain the comfort and physical well being of the employees. Table 1 summarizes some of the human resource advantages and disadvantages observed in the research. Jobs designed according to the biological approach require less physical effort, result in less fatigue, and create fewer injuries and aches and pains than jobs low on this approach. Occupational injuries and illnesses, such as lower back pain and carpal tunnel syndrome, are fewer on well-designed jobs. There may even be lower absenteeism and higher job satisfaction on jobs that are not physically arduous.

A direct cost of this approach may be the expense of changes in equipment or job environments needed to implement the recommendations. At the extreme, there may be other costs. For example, it is possible to design jobs with so few physical demands that the workers become drowsy or lethargic, thus reducing their performance or encouraging them to leave their workplace. Clearly, extremes of physical activity and inactivity should be avoided, and there may even be an optimal level of physical activity for various employee groups (e.g., male, female, young, old).

2.5. Conflicts and Trade-offs among Approaches

Although one should strive to construct jobs that are well designed on all the approaches, it is clear that there are some direct conflicts in design philosophies. As Table 1 illustrates, the benefits of some approaches are the costs of others. No one approach can satisfy all outcomes. As noted above, the greatest potential conflicts are between the motivational approach on the one hand and the mechanistic and perceptual/motor approaches on the other. They produce nearly opposite outcomes. The mechanistic and perceptual/motor approaches recommend designing jobs that are simple, easy to learn,

safe, and reliable, with minimal mental demands on workers. The motivational approach encourages more complicated, challenging, and stimulating jobs, with greater mental demands.

Because of these conflicts, trade-offs and compromises may be necessary in many practical situations. The major trade-offs will be in terms of the mental demands of jobs created by the alternative design strategies. Making the job more mentally demanding increases the likelihood of achieving the workers' goals of satisfaction and motivation. On the other hand, making the job less mentally demanding increases the chances of reaching the organization's goals of reduced training and staffing costs and errors. Which trade-offs will be made depends on which types of outcomes one wants to maximize. In most situations, probably a compromise strategy may be optimal.

Trade-offs may not be needed in all situations, however. Jobs can often be improved on one approach while still maintaining their quality on other approaches. For example, in a recent redesign study, the motivational approach was applied to a group of clerical jobs to improve employee satisfaction and customer service (Campion and McClelland 1991). The expected benefits occurred along with some expected costs (e.g., increased training and compensation requirements), but not all potential costs occurred (e.g., efficiency did not decrease).

One strategy for minimizing trade-offs is to avoid design decisions that influence the mental demands of jobs. An example of this strategy is to enhance motivational design by focusing on the social aspects (e.g., social interaction, communication, participation, recognition, feedback, etc.). These design features can be increased without incurring the costs of increased mental demands. Moreover, many of these design features are under the direct control of those who manage the job.

The independence of the biological approach provides another opportunity to improve design without incurring trade-offs with the other approaches. One can reduce physical demands without influencing the mental demands of a job. Of course, the cost of equipment may need to be considered.

Finally, the adverse effects of trade-offs can often be reduced by avoiding designs that are extremely high or low on any of the approaches. Alternatively, one might require minimally acceptable levels on each approach. Knowing all the approaches to job design and their corresponding outcomes will help one make more intelligent job-design decisions and avoid unanticipated consequences.

3. TEAM-DESIGN

3.1. Historical Background

The major approaches to job design, as discussed in Section 2, typically focus on designing jobs for individual workers; however, it is also possible to design jobs around work teams. In designing jobs for teams, one assigns a task or set of tasks to a group of workers rather than an individual and considers the group to be the unit of performance. Objectives and rewards focus on group, not individual, behavior. Depending on the nature of the tasks, a team's workers may be performing the same tasks simultaneously or they may break tasks into subtasks to be performed by individuals within the team. Subtasks could be assigned on the basis of expertise or interest, or team members might rotate from one subtask to another to provide job variety and increase the breadth of skills and flexibility in the workforce.

Some tasks, because of their size or complexity or for other reasons, seem to fit naturally into a team job design, whereas others may seem to be appropriate only at the individual job level. In many cases, though, there may be a considerable degree of choice regarding whether to organize work around teams or individuals. In such situations, the engineer should consider the advantages and disadvantages of the use of teams as the unit for job design with respect to an organization's goals, policies, technologies, and constraints.

Team-based approaches to organizing work have become very popular in the last two decades in the United States (Goodman et al. 1987; Guzzo and Shea 1992; Hollenbeck et al. 1995; Tannenbaum et al. 1996). Theoretical treatments of team effectiveness have predominantly used input–process–output (IPO) models, as popularized by such authors as McGrath (1964), as frameworks to discuss team design and effectiveness (Guzzo and Shea 1992). Many variations on the IPO model have been presented in the literature over the years (e.g., Denison et al. 1996; Gladstein 1984; Sundstrom et al. 1990).

Social psychologists have studied groups and teams for several decades, mostly in laboratory settings. They have identified problems such as social loafing or free riding, groupthink, decision-making biases, and process losses and inhibitions that operate in groups (Diehl and Strobe 1987; Harkins 1987; Janis 1972; McGrath 1984; Paulus 1998; Steiner 1972; Zajonc 1965). Some empirical field studies have found that the use of teams does not necessarily result in positive outcomes (e.g., Katz et al. 1987; Tannenbaum et al. 1996), while others have shown positive effects from the implementation of teams (e.g., Banker et al. 1996; Campion et al. 1993, 1996; Cordery et al. 1991). Given that so many organizations are transitioning to team-based work design, it is imperative that the design and implementation of teams be based on the increasing knowledge from team-design research.

3.2. Design Recommendations

Design recommendations are organized around the IPO model of work team effectiveness shown in Figure 1. The variables in the model are briefly described below. A more detailed explanation of each variable is contained in Figure 1.

3.2.1. Input Factors

Inputs are the design ingredients that predispose team effectiveness. There are at least four basic types of inputs needed to ensure that teams are optimally designed:

1. Design the jobs to be motivating and satisfying. The characteristics of jobs that make them motivating in a team setting are basically the same as those that make them motivating in an individual setting. Some of the key characteristics applicable in teams are listed below and described in Figure 1 in more detail. They can be used to evaluate or design the jobs in your client's organization.
   (a) Allow the team adequate self-management.
   (b) Encourage participation among all members.
   (c) Encourage task variety; all members should perform varied team tasks.
   (d) Ensure that tasks are viewed by members as important.
   (e) Allow the team to perform a whole piece of work.
   (f) Make sure the team has a clear goal or mission.
2. Make the jobs within the team interdependent. Teams are often formed by combining interdependent jobs. In other cases, the jobs can be made to be interdependent to make them appropriate for teams. For example, reorganizing a company around its business processes normally requires making the work interdependent. Listed below (and in Figure 1) are several ways jobs can be interdependent.

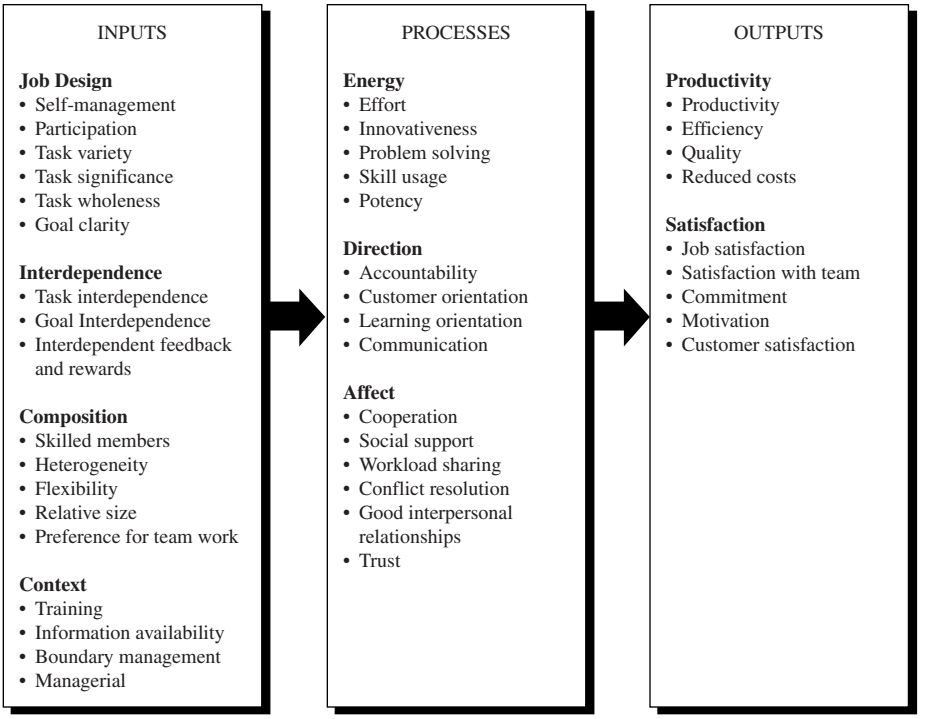

Figure 1 Model of Work Team Effectiveness.

(a) Make tasks interdependent; jobs must be linked or teams are not needed.
(b) Set interdependent goals for team members.
(c) Have interdependent feedback and rewards for team members, with both linked to team performance.

3. Compose the team of the right people. Properly selecting people for a team may be even more important than for individual jobs because a poor selection decision can affect the performance of the entire team. Staffing teams may also be more complex. Some of the key variables to consider are as follows.
   (a) Ensure that team members have a high level of skills.
   (b) Have varied team membership, especially in terms of complementary skills.
   (c) Staff the team with people who are flexible in terms of job assignments.
   (d) Ensure appropriate team size; just large enough (but not too large) for the work involved.
   (e) Select employees with a preference for working in teams.
4. Arrange the context to support teamwork. In order for a new work arrangement like teams to be effective, the organization must be arranged to enable or facilitate them. Following are several key examples.
   (a) Train the work teams in both team skills and task skills.
   (b) Make all necessary information available to the team.
   (c) Ensure proper boundary management by facilitating communication and cooperation between teams.
   (d) Provide managerial support for the team.

3.2.2. Process Factors

Process factors are intermediate indicators of effectiveness. (Note that ''team process,'' which refers to how the team operates, is different than ''business process,'' which refers to how the work flows through the organization to get accomplished.) There are at least three categories of team process indicators of effectiveness. Although these are intermediate outcomes, they can also be influenced through the design of the team or through encouragement, as indicated below.

1. Encourage a high-energy environment. This is the first indication that the team may be properly designed. It refers not just to working harder, but to heightened levels of interest and enthusiasm. Even if this is not forthcoming immediately, it can be encouraged in many ways, such as the following (also see Figure 1).
   (a) Create or encourage a high-effort norm within the team.
   (b) Create an environment that encourages innovation within the team.
   (c) Facilitate problem solving within the team.
   (d) Create opportunities for skill usage.
   (e) Encourage team spirit (potency).
2. Ensure that the team is properly directed. The higher energy of the team must be properly directed if it is going to enhance the attainment of organizational goals. There are a number of indicators that a team is properly directed. Key examples follow below. Each can also be encouraged by the management above the team or the consultant.
   (a) Encourage a sense of accountability and responsibility within the team.
   (b) Create or encourage a customer orientation in the team.
   (c) Create a learning orientation in the team.
   (d) Facilitate communication within the team.
3. Encourage proper affective and interpersonal behavior on the team. Not only is this important from a quality of work life point of view, but the long-term viability of the team depends on the members' willingness to work with each other in the future. Many key indicators of proper affect within the team should be present or encouraged, such as the following:
   (a) Facilitate cooperation within the team.
   (b) Encourage social support among team members.
   (c) Ensure the workload is shared appropriately among team members.
   (d) Facilitate the prompt resolution of conflict within the team.
   (e) Encourage good interpersonal relationships within the team.
   (f) Encourage trust within the team.

3.2.3. Output Factors

Outputs are the ultimate criteria of team effectiveness. The most important outcome is whether the teams enhance the business process. There are two basic categories of outputs. Both are central to the definition of team effectiveness as well as to effective business processes.

1. Effective teams are productive and efficient, and they may also improve quality and reduce costs, as explained in the first part of this chapter.
2. Effective teams are satisfying. This includes not only job satisfaction, but motivated and committed employees. Satisfaction also applies to the customers of the team's products or services. These outcomes were also explained in more detail in the first part of the chapter.

3.3. Advantages and Disadvantages

Work teams can offer several advantages over the use of individuals working separately. Table 3 lists some of these advantages. To begin with, teams can be designed so that members bring a combination of different knowledge, skills, and abilities (KSAs) to bear on a task. Team members can improve their KSAs by working with those who have different KSAs (McGrath 1984), and cross-training on different tasks can occur as a part of the natural workflow. As workers become capable of performing different subtasks, the workforce becomes more flexible. Members can also provide performance feedback to one another that they can use to adjust and improve their work behavior. Creating teams whose members have different KSAs provides an opportunity for synergistic combinations of ideas and abilities that might not be discovered by individuals working alone. Heterogeneity of abilities and personalities has been found to have a generally positive effect on team performance, especially when task requirements are diverse (Goodman et al. 1986; Shaw 1983).

Other advantages include social facilitation and support. Facilitation refers to the fact that the presence of others can be psychologically stimulating. Research has shown that such stimulation can have a positive effect on performance when the task is well learned (Zajonc 1965) and when other team members are perceived as potentially evaluating the performer (Harkins 1987; Porter et al. 1987). With routine jobs, this arousal effect may counteract boredom and performance decrements (Cartwright 1968). Social support can be particularly important when teams face difficult or unpopular decisions. It can also be important in groups such as military squads and medical teams for helping workers deal with difficult emotional and psychological aspects of tasks they perform.

Another advantage of teams is that they may increase the information exchanged between members. Communication can be increased through proximity and the sharing of tasks (McGrath 1984). Intrateam cooperation may also be improved because of team-level goals, evaluation, and rewards (Deutsch 1949; Leventhal 1976). Team rewards can be helpful in situations where it is difficult or impossible to measure individual performance or where workers mistrust supervisors' assessments of performance (Milkovich and Newman 1996).

Increased cooperation and communication within teams can be particularly useful when workers' jobs are highly coupled. There are at least three basic types of coupling, or sequencing of work: pooled, sequential, and reciprocal. In pooled coupling, members share common resources but are otherwise independent. In sequential coupling, members work in a series. Workers whose tasks come later in the process must depend on the performance of workers whose tasks come earlier. In reciprocal coupling, workers feed their work back and forth among themselves. Members receive both inputs and outputs from other members (Thompson 1967; Mintzberg 1979). Team job design would be especially useful for workflows that have sequential or reciprocal coupling.

Many of the advantages of work teams depend on how teams are designed and supported by their organization. The nature of team tasks and their degree of control can vary. According to much of the theory behind team job design, which is primarily from the motivational approach, decision making and responsibility should be pushed down to the team members (Hackman 1987). By pushing decision making down to the team and requiring consensus, the organization should find greater acceptance, understanding, and ownership of decisions among workers (Porter et al. 1987). The increased autonomy resulting from making work decisions should be both satisfying and motivating for teams (Hackman 1987).

The motivational approach would also suggest that the set of tasks assigned to a team should provide a whole and meaningful piece of work (i.e., have task identity) (Hackman 1987). This allows team members to see how their work contributes to a whole product or process, which might not be possible for individuals working alone. This can give workers a better idea of the significance of their work and create greater identification with a finished product or service. If team workers rotate among a variety of subtasks and cross-train on different operations, workers should also perceive greater variety in the work. Autonomy, identity, significance, variety, and feedback are all characteristics of jobs that have been found to enhance motivation. Finally, teams can be beneficial to the organization if team members develop a feeling of commitment and loyalty to their team (Cartwright 1968).

Thus, designing work around teams can provide several advantages to organizations and their workers. Unfortunately, there are also some disadvantages to using work teams. Whether or not teams are beneficial can depend on several factors particular to the composition, structure, and environment of teams and the nature of their tasks. Table 3 lists some of the possible disadvantages of designing work around teams.

For example, some individuals may dislike teamwork and may not have the necessary interpersonal skills or desire to work in a team. In addition, individuals may experience less autonomy and less personal identification when working on a team task than on an individual task. Designing work around teams does not guarantee individual team members greater variety, significance, and identity. If members within the team do not rotate among tasks or if some team members are assigned exclusively to less desirable tasks, not all members will benefit from team job-design. Members can still have fractionated, demotivating jobs. How one organizes work within the team is important in determining the effects of team job design.

Teamwork can also be incompatible with cultural norms. The United States has a very individualistic culture (Hofstede 1980). In addition, organizational norms, practices, and labor–management relations may be incompatible with team job design, making its use more difficult.

Some of the advantages of team design can create other disadvantages. Although team rewards can spur greater cooperation and reduce competition *within* a team, they may cause greater competition and reduced communication *between* teams. If members identify too strongly with the team, they may fail to recognize when behaviors that benefit the team detract from organizational goals. Competition between teams can be motivating up to a point, after which it can create conflicts that are detrimental to productivity.

Increased communication within teams may not always be task relevant. Teams may spend work time socializing. Team decision making can take longer than individual decision making, and reaching a consensus can be time consuming. The need for coordination within teams takes time and faulty coordination can create problems.

Team processes can also inhibit decision making and creativity. When teams become highly cohesive they may become so alike in their views that they develop ''groupthink'' (Janis 1972; Paulus 1998). When groupthink occurs, teams tend to underestimate their competition, fail to adequately critique fellow team members' suggestions, fail to survey and appraise alternatives adequately, and fail to work out contingency plans. In addition, team pressures can distort judgments. Decisions may be based more on the persuasive abilities of dominant individuals or the power of majorities than on the quality of information and decisions. Research has found a tendency for group judgments to be more extreme than the average of individual members' predecision judgments (Isenberg 1986; McGrath 1984; Pruitt 1971). This may aid reaching a consensus, but it may be detrimental if judgments are poor.

Although evidence shows that highly cohesive groups are more satisfied with the group, high cohesiveness is not necessarily related to high productivity. Whether cohesiveness is related to performance depends on group norms and goals. If a group's norm is to be productive, cohesiveness

TABLE 3 Advantages and Disadvantages of Work Teams

Advantages	Disadvantages
Group members learn from one another	Lack of compatability of some individuals with group work
Possibility of greater workforce flexibility with cross-training	Additional need to select workers to fit group as well as job
Opportunity for synergistic combinations of ideas and abilities	Possibility some members will experience less-motivating jobs
New approaches to tasks may be discovered	Possible incompatibility with cultural, organizational, or labor–management norms
Social facilitation and arousal	Increased competition and conflict between groups
Social support for difficult tasks	More time consuming due to socializing coordination losses, and need for consensus
Increased communication and information exchange between team members	Inhibition of creativity and decision-making processes; possibility of groupthink
Greater cooperation among team members	Less powerful evaluation and rewards; social loafing or free-riding may occur
Beneficial for interdependent workflows	Less flexibility in cases of replacement, turnover, or transfer
Greater acceptance and understanding of decisions when team makes decisions	
Greater autonomy, variety, identity, significance, and feedback possible for workers	
Commitment to the group may stimulate performance and attendance	

TABLE 4 When to Design Jobs around Work Teams

1. Do the tasks require a variety of knowledge, skills, abilities such that combining individuals with different backgrounds would make a difference in performance?
2. Is cross-training desired? Would breadth of skills and work force flexibility be essential to the organization?
3. Could increased arousal, motivation, and effort to perform make a difference in effectiveness?
4. Can social support help workers deal with job stresses?
5. Could increased communication and information exchange improve performance rather than interfere?
6. Could increased cooperation aid performance?
7. Are individual evaluation and rewards difficult or impossible to make or are they mistrusted by workers?
8. Could common measures of performance be developed and used?
9. Would workers' tasks be highly interdependent?
10. Is it technologically possible to group tasks in a meaningful and efficient way?
11. Would individuals be willing to work in groups?
12. Does the labor force have the interpersonal skills needed to work in groups?
13. Would group members have the capacity and willingness to be trained in interpersonal and technical skills required for group work?
14. Would group work be compatible with cultural norms, organizational policies, and leadership styles?
15. Would labor–management relations be favorable to group job design?
16. Would the amount of time taken to reach decisions, consensus, and coordination not be detrimental to performance?
17. Can turnover be kept to a minimum?
18. Can groups be defined as a meaningful unit of the organization with identifiable inputs, outputs, and buffer areas that give them a separate identity from other groups?
19. Would members share common resources, facilities, or equipment?
20. Would top management support group job design?

Affirmative answers support the use of team work design.

will enhance productivity; however, if the norm is not one of commitment to productivity, cohesiveness can have a negative influence (Zajonc 1965; Stogdill 1972).

The use of teams and team-level rewards can also decrease the motivating power of evaluation and reward systems. If team members are not evaluated for their individual performance, do not believe that their output can be distinguished from the team's, or do not perceive a link between their own performance and their outcomes, free-riding or social loafing (Albanese and Van Fleet 1985; Cartwright 1968; Latane et al. 1979) can occur. In such situations, teams do not perform up to the potential expected from combining individual efforts.

Finally, teams may be less flexible in some respects because they are more difficult to move or transfer as a unit than individuals (Sundstrom et al. 1990). Turnover, replacements, and employee transfers may disrupt teams. And members may not readily accept new members.

Thus, whether work teams are advantageous or not depends to a great extent on the composition, structure, reward systems, environment, and task of the team. Table 4 presents questions that can help determine whether work should be designed around teams rather than individuals. The greater the number of questions answered in the affirmative, the more likely teams are to succeed and be beneficial. If one chooses to design work around teams, suggestions for designing effective work teams and avoiding problems are presented below.

4. IMPLEMENTATION ADVICE FOR JOB AND TEAM DESIGN

4.1. When to Consider Design and Redesign of Work

There are at least eight situations when design or redesign of work should be considered.

1. When starting up or building a new plant or work unit. This is the most obvious application of job design.
2. During innovation or technological change. Continual innovation and technological change are important for survival in most organizations. These changes in procedures and equipment mean there are changes in job design. This is not unique to manufacturing jobs. The introduction of

electronic equipment is changing many office jobs. Proper consideration of job design is needed to ensure that the innovations are successful.

3. When markets, products, or strategies change. Modern consumer and industrial markets change rapidly. To keep up with changing demands, organizations must often change marketing strategies and product line mixes. Such changes can affect many jobs throughout an organization and require redesign. For example, salespersons' territories, product line responsibilities, and compensation packages may need to be modified to reflect changing strategies. Production workers' jobs may also require redesign as styles and quantities of products change.
4. During reorganization. Reorganizations of management hierarchies and organizational units frequently mean changes in job assignments or responsibilities of many employees due to the creation and elimination of jobs. In order to ensure a successful reorganization, principles of proper job design must be considered.
5. During growth or downsizing. As an organization grows, new jobs are formed. These jobs are often designed haphazardly, reflecting a collection of tasks other employees do not have time to do. Likewise, during downsizing, jobs are eliminated and some tasks are included in other jobs. This can lead to unfavorable changes in the designs of the remaining jobs.
6. When jobs are needed for special positions or persons. Even existing organizations create new positions. Also, new persons may be hired to fill positions that have different backgrounds, skills, and capabilities than former employees. Both these situations may create a need to reevaluate job-design. For example, hiring handicapped workers may require that managers redesign jobs for them. Frequently, special jobs are also designed for newcomers to the organization, for special administrative assistants, or for temporary assignments.
7. When the workforce or labor markets change. Changing demographics, education levels, and economic conditions affecting employment levels can cause changes in the quality and size of the organization's labor force and labor markets from which the organization hires new workers. Jobs may need to be redesigned to fit a workforce whose average education level has increased over time, or physically demanding jobs may need to be redesigned to accommodate increasing numbers of older or female workers.
8. When there are performance, safety, or satisfaction problems. It is quite common for the employee to be blamed when there are problems with performance, safety, or satisfaction. In many of these instances, the job design is at least partly to blame. Several examples may illustrate this. Human error was named as the cause of the nearly catastrophic nuclear power plant incident at Three Mile Island noted previously, but the design of the operator's job might have been the actual cause. In a study of a wood products company (Campion and Thayer 1985), one sawmill job with multiple employees involved pulling two-by-fours off a moving belt and placing them in racks. The employees were described as lazy and apathetic. But examination of the job from a motivational design point of view revealed that it lacked variety and any significant skill requirements. It was unimportant, repetitive, and boring. It is no surprise that the employees were not motivated or satisfied. In that same study, a plywood plant required an employee to align strips of wood on a moving belt just before they entered the dryer. One time when dryer utilization was not up to standard, the supervisor concluded that the incumbent was negligent and gave her a written reprimand. But the job was very poorly designed from a biological perspective. The employee had to operate a foot pedal while standing and thus spent all day with most of the body weight on one foot. She also had to bend over constantly while extending her arms to adjust the strips of wood, resulting in biomechanical stresses on the back, arms, and legs. Everyone hated the job, yet the employee was blamed.

As a final example, the authors discovered that a personnel-recruiter job in a large company was in need of improved mechanistic design. The job involved running the engineering co-op program that consisted of hundreds of engineering students coming to the company and returning to school each semester. The recruiter had to match employees' interests with managers' needs, monitor everyone's unique schedule, keep abreast of the requirements of different schools, administer salary plans and travel reimbursement, and coordinate hire and termination dates. The job was completely beyond the capability of any recruiter. The solution involved having a team of industrial engineers study the job and apply the mechanistic approach to simplify tasks and streamline procedures.

It is clear that some types of jobs are naturally predisposed to be well designed on some job-design approaches and poorly designed on others. It may be in these latter regards that the greatest opportunities exist to benefit from job redesign. For example, many factory, service, and otherwise low-skilled jobs lend themselves well to mechanistic design, but the ideas of specialization and simplification of tasks and skill requirements can be applied to other jobs in order to reduce staffing difficulties and training requirements. Jobs can often be too complex or too large for employees,

leading to poor performance or excessive overtime. This is common with professional and managerial jobs, as was illustrated in the recruiter example above. Professional jobs are usually only evaluated in terms of the motivational approach to job design, but often they can be greatly improved by mechanistic design principles. Finally, if workload in an area temporarily rises without a corresponding increase in staffing levels, the mechanistic approach may be applied to the jobs to enhance efficiency.

Most managerial, professional, and skilled jobs are fairly motivational by their nature. Factory, service, and low-skilled jobs tend naturally not to be motivational. The latter clearly represent the most obvious examples of needed applications of the motivational approach. But there are many jobs in every occupational group, and aspects of almost every job, where motivational features are low. Application of motivational job-design is often limited only by the creativity of the designer.

Jobs involving the operation of complex machinery (e.g., aircraft, construction, and factory control rooms) are primary applications of the perceptual/motor approach. Likewise, many product-inspection and equipment-monitoring jobs can tax attention and concentration capabilities of workers. But jobs in many other occupations may also impose excessive attention and concentration requirements. For example, some managerial, administrative, professional, and sales jobs can be excessively demanding on the information-processing capabilities of workers, thus causing errors and stress. And nearly all jobs have periods of overload. Perceptual/motor design principles can often be applied to reduce these demands of jobs.

Traditional heavy industries (e.g., coal, steel, oil, construction, and forestry) represent the most obvious applications of the biological approach. Similarly, this approach also applies to many jobs that are common to most industries (e.g., production, maintenance) because there is some physical demands component. Biological design principles can be applied to physically demanding jobs so that women can better perform them (e.g., lighter tools with smaller hand grips). But there may also be applications to less physically demanding jobs. For example, seating, size differences, and posture are important to consider in the design of many office jobs, especially those with computer terminals. This approach can apply to many light-assembly positions that require excessive wrist movements that can eventually lead to the wrist ailment carpal tunnel syndrome. It should be kept in mind, however, that jobs designed with too little physical activity (i.e., movement restricted due to single position or workstation) should be avoided. Likewise, jobs that require excessive travel should be avoided because they can lead to poor eating and sleeping patterns.

4.2. Procedures to Follow

There are at least several general guiding philosophies that are helpful when designing or redesigning jobs:

1. As noted previously, designs are not fixed, unalterable, or dictated by the technology. There is at least some discretion in the design of all jobs and substantial discretion in most jobs.
2. There is no single best design for a given job, there are simply better and worse designs depending on one's job-design perspective.
3. Job design is iterative and evolutionary. It should continue to change and improve over time.
4. When possible, participation of the workers affected generally improves the quality of the resulting design and acceptance of suggested changes.
5. Related to number 4, the process aspects of the project are very important to success. That is, how the project is conducted is important in terms of involvement of all the parties of interest, consideration of alternative motivations, awareness of territorial boundaries, and so on.

As noted previously, surveys of industrial job designers have consistently indicated that the mechanistic approach represents the dominant theme of job design (Davis et al. 1955; Taylor 1979). Other approaches to job design, such as the motivational approach, have not been given as much explicit consideration. This is not surprising because the surveys only included job designers trained in engineering-related disciplines, such as industrial engineers and systems analysts. It is not necessarily certain that other specialists or line managers would adopt the same philosophies. Nevertheless, there is evidence that even fairly naive job designers (i.e., college students taking management classes) also seem to adopt the mechanistic approach in job-design simulations. That is, their strategies for grouping tasks were primarily similarity of functions or activities, and also similarity of skills, education, difficulty, equipment, procedures, or location (Campion and Stevens 1989). Even though the mechanistic approach may be the most natural and intuitive, this research has also revealed that people can be trained to apply all four of the approaches to job design.

4.2.1. Procedures for the Initial Design of Jobs or Teams

In consideration of process aspects of conducting a design project, Davis and Wacker (1982) have suggested a strategy consisting of four steps:

1. Form a steering committee. The steering committee usually consists of a group of high-level executives that have a direct stake in the new jobs. The purpose of this committee is fourfold: (a) to bring into focus the objective of the project, (b) to provide resources and support for the project, (c) to help gain the cooperation of all the parties affected by the project, and (d) to oversee and guide the project.
2. Form a design task force. The task force may include engineers, managers, job-design experts, architects, specialists, and others with knowledge or responsibility relevant to the project. The purpose of the task force is to gather data, generate and evaluate design alternatives, and help implement recommended designs.
3. Develop a philosophy statement. The first goal of the task force is to develop a philosophy statement to guide the many decisions that will be involved in the project. The philosophy statement is developed with considerable input from the steering committee and may include such factors as the purposes of the project, the strategic goals of the organization, assumptions about workers and the nature of work, process considerations, and so on.
4. Proceed in an evolutionary manner. The essential point here is that jobs should not be overspecified. With considerable input from eventual jobholders, the designs of the jobs will continue to change and improve over time.

4.2.2. Procedures for Redesigning Existing Jobs or Teams

According to Davis and Wacker (1982), the process of redesigning existing jobs is much the same as that of designing original jobs with two additions. First, the existing job incumbents must be involved. Second, more attention needs to be given to implementation issues. Most importantly, those involved in the implementation must feel ownership of the change. They should believe that the redesign represents their own interests and efforts. This is important not only so that they will be emotionally committed to the change and willing to put in the effort to make it happen, but also so that they will understand the details of the redesign so as to reduce inherent uncertainty.

Along with steps related to the process issues discussed above and in the previous subsection, a redesign project would also include the following five steps:

1. Measure the design of the existing job or team. A questionnaire methodology may be used as well as other analysis tools such as job analysis, time and motion study, and variance analysis. The goal is to gain a measure of the job as it currently exists.
2. Diagnose potential job- and team-design problems. Based partly on the measures collected in step 1, the job is analyzed for potential problems. The job/team-design task force and employee involvement are particularly important at this step. Focused group meetings are often a useful vehicle for identifying and evaluating potential problems.
3. Determine job- and team-design changes. These changes will be guided by the goals of the project, the problems identified in step 3, and one or more of the theoretical approaches to job and team design. Often several potential changes are generated and evaluated. Evaluation of alternative changes may consist of a consideration of the costs and benefits identified in previous research (see Table 1) and the opinions of engineers, managers, and employees. This may be the point when trade-offs become the most apparent.
4. Make the job- and team-design changes. Implementation plans should be developed in detail along with back-up plans in case there are a few difficulties with the new design. Communication and training are keys to successful implementation. Consideration might also be given to pilot testing the changes before widespread implementation is undertaken.
5. Conduct a follow-up evaluation of the new design. Evaluating the new design after implementation is probably the most neglected component of the process in most applications. Part of the evaluation might include the collection of job and team-design measurements on the redesigned job or team using the same instruments as in step 1. Evaluation may also be conducted on the outcomes from the redesign, such as employee satisfaction, error rates, and training times (e.g., Table 1). And it should be noted that some of the effects of job and team design are not always easy to demonstrate. Scientifically valid evaluations require experimental research strategies with control groups. Such studies may not always be possible in ongoing organizations, but often quasiexperimental and other field research designs are possible (Cook and Campbell 1979). Finally, the need for iterations and fine adjustments is identified through the follow-up evaluation.

4.3. Methods for Combining Tasks

In many cases, designing jobs or teams is largely a function of combining tasks. Generally speaking, most writing on job design has focused on espousing overall design philosophies or on identifying those dimensions of jobs (once the jobs exist) that relate to important outcomes, but little research has focused on how tasks should be combined to form jobs in the first place. Some guidance can be

gained by extrapolating from the specific design recommendations in Table 2. For example, variety in the motivational approach can be increased by simply combining different tasks into the same job.

Conversely, specialization from the mechanistic approach can be increased by including only very similar tasks in the same job. It is also possible when designing jobs to first generate alternative combinations of tasks, then evaluate them using the design approaches in Table 2.

A small amount of research within the motivational approach has focused explicitly on predicting the relationships between combinations of tasks and the design of resulting jobs (Wong 1989; Wong and Campion 1991). This research suggests that the motivational quality of a job is a function of three task-level variables.

1. Task design. The higher the motivational quality of the individual tasks, the higher the motivational quality of the job. Table 2 can be used to evaluate the individual tasks, then motivational scores for the individual tasks can be summed together. Summing is recommended rather than averaging because it includes a consideration of the number of tasks (Globerson and Crossman 1976). That is, both the motivational quality of the tasks and the number of tasks are important in determining the motivational quality of a job.
2. Task interdependence. Interdependence among the tasks has been shown to have an inverted-U relationship with the motivational quality of a job. That is, task interdependence is positively related to motivational value up to some moderate point; beyond that point, increasing interdependence leads to lower motivational value. Thus, when tasks are being combined to form motivational jobs, the total amount of interdependence among the tasks should be kept at a moderate level. Both complete independence among the tasks and excessively high interdependence should be avoided. Table 5 contains the dimensions of task interdependence and provides a questionnaire that can be used to measure interdependence. Table 5 can be used to judge the interdependence of each pair of tasks being evaluated for inclusion into a particular job.
3. Task similarity. Some degree of similarity among tasks may be the oldest rule of job-design (as discussed previously) and seems to have little influence on the motivational quality of the job. But beyond a moderate level, it tends to decrease the motivational value. Thus, when motivational jobs are being designed, high levels of similarity should be avoided. Similarity at the task pair level can be judged in much the same manner as interdependence by using a subset of the dimensions in Table 5 (see the note).

Davis and Wacker (1982 1987) have provided a list of criteria for grouping tasks into jobs. Part of their list is reproduced below. There are two points to notice. First, the list represents a collection of criteria from both the motivational approach to job-design (e.g., 1, 5, 9) as well as the mechanistic approach (e.g., 2, 8). Second, many of the recommendations could be applied to designing work for teams, as well as individual jobs.

1. Each set of tasks is a meaningful unit of the organization.
2. Task sets are separated by stable buffer areas.
3. Each task set has definite, identifiable inputs and outputs.
4. Each task set has associated with it definite criteria for performance evaluation.
5. Timely feedback about output states and feedforward about input states are available.
6. Each task set has resources to measure and control variances that occur within its area of responsibility.
7. Tasks are grouped around mutual cause–effect relationships.
8. Tasks are grouped around common skills, knowledge, or data bases.
9. Task groups incorporate opportunities for skill acquisition relevant to career advancement.

4.4. Individual Differences Among Workers

A common observation made by engineers and managers is that not all employees respond the same way to the same job. Some people on a given job have high satisfaction, while others on the very same job have low satisfaction. Some people seem to like all jobs, while others dislike every job. Clearly, there are individual differences in how people respond to their work.

There has been a considerable amount of research looking at individual differences in reaction to the motivational approach to job design. It has been found that some people respond more positively (e.g., are more satisfied) than others to highly motivational work. These differences were initially considered to be reflections of underlying work ethic (Hulin and Blood 1968), but later were viewed more generally as differences in needs for personal growth and development (Hackman and Oldham 1980).

TABLE 5 Dimensions of Task Interdependence

Instructions: Indicate the extent to which each statement is descriptive of the pair of tasks using the scale below. Circle answers to the right of each statement. Scores are calculated by averaging applicable items.

Please use the following scale:
(5) Strongly agree
(4) Agree
(3) Neither agree nor disagree
(2) Disagree
(1) Strongly disagree
( ) Leave blank if do not know or not applicable

Inputs of the Tasks					
1. *Materials/supplies:* One task obtains, stores, or prepares the materials or supplies to perform the other task.	1	2	3	4	5
2. *Information:* One task obtains or generates information for the other task.	1	2	3	4	5
3. *Product/service:* One task stores, implements, or handles the products or services produced by the other task.	1	2	3	4	5
Processes of the Task					
4. *Input–output* relationship: The products (or outputs) of one task are the supplies (or inputs) necessary to perform the other task.	1	2	3	4	5
5. *Method and procedure:* One task plans the procedures or work methods for the other task.	1	2	3	4	5
6. *Scheduling:* One task schedules the activities of the other task.	1	2	3	4	5
7. *Supervision:* One task reviews or checks the quality of products or services produced by the other task.	1	2	3	4	5
8. *Sequencing:* One task needs to be performed before the other task.	1	2	3	4	5
9. *Time sharing:* Some of the work activities of the two tasks must be performed at the same time.	1	2	3	4	5
10. *Support service:* The purpose of one task is to support or otherwise help the other task be performed.	1	2	3	4	5
11. *Tools/equipment:* One task produces or maintains the tools or equipment used by the other task.	1	2	3	4	5
Outputs of the Tasks					
12. *Goal:* One task can only be accomplished when the other task is properly performed.	1	2	3	4	5
13. *Performance:* How well one task is performed has a great impact on how well the other task can be performed.	1	2	3	4	5
14. *Quality:* The quality of the product or service produced by one task depends on how well the other task is performed.					

Adapted from Wong and Campion (1991). The task similarity measure contains 10 comparable items (excluding items 4, 6, 8, 9, and 14 and including an item on customer/client).

Using the broader notion of preferences/tolerances for types of work, the consideration of individual differences has been expanded to all four approaches to job design (Campion 1988; Campion and McClelland 1991). Table 6 provides a set of rating scales that can be used with job incumbents to determine their preferences/tolerances. These scales can be administered in the same manner as the questionnaire measures of job design discussed previously.

Although a consideration of employee differences is strongly encouraged, in many situations there are limits to which such differences can be accommodated. As examples, many jobs have to be designed for groups of people that may differ in their preferences/tolerances, often jobs need to be designed without knowledge of the future workers, and the workers on a job may change over time. Fortunately, even though the cumulative evidence is that individual differences moderate reactions to the motivational approach (Loher et al. 1985) the differences are of degree, not direction. In other words, some people respond more positively than others to motivational work, but very few respond negatively. It is likely that this also applies to the other approaches to job design.

TABLE 6 Preferences/Tolerances for Types of Work

Instructions: Indicate the extent to which each statement is descriptive of the job incumbent's preferences and tolerances for types of work on the scale below. Circle answers to the right of each statement. Scores are calculated by averaging applicable items.

Please use the following scale:
(5) Strongly agree
(4) Agree
(3) Neither agree nor disagree
(2) Disagree
(1) Strongly disagree
( ) Leave blank if do not know or not applicable

Preferences/Tolerances for Mechanistic Design					
I have a high tolerance for routine work.	1	2	3	4	5
I prefer to work on one task at a time.	1	2	3	4	5
I have a high tolerance for repetitive work.	1	2	3	4	5
I prefer work that is easy to learn.	1	2	3	4	5
Preferences/Tolerances for Motivational Design					
I prefer highly challenging work that taxes my skills and abilities.	1	2	3	4	5
I have a high tolerance for mentally demanding work.	1	2	3	4	5
I prefer work that gives a great amount of feedback as to how I am doing.	1	2	3	4	5
I prefer work that regularly requires the learning of new skills.	1	2	3	4	5
I prefer work that requires me to develop my own methods, procedures, goals, and schedules.	1	2	3	4	5
I prefer work that has a great amount of variety in duties and responsibilities	1	2	3	4	5
Preferences/Tolerances for Perceptual/Motor Design					
I prefer work that is very fast paced and stimulating.	1	2	3	4	5
I have a high tolerance for stressful work.	1	2	3	4	5
I have a high tolerance for complicated work.	1	2	3	4	5
I have a high tolerance for work where there are frequently too many things to do at one time.	1	2	3	4	5
Preferences/Tolerances for Biological Design					
I have a high tolerance for physically demanding work.	1	2	3	4	5
I have a fairly high tolerance for hot, noisy, or dirty work.	1	2	3	4	5
I prefer work that gives me some physical exercise.	1	2	3	4	5
I prefer work that gives me some opportunities to use my muscles.	1	2	3	4	5

Adapted from Campion (1988). See reference for reliability and validity information. Interpretations differ slightly across the scales. For the mechanistic and motivational designs, higher scores suggest more favorable reactions from incumbents to well designed jobs. For the perceptual/motor and biological approaches, higher scores suggest less unfavorable reactions from incumbents to poorly designed jobs.

4.5. Some Basic Decisions

Hackman and Oldham (1980) have provided five strategic choices that relate to implementing job redesign. They note that little research exists indicating the exact consequences of each choice and that correct choices may differ by organization. The basic decisions are given below:

1. Individual vs. group designs for work. A key initial decision is to either enrich individual jobs or create self-managing work teams. This also includes consideration of whether any redesign should be undertaken and its likelihood of success.
2. Theory-based vs. intuitive changes. This choice was basically defined as the motivational (theory) approach vs. no particular (atheoretical) approach. In the present chapter, this choice may be better framed as choosing among the four approaches to job design. However, as argued earlier, consideration of only one approach may lead to some costs or additional benefits being ignored.
3. Tailored vs. broadside installation. The choice here is between tailoring the changes to the individual employee or making the changes for all employees in a given job.
4. Participative vs. top-down change processes. The most common orientation, and that of this chapter, is that participative is best. However, there are costs to participation, including the

time commitment involved and the fact that incumbents may lack needed broader knowledge of the business.

5. Consultation vs. collaboration with stakeholders. The effects of job-design changes often extend far beyond the individual incumbent and department. For example, the output from the job may be an input to another job elsewhere in the organization, and the presence of a union always constitutes another interested party. Depending on many considerations, participation of stakeholders may range from no involvement to consultation to full collaboration.

4.6. Overcoming Resistance to Change

Resistance to change can be a problem in any project involving major change. Failure rates of implementations demonstrate a need to give more attention to the human aspects of change projects. It has been estimated that between 50% and 75% of newly implemented manufacturing technologies in the United States have failed, with a disregard for human and organizational issues considered to be a bigger cause of failure than technical problems (Majchrzak 1988; Turnage 1990). The number one obstacle to implementation was considered to be resistance to change (Hyer 1984).

Guidelines for reducing resistance to change include the following (Gallagher and Knight 1986; Majchrzak 1988; Turnage 1990):

1. Involve workers in planning the change. Workers should be informed in advance of changes and involved in the process of diagnosing problems and developing solutions because resistance is reduced when workers participate and feel the project is their own.
2. Top management should visibly support the change. When workers feel managers are not committed, they are less likely to take a project seriously.
3. Create change that is consistent with workers' needs and existing values. Resistance is less if change is seen to reduce burdens, offer interesting experience, and not threaten workers' autonomy or security. Workers need to see advantages to them of their involvement in the change.
4. Create an environment of open, supportive communication. If participants experience support and trust, there will be less resistance. Misunderstandings and conflicts should be expected as natural to the innovation process. Adequate provision should be made for clarification and communication.
5. Allow for flexibility. Resistance is reduced if a project is open to revision and reconsideration based on experience.

5. MEASUREMENT AND EVALUATION OF JOB AND TEAM DESIGN

5.1. Using Questionnaires to Evaluate Job and Team Design

One easy and versatile way to measure job design is by using questionnaires or checklists. Job design can then be defined from an operational point of view as "a set of dimensions of jobs that can be used to describe all jobs, regardless of job content, which influence a wide range of benefits and costs for both the organization and the employee." This method of measuring job-design is also highlighted because it has been used widely in research on job design, especially on the motivational approach.

Several questionnaires exist for measuring the motivational approach to job design (Hackman and Oldham 1980; Sims et al. 1976). Only one questionnaire has been developed that measures all four approaches to job design. A version of that questionnaire is presented in Table 2. It is called the multimethod job-design questionnaire (MJDQ) because of its interdisciplinary emphasis. It yields an evaluation of the quality of a job's design based on each of the four approaches. Table 2 also includes a rating scale so that it can simply be copied and used without being retyped.

Table 7 presents a scale that can be used to measure team-design characteristics. It can be used to evaluate input and process characteristics of teams. Background information and examples of the use of this measure can be found by Campion et al. (1993 1996).

Questionnaires may be used in several different contexts:

1. When designing new jobs. When a job does not yet exist, the questionnaire is used to evaluate proposed job descriptions, workstations, equipment, and so on. In this role, it often serves as a simple design checklist.
2. When redesigning existing jobs. When a job exists, there is a much greater wealth of information. Questionnaires can be completed by incumbents, managers, and engineers. Questionnaires can be used to measure job design before and after changes are made and to evaluate proposed changes.

TABLE 7 Team-Design Measure

Instructions: This questionnaire contains statements about your team and how your team functions as a group. Please indicate the extent to which each statement describes your team by circling a number to the right of each statement.

Please use the following scale:
(5) Strongly agree
(4) Agree
(3) Neither agree nor disagree
(2) Disagree
(1) Strongly disagree
( ) Leave blank if do not know or not applicable

Self-Management					
1. The members of my team are responsible for determining the methods, procedures, and schedules with which the work gets done.	1	2	3	4	5
2. My team, rather than my manager, decides who does what tasks within the team.	1	2	3	4	5
3. Most work-related decisions are made by the members of my team rather than by my manager.	1	2	3	4	5
Participation					
4. As a member of a team, I have a real say in how the team carries out its work.	1	2	3	4	5
5. Most members of my team get a chance to participate in decision making.	1	2	3	4	5
6. My team is designed to let everyone participate in decision making.	1	2	3	4	5
Task Variety					
7. Most members of my team get a chance to learn the different tasks the team performs.	1	2	3	4	5
8. Most everyone on my team gets a chance to do the more interesting tasks.	1	2	3	4	5
9. Task assignments often change from day to day to meet the workload needs of the team.	1	2	3	4	5
Task Significance (Importance)					
10. The work performed by my team is important to the customers in my area.	1	2	3	4	5
11. My team makes an important contribution to serving the company's customers.	1	2	3	4	5
12. My team helps me feel that my work is important to the company,	1	2	3	4	5
Task Identity (Mission)					
13. The team concept allows all the work on a given product to be completed by the same set of people.	1	2	3	4	5
14. My team is responsible for all aspects of a product for its area.	1	2	3	4	5
15. My team is responsible for its own unique area or segment of the business.	1	2	3	4	5
Task Interdependence					
16. I cannot accomplish my tasks without information or materials from other members of my team.	1	2	3	4	5
17. Other members of my team depend on me for information or materials needed to perform their tasks.	1	2	3	4	5
18. Within my team, jobs performed by team members are related to one another.	1	2	3	4	5
19. My work goals come directly from the goals of my team.	1	2	3	4	5
20. My work activities on any given day are determined by my team's goals for that day.	1	2	3	4	5
21. I do very few activities on my job that are not related to the goals of my team.	1	2	3	4	5
Interdependent Feedback and Rewards					
22. Feedback about how well I am doing my job comes primarily from information about how well the entire team is doing.	1	2	3	4	5
23. My performance evaluation is strongly influenced by how well my team performs.	1	2	3	4	5
24. Many rewards from my job (pay, promotion, etc.) are determined in large part by my contributions as a team member.	1	2	3	4	5

TABLE 7 (*Continued*)

Heterogeneity (Membership)					
25. The members of my team vary widely in their areas of expertise.	1	2	3	4	5
26. The members of my team have a variety of different backgrounds and experience.	1	2	3	4	5
27. The members of my team have skills and abilities that complement each other.	1	2	3	4	5
Flexibility					
28. Most members of my team know each other's jobs.	1	2	3	4	5
29. It is easy for the members of my team to fill in for one another.	1	2	3	4	5
30. My team is very flexible in terms of membership.	1	2	3	4	5
Relative Size					
31. The number of people in my team is too small for the work to be accomplished. (Reverse score)	1	2	3	4	5
Preference for Team Work					
32. If given the choice, I would prefer to work as part of a team than work alone.	1	2	3	4	5
33. I find that working as a member of a team increased my ability to perform effectively.	1	2	3	4	5
34. I generally prefer to work as part of a team.	1	2	3	4	5
Training					
35. The company provides adequate technical training for my team.	1	2	3	4	5
36. The company provides adequate quality and customer service training for my team.	1	2	3	4	5
37. The company provides adequate team skills training for my team (communication, organization, interpersonal relationships, etc.).	1	2	3	4	5
Managerial Support					
38. Higher management in the company supports the concept of teams.	1	2	3	4	5
39. My manager supports the concept of teams.	1	2	3	4	5
Communication/Cooperation between Work Groups					
40. I frequently talk to other people in the company besides the people on my team.	1	2	3	4	5
41. There is little competition between my team and other teams in the company.	1	2	3	4	5
42. Teams in the company cooperate to get the work done.	1	2	3	4	5
Potency (Team Spirit)					
43. Members of my team have great confidence that the team can perform effectively.	1	2	3	4	5
44. My team can take on nearly any task and complete it.	1	2	3	4	5
45. My team has a lot of team spirit.	1	2	3	4	5
Social Support					
46. Being in my team gives me the opportunity to provide support to other team members.	1	2	3	4	5
47. My team increases my opportunities for positive social interaction.	1	2	3	4	5
48. Members of my team help each other out at work when needed.	1	2	3	4	5
Workload Sharing					
49. Everyone on my team does their fair share of the work.	1	2	3	4	5
50. No one in my team depends on other team members to do their work for them.	1	2	3	4	5
51. Nearly all the members of my team contribute equally to the work.	1	2	3	4	5
Communication/Cooperation with the Work Group					
52. Members of my team are very willing to share information with other team members about our work.	1	2	3	4	5
53. Teams enhance the communications among people working on the same product.	1	2	3	4	5
54. Members of my team cooperate to get the work done.	1	2	3	4	5

Adapted from Campion et al. (1993). Scores for each preference/tolerance are calculated by averaging applicable items. Adapted with permission of Personnel Psychology, Inc.

3. When diagnosing problem jobs. When problems occur, regardless of the apparent source of the problem, the job-design questionnaire can be used as a diagnostic device to determine whether any problems exist with the design of the jobs.

The administration of questionnaires can be conducted in a variety of ways. Employees can complete them individually at their convenience at their workstation or some other designated area, or they can complete them in a group setting. Group settings allow greater standardization of instructions and provide the opportunity to answer questions and clarify ambiguities. Managers and engineers can also complete the questionnaires either individually or in a group session. Engineers and analysts usually find that observation of the job site, examination of the equipment and procedures, and discussions with any incumbents or managers are important methods of gaining information on the job before completing the questionnaires.

Scoring for each job-design approach is usually accomplished by simply averaging the applicable items. Then the scores from different incumbents, managers, or engineers are combined by averaging (Campion 1988; Campion and McClelland 1991). The implicit assumption is that slight differences among respondents are to be expected because of legitimate differences in viewpoint. However, the absolute differences in scores should be examined on an item-by-item basis, and large discrepancies (e.g., more than one point) should be discussed to clarify possible differences in interpretation. It is often useful to discuss each item until a consensus group rating is reached.

The higher the score on a particular job-design scale, the better the quality of the design of the job based on that approach. Likewise, the higher the score on a particular item, the better the design of the job on that dimension. How high a score is needed or necessary cannot be stated in isolation. Some jobs are naturally higher or lower on the various approaches as described previously, and there may be limits to the potential of some jobs. The scores have most value in comparing jobs or alternative job designs rather than evaluating the absolute level of the quality of job design. However, a simple rule of thumb is that if the score for an approach is smaller than three, the job is poorly designed on that approach and should be reconsidered. Even if the average score on an approach is greater than three, examine any individual item scores that are at two or one.

5.2. Choosing Sources of Data

1. Incumbents. Incumbents are probably the best source of information if there is an existing job. In the area of job analysis, incumbents are considered subject matter experts on the content of their jobs. Also, having input into the job design can enhance the likelihood that suggested changes will be accepted. Involvement in such work-related decisions can enhance feelings of participation, thus increasing motivational job design in itself (see item 22 of the motivational scale in Table 2). One should include a large number of incumbents for each job because there can be slight differences in perceptions of the same job due to individual differences. Evidence suggests that one should include all incumbents or at least 10 incumbents for each job (Campion 1988; Campion and McClelland 1991).
2. Managers or supervisors. First-level managers or supervisors may be the next-most knowledgeable persons about an existing job. They may also provide information on jobs under development if they have insight into the jobs through involvement in the development process. Differences in perceptions of the same job among managers should be smaller than among incumbents, but slight differences will exist and multiple managers should be used. Evidence suggests that one should include all managers with knowledge of the job or at least three to five managers for each job (Campion 1988; Campion and McClelland 1991).
3. Engineers or analysts. Engineers, if the job has not been developed yet, may be the only source of information because they are the only ones with insight into what the job will eventually look like. But also for existing jobs, an outside perspective by an engineer, analyst, or consultant may provide a more objective viewpoint. Again, there can be small differences among engineers, so at least two to five should evaluate each job (Campion and Thayer 1985; Campion and McClelland 1991).

5.3. Evaluating Long-Term Effects and Potential Biases

It is important to recognize that some of the effects of job design may not be immediate, others may not be long lasting, and still others may not be obvious. The research has not tended to address these issues directly. In fact, these effects are offered here as potential explanations for some of the inconsistent findings in the literature. The purpose is to simply put the reader on the alert for the possibility of these effects.

Initially when jobs are designed and employees are new, or right after jobs are redesigned, there may be a short-term period of positive attitudes (often called a ''honeymoon effect''). As the legendary Hawthorne studies indicated, often changes in jobs or increased attention given to workers tends to create novel stimulation and positive attitudes (Mayo 1933). Such transitory elevations in affect should not be mistaken for long-term improvements in satisfaction, as they may wear off over

time. In fact, with time the employees may realize that the job is now more important or bigger and should require higher compensation (Campion and Berger 1990). These are only examples to illustrate how dissipating and lagged effects might occur.

Likely candidates for costs that may lag in time include compensation, as noted. Stress and fatigue may also take a while to build up if a job's mental demands have been increased excessively, and boredom may take a while to set in after a job's mental demands have been overly decreased. In terms of lagged benefits, productivity and quality are likely to improve with practice and learning on the new job. And some benefits, like reduced turnover, simply take a period of time to estimate accurately.

Benefits that may potentially dissipate with time include satisfaction, especially if the elevated satisfaction is a function of novelty rather than basic changes to the motivating value of the job. Short-term increases in productivity due to heightened effort rather than better design may not last over time. Costs that may dissipate include the training requirements and staffing difficulties. Once the jobs are staffed and everyone is trained, these costs disappear until turnover occurs. So these costs will not go away completely, but they may be less after initial start-up. Dissipating heightened satisfaction but long-term increases in productivity were observed in a recent motivational job-redesign study (Griffin 1989).

Another potential effect that may confuse the proper evaluation of the benefits and costs of job-design is spillover. Laboratory research has shown that job satisfaction can bias employees' perceptions of the motivational value of their jobs (O'Reilly et al. 1980). Likewise, the level of morale in the organization can have a spillover effect onto employees' perceptions of job design in applied settings. If morale is particularly high, it may have an elevating effect on how employees view their jobs; conversely, low morale may have a depressing effect on employees' views. The term *morale* refers to the general level of job satisfaction across employees, and it may be a function of many factors, including management, working conditions, and wages. Another factor included that has an especially strong effect on employee reactions to job-design changes is employment security. Obviously, employee enthusiasm for job-design changes will be negative if they view them as potentially decreasing their job security, and every effort should be made to eliminate these fears. The best method of addressing these effects is to be attentive to their potential existence and conduct longitudinal evaluations of job design.

5.4. Example of an Evaluation of a Job Design

One study is briefly described here as an illustration of a job-redesign project (Campion and McClelland 1991). It best illustrates the evaluation component of redesign and the value of considering both potential benefits and costs, rather than the implementation and process components of redesign. The setting was a large financial services company. The unit under study processed the paperwork in support of other units that sold the company's products. Jobs were designed in a mechanistic manner in that separate employees prepared, sorted, coded, computer keyed, and performed other specific functions on the paper flow.

The organization viewed the jobs as perhaps too mechanistically designed. Guided by the motivational approach, the project intended to enlarge jobs by combining existing jobs. In so doing, the organization hoped to attain three objectives. First, larger jobs might enhance motivation and satisfaction of employees. Second, larger jobs might increase incumbent feelings of ownership of the work, thus increasing customer service. Third, management recognized that there might be potential costs of enlarged jobs in terms of lost efficiency, and thus every attempt was made to maintain (i.e., avoid decreased) productivity.

As indicated by the third objective, the study considered the consequences of the redesign in terms of all approaches to job design. It was anticipated that the project would increase motivational consequences, decrease mechanistic and perceptual/motor consequences, and have no effect on biological consequences (Table 1).

The evaluation consisted of collecting detailed data on job design and a broad spectrum of potential benefits and costs of enlarged jobs. The research strategy involved comparing several varieties of enlarged jobs with each other and with unenlarged jobs. Questionnaire data were collected and focus group meetings were conducted with incumbents, managers, and analysts. The study was repeated at five different geographic sites.

Results indicated that enlarged jobs had the benefits of more employee satisfaction, less boredom, better quality, and better customer service; but they also had the costs of slightly higher training, skill, and compensation requirements. Another finding was that all the potential costs of enlarging jobs were not observed, suggesting that redesign can lead to benefits without incurring every cost in a one-to-one fashion. Finally, the study revealed several improvements to the enlarged jobs.

5.5. Example of an Evaluation of a Team Design

This illustration demonstrates the use of multiple sources of data and multiple types of team-effectiveness outcomes. The setting was the same financial services company as in the job-design

evaluation above. Questionnaires based on Table 7 were administered to 391 clerical employees and 70 managers on 80 teams (Campion et al. 1993) and to 357 professional workers on 60 teams (Campion et al. 1996) to measure teams' design characteristics. Thus, two sources of data were used, both team members and managers, to measure the team-design characteristics.

In both studies, effectiveness outcomes included the organization's satisfaction survey, which had been administered at a different time than the team-design characteristics questionnaire, and managers' judgments of team effectiveness. In the first study, several months of records of teams' productivity were also used to measure effectiveness. In the second study, employees' judgments of team effectiveness, managers' judgments of team effectiveness measured three months after the first managers' judgements measure, and the average of team members' most recent performance ratings were also used as outcome measures.

Results indicated that all of the team-design characteristics had positive relationships with at least some of the outcomes. Relationships were strongest for process characteristics. Results also indicated that when teams were well designed according to the team-design approach, they were higher on both employee satisfaction and team-effectiveness ratings.

One final cautionary note regarding evaluation. Different sources (e.g., incumbents, managers) provide different perspectives and should always be included. Collecting data from a single source could lead one to draw different conclusions about a project than if one obtains a broader picture of results by using multiple sources of data.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

Why is it that Sam Jones, engineer, makes more money than Ann Banks, who is also an engineer in the same company? Is this an example of sex discrimination in wages? What if we were also to report that Ann Banks makes more money in her engineering job than Ted Adams, an entry-level programmer? Would this lessen your suspicions about the wage-setting practices of our fictitious company? If your response is one of uncertainty, then you probably recognize that several factors need to be considered in determining wages for individuals. First, any wages paid to employees should satisfy an internal consistency criterion. Jobs *inside an organization* are compared to a set of standards and each other to determine their relative contributions to the organization's objectives. To satisfy employee expectations about fairness, more valuable jobs should receive higher ''scores'' in the comparison process. In our example above, internal consistency triggers the question: How does the work of an engineer compare with that of an entry-level computer programmer? The second wage-determination factor is external competitiveness. Wages for jobs inside an organization should be compared against *wages outside the organization paid by competitors.* How much do other employers pay engineers, and how much do we wish to pay our engineers in comparison to what other employers would pay them? Finally, wages are also a function of the distinctive contributions that individual employees make on their jobs. The level of individual contributions depends on an assessment of *performance and/or seniority of people doing the same job or possessing the same job skills.* Before we jump to the conclusion that Sam Jones should not be making more than Ann Banks because they both are engineers, we must first assess whether their individual contributions have been identical. The pay differential may be warranted if Sam consistently performs better than Ann or if he has more seniority.

Of these three factors affecting wages, this chapter concentrates on only one: the process of determining internal consistency. Specifically, we focus on ways that organizations compare jobs in terms of their relative contributions to the goals of the firm. To the extent this process of ensuring internal consistency is successful, several positive outcomes can be expected. Research suggests that internal consistency may improve both employee satisfaction and performance (Lawler 1986). Alternatively, a lack of internal consistency can lead to turnover, grievances and decreased motivation (Livernash 1957). Without a fair structure, employees may resent the employer, resist change, become depressed, and ''lack that zest and enthusiasm which makes for high efficiency and personal satisfaction in work'' (Jacques 1961).

The first stage in determining the relative worth of jobs is to assess what the content of these jobs is! This process, as described elsewhere in this Handbook, is called job analysis. A job analyst is charged with the responsibility of acquiring valid (relevant) and reliable (consistent) information about the contents and requirements of jobs. The information obtained through job analysis is usually codified and documented in a job description. It provides a foundation for various human resource management functions, such as establishing selection criteria, setting performance standards, and determining compensation. For our purposes here, the most important function of job analysis is to provide input information into determining the relative worth of jobs within an organization. This process of systematically comparing the contents and requirements of jobs to determine their relative worth (rank ordering) within the organization is called job evaluation. One of the outcomes of this evaluation process is usually a hierarchy of jobs arranged from most valuable to least valuable.

The resulting job structure can be used as a guide in setting pay rates. For the rates to be equitable, jobs that are higher in the structure should be paid more than jobs that are lower in the job structure. This is an important point! Even though this chapter focuses primarily on the ways that organizations determine the relative value (i.e., compared to each other) of jobs, at some point a comparison must be made to external market wages. This external comparison may be the source of an important conflict. Occasionally, jobs that are similar in worth to the organization may be dissimilar in price in the labor market! Suppose, for example, that for a particular organization ''skill'' and ''effort'' are judged by top management to be equally important in achieving corporate objectives. Some jobs in that organization may require more skill than effort and other jobs may require more effort than skill.

These jobs will nonetheless be valued similarly in the job structure. The market rates for these jobs, however, may be quite different. Other organizations may not value skill and effort equally. Or perhaps market supply is lower and market demand is higher for people capable of performing the skilled jobs, resulting in higher market wages for the ''skill'' jobs relative to the ''effort'' jobs. Thus, for the organization to attract the most qualified workers, it may have to offer wages that are higher than it would offer on the basis of internal consistency alone.

The balance between internal consistency and external competitiveness is a key issue in any employer's compensation strategy. One firm may emphasize an integrated approach to all human resource management, and internal consistency of pay would be part of that strategy. If so, there would be a relatively close correspondence between its job structure and its pay structure. Another firm may emphasize the relationship between its pay level and pay levels in the labor market. In this firm, there may not be as close a correspondence between the company's job structure, as originally determined through job evaluation, and its pay structure. Indeed, as we shall discover, the firm may not even systematically develop a job structure through job evaluation, choosing rather to adopt the external market's evaluation of jobs (i.e., adopt wholesale the market rate without considering internal worth).

This tension between value as assessed within an organization and value as assessed by competitors in the external labor market is but one of several conflicts that may arise in deciding on wages for jobs. Indeed, other ''actors'' have also influenced the wage-determination process.

1.1. The Influence of Society and Its Values on Job Evaluation

In some societies, at different times through history, egalitarian value systems have been adopted by entire countries. An egalitarian philosophy implies a belief that all workers should be treated equally (Matthew 20.1–16). To some extent, this philosophy underlies the job-evaluation process in those remaining countries that can be classified as communist or socialist. Although some differentials do exist across different jobs, the size of these differentials is much smaller than if this societal influence were not present. Given the recent movement toward capitalism around the world, it is evident that an egalitarian policy may not continue to exert a strong influence over the valuation of jobs.

A second example of societal impacts on wage determination is illustrated by the ''just wage'' doctrine (Cartter 1959). In the 13th century, skilled artisans and craftsmen began to prosper at the expense of nobles and landowners by selling goods and services to the highest bidders. The church and state reacted by proclaiming a schedule of ''just wages'' that tended to reflect that society's class structure and that were consistent with the prevailing notion of birthrights. In essence, the policy explicitly denied economic factors as appropriate determinants of pay.

The proliferation of computers and accompanying information explosion in the recent past has forever changed the way work is done. Not surprisingly, countless companies (like Bayer) have been forced to make ''retain, reject, or redesign'' decisions about their job-evaluation systems. Most have chosen the redesign option in order to keep the values that have made them so successful but incorporate their new perspectives regarding employee autonomy, teamwork, responsibility, and the like (Laabs 1997). Sometimes referred to as competencies or value driver, job characteristics such as leadership required and customer impact are beginning to form the basis for a whole new set of compensable factors (Kanin-Lovers et al. 1995; McLagan 1997).

1.2. The Influence of Individuals on Job Evaluation

Normally great pains are taken to ensure that position evaluation is kept entirely independent from person evaluation (i.e., job evaluation is kept distinct from performance evaluation, which involves the evaluation of individuals as they perform jobs). Seasoned job evaluators counsel novices to determine the worth of a job independent of its incumbent. The focus should always be on the work, not the worker. After all, a job is relatively stable, whereas the person holding that job may change regularly. For the purposes of determining job worth, individuals are viewed as interchangeable. To deal with the distinction between job and person value, organizations traditionally have set upper and lower limits on job worth (called pay grade minimums and pay grade maximums) and allowed salary to fluctuate within that grade as a function of individual performance or worth.

For certain jobs, though, the worth of the job is inextricably linked to the incumbent performing the job (Pierson 1983). This exception is particularly evident for managerial and executive positions. The person's unique abilities and knowledge may shape the job. For these jobs, the relative importance of the individual occupying the job leads to increased emphasis on personal attributes in job valuation. The top jobs in almost any organization seem to be designed more around the talents and experience of the individuals involved than around any rigidly defined duties and responsibilities. For professional workers, too, the nature of their work and the knowledge they bring to the task may make it difficult to distinguish job worth from individual worth. Thus, for professionals such as scientists or engineers, pay may reflect individual attributes, accomplishments, or credentials (i.e., a B.S. in Chemistry, a Ph.D. in Engineering).

2. TRADITIONAL JOB EVALUATION

The traditional way to value jobs involves a mix of internal organizational factors as well as external market conditions in setting pay rates. Various job-evaluation techniques have evolved different strategies for incorporating both of these essential influences into the wage-setting process.

In spite of the long-standing existence and recent expansion of some alternative individual (such as commissions and bonuses), market-based (free agent auctions), and parsimonious (delayering and broadbanding) compensation schemes, formal job evaluation continues to stand the test of time. Like the employment interview, which has been criticized harshly but still is most useful, job evaluation has been accused of being "a barrier to excellence" and "an institutional myth" (Emerson 1991; Quaid 1993). Nevertheless, it, too, remains as an essential building block for human resource management. In fact, over 70% of the organizations in this country are estimated to use job evaluation (Bureau of National Affairs 1976).

As noted in the following sections, for both the ranking method and the factor comparison method, external and internal factors are incorporated throughout the job-evaluation process. In the classification method and the point method, internal factors and external factors are considered separately at first and are later reconciled with each other. In the point method, for example, point totals denoting relative internal worth can be reconciled with market data through statistical procedures such as regression analysis.

Determining which of the job-evaluation processes (outlined in the pages that follow) provides the best fit for a given organization depends on numerous considerations. One may be more appropriate than the other, but there is no one best scheme (Fowler 1996).

2.1. Ranking Method

Ranking simply involves ordering the job descriptions from highest to lowest based on a predetermined definition of value or contribution. Three ways of ranking are usually considered: simple ranking, alternation ranking, and paired comparison ranking. Simple ranking requires that evaluators order or rank jobs according to their overall value to the organization. Alternation ranking involves ordering the job descriptions alternately at each extreme (e.g., as shown in Figure 1).

Agreement is reached among evaluators on which job is the most valuable, then the least valuable. Job evaluators alternate between the next most valued and next-least valued, and so on, until all the jobs have been ordered. For example, evaluators agreed that the job of master welder was the most valued of the six jobs listed above and receiving clerk was the least valued. Then they selected most and least valued jobs from the four remaining titles on the list. After this, a final determination would be made between the last two jobs.

The paired comparison method involves comparing all possible pairs of jobs under study. A simple way to do paired comparison is to set up a matrix, as shown in Figure 2.

The higher-ranked job is entered in the cell. For example, of the shear operator and the electrician, the electrician is ranked higher. Of the shear operator and the punch press operator, the shear operator is ranked higher. When all comparisons have been completed, the job with the highest tally of "most valuable" rankings (the biggest winner) becomes the highest-ranked job, and so on. Some evidence suggests that the alternation ranking and paired comparison methods are more reliable (produce similar results more consistently) than simple ranking (Chesler 1948).

Caution is required if ranking is chosen. The criteria or factors on which the jobs are ranked are usually so poorly defined (if they are specified at all) that the evaluations become subjective opinions

Jobs		*Rank*
Number	*Title*	*Most valued*
1	Shear operator	Master welder
2	Electrician	Electrician
3	Punch press operator	
4	Master welder	
5	Grinder	
6	Receiving clerk	Receiving clerk
		Least valued

Figure 1 Alternation Ranking.

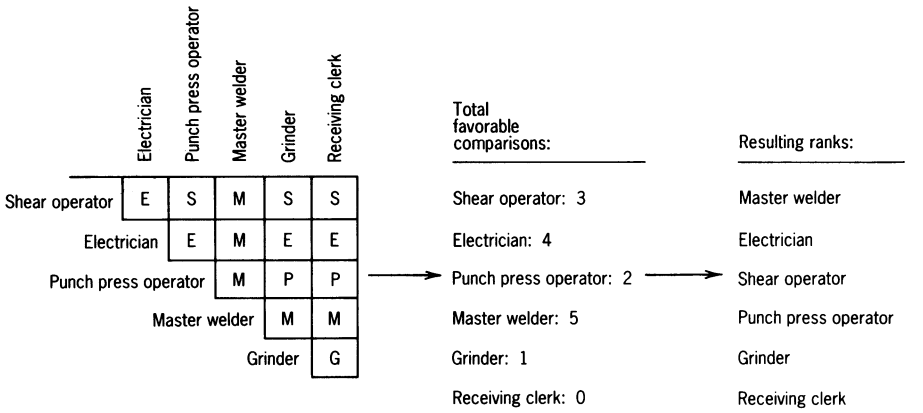

Figure 2 Paired Comparison Ranking. (From Milkovich and Newman 1993)

that are difficult, if not impossible, to explain and justify in work-related terms. Further, evaluators using this method must be knowledgeable about every single job under study. And as the organization changes, it is difficult to retain command of all this job information. Even if such a person exists, the sheer number of rankings to complete becomes onerous, if not impossible. For example, using the paired comparison process where 50 jobs are involved requires $(n)(n-1)/2 = 1225$ comparisons. Some organizations try to overcome these difficulties by ranking jobs within single departments and merging the results. However, without greater specification of the factors on which the rankings are based, merging ranks is a major problem.

2.2. Classification Method

The classification method has been in use for over 100 years. It originated as a technique to reform abuses in hiring and paying government workers. Variations of the classification method are still widely used by public-sector employers. The basic procedure is simple: create a set of job categories and sort jobs into them. The categories should be conceived such that jobs that fall into the same category are more similar to each other than to any jobs in other categories. Then, for pay purposes, jobs are treated equally within each category and are treated differently across categories.

Each category is defined by a *class description*. For example, the federal government classification method describes grade 1 as all classes of positions the duties of which are to be performed under immediate supervision, with little or no latitude for the exercise of independent judgment, (1) the simplest routine work in office, business, or fiscal operations, or (2) elementary work of a subordinate technical character in a professional, scientific, or technical field. These class descriptions should be detailed enough to differentiate jobs but general enough to make it fairly easy to slot jobs. While detailed class descriptions make some evaluations more consistent, they can limit the variety of jobs that can readily be classified. It would be difficult, for example, to slot clerical jobs into classes created with sales jobs in mind.

Job classes can be made more concrete by anchoring them with benchmark jobs. For a job to be used as a benchmark, it must be commonly known, relatively stable in content, and perceived to be paid fairly. Where feasible, there should be at least one benchmark job for each job class.

The appropriate number of job classes depends on the diversity of jobs and on promotion paths. A common rule of thumb is 7 to 14 classes (Belcher 1974). Some argue for having many classes, saying that employees favor frequent advancement to higher grades. Today, however, prevailing opinion argues for having fewer classes, saying that it reduces needless bureaucracy.

A problem with the classification method is that it provides incentive for incumbents to "aggrandize" a job title to get it into a higher classification. This may seem appropriate to a manager whose immediate concern is to secure a pay raise for a subordinate; but others may see it as underhanded, and it may even lead to a pay discrimination lawsuit.

2.3. Factor Comparison Method

In the factor comparison method, jobs are evaluated based on two criteria: (1) a set of compensable factors and (2) wages for a select group of benchmark jobs. The two criteria are combined to form a job-comparison scale, which is then applied to nonbenchmark jobs. Unfortunately, the method's

complexity often limits its usefulness (Benge et al. 1941). A simplified explanation of this method would include the following steps:

2.3.1. Conduct Job Analysis

As with all job-evaluation methods, information about the jobs must be collected and job descriptions prepared. The Factor Comparison Method differs, however, in that it requires that jobs be analyzed and described in terms of the compensable factors used in the plan. The originators of the method, Benge et al. (1941), prescribed five factors: mental requirements, skill requirements, physical factors, responsibility, and working conditions. They considered these factors to be universal (applicable to all jobs in all organizations) but allowed some latitude in the specific definition of each factor among organizations.

2.3.2. Select Benchmark Jobs

The selection of benchmark jobs is critical because the entire method is based on them. Benchmark jobs (also called key jobs) serve as reference points. The exact number of benchmarks required varies; some rules of thumb have been suggested (15 to 25), but the number depends on the range and diversity of the work to be evaluated.

2.3.3. Rank Benchmark Jobs on Each Factor

Each benchmark job is ranked on each compensable factor. In Table 1, a job family consisting of six jobs is first ranked on mental requirements (rank of 1 is highest), then on experience/skills, and so on.

This approach differs from the straight ranking plan in that each job is ranked on each factor rather than as a whole job.

2.3.4. Allocate Benchmark Wages across Factors

Once each benchmark job is ranked on each factor, the next step is to allocate the current wages paid for each benchmark job among the compensable factors. Essentially, this is done by deciding how much of the wage rate for each benchmark job is associated with mental demands, how much with physical requirements, and so on, across all the compensable factors. This is done for each benchmark job and is usually based on the judgment of a compensation committee. For example, in Table 2, of the $5.80 per hour paid to the punch press operator, the committee had decided that $0.80 of it is attributable to the job's mental requirements, another $0.80 is attributable to the job's experience/skill requirements, $2.40 is attributable to the job's physical requirements, $1.10 is attributable to the job's supervisory requirements, and $0.70 is attributable to the job's other responsibilities. The total $5.80 is thus allocated among the compensable factors. This process is repeated for each of the benchmark jobs.

After the wage for each job is allocated among that job's compensable factors, the dollar amounts for each factor are ranked. The job that has the highest wage allocation for mental requirements is ranked 1 on that factor, next highest is 2, and so on. Separate rankings are done for the wage allocated to each compensable factor. In Table 3, the parts-inspector position has more of its wages allocated to mental demands than does any other job and so it receives the highest rank for that factor.

There are now two sets of rankings. The first ranking is based on comparisons of each benchmark job on each compensable factor. It reflects the relative presence of each factor among the benchmark jobs. The second ranking is based on the proportion of each job's wages that is attributed to each factor. The next step is to see how well the two rankings agree.

TABLE 1 Factor Comparison Method: Ranking Benchmark Jobs by Compensable Factors[a]

Benchmark Jobs	Mental Requirements	Experience/ Skills	Physical Factors	Supervision	Other Responsibilities
A. Punch press operator	6	5	2	4	4
B. Parts attendant	5	3	3	6	1
C. Riveter	4	6	1	1	3
D. Truck operator	3	1	6	5	6
E. Machine operator	2	2	4	2	5
F. Parts inspector	1	3	5	3	2

[a] Rank of 1 is high.

2.3.5. Compare Factor and Wage-Allocation Ranks

The two rankings are judgments based on comparisons of compensable factors and wage distributions. They agree when each benchmark is assigned the same location in both ranks. If there is disagreement, the rationale for the wage allocations and factor rankings is reexamined. Both are judgments, so some slight tuning or adjustments may bring the rankings into line. The comparison of the two rankings is simply a cross-checking of judgments. If agreement cannot be achieved, then the job is no longer considered a benchmark and is removed.

2.3.6. Construct Job Comparison Scale

Constructing a job-comparison scale involves slotting benchmark jobs into a scale for each factor based on the amount of pay assigned to each factor. Such a scale is illustrated in Figure 3. Under mental requirements, the punch press operator is slotted at \$0.80, the parts attendant at \$2.15, and so on. These slottings correspond to the wage allocations shown in Figure 3.

2.3.7. Apply the Scale

The job-comparison scale is the mechanism used to evaluate the remaining jobs. All the nonbenchmark jobs are now slotted into the scales under each factor at the dollar value thought to be appro-

$ Value	Mental requirements	Experience/ skills	Physical demands	Supervision	Other responsibilities
.00					
.20			Truck operator	Parts attendant	Truck operator
.40					Machine operator
.60					Punch press operator

priate. This is done by comparing the factors in the job descriptions of nonbenchmark jobs with the factors in the reference points. Consider the position of parts stocker, a nonbenchmark job. The evaluator reads the stocker job description, examines the first compensable factor on the job comparison scale (mental requirements), and locates two benchmark jobs between which the mental requirements of the stocker job rank. After examining the job descriptions for punch press operator and parts attendant the stocker job might be judged to require greater mental demands than those required for the punch press operator but less than those for the parts attendant and might be slotted at a rate of $1.40 for mental requirements. The final worth of each job is derived from a summation of the dollars allocated to the job across all compensable factors.

Historically, only about 10% of employers using formal job evaluations have used the factor comparison approach (Nash and Carroll 1975). The method is complex and difficult to explain, particularly to employees who are dissatisfied with the final ranking their job achieves. In addition, as the agreed-upon wage rates of the benchmark jobs change, the relationships among the jobs may change, and the allocation of the wages among the factors must be readjusted. So continuous updating is required.

In spite of these difficulties, the factor comparison approach represents a significant improvement over simple ranking and classification. First, the criteria for evaluating jobs (i.e., the compensable factors) are agreed upon and made explicit. Second, the use of existing wage rates of benchmark jobs as one of the criteria for designing and explaining the pay structure is unique. In a sense, factor comparison more systematically links external market forces with internal, work-related factors. Finally, in the factor comparison approach, we see the use of a scale of degrees of worth (dollars) for each compensable factor in the job-comparison scale.

These three features—defining compensable factors, scaling the factors, and linking an agreed-upon wage structure with the compensable factors—are also the basic building blocks on which point plans are based.

2.4. Point Method

Like factor comparison, designing a point system is rather complex and often requires outside assistance by consultants. But once designed, the plan is relatively simple to understand and administer, which accounts for its widespread use. Indeed, it is the system used by the vast majority of companies in this country (Milkovich and Newman 1993).

Point methods have three common characteristics: (1) compensable factors, with (2) numerically scaled factor degrees to distinguish different levels within a factor, and (3) weights reflecting the relative importance of each factor.

With the point method, as with all job-evaluation plans, the first step is job analysis. The next steps are to choose the factors, scale them, establish the factor weights, and then evaluate jobs.

2.4.1. Conduct Job Analysis

Information about the jobs to be evaluated is the cornerstone of all job evaluation. While ideally, all jobs will be analyzed, the relevant work content—the behaviors, tasks performed, abilities/skills required, and so on—of a representative sample of jobs forms the basis for deriving compensable factors.

2.4.2. Choose Compensable Factors

Compensable factors play a pivotal role in the point method. In choosing factors, an organization must decide: ''What factors are valued in our jobs? What factors will be paid for in the work we do?'' Compensable factors should possess the following characteristics:

Work Related They must be demonstrably derived from the actual work performed in the organization. Some form of documentation (i.e., job descriptions, job analysis, employee and/or supervisory interviews) must support the factors. Factors that are embedded in a work-related logic can help withstand a variety of challenges to the pay structure. For example, managers often argue that the salaries of their subordinates are too low in comparison to other employees or that the salary offered to a job candidate is too low for the job. Union members may question their leaders about why one job is paid differently from another. Allegations of illegal pay discrimination may be raised. Line managers, union leaders, and compensation specialists must be able to explain differences in pay among jobs. Differences in factors that are work related help provide that rationale. Properly selected factors may even diminish the likelihood of these challenges arising.

Business Related Compensable factors need to be consistent with the organization's culture and values, its business directions, and the nature of the work. Changes in the organization or its business strategies may necessitate changing factors. While major changes in organizations are not daily occurrences, when they do occur, the factors need to be reexamined to ensure that they are consistent with the new circumstances.

Acceptable to the Parties Acceptance of the pay structure by managers and employees is critical. This is also true for the compensable factors used to slot jobs into the pay structure. To achieve acceptance of the factors, all the relevant parties' viewpoints need to be considered.

Discriminable In addition to being work related, business related, and acceptable, compensable factors should have the ability to differentiate among jobs. As part of differentiating among jobs, each factor must be unique from other factors. If two factors overlap in what they assess in jobs, then that area of overlap will contribute disproportionately to total job points, which may bias the results. Factor definitions must also possess clarity of terminology so that all concerned can understand and relate to them.

There are two basic ways to select and define factors: Adapt factors from an existing standard plan or custom design a plan. In practice, most applications fall between these two. Standard plans often are adjusted to meet the unique needs of a particular organization, and many custom-designed plans rely heavily on existing factors. Although a wide variety of factors are used in conventional, standard plans, they tend to fall into four generic groups: skills required, effort required, responsibility, and working conditions. These four were used originally in the National Electrical Manufacturers Association (NEMA) plan in the 1930s and are also included in the Equal Pay Act (1963) to define equal work (Gomberg 1947). The Hay System is perhaps the most widely used (Milkovich and Newman, 1993). The three Hay factors are know-how, problem solving, and accountability (note that Hay Associates does not define its guide chart–profile method as a variation of the point method) (Hay Associates 1981). Adapting factors from existing plans usually involves relying on the judgment of a task force or job evaluation committee. More often than not, the committee is made up of key decision makers (or their representatives) from various functions (or units, such as finance, operations, engineering, and marketing). Approaches vary, but typically it begins with a task force or committee representing key management players. To identify compensable factors involves getting answers to one central question: Based on our operating and strategic objectives, what should we value and pay for in our jobs? Obviously, custom designing factors is time consuming and expensive. The argument in favor of it rests on the premise that these factors are more likely to be work related, business related, and acceptable to the employees involved.

In terms of the optimal number of factors, it is generally recommended to stay below 10 in order to avoid dilution of effect, information overload, and factor redundancy. Five to 7 factors are usually a manageable number to capture the essence of jobs in an organization. With regard to the number of total points to be allocated across the factors, most firms choose either 500 or 1000 points.

2.4.3. Establish Factor Scales

Once the factors to be included in the plan are chosen, scales reflecting the different degrees within each factor are constructed. Each degree may also be anchored by the typical skills, tasks, and behaviors taken from benchmark jobs that illustrate each factor degree. Table 4 shows the National Metal Trade Association's scaling for the factor of knowledge.

Belcher (1974) suggests the following criteria for determining degrees:

1. Limit to the number necessary to distinguish among jobs.
2. Use understandable terminology.
3. Anchor degree definition with benchmark job titles.
4. Make it apparent how the degree applies to the job.

Using too many degrees makes it difficult for evaluators to accurately choose the appropriate degree and may result in a wide variance in total points assigned by different evaluators. The threat this poses to acceptance of the system is all too apparent.

Some plans employ 2D grids to define degrees. For example, in the Hay plan, degrees of the factor know-how are described by four levels of managerial know-how (limited, related, diverse, and comprehensive) and eight levels of technical know-how (ranging from professional mastery through elementary vocational). An evaluator may select among at least 32 (4×8) different combinations of managerial and technical know-how to evaluate a job.

2.4.4. Establish Factor Weights

Once the degrees have been assigned, the factor weights must be determined. Factor weights are important because different weights reflect differences in importance attached to each factor by the employer. There are two basic methods used to establish factor weights: committee judgment and statistical analysis. In the first, a standing compensation committee or a team of employees is asked to allocate 100% of value among the factors. Some structured decision process such as Delphi or other nominal group technique may be used to facilitate consensus (Elizur 1980). For the statistical method, which typically utilizes multiple regression analysis, the weights are empirically derived in

TABLE 4 Illustration of a Compensable Factor Scheme

I. Knowledge

This factor measures the knowledge or equivalent training required to perform the position duties.

First Degree

Use of reading and writing, adding and subtracting of whole numbers; following of instructions; use of fixed gauges, direct reading instruments and similar devices; where interpretation is not required.

Second Degree

Use of addition, subtraction, multiplication, and division of numbers including decimals and fractions; simple use of formulas, charts, tables, drawings, specifications, schedules, wiring diagrams; use of adjustable measuring instruments; checking of reports, forms, records and comparable data; where interpretation is required.

Third Degree

Use of mathematics together with the use of complicated drawings, specifications, charts, tables; various types of precision measuring instruments. Equivalent to 1 to 3 years applied trades training in a particular or specialized occupation.

Fourth Degree

Use of advanced trades mathematics, together with the use of complicated drawings, specifications, charts, tables, handbook formulas; all varieties of precision measuring instruments. Equivalent to complete accredited apprenticeship in a recognized trade, craft, or occupation; or equivalent to a 2-year technical college education.

Fifth Degree

Use of higher mathematics involved in the application of engineering principles and the performance of related practical operations, together with a comprehensive knowledge of the theories and practices of mechanical, electrical, chemical, civil or like engineering field. Equivalent to complete 4 years of technical college or university education.

Source: Milkovich and Newman 1993.

such a way as to correlate as closely as possible to a set of pay rates that is agreed upon by the parties involved (Delbecq et al. 1975). The criterion is usually the pay rate for benchmark jobs, and the predictors are the jobs' degree levels on each of the factors.

Initial results of either the committee judgment or statistical approach for deriving factor weights may not lead to completely satisfactory results. The correspondence between internal value (the job-evaluation results) and the external value (what the market says you should be paying) may not be sufficiently high. Several procedures are commonly used to strengthen this relationship. First, the sample of benchmark jobs may be changed through adding or deleting jobs. Second, the factor degree levels assigned to each benchmark job may be adjusted. Third, the pay structure serving as the criterion may be revised. And finally, the factor-weighting scheme may be modified. Thus, a task force beginning with exactly the same factors and degrees could end up with very different job-evaluation plans, depending on the benchmark jobs used, the pay rates chosen as the criterion, and the method employed to establish the weights.

2.4.5. Evaluate Jobs

To translate weights and factor scales into actual job points, the maximum number of points to be used in the system is first divided among the factors according to their weights. The points for each factor are then attached to that factor's scale. For example, if a factor is weighted 20% in a 500-point system, then a total of 100 points is assigned to this factor; and if there are five degrees on the factor, then each degree is worth 20 points.

In the point method, each job's relative value, and hence its location in the pay structure, is determined by the total points assigned to it. A job's total point value is the sum of the numerical values for each degree of compensable factor that the job possesses. In Table 5, the point plan has four factors: skills required, effort required, responsibility, and working conditions. There are five degrees for each factor.

In addition to factor definitions, the evaluator will be guided by benchmark jobs and written descriptions that illustrate each degree for each respective factor. Thus, the evaluator chooses a degree

TABLE 5 The Point Method of Job Evaluation: Factors, Weights, and Degrees

(3) Weights	(1) Factors	(2) Degrees				
40%	Skills required	1	2	3	4	5
30%	Effort required	1	2	3	4	5
20%	Responsibility	1	2	3	4	5
10%	Working conditions	1	2	3	4	5

Source: Milkovich and Newman 1993.

for each factor according to the correspondence between the job being evaluated and the benchmark jobs or descriptions for each factor scale. Then the ratings are multiplied by the factor weights and the products are summed. In the above example, skills required carries a greater weight (40% of the total points) for this employer than does working conditions (10% of the total points). Thus, a job's 240 total points may result from two degrees of skills required ($2 \times 40 = 80$), three each of effort required ($3 \times 30 = 90$) and responsibility ($3 \times 20 = 60$), and one of working conditions ($1 \times 10 = 10$); ($80 + 90 + 60 + 10 = 240$).

Once the total points for all jobs are computed and a hierarchy based on points established, then jobs are compared to each other to ensure that their relative locations in the hierarchy are acceptable. Almost without fail, certain naturally occurring clusters of jobs will emerge.

2.5. Single-Factor Systems

The premise underlying single-factor approaches is that the job content or value construct is unidimensional. In other words, proponents argue that internal value of jobs can be determined by evaluating them against each other on a single factor, instead of the more traditional 5- to 10-factor systems. The two most widely known single-factor plans are Jaques's time span of discretion (TSD) and Arthur Young's decision banding (Jaques 1970). In time span of discretion, each job is made up of tasks and each task is judged to have an implicit or explicit time before its consequences become evident. Jaques defines TSD as ''the longest period of time in completing an assigned task that employees are expected to exercise discretion with regard to the pace and quality of the work without managerial review'' (Jaques 1964). According to Jaques, TSD is distinct from job evaluation in that it represents measurement (of time units) rather than subjective judgement.

The single factor used in the decision banding method is the decision making required on the job (Patterson and Husband 1970). It identifies and describes six types of decisions that may be required on the job. In order from simplest to most complex, they are: defined, operational, process, interpretive, programming, and policy making. Under this approach, results of job analysis are examined to determine the highest level of decision-making required of the job. Each job is then placed in the corresponding decision band.

Over 50 years ago, Lawshe and others demonstrated that a few factors will yield practically the same results as many factors (Lawshe 1947). Some factors may have overlapping definitions and may fail to account for anything unique in the criterion chosen. In multifactor plans, 3 to 5 factors explained most of the variation in the job hierarchy. In a study conducted 30 years ago, a 21-factor plan produced the same job structure that could be generated using only 7 of the factors. Further, the jobs could be correctly slotted into classes using only 3 factors. Yet the company decided to keep the 21-factor plan because it was ''accepted and doing the job.''

3. OTHER METHODS OF VALUING JOBS

3.1. Market-Based Pay Systems

For every organization, prevailing wages in the labor market will affect compensation. For some jobs and some organizations, market wage levels and ability to pay are virtually the only determinants of compensation levels. An organization in a highly competitive industry may, by necessity, merely price jobs according to what the market dictates. For most companies, however, to take all their jobs (which may number in the hundreds or thousands) and compare them to the market is not realistic. One can only imagine the effort required for a company to conduct and/or participate in wage surveys for thousands of jobs every year. Alternatively, one computer company was able to slot thousands of jobs into 20 pay grades using a version of the point factor method.

Market pricing basically involves setting pay structures almost exclusively through reliance on rates paid in the external market. Employers following such an approach typically match a large percentage of their jobs with market data and collect as much summarized market data as possible. Opting for market pricing usually reflects more of an emphasis on external competitiveness and less of a focus on internal consistency (the relationships among jobs within the firm).

Market pricers often use the ranking method to determine the pay for jobs unique to their firms. Often called rank to market, it involves first determining the competitive rates for positions for which external market data is available and then slotting the remaining (nonbenchmark) jobs into the pay hierarchy. At Pfizer, for example, job analysis results in written job descriptions. This is immediately followed by labor market analysis and market pricing for as many jobs as possible. After that, the internal job relationships are reviewed to be sure they are ''reasonable in light of organization needs.'' The final step is pricing those jobs not included in the survey. These remaining jobs are compared to the survey positions ''in terms of their total value to Pfizer.'' This internal evaluation seeks to ensure consistency with promotion opportunities and to properly reflect ''cross-functional job values'' (e.g., production vs. clerical jobs).

3.2. Knowledge-Based Pay Systems

As we indicated earlier, some organizations consider individual employee characteristics, in accordance with internal organizational factors and external market conditions, in setting pay rates. Increasing foreign and domestic competition and rapid technological change have inspired innovative individual and team pay-for-performance and knowledge- and skill-based pay systems. Such systems are posited to engender (1) greater mutual commitment between individuals and organizations, and (2) stronger linkages between the rewards given to employees and the performance of the organization.

Technically, knowledge-based pay systems do not involve job evaluation. Instead, they are an alternative to systems that do involve job evaluation. Knowledge-based pay systems pay employees based on what they *know* rather than what particular job they are doing (Gupta., et al 1986). Generally, such systems base pay on the depth of knowledge in a particular field (e.g., scientists and teachers) (Luthans and Fox 1989). For instance, all else equal, a sixth-grade teacher with a Master's degree will be paid more than a sixth-grade teacher with a Bachelor's degree under this system.

3.3. Skill-Based Pay Systems

Similarly, skill-based pay systems reward employees for their breadth of knowledge pertaining to different jobs (e.g., proficiency in a number of various production jobs). For instance, if one person could operate machines A, B, and C, she may be paid $15 per hour (even if she only works on machine A all year). Her colleague may be qualified to work on machines A and C, and therefore he would only make $13 per hour (even if he worked on both machines over the course of the year). As can be seen, pay is driven by the quantity of tasks a person is qualified to perform.

The chief advantages of knowledge- and skill-based pay systems are leaner staffs and greater flexibility in scheduling. Advocates claim they benefit employees: job satisfaction increases because employees get a sense of having an impact on the organization, and motivation increases because pay and performance are closely linked. Potential disadvantages include higher pay rates and increased training costs, the administrative burden of maintaining records, the erosion of knowledge/skills if not used, and the challenge of managing an equitable job rotation. These disadvantages may or may not be offset by having a leaner workforce and greater productivity.

4. CREATING THE JOB-EVALUATION SYSTEM

4.1. Implementing Job Evaluation

The major decisions involved in the design and administration of job evaluation include:

1. What are the objectives of job evaluation?
2. Which job-evaluation method should be used?
3. Should a single plan or multiple plans be used?
4. Who should participate in designing the system?

4.2. Specifying the Macro Objectives of Job Evaluation

From a macro standpoint, job evaluation allows an organization to establish a pay structure that is internally equitable to employees and consistent with the goals of the organization. Once an organization decides on its strategic goals and its value system, job evaluation can help to reward jobs in a manner consistent with the strategic mission. For example, organizations in mature industries may decide that continued success depends on greater risk taking amongst employees, particularly in new product development. Compensable factors can be chosen to reinforce risk by valuing more highly those jobs with a strong risk-taking component. Once this emphasis on risk taking is communicated to employees, the first step in reshaping the value system has begun.

Since they guide the design and administration of job evaluation, strategic plans and business objectives need to be clearly and emphatically specified. Unfortunately, these initially established objectives too often get diluted, discarded, or muddled in the midst of all the statistical procedures

performed. Another complication can be the bureaucracy that tends to accompany the administration of job evaluation. Job evaluation sometimes seems to exist for its own sake, rather than as an aid to achieving the organization's mission (Burns 1978). So an organization is best served by initially establishing its objectives for the process and using these objectives as a constant guide for its decisions.

4.3. Specifying the Micro Objectives of Job Evaluation

Some of the more micro objectives associated with job evaluation include:

Help foster equity by integrating pay with a job's contributions to the organization.

Assist employees to adapt to organization changes by improving their understanding of job content and what is valued in their work.

Establish a workable, agreed-upon pay structure.

Simplify and rationalize the pay relationships among jobs, and reduce the role that chance, favoritism, and bias may play.

Aid in setting pay for new, unique, or changing jobs.

Provide an agreed-upon device to reduce and resolve disputes and grievances.

Help ensure that the pay structure is consistent with the relationships among jobs, thereby supporting other human resource programs such as career planning, staffing, and training.

4.4. Choosing the Job-Evaluation Method

Obviously, the organization should adopt a job-evaluation method that is consistent with its job-evaluation objectives. More fundamentally, however, the organization should first decide whether job evaluation is necessary at all. In doing so, it should consider the following questions (Hills 1989):

Does management perceive meaningful differences between jobs?

Can legitimate criteria for distinguishing between jobs be articulated and operationalized?

Will job evaluation result in clear distinctions in employees' eyes?

Are jobs stable and will they remain stable in the future?

Is traditional job evaluation consistent with the organization's goals and strategies?

Do the benefits of job evaluation outweigh its costs?

Can job evaluation help the organization be more competitive?

Many employers design different job-evaluation plans for different job families. They do so because they believe that the work content of various job families is too diverse to be adequately evaluated using the same plan. For example, production jobs may vary in terms of working conditions and the physical skills required. But engineering and marketing jobs do not vary on these factors, nor are those factors particularly important in engineering or marketing work. Rather, other factors such as technical knowledge and skills and the degree of contact with external customers may be relevant. Another category of employees that might warrant special consideration, primarily due to supervisory responsibilities, is management.

The most common criteria for determining different job families include similar knowledge/skill/ability requirements, common licensing requirements, union jurisdiction, and career paths. Those who argue for multiple plans, each with unique compensable factors, claim that different job families have different and unique work characteristics. To design a single set of compensable factors capable of universal application, while technically feasible, risks emphasizing generalized commonalities among jobs and minimizing uniqueness and dissimilarities. Accurately gauging the similarities and dissimilarities in jobs is critical to establish and justify pay differentials. Therefore, more than one plan is often used for adequate evaluation.

Rather than using either a set of company-wide universal factors or entirely different sets of factors for each job family, some employers, such as Hewlett-Packard, start with a core set of common factors, then add other sets of specialized factors unique to particular occupational or functional areas (finance, manufacturing, software and systems, sales, management). These companies' experiences suggest that unique factors tailored to different job families are more likely to be both acceptable to employees and managers and easier to verify as work related than are generalized universal factors.

4.5. Deciding Who Will Participate in the Job Evaluation Process

Who should be involved in designing job evaluation? The choice is usually among compensation professionals, managers, and/or job incumbents. If job evaluation is to be an aid to managers and if

maximizing employee understanding and acceptance is an important objective, then all these groups need to be included.

4.5.1. Compensation/Job-Evaluation Committees

A common approach to gaining acceptance and understanding of pay decisions is through use of a compensation (job-evaluation) committee. Membership on these committees seems to vary among firms. They all include representatives from key operating functions, and increasingly, with the emphasis on employee empowerment, they are including nonmanagerial employees. In some cases, the committee's role is only advisory; in others its approval may be required for all major decisions.

4.5.2. Employee–Manager Participation

Participation in the design and administration of compensation plans seems related to increased trust and commitment on the part of employees and managers. Lack of participation makes it easier for employees and managers to imagine ways the structure might have been rearranged to their personal liking. For example, an operating manager may wish to elevate the job title for a star performer in order to exceed the maximum pay permitted for the existing job title. This is less likely to occur if the people affected by job-evaluation outcomes are involved in the design and administration processes. Some evidence has been found, however, for the assertion that incumbents tend to rate their jobs higher than their supervisors. Hence, there is a need for a system of checks and balances in the process (Huber 1991).

4.5.3. Unions

Management probably will find it advantageous to include union representation as a source of ideas and to help promote acceptance of the results. For example, at both AT&T and Borg-Warner, union–management task forces have participated in the design of new job-evaluation systems. When this occurs, the union joins with management to identify, negotiate, and resolve problems related to the job-evaluation process. As noted below, not everyone buys into this notion of cooperation.

Other union leaders, however, feel that philosophical differences prevent their active participation in job evaluation (Burns 1978). They take the position that collective bargaining yields more equitable results than does job evaluation. In other cases, jobs are jointly evaluated by union and management representatives, and disagreements are submitted to an arbitrator.

5. MAINTAINING THE JOB-EVALUATION SYSTEM

As an administrative procedure, job evaluation invites give and take. Consensus building often requires active participation by all those involved. Employees, union representatives, and managers may be included in discussions about the pay differences across various jobs. Job evaluation even involves negotiations among executives or managers of different units or functions within the same organization. So viewed as an administrative procedure, job evaluation is used for resolving conflicts about pay differences that inevitably arise over time.

5.1. Handling Appeals and Reviews

Once the job structure or structures are established, compensation managers must ensure that they remain equitable. This requires seeing that jobs that employees feel have been incorrectly evaluated are reanalyzed and reevaluated. Likewise, new jobs or those that experience significant changes must be submitted to the evaluation process.

5.2. Training Job Evaluators

Once the job-evaluation system is complete, those who will be conducting job analyses and evaluations will require training, especially those evaluators who come from outside the human resource department. These employees may also need background information on the entire pay system and how it is related to the overall strategies for managing human resources and the organization's objectives.

5.3. Approving and Communicating the Results of the Job-Evaluation Process

When the job evaluations are completed, approval by higher levels in the organization (e.g., Vice President of Human Resources) is usually required. Essentially, the approval process serves as a control. It helps ensure that any changes that result from job evaluation are consistent with the organization's overall strategies and human resource practices. The particular approval process differs among organizations. Figure 4 is one example.

The emphasis on employee and manager understanding and acceptance of the job-evaluation system requires that communications occur during the entire process. Toward the end of the process,

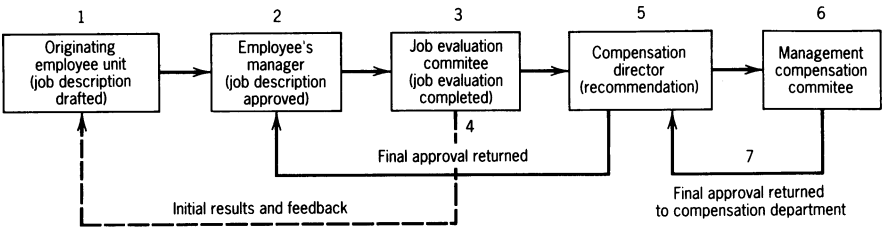

Figure 4 Job Evaluation Approval Process. (From Milkovich and Newman 1993)

the goals of the system, the parties' roles in it, and the final results will need to be thoroughly explained to all employees.

5.4. Using Information Technology in the Job-Evaluation Process

Almost every compensation consulting firm offers a computer-based job evaluation system. Their software does everything from analyzing the job-analysis questions to providing computer-generated job descriptions to predicting the pay classes for each job. Some caution is required, however, because "computer assisted" does not always mean a more efficient, more acceptable, or cheaper approach will evolve. The primary advantages for computer-aided job evaluation according to its advocates include:

Alleviation of the heavy paperwork and tremendous time saving
Marked increase in the accuracy of results
Creation of more detailed databases
Opportunity to conduct improved analyses (Rheaume and Jones 1988)

The most advanced use of computers for job evaluation is known as an expert system. Using the logic built by subject matter experts and coded into the computer, this software leads a job evaluator through a series of prompted questions as part of a decision tree to arrive at a job-evaluation decision (Mahmood et al. 1995).

But even with the assistance of computers, job evaluation remains a subjective process that involves substantial judgment. The computer is only a tool, and misused, it can generate impractical, illogical, and absurd results (Korukonda 1996).

5.5. Future Trends in the Job Evaluation Process

Job evaluation is not going to go away. It has emerged and evolved through the industrial, and now the informational, revolution. Unless everyone is paid the same, there will always be a need to establish and institutionalize a hierarchy of jobs in the organization. The process should, and will, continue to be improved upon. The use of computer software will dramatically simplify the administrative burdens of job evaluation. Furthermore, new technologies and processes will enable organizations to combine internal job-evaluation information with labor market data to strengthen the internal consistency–external competitiveness model discussed above.

6. EVALUATING THE JOB-EVALUATION SYSTEM

Job evaluation can take on the appearance of a bona fide measurement instrument (objective, numerical, generalizable, documented, and reliable). If it is viewed as such, then job evaluation can be judged according to precise technical standards. Just as with employment tests, the reliability and validity of job evaluation plans should be ascertained. In addition, the system should be evaluated for its utility, legality, and acceptability.

6.1. Reliability: Consistent Results

Job evaluation involves substantial judgment. Reliability refers to the consistency of results obtained from job evaluation conducted under different conditions. For example, to what extent do different job evaluators produce similar results for the same job? Few employers or consulting firms report the results of their studies. However, several research studies by academics have been reported (Arvey 1986; Schwab 1980; Snelgar 1983; Madigan 1985; Davis and Sauser 1993; Cunningham and Graham 1993; Supel 1990). These studies present a mixed picture; some report relatively high consistency (different evaluators assign the same jobs the same total point scores), while others report lower

agreement on the values assigned to each specific compensable factor. Some evidence also reports that evaluators' background and training may affect the consistency of the evaluations. Interestingly, an evaluator's affiliation with union or management appears to have little effect on the consistency of the results (Lawshe and Farbo 1949; Harding et al. 1960; Moore 1946; Dertien 1981).

6.2. Validity: Legitimate Results

Validity is the degree to which a job-evaluation method yields the desired results. The desired results can be measured several ways: (1) the hit rate (percentage of correct decisions it makes), (2) convergence (agreement with results obtained from other job-evaluation plans), and (3) employee acceptance (employee and manager attitudes about the job-evaluation process and the results) (Fox 1962; Collins and Muchinsky 1993).

6.2.1. Hit Rates: Agreement with Predetermined Benchmark Structures

The hit rate approach focuses on the ability of the job-evaluation plan to replicate a predetermined, agreed-upon job structure. The agreed-upon structure, as discussed earlier, can be based on one of several criteria. The jobs' market rates, a structure negotiated with a union or a management committee, and rates for jobs held predominately by men are all examples.

Figure 5 shows the hit rates for a hypothetical job-evaluation plan. The agreed-upon structure has 49 benchmark jobs in it. This structure was derived through negotiation among managers serving on the job-evaluation committee along with market rates for these jobs. The new point factor job-evaluation system placed only 14, or 29%, of the jobs into their current (agreed-upon) pay classes. It came within ± 1 pay class for 82% of the jobs in the agreed-upon structure. In a study conducted at Control Data Corporation, the reported hit rates for six different types of systems ranged from 49 to 73% of the jobs classified within ± 1 class of their current agreed-upon classes (Gomez-Mejia et al. 1982). In another validation study, Madigan and Hoover applied two job-evaluation plans (a modification of the federal government's factor evaluation system and the position analysis questionnaire) to 206 job classes for the State of Michigan (Madigan and Hoover 1986). They reported hit rates ranging from 27 to 73%, depending on the scoring method used for the job-evaluation plans.

Is a job-evaluation plan valid (i.e., useful) if it can correctly slot only one-third of the jobs in the "right" level? As with so many questions in compensation, the answer is "it depends." It depends on the alternative approaches available, on the costs involved in designing and implementing these plans, on the magnitude of errors involved in designing and implementing these plans, and on the magnitude of errors involved in missing a "direct hit." If, for example, being within ± 1 pay class translates into several hundred dollars in pay, then employees probably are not going to express much confidence in the "validity" of this plan. If, on the other hand, the pay difference between ± 1 class is not great or the plan's results are treated only as an estimate to be adjusted by the job-evaluation committee, then its "validity" (usefulness) is more likely.

6.2.2. Convergence of Results

Job-evaluation plans can also be judged by the degree to which different plans yield similar results. The premise is that convergence of the results from independent methods increases the chances that the results, and hence the methods, are valid. Different results, on the other hand, point to lack of validity. For the best study to date on this issue, we again turn to Madigan's report on the results of three job-evaluation plans (guide chart, PAQ, and point plan) (Madigan 1985). He concludes that the three methods generate different and inconsistent job structures. Further, he states that the measurement adequacy of these three methods is open to serious question. An employee could have received up to $427 per month more (or less), depending on the job-evaluation method used.

These results are provocative. They are consistent with the proposition that job evaluation, as traditionally practiced and described in the literature, is not a measurement procedure. This is so because it fails to consistently exhibit properties of reliability and validity. However, it is important

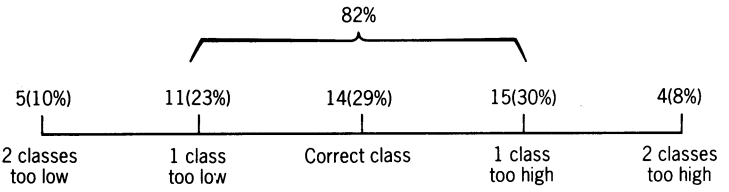

Figure 5 Illustration of Plan's Hit Rate as a Method to Judge the Validity of Job Evaluation Results. (From Milkovich and Newman 1993)

to maintain a proper perspective in interpreting these results. To date, the research has been limited to only a few employers. Further, few compensation professionals seem to consider job evaluation a measurement tool in the strict sense of that term. More often, it is viewed as a procedure to help rationalize an agreed-upon pay structure in terms of job- and business-related factors. As such, it becomes a process of give and take, not some immutable yardstick.

6.3. Utility: Cost-Efficient Results

The usefulness of any management system is a function of how well it accomplishes its objectives (Lawler 1986). Job evaluation is no different; it needs to be judged in terms of its objectives. Pay structures are intended to influence a wide variety of employee behaviors, ranging from staying with an employer to investing in additional training and willingness to take on new assignments. Consequently, the structures obtained through job evaluation should be evaluated in terms of their ability to affect such decisions. Unfortunately, little of this type of evaluation seems to be done.

The other side of utility concerns costs. How costly is job evaluation? Two types of costs associated with job evaluation can be identified: (1) design and administration costs and (2) labor costs that result from pay structure changes recommended by the job evaluation process. The labor cost effects will be unique for each application. Winstanley offers a rule of thumb of 1 to 3% of covered payroll (Winstanley). Experience suggests that costs can range from a few thousand dollars for a small organization to over $300,000 in consultant fees alone for major projects in firms like Digital Equipment, 3M, TRW, or Bank of America.

6.4. Nondiscriminatory: Legally Defensible Results

Much attention has been directed at job evaluation as both a potential source of bias against women and as a mechanism to reduce bias (Treiman and Hartmann 1981). We will discuss some of the studies of the effects of gender in job evaluation and then consider some recommendations offered to ensure bias-free job evaluation.

It has been widely speculated that job evaluation is susceptible to gender bias. To date, three ways that job evaluation can be biased against women have been studied (Schwab and Grams 1985).

First, direct bias occurs if jobs held predominantly by women are undervalued relative to jobs held predominantly by men, simply because of the *jobholder's gender*. The evidence to date is mixed regarding the proposition that the gender of the jobholder influences the evaluation of the job. For example, Arvey et al. found no effects on job evaluation results when they varied the gender of jobholders using photographs and recorded voices (Arvey et al. 1977). In this case, the evaluators rightfully focused on the work, not the worker. On the other hand, when two different job titles (special assistant—accounting and senior secretary—accounting) were studied, people assigned lower job-evaluation ratings to the female-stereotyped title ''secretary'' than to the more gender-neutral title, ''assistant'' (McShane 1990).

The second possible source of gender bias in job evaluation flows from the *gender of the individual evaluators*. Some argue that male evaluators may be less favorably disposed toward jobs held predominantly by women. To date, the research finds no evidence that the job evaluator's gender or the predominant gender of the job-evaluation committee biases job-evaluation results (Lewis and Stevens, 1990).

The third potential source of bias affects job evaluation indirectly through the *current wages paid for jobs*. In this case, job-evaluation results may be biased if the jobs held predominantly by women are incorrectly underpaid. Treiman and Hartmann argue that women's jobs are unfairly underpaid simply because women hold them (Trieman and Hartmann 1995). If this is the case and if job evaluation is based on the current wages paid in the market, then the job-evaluation results simply mirror any bias that exists for current pay rates. Considering that many job-evaluation plans are purposely structured to mirror the existing pay structure, it should not be surprising that the current wages for jobs influence the results of job evaluation, which accounts for this perpetual reinforcement. In one study, 400 experienced compensation administrators were sent information on current pay, market, and job-evaluation results (Rynes et al. 1989). They were asked to use this information to make pay decisions for a set of nine jobs. Half of the administrators received a job linked to men (i.e., over 70% of job holders were men, such as security guards) and the jobs given the other half were held predominately by women (e.g., over 70% of job holders were women, such as secretaries). The results revealed several things: (1) Market data had a substantially larger effect on pay decisions than did job evaluations or current pay data. (2) The jobs' gender had no effects. (3) There was a hint of possible bias against physical, nonoffice jobs over white-collar office jobs. This study is a unique look at several factors that may affect pay structures. Other factors, such as union pressures and turnover of high performers, that also affect job-evaluation decisions were not included.

The implications of this evidence are important. If, as some argue, market rates and current pay already reflect gender bias, then these biased pay rates could work indirectly through the job-evaluation process to deflate the evaluation of jobs held primarily by women (Grams and Schwab

1985). Clearly the criteria used in the design of job evaluation plans are crucial and need to be business and work related.

Several recommendations help to ensure that job evaluation plans are bias free (Remick 1984). Among them are:

1. Ensuring that the compensable factors and scales are defined to recognize the content of jobs held predominantly by women. For example, working conditions should include the noise and stress of office machines and the working conditions surrounding computers.
2. Ensuring that compensable factor weights are not consistently biased against jobs held predominantly by women. Are factors usually associated with these jobs always given less weight?
3. Ensuring that the plan is applied in as bias-free a manner as feasible. This includes ensuring that the job descriptions are bias free, that incumbent names are excluded from the job-evaluation process, and that women are part of the job-evaluation team and serve as evaluators.

Some writers see job evaluation as the best friend of those who wish to combat pay discrimination. Bates and Vail argue that without a properly designed and applied system, ''employers will face an almost insurmountable task in persuading the government that ill-defined or whimsical methods of determining differences in job content and pay are a business necessity'' (Bates and Vail 1984).

6.5. Acceptability: Sensible Results

Acceptance by the employees and managers is one key to a successful job-evaluation system. Any evaluation of the worthiness of pay practices must include assessing employee and manager acceptance. Several devices are used to assess and improve the acceptability of job evaluation. An obvious one is the inclusion of a formal appeals process, discussed earlier. Employees who feel their jobs are incorrectly evaluated should be able to request reanalysis and reevaluation. Most firms respond to such requests from managers, but few extend the process to all employees, unless those employees are represented by unions who have a negotiated grievance process. They often justify this differential treatment on the basis of a fear of being inundated with appeals. Employers who open the appeals process to all employees theorize that jobholders are the ones most familiar with the work performed and know the most about changes, misrepresentations, or oversights that pertain to their job. No matter what the outcome from the appeal, the results need to be explained in detail to any employee who requests that his or her job be reevaluated.

A second method of assessing acceptability is to include questions about the organization's job structure in employee attitude surveys. Questions can assess perceptions of how useful job evaluation is as a management tool. Another method is to determine to what extent the system is actually being used. Evidence of acceptance and understanding can also be obtained by surveying employees to determine the percentage of employees who understand the reasons for job evaluation, the percentage of jobs with current descriptions, and the rate of requests for reevaluation.

As noted earlier, stakeholders of job evaluations extend beyond employees and managers to include unions and, some argue, comparable worth activists. The point is that acceptability is a somewhat vague test of the job evaluation—acceptable to whom is an open issue. Clearly managers and employees are important constituents because acceptance makes it a useful device; but others, inside and outside the organization, also have a stake in job evaluation and the pay structure.

7. SUMMARY

In exchange for services rendered, individuals receive compensation from organizations. This compensation is influenced by a wide variety of ever-changing dynamics, many of which are identified in this chapter. The central focus of this chapter, though, was on just one of these influences: the internal worth of jobs. We introduced the different systems for evaluating jobs, the procedures necessary to operationalize these systems, and the criteria for evaluating the effectiveness of these systems in an organization.

CHAPTER 35

Selection, Training, and Development of Personnel

ROBERT W. SWEZEY
InterScience America, Inc.

RICHARD B. PEARLSTEIN
American Red Cross

1. INTRODUCTION

Selection, training, and development are the primary tools used to promote human performance in industrial engineering settings. In this chapter, we will review important research issues in these areas. We have elected to emphasize training over the equally important topics of selection and development, primarily because training can often have substantial impact in existing application areas. In many industrial engineering situations, staff members are already in place, and even if personnel selection is an option, it is performed by other agencies, such as the human resources

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

department. Second, ''development'' activities often consist of training—either the construction of new training programs or the use of existing ones, or both. Consequently, in our view, training (plus judicious use of other, ancillary, performance-improvement technologies) constitutes a serious potential impact area for industrial engineering situations.

Further, a major concern in the domain of selection research is the development of technologies designed to address the validity and reliability of instruments used to select personnel. (''Validity'' deals with the question of determining the extent to which an assessment technique actually measures what it purports to measure, such as intelligence, clerical skill, and mathematical aptitude. ''Reliability'' addresses the extent to which such an instrument measures whatever it purports to measure consistently, that is, without major score differences upon repeated applications of the instrument to the same people.) Such topics as these, while very important, are beyond the scope of this chapter.

For the same reason, we have chosen not to deal with other widely researched topics in this domain, such as recruitment of personnel, employee retention, personnel turnover, metaanalysis (statistical technologies for collapsing data from multiple research programs in order to reach generalizable conclusions), and validity generalization (techniques designed to apply known measurement validities obtained in one situation to another). Readers interested in these topics may consult the many current textbooks available in these areas or an overall review article (Guion 1991). An authoritative reference for those involved in the methods used in selection and classification of personnel is the *Standards for Educational and Psychological Testing* (AERA et al. 1999).

2. SELECTION

In selection research, *predictor* refers to any technique or technology used to predict the success of individuals in the application context. In general, it is the goal of selection technologies to predict successfully how well people will perform if hired or selected for admission to a specific situation, such as a college. In the following pages, we briefly review several of the most popular predictor categories.

2.1. Predictors

2.1.1. Aptitude and Ability Tests

Very generally, *aptitude* refers to a capacity or suitability for *learning* in a particular domain or topic area (such as mechanical aptitude), whereas *ability* refers to a natural or inborn talent to *perform* in a given area (such as athletic ability). Development and application of tests of aptitude and ability have long been a major focus of activity in the area of selection research. In general, ability and aptitude tests consist of several subcategories. Cognitive ability tests address issues that involve remembering information, producing ideas, thinking, and comparing or evaluating data. Sensory motor tests include physical, perceptual, motor, and kinesetic measures. Personality, temperament, and motivational tests address those issues as predictors of job success. Additionally, so-called lie-detector or polygraph tests are increasingly used in some situations as a selection and/or screening device, despite the existence of a substantial amount of data that question their validity (see Guion 1991; Sackett and Decker 1979).

One series of projects that have recently addressed aptitude testing involves the development and validation of the (U.S.) Armed Services Vocational Aptitude Battery (ASVAB) (Welsh et al. 1990). This effort involved years of research and dozens of studies that applied and researched the contributions of aptitude-testing techniques to a huge variety of military job settings. To transfer these military technologies to civilian settings, researchers compared ASVAB counterparts to the civilian General Aptitude Test Battery (GATB). These comparisons were reviewed by Hunter (1986) and others, who have demonstrated that many ASVAB components are highly similar to their civilian counterparts, thus arguing that many of the military's scales and testing procedures are directly relevant for nonmilitary applications.

A second major research program in this area is known as Project A. That effort (see Campbell 1990 for a review) involved a number of complex research projects designed to validate predictors of hands-on job-performance measures and other criteria for U.S. Army jobs. Project A, conducted at a cost of approximately $25 million, is certainly one of the largest selection-research projects in history. It found that ''core job performance'' was predicted by general cognitive ability (assessed by the ASVAB), while ratings of effort and leadership, personal discipline, and physical fitness were best predicted by personality measures (McHenry et al. 1990). Other predictors produced only small increments in validity over general cognitive ability in predicting core job performance (Schmidt et al. 1992).

A common issue in selection research is the question of whether ''general'' ability is more important in determining job success than are various ''special'' abilities (which presumably are components of the more overall ''general'' factor). Various authors (Hunter 1986; Jensen 1986; Thorndike 1986; and many others) have argued in favor of the general factor, whereas others (cf. Prediger 1989)

have challenged these conclusions, suggesting that specific aptitudes are more important in predicting job performance.

2.1.2. Simulations

Simulations are increasingly used as predictors in selection situations. Simulations are representations of job situations. Although presumably task relevant, they are nonetheless abstractions of real-world job tasks. Many simulations used in selection occur in so-called assessment centers, in which multiple techniques are used to judge candidates. In such situations, people are often appraised in groups so that both interpersonal variables and individual factors can be directly considered. Simulation exercises are often used to elicit behaviors considered relevant to particular jobs (or tasks that comprise the jobs) for which people are being selected. This includes so-called in-basket simulations for managerial positions, where hypothetical memos and corporate agenda matters are provided to job candidates in order to assess their decision-making (and other) skills.

Recently, computer-based simulations—ranging from low-fidelity ''games'' to highly sophisticated complex environments coupled with detailed performance-measurement systems—have been developed for use as predictors in selection and assessment situations. One example of this approach is team performance assessment technology (TPAT) (e.g., Swezey et al. 1999). This and similar methods present simulated task environments that assess how individuals and/or teams develop plans and strategies and adapt to changes in fluctuating task demands. This technology exposes respondents to complex environments that generate task-relevant challenges. At known times, participants have an opportunity to engage in strategic planning; at other times, emergencies may require decisive action. These technologies are designed to allow participants to function across a broad range of situations that include unique demands, incomplete information, and rapid change. They often employ a performance-measurement technology termed ''quasi-experimental'' (Streufert and Swezey 1985). Here, fixed events of importance require that each participant deal with precise issues under identical conditions. Other events, however, are directly influenced by actions of participants. In order to enable reliable measurement, fixed (preprogrammed) features are inserted to allow for comparisons among participants and for performance assessment against predetermined criteria. Other methodologies of this sort include the tactical naval decision making system (TANDEM), a low-fidelity simulation of a command, control, and communication environment (Dwyer et al. 1992; Weaver et al. 1993), and the team interactive decision exercise for teams incorporating distributed expertise (TIDE^2) (Hollenbeck et al. 1991).

2.1.3. Interviews and Biodata

Most reviews concerning the reliability and validity of interviews as a selection device ''have ended with the depressing but persistent conclusion that they have neither'' (Guion 1991, p. 347). Then why are they used at all? Guion provides four basic reasons for using interviews as selection devices in employment situations:

1. They serve a public relations role. Even if rejected, a potential employee who was interviewed in a competent, professional manner may leave with (and convey to others) the impression that he was treated fairly.
2. They can be useful for gathering ancillary information about a candidate. Although collecting some forms of ancillary information (such as personal, family, and social relationship data) is illegal, other (perfectly legitimate) information on such topics as work history and education that may have otherwise been unavailable can be collected in a well-structured interview protocol.
3. They can be used to measure applicant characteristics that may otherwise not be adequately measured, such as friendliness, ability to make a good first impression, and conversational etc.
4. Interviewers are themselves decision makers. In some circumstances, interviewers may be used to arrive at overall judgments about candidate suitability that can be used in the decision process.

Many alternative ways of conducting interviews have been studied. For instance, Martin and Nagao (1989) compared paper-and-pencil, face-to-face, and computerized versions of interviews. They found that socially desirable responses often occurred when impersonal modes of interviewing were used, but that applicants for high-status jobs often resented impersonal interviews. Tullar (1989) found that successful applicants are given longer interviews and dominate the conversation more than less-successful applicants.

As to biodata, information about an individual's past, Hammer and Kleiman (1988) found that only 6.8% of 248 firms surveyed stated that they had ever used biodata in employment decisions, and only 0.4% indicated that they currently used biodata. Yet there is evidence that biodata has

substantial validity as a selection device (Schmidt et al. 1992). The most frequent reasons for not using biodata were (a) lack of knowledge, (b) lack of methodological expertise, and (c) lack of personnel, funding, and time.

An important assumption in use of biodata as a selection tool is that past behaviors—often behaviors far in the past (e.g., high school achievements)—are good predictors of future behaviors. However Kleiman and Faley (1990) found that biodata items inquiring about *present* behaviors were just as valid as those focusing on past behaviors in predicting intention to reenlist in the Air National Guard; and Russell et al. (1990) found that retrospective life-history essays could serve as the source of valid biodata. These and other studies indicate that biodata may be a significantly underutilized source of information in personnel selection situations.

2.1.4. Work Samples

Unlike simulations, which are not the actual activities performed in the workplace but an abstraction or representation of aspects of those activities, work sample testing involves the actual activities performed on the job. These are measured or rated for use as a predictor. The logic applied to work sample testing is somewhat different from other selection technologies in that it employs a ''criterion-based'' perspective: the performance being tested *is* usually a subset of the actual task employed and is derived directly from the content domain of that task. This stands in contrast to other types of selection methodologies where a measure of some ''construct'' (such as personality, aptitude, ability, or intelligence) is measured and related statistically (usually correlated) with actual job performance (see Swezey 1981 for a detailed discussion of this issue).

In work sample testing, a portion of an actual clerical task that occurs everyday may be used to measure clerical performance (e.g., ''type this letter to Mr. Elliott''). Typically, such tests actually sample the work domain in some representative fashion; thus, typing a letter would be only one aspect of a clerical work sample test that may also include filing, telephone answering, and calculating tasks.

Work sample testing is less abstract than other predictive techniques in that actual performance measurement indices (e.g., counts, errors) or ratings (including checklists) may be used as indices of performance. Where possible, work sample testing (or its close cousin, simulation) is the preferred method for use in selection research and practice because one does not get mired down trying to decide how to apply abstract mental constructs to the prediction of job performance.

2.1.5. References

The use of references (statements from knowledgeable parties about the qualifications of a candidate for a particular position) as a predictor of job performance or success is the most underresearched—yet widely used—selection technique. The problem with using references as a selection technique is that, in most cases, the persons supplying the references have unspecified criteria. That is, unless the requesting parties provide explicit standards for use in providing the reference, referees may address whatever qualities, issues, or topics they wish in providing their comments. This wide-ranging, subjective, unstructured technique is therefore of highly questionable validity as a predictor of job performance. Nevertheless, the technique is widely used in employment and other application-oriented settings (e.g., college applications) because we typically value the unstructured opinions of knowledgeable people concerning assets and/or liabilities of an applicant or candidate. The key word here is ''knowledgeable.'' Unfortunately, we often have no way of determining a referee's level of knowledge about a candidate's merits.

2.1.6. Others

Among the many other predictors used as selection devices are such areas as graphology, genetic testing, investigative background checks, and preemployment drug testing. Of these, preemployment drug testing has undoubtedly received the most attention in the literature. In one noteworthy effort, Fraser and Kroeck (1989) suggested that the value of drug screening in selection situations may be very low. In partial reaction to this hypothesis, a number of investigations were reviewed by Schmidt et al. (1992). Those authors cite the work of Fraser and Kroeck and of Murphy et al. (1990), who, using college student samples, found that individual drug use and self-reported frequency of drug use were consistently correlated with disapproval of employee drug testing. However, no substantial associations between acceptability of drug testing and employment experience or qualifications were established.

2.2. Validity and Fairness

As mentioned above, test validity is a complex and ambiguous topic. Basically, one can break this domain into two primary categories: (1) psychometric validities, including criterion-based validities (which address—either in the future [predictive] or simultaneously [concurrent]—the relationship(s) among predictors and criteria), and construct validity (which relates predictors to psychological con-

structs, such as abilities, achievement, etc.); and (2) content (or job/task-related) validities. See Guion (1991) for a discussion of these topics.

Various U.S. court rulings have mandated that job-related validities be considered in establishing test fairness for most selection and classification situations. These issues are addressed in the latest *Standards for Educational and Psychological Testing* (1999) document.

2.3. Performance Measurement and Criterion Assessment

An oft-quoted principle is that the best predictor of future performance is past performance. However, current performance can be a good predictor as well. In selecting personnel to perform specific tasks, one may look at measurements of their performance on similar tasks in the past (e.g., performance appraisals, certification results, interviews, samples of past work). As noted earlier, one may also measure their current performance on the tasks for which one is selecting them, either by assessing them on a simulation of those tasks or, when feasible, by using work samples. A combination of both types of measures may be most effective. Measures of past performance show not only what personnel can do, but what they have done. In other words, past performance reflects motivation as well as skills. A disadvantage is that, because past performance occurred under different circumstances than those under which the candidates will perform in the future, ability to generalize from past measures is necessarily limited. Because measures of current performance show what candidates can do under the actual (or simulated) conditions in which they will be performing, using both types of measures provides a more thorough basis on which to predict actual behaviors.

Whether based on past performance or current performance, predictors must not only be accurate, they must also be relevant to the actual tasks to be performed. In other words, the criteria against which candidates' performance is assessed must match those of the tasks to be performed (Swezey 1981). One way to ensure that predictors match tasks is to use criterion-referenced assessment of predictor variables for employee selection. To do this, one must ensure that the predictors match the tasks for which one is selecting candidates as closely as possible on three relevant dimensions: the conditions under which the tasks will be performed, the actions required to perform the task, and the standards against which successful task performance will be measured. While it is better to have multiple predictors for each important job task (at least one measure of past performance and one of current performance), it may not always be possible to obtain multiple predictors. We do not recommend using a single predictor for multiple tasks—the predictor is likely to be neither reliable nor valid.

3. TRAINING

3.1. Differences between Training and Education

"Training" (the systematic, structured development of specific skills required to perform job tasks) differs from "education" (development of broad-based informational background and general skills). Most people are more familiar with education than training because (a) their experiences from elementary school through college usually fall within an educational model, and (b) much of what is called training in business and industry is actually more akin to education than training.

Education is important, even essential, for building broad skill areas, but training is the approach of preference for preparing people to perform specific tasks or jobs. Table 1 shows differences between education and training and between educators and trainers. Not all differences apply to any specific instance of training or education, but as a whole they illustrate the distinction between the two.

3.2. Training, Learning, Performance, and Outcomes

The *purpose* of training is to facilitate learning skills and knowledges required to perform specific tasks. The *outcome* of training is acceptable performance on those tasks. People often learn to perform tasks without training, but if training is effective, it enables people to learn faster and better. For example, a person might be able to learn to apply the principle of cantilevering to bridge construction through reading and trial and error, but the process would be lengthier and the outcomes would probably be less precise than if the person received systematic, well-designed training.

Because training is a subsystem of a larger organizational system, it should not be treated outside the context of the larger system. In organizations, training is usually requested in two types of circumstances: either current performance is inadequate or new performance is required. In other words, organizations train either to solve current problems or to take advantage of new opportunities. A second factor affecting training is whether it is intended for new or incumbent employees. Basically, training for new opportunities is essentially the same for new and incumbent employees. However, new employees may require prerequisite or remedial training prior to receiving training on new tasks to help take advantage of opportunities, whereas incumbents presumably would have already completed the prerequisite training (or would have otherwise mastered the necessary skills).

TABLE 1 Education and Educators Compared to Training and Trainers

Education	Training
Increases knowledge	Increases job performance
Broadens understanding	Focuses on job skills
Conceptualizes experience	Simulates experience
Asks ''How much do you know?''	Asks ''What can you do with what you know?''
Provides base of knowledge	Uses knowledge to build skills
Often requires broad generalization of knowledge	Requires knowledge to be applied in specific situations
Educator	**Trainer**
Dispenses information	Facilitates learning experience
Is primary learning resource	Allows participants to serve as learning resources
Stresses inquiry	Stresses practical application
Groups students according to ability (norm-referenced)	Tries to help all participants perform to specified level (criterion-referenced)
Focuses on information	Focuses on performance
Evaluates via classroom testing	Evaluates via on-the-job performance assessment

Just as learning can take place without training, organizational outcomes can be achieved without training. In fact, when acceptable performance on specific tasks is a desired organizational outcome, training is frequently *not* the appropriate way to achieve that outcome (see Gilbert 1978; Harless 1975; Mager and Pipe 1970). The type of analysis that determines factors contributing to performance of an organization's personnel subsystem has been called by a variety of names, including performance analysis (Mager and Pipe 1970), and front-end analysis (Harless 1975). Mager and Pipe (1970), noting that training is appropriate only when performance is unacceptable because performers lack necessary skills and knowledge, suggested this classic question for making the determination: ''Could they do it if their lives depended on it?'' If the answer is ''no,'' then training is warranted. If the answer is ''yes,'' the next question is, ''What is preventing them from performing as required?'' Mager and Pipe also suggested various ways of categorizing obstacles to desired performance outcomes that do not consist of skill/knowledge deficiencies (see also Harless 1975; Rummler and Brache 1990). These can be reduced to two broad categories:

1. Lack of environmental support (e.g., well-specified processes, job aids, tools and equipment, management expectations, adequate facilities)
2. Lack of appropriate motivational systems (e.g., clear and immediate feedback, appropriate consequences for action, well-designed reward systems)

For skill/knowledge deficiencies, training interventions are appropriate. Deficiencies involving environmental support and/or appropriate motivational systems should be remedied through other human performance interventions, such as providing clear instructions and developing reward systems. Regardless of the intervention, implementation should always include pilot testing and evaluation components. If desired outcomes are not achieved, the analysis, design, and/or implementation may have been flawed.

3.3. Analysis of Organizations, Jobs, Tasks, and People

Organizations consist of people performing tasks to achieve a particular mission. A job is defined as a collection of related tasks that helps accomplish significant elements of an organization's products and/or services. For training and other human performance-improvement interventions to be successful, they must address appropriate organizational levels and/or units. Organizational analysis seeks to determine relationships among an organization's inputs, functions, jobs, and products/services. This type of analysis builds upon front-end and performance analysis.

Rummler and Wilkins (1999) introduced a technique known as performance logic to diagnose an organization's problems and opportunities. The process highlights disconnects among procedures, skills, jobs, and desired product/service outcomes, pointing the way to appropriate training and other

human performance-improvement interventions. Others (Mourier 1998) have also demonstrated successes using this approach.

Job analysis has several purposes. One deals with determining how to apportion an organization's tasks among jobs. This process identifies the tasks that belong with each job, the goal being to reduce overlap while providing clean demarcations between products and processes. From the perspective of an organization's human resources subsystem, job analysis can be used to organize tasks into clusters that take advantage of skill sets common to personnel classification categories (e.g., tool and die press operator, supervisory budget analyst) and consequently reduce the need for training. By distributing tasks appropriately among jobs, an organization may be able to select skilled job candidates, thereby reducing attendant training costs.

A second purpose of job analysis involves job redesign. During the 1970s, researchers addressed various ways to redesign jobs so that the nature of the jobs themselves would promote performance leading to desired organizational outcomes. For example, Lawler et al. (1973) found that several factors, such as variety, autonomy, and task identity, influenced employee satisfaction and improved job performance. Herzberg (1974) identified other factors, such as client relationship, new learning, and unique expertise, having similar effects on satisfaction and performance. Peterson and Duffany (1975) provide a good overview of the job redesign literature.

Needs analysis (sometimes called needs assessment) examines what should be done so that employees can better perform jobs. Needs analysis focuses on outcomes to determine optimal performance for jobs. Rossett (1987) has provided a detailed needs-analysis technique. Instead of needs analysis, many organizations unfortunately conduct a kind of wants analysis, a process that asks employees and/or supervisors to state what is needed to better perform jobs. Because employees and managers frequently cannot distinguish between their wants and their needs, wants analysis typically yields a laundry list of information that is not linked well to performance outcomes.

Finally, task analysis is a technique that determines the inputs, tools, and skills/knowledge necessary for successful task performance. In training situations, task analysis is used to determine the skill/knowledge requirements for personnel to accomplish necessary job outcomes. Skills gaps are defined as the difference between required skills/knowledge and those possessed by the individuals who are (or will be) performing jobs. Training typically focuses on eliminating the skills gaps. Helpful references for conducting task analyses include Carlisle (1986) and Zemke and Kramlinger (1982).

3.4. Training Design and Development

A comprehensive reference work with respect to training design and development (Goldstein 1993) refers to what is generally known as a systems approach to training. Among many other things, this approach includes four important components:

1. Feedback is continually used to modify the instructional process, thus training programs are never completely finished products but are always adaptive to information concerning the extent to which programs meet stated objectives.
2. Recognition exists that complicated interactions occur among components of training such as media, individual characteristics of the learner, and instructional strategies.
3. The systems approach to training provides a framework for reference to planning.
4. This view acknowledges that training programs are merely one component of a larger organizational system involving many variables, such as personnel issues, organization issues, and corporate policies.

Thus, in initiating training program development, it is necessary, according to Goldstein, to consider and analyze not only the tasks that comprise the training, but characteristics of the trainees and organizations involved.

This approach to instruction is essentially derived from procedures developed in behavioral psychology. Two generic principles underlie technological development in this area. First, the specific behaviors necessary to perform a task must be precisely described, and second, feedback (reinforcement for action) is utilized to encourage mastery.

This (and previous work) served as a partial basis for the military's instructional systems development (ISD) movement (Branson et al. 1975) and the subsequent refinement of procedures for criterion-referenced measurement technologies (Glaser 1963; Mager 1972; Swezey 1981).

For a discussion of the systems approach to training, we briefly review the Branson et al. (1975) ISD model. This model is possibly the most widely used and comprehensive method of training development. It has been in existence for over 20 years and has revolutionized the design of instruction in many military and civilian contexts. The evolutionary premises behind the model are that performance objectives are developed to address specific behavioral events (identified by task analyses), that criterion tests are developed to address the training objectives, and that training is essentially developed to teach students to pass the tests and thus achieve the requisite criteria.

The ISD method has five basic phases: analysis, design, development, implementation, and control (evaluation).

Phase one—analysis:

(a) Perform a task analysis. Develop a detailed list of tasks, the conditions under which the tasks are performed, the skills and/or knowledge required for their performance, and the standards that indicate when successful performance has been achieved.

(b) Select pertinent tasks/functions. Note, by observation of an actual operation, the extent to which each task is actually performed, the frequency with which it is performed, and the percentage of a worker's time devoted to it. Then make an assessment concerning the importance of each task to the overall job.

(c) Construct job-performance measures from the viewpoint that job-performance requirements are the basis for making decisions about instructional methods.

(d) Analyze training programs that already exist to determine their usefulness to the program being developed.

(e) Identify the instructional setting/location for each task selected for instruction.

Phase two—design:

(a) Describe student entry behavior. Classify, at the task level, categories into which each entry behavior falls (i.e., cognitive, procedural, decision making, problem solving, etc.). Then check whether each activity is within the existing performance repertoire of the trainees (something the potential students already know) or is a specialized behavior (something the students will have to learn).

(b) Develop statements that translate the performance measures into terminal learning objectives. Consider the behavior to be exhibited, the conditions under which the learning will be demonstrated, and the standards of performance that are considered acceptable.

(c) Develop criterion-referenced tests (CRTs). CRTs are tests that measure what a person needs to know or do in order to perform a job. Ensure that at least one test item measures each instructional objective. Determine whether the testing should be done by pencil and paper, by practical exercise, or by other methods. Criterion-referenced tests perform three essential functions:

- They help to construct training by defining detailed performance goals.
- They aid in diagnosis of whether a student has absorbed the training content because the tests are, in fact, operational definitions of performance objectives.
- They provide a validation test for the training program.

(d) Determine the sequence and structure of the training. Develop instructional strategies and the sequencing of instruction for the course.

Phase three—development:

(a) Specify specific learning events and activities.

(b) Specify an instructional management plan. Determine how instruction will be delivered and how the student will be guided through it: by group mode, self-paced mode, or combinations of the two. Determine how the curriculum will be presented (e.g., lectures, training aids, simulators, job-performance aids, television, demonstration, and computer based).

(c) Review and select existing instructional materials for inclusion in the curriculum.

(d) Develop new instructional materials.

(e) Validate the instruction by having it reviewed by experts or job incumbents or by trying it out on typical students.

Phase four—implementation:

(a) Implement the instructional management plan by ensuring that all materials, equipment, and facilities are available and ready for use. Before beginning instruction, schedule students and train instructors.

(b) Conduct the instruction under the prescribed management plan in the designated setting under actual conditions using final course materials.

Phase five—control (evaluation):

(a) Monitor course effectiveness, assess student progress, assess the quality of the course, and compare results with the original learning objectives.

(b) Determine how graduates perform on the job.

(c) Revise the course as appropriate.

3.5. Training Techniques, Strategies, and Technologies

Two factors known to affect quality of training are the techniques used to deliver the instruction and the methods or strategies used to convey the instructional content. One of the main tasks in the development of training, therefore, is the selection and implementation of appropriate instructional methods and techniques.

One function of technology-assessment research is to provide a basis for estimating the utility of particular technology-based approaches for training. Researchers have analyzed virtually every significant technology trend of the last two decades, including effects of programmed instruction (Kulik et al. 1980), computer-based instruction (Kulik and Kulik 1987), and visual based instruction (Cohen et al. 1981). The majority of these studies show no significant differences among technology groups and, when pooled, yield only slight advantages for innovative technologies. Kulik and associates report that the size of these statistically significant gains is in the order of 1.5 percentage points on a final exam. Cohen et al. (1981) conducted an analysis of 65 studies in which student achievement using traditional classroom-based instruction was compared with performance across a variety of video-based instructional media, including films, multimedia, and educational TV. They found that only one in four studies (approximately 26%) reported significant differences favoring visual-based instruction. The overall effect size reported by Cohen et al. was relatively small compared to studies of computer-based instruction or of interactive video.

Computer-based instruction and interactive video both represent areas where some data reporting advantages have emerged; specifically, reductions in the time required to reach threshold performance levels (Fletcher 1990; Kulik and Kulik 1987). Results of an analysis of 28 studies, conducted by Fletcher (1990), suggested that interactive video-based instruction increases achievement by an average of 0.50 standard deviations over conventional instruction (lecture, text, on-the-job training, videotape).

Results of decades of work in the area of media research led Clark (1983, 1994) to conclude that media have no significant influence on learning effectiveness but are mere vehicles for presenting instruction. According to Clark (1983, p. 445), ''the best current evidence is that media are mere vehicles that deliver instruction but do not influence student achievement any more than the truck that delivers our groceries causes changes in our nutrition.'' Similarly, Schramm (1977) commented that ''learning seems to be affected more by what is delivered than by the delivery system.'' Although students may prefer sophisticated and elegant media, learning appears largely unaffected by these features. Basically, all media can deliver either excellent or ineffective instruction. It appears that it is the instructional methods, strategies, and content that facilitate or hinder learning. Thus, many instructional technologies are considered to be equally effective provided that they are capable of dealing with the instructional methods required to achieve intended training objectives.

Meanwhile, teaching methods appear to be important variables influencing the effectiveness of instructional systems. Instructional methods define how the process of instruction occurs: what information is presented, in what level of detail, how the information is organized, how information is used by the learner, and how guidance and feedback are presented. The choice of a particular instructional method often limits the choice of presentation techniques. Technology-selection decisions, therefore, should be guided by: (1) capacity of the technology to accommodate the instructional method, (2) compatibility of the technology with the user environment, and (3) trade-offs that must be made between technology effectiveness and costs.

Conventional instructional strategies such as providing advance organizers (Allen 1973), identifying common errors (Hoban and Van Ormer 1950), and emphasizing critical elements in a demonstration (Travers 1967) work well with many technology forms, including video-based instructional technologies. Embedding practice questions within instructional sequences also appears to be a potent method supported by interactive video and computer-based instruction. Benefits of embedded questions apparently occur whether responses to the questions are overt or covert or whether the material is preceded or followed by the questions (Teather and Marchant 1974). Compared to research on instructional delivery systems, relatively little research has examined the application of instructional methods.

Morris and Rouse (1985) have suggested that strategies used to teach troubleshooting skills should combine both theoretical and procedural knowledge. This was confirmed by Swezey et al. (1991), who addressed these issues using a variety of instructional strategies. Three strategies, termed ''procedural,'' ''conceptual,'' and ''integrated,'' were used. Results indicated that integrated training strategies that combine procedural and theoretical information facilitate retention of concepts and improve transfer to new settings. Swezey and Llaneras (1992) examined the utility of a technology that provides training program developers with guidance for use in selecting *both* instructional strategies and media. The technology distinguishes among 18 instructional strategies, as well as among 14 types of instructional media. Outputs are based upon decisions regarding the types of tasks for which training is to be developed, as well as consideration of various situational characteristics operating in the particular setting. Three general classes of situational characteristics are considered: (1) task

attributes (motion, color, difficulty, etc.), (2) environmental attributes (hazardous, high workload, etc.), and (3) user attributes (level of experience and familiarity with the task). Results indicated that participants who had access to the selection technology made better presentation strategy, media, and study/practice strategy selections than those relying on their own knowledge.

3.5.1. Simulation as a Training Technology

As technology develops, progress is being made in linking various types of instructional devices. Fletcher (1990) has reviewed much of the literature in this area. In general, he has found that computer-based instructional techniques were often more effective than conventional instruction if they included interactive features such as tutorials. Fletcher also notes that the available studies provide little insight into the relative contributions of various features of interactive technology to learning.

Equipment simulators have been used extensively for training aircraft pilots. Jacobs et al. (1990), and Andrews et al. (1992) have reviewed this research. In general, it appears that simulator training combined with training in actual aircraft is more effective than training in the aircraft by itself. According to Tannenbaum and Yukl (1992), the realism of simulators is being enhanced greatly by continuing developments in video technology, speech simulation, and speech recognition; and advancements in networking technology have opened up new possibilities for large-scale simulator networking. Although simulators have been used extensively for training small teams in the military, networking allows larger groups of trainees to practice their skills in large-scale interactive simulations (Thorpe 1987; Alluisi 1991; Weaver et al. 1995). Often in these circumstances, the opponent is not merely a computer but other teams, and trainees are therefore often highly motivated by the competition. In such situations, as in the actual environment, simulations are designated to operate directly as well as to react to unpredictable developments. A thorough history of the development of one such complex, networked system, known as SIMNET, has been provided by Alluisi (1991). Comprehensive, system-based evaluations of these technologies, however, remain to be performed.

3.6. Acquisition, Retention, and Transfer of Learned Information

3.6.1. Acquisition

Much literature has indicated that it is necessary to separate the initial acquisition of a performance skill or concept from longer-term learning (Schmidt and Bjork 1992; Cormier 1984; Salmoni et al. 1984). Schmidt and Bjork (1992), for instance, have described a process by which characteristics of a task create an environment in which performance is depressed but learning is apparently enhanced. The implications of this phenomenon, known as contextual interference (Battig 1966; Shea and Morgan 1979), for training are that variations of task conditions, manipulation of task difficulty, or other means of inducing extra effort by trainees are likely to be beneficial for retention and transfer. Recent research by Schneider et al. (1995) investigated effects of contextual interference in rule-based learning, a skill underlying many applied tasks found in the aviation, military, and computer fields. Results mirrored those found in the verbal learning and motor skill-acquisition literatures, indicating that a random practice schedule leads to the best retention performance after initial acquisition but hinders initial learning. Thus, training conditions designed to achieve a particular training objective (long-term retention, transfer, and/or resistance to altered contexts) are not necessarily those that maximize performance during acquisition. This concept has significant implications for predicting trainee performance. Although a typical method employed to predict trainee performance involves monitoring acquisition data during training, using immediate past performance data as predictors to estimate future retention performance, this strategy may not appropriately index performance on the job or outside of the training environment. Further, initial performance of complex skills tends to be unstable and often is a poor indicator of final performance. Correlations between initial and final performance levels for a grammatical reasoning task, for example, reached only 0.31 (Kennedy et al. 1980), a moderate level at best. Using initial performance during learning as a predictor, therefore, may lead to inconsistent and/or erroneous training prescriptions.

Skill acquisition is believed by many to proceed in accordance with a number of stages or phases of improvement. Although the number of stages and their labels differ among researchers, the existence of such stages is supported by a large amount of research and theoretical development during the past 30 years. Traditional research in learning and memory posits a three-stage model for characterizing associative-type learning involving the process of differentiating between various stimuli or classes of stimuli to which responses are required (stimulus discrimination), learning the responses (response learning), and connecting the stimulus with a response (association). Empirical data suggest that this process is most efficient when materials are actively processed in a meaningful manner, rather than merely rehearsed via repetition (Craik and Lockhart 1972; Cofer et al. 1966).

Anderson (1982) has also proposed a three-stage model of skill acquisition, distinguishing among cognitive, associative, and autonomous stages. The cognitive stage corresponds to early practice in which a learner exerts effort to comprehend the nature of the task and how it should be performed.

In this stage, the learner often works from instructions or an example of how a task is to be performed (i.e., modeling or demonstration). Performance may be characterized by instability and slow growth, or by extremely rapid growth, depending upon task difficulty and degrees of prior experience of the learner. By the end of this stage, learners may have a basic understanding of task requirements, rules, and strategies for successful performance; however, these may not be fully elaborated. During the associative stage, declarative knowledge associated with a domain (e.g., facts, information, background knowledge, and general instruction about a skill acquired during the previous stage) is converted into procedural knowledge, which takes the form of what are called production rules (condition–action pairs). This process is known as knowledge compilation. It has been estimated that hundreds, or even thousands, of such production rules underlie complex skill development (Anderson 1990). Novice and expert performance is believed to be distinguished by the number and quality of production rules. Experts are believed to possess many more elaborate production rules than novices (Larkin 1981).

Similarly, Rumelhart and Norman (1978) recognized three kinds of learning processes: (1) the acquisition of facts in declarative memory (accretion), (2) the initial acquisition of procedures in procedural memory (restructuring), and (3) the modification of existing procedures to enhance reliability and efficiency (tuning). Kyllonen and Alluisi (1987) reviewed these concepts in relation to learning and forgetting facts and skills. Briefly, they suggest that new rules are added to established production systems through the process of accretion, fine-tuned during the process of tuning, and subsequently reorganized into more compact units during the restructuring process.

Rasmussen (1979) has also distinguished among three categories, or modes, of skilled behavior: skill based, rule based, and knowledge based. Skill-based tasks are composed of simple stimulus-response behaviors, which are learned by extensive rehearsal and are highly automated. Rule-based behavior is guided by conscious control and involves the application of appropriate procedures based on unambiguous decision rules. This process involves the ability to recognize specific well-defined situations that call for one rule rather than the other. Knowledge-based skills are used in situations in which familiar cues are absent and clear and definite rules do not always exist. Successful performance involves the discrimination and generalization of rule-based learning. Rasmussen proposes that, in contrast to Anderson's model, performers can move among these modes of performance as dictated by task demands. This general framework is useful in conceptualizing links between task content and the type of training required for proficiency in complex tasks.

3.6.2. Retention

Instructional designers must consider not only how to achieve more rapid, high-quality training, but also how well the skills taught during training will endure after acquisition. Further, what has been learned must be able to be successfully transferred or applied to a wide variety of tasks and job-specific settings. Swezey and Llaneras (1997) have recently reviewed this area.

Retention of learned material is often characterized as a monotonically decreasing function of the retention interval, falling sharply during the time immediately following acquisition and declining more slowly as additional time passes (Wixted and Ebbesen 1991; Ebbinghaus 1913; McGeoch and Irion 1952). There is general consistency in the loss of material over time. Subjects who have acquired a set of paired items, for example, consistently forget about 20% after a single day and approximately 50% after one week (Underwood 1966). Bahrick (1984), among others, demonstrated that although large parts of acquired knowledge may be lost rapidly, significant portions can also endure for extended intervals, even if not intentionally rehearsed.

Evidence suggests that the rate at which skills and knowledge decay in memory varies as a function of the degree of original learning; decay is slower if material has previously been mastered than if lower-level acquisition criteria were imposed (Loftus 1985). The slope and shape of retention functions also depend upon the specific type of material being tested as well as upon the methods used to assess retention. As meaningfulness of material to the student increases, for example, rate of forgetting appears to slow down. Further, recognition performance may be dramatically better than recall, or vice versa, depending simply upon how subjects are instructed (Tulving and Thomson 1973; Watkins and Tulving 1975). Also, various attributes of the learning environment, such as conditions of reinforcement, characteristics of the training apparatus, and habituation of responses, appear to be forgotten at different rates (Parsons et al. 1973).

Retention, like learning and motivation, cannot be observed directly; it must be inferred from performance following instruction or practice. To date, no uniform measurement system for indexing retention has been adopted. General indices of learning and retention used in the research literature over the past 100 years include a huge variety of methods for measuring recall, relearning, and recognition. Luh (1922), for instance, used five different measures to index retention: recognition, reconstruction, written reproduction, recall by anticipation, and relearning.

The list of variables known to reliably influence rate of forgetting of learned knowledge and skills is relatively short. In a recent review, Farr (1987) surveyed the literature and identified a list of

variables known to influence long-term retention, including degree of original learning, characteristics of the learning task, and the instructional strategies used during initial acquisition. According to Farr, the single largest determinant of magnitude of retention appears to be the degree of original learning. In general, the greater the degree of learning, the slower will be the rate of forgetting (Underwood and Keppel 1963). This relationship is so strong that it has prompted some researchers to argue that any variable that leads to high initial levels of learning will facilitate retention (Prophet 1976; Hurlock and Montague 1982).

The organization and complexity of material to be learned also appear to have a powerful influence on retention. The efficiency of information acquisition, retrieval, and retention appears to depend to a large degree on how well the material has been organized (Cofer et al. 1966). Conceptually organized material appears to show considerably less memory loss and to be more generalizable than material that is not so organized.

Research has identified numerous variables that fall under the banner of strategies for skill and knowledge acquisition and retention, including spaced reviews, massed/distributed practice, part/whole learning, and feedback. An important variable with respect to forgetting is spaced practice. The ''spacing effect'' (the dependency of retention on the spacing of successive study sessions) suggests that material be studied at widely spaced intervals if retention is required. Similarly, research comparing distributed practice (involving multiple exposures of material over time) vs. massed practice (requiring concentrated exposure in a single session), has occurred in a wide variety of contexts, including the acquisition of skills associated with aircraft carrier landings (Wightman and Sistrunk 1987), word-processing skills (Bouzid and Crawshaw 1987), perceptual skills associated with military aircraft recognition (Jarrard and Wogalter 1992), and learning and retention of second-language vocabulary (Bloom and Shuell 1981). Most research in this area, however, has emphasized acquisition of verbal knowledge and motor skills. In general, research on the issue of distribution of practice has emphasized effects on acquisition and found that distribution of practice is superior to massed practice in most learning situations, long rest periods are superior to short rest periods, and short practice sessions between rests yield better performance than do long practice sessions (Rea and Modigliani 1988). However, no consistent relationships between these variables and long-term retention have emerged.

Techniques that help learners to build mental models that they can use to generate retrieval cues, recognize externally provided cues, and/or generate or reconstruct information have also generally facilitated retention (Kieras and Bovair 1984). Gagné (1978) identified three general strategies for enhancing long-term retention, including reminding learners of currently possessed knowledge that is related to the material to be learned, ensuring that the training makes repeated use of the information presented, and providing for and encouraging elaboration of the material during acquisition as well as during the retention interval.

Other factors that have been shown to induce forgetting include interference by competing material that has been previously or subsequently acquired and the events encountered by individuals between learning and the retention test. Information acquired during this interval may impair retention, while simple rehearsal or reexposure may facilitate retention. Additional factors influencing skill and knowledge retention include the length of the retention interval, the methods used to assess retention, and individual difference variables among trainees. The absolute amount of skill/knowledge decay, for example, tends to increase with time, while the rate of forgetting declines over time. Researchers have also postulated a critical period for skills loss during a nonutilization period at between six months and one year after training (O'Hara 1990). Psychomotor flight skills, for example, are retained many months longer than procedural flight skills (Prophet 1976), and decay of flight skills begins to accelerate after a six-month nonutilization period (Ruffner et al. 1984).

3.6.3. Transfer

The topic of transfer-of-training is integrally related to other training issues, such as learning, memory, retention, cognitive processing, and conditioning; these fields make up a large subset of the subject matter of applied psychology (Swezey and Llaneras 1997). In general, the term *transfer-of-training* concerns the way in which previous learning affects new learning or performance. The central question is how previous learning transfers to a new situation. The effect of previous learning may function either to improve or to retard new learning. The first of these is generally referred to as positive transfer, the second as negative transfer. (If new learning is unaffected by prior learning, zero transfer is said to have occurred.) Many training programs are based upon the assumption that what is learned during training will transfer to new situations and settings, most notably the operational environment. Although U.S. industries are estimated to spend billions annually on training and development, only a fraction of these expenditures (not more than 10%) are thought to result in performance transfer to the actual job situation (Georgenson 1982). Researchers, therefore, have sought to determine fundamental conditions or variables that influence transfer-of-training and to develop comprehensive theories and models that integrate and unify knowledge about these variables.

Two major historical viewpoints on transfer exist. The identical elements theory (first proposed by Thorndike and Woodworth 1901) suggests that transfer occurs in situations where identical elements exist in both original and transfer situations. Thus, in a new situation, a learner presumably takes advantage of what the new situation offers that is in common with the learner's earlier experiences. Alternatively, the transfer-through-principles perspective suggests that a learner need not necessarily be aware of similar elements in a situation in order for transfer to occur. This position suggests that previously used "principles" may be applied to occasion transfer. A simple example involves the principles of aerodynamics, learned from kite flying by the Wright brothers, and the application of these principles to airplane construction. Such was the position espoused by Judd (1908), who suggested that what makes transfer possible is not the objective identities between two learning tasks, but the appropriate generalization in the new situation of principles learned in the old. Hendriksen and Schroeder (1941) demonstrated this transfer-of-principles philosophy in a series of studies related to the refraction of light. Two groups were given practice shooting at an underwater target until each was able to hit the target consistently. The depth of the target was then changed, and one group was taught the principles of refraction of light through water while the second was not. In a subsequent session of target shooting, the trained group performed significantly better than did the untrained group. Thus, it was suggested that it may be possible to design effective training environments without a great deal of concern about similarity to the transfer situation, as long as relevant underlying principles are utilized.

A model developed by Miller (1954) attempted to describe relationships among simulation fidelity and training value in terms of cost. Miller hypothesized that as the degree of fidelity in a simulation increased, the costs of the associated training would increase as well. At low levels of fidelity, very little transfer value can be gained with incremental increases in fidelity. However, at greater levels of fidelity, larger transfer gains can be made from small increments in fidelity. Thus, Miller hypothesized a point of diminishing returns, where gains in transfer value are outweighed by higher costs. According to this view, changes in the requirements of training should be accompanied by corresponding changes in the degree of fidelity in simulation if adequate transfer is to be provided. Although Miller did not specify the appropriate degree of simulation for various tasks, subsequent work (Alessi 1988) suggests that the type of task and the trainee's level of learning are two parameters that interact with Miller's hypothesized relationships. To optimize the relationship among fidelity, transfer, and cost, therefore, one must first identify the amount of fidelity of simulation required to obtain large amount of transfer and the point where additional increments of transfer are not worth the added costs.

Another model, developed by Kinkade and Wheaton (1972), distinguishes among three components of simulation fidelity: equipment fidelity, environmental fidelity, and psychological fidelity. Equipment fidelity refers to the degree to which a training device duplicates the "appearance and feel" of the operational equipment. This characteristic of simulators has also been termed physical fidelity. Environmental, or functional, fidelity refers to the degree to which a training device duplicates the sensory stimulation received from the task situation. Psychological fidelity (a phenomenon that Parsons [1980], has termed "verisimilitude") addresses the degree to which a trainee perceives the training device as duplicating the operational equipment (equipment fidelity) and the task situation (environmental fidelity). Kinkade and Wheaton postulated that the optimal relationship among levels of equipment, environmental, and psychological fidelity varies as a function of the stage of learning. Thus, different degrees of fidelity may be appropriate at different stages of training.

The relationship between degree of fidelity and amount of transfer is complex. Fidelity and transfer relationships have been shown to vary as a function of many factors, including instructor ability, instructional techniques, types of simulators, student time on trainers, and measurement techniques (Hays and Singer 1989). Nevertheless, training designers often favor physical fidelity in a training device, rather than the system's functional characteristics, assuming that increasing levels of physical fidelity are associated with higher levels of transfer. The presumption that similarity facilitates transfer can be traced to the identical elements theory of transfer first proposed by Thorndike and Woodworth (1901). In fact, numerous studies show that similarity does not need to be especially high in order to generate positive transfer-of-training (see Hays 1980; Provenmire and Roscoe 1971; Valverde 1973). Hay's (1980) review of fidelity research in military training found no evidence of learning deficits due to lowered fidelity, and others have shown an advantage for lower-fidelity training devices, suggesting that the conditions of simulation that maximize transfer are not necessarily those of maximum fidelity. One possible reason for this may be that widespread use of such well-known techniques as corrective feedback and practice to mastery in simulators and training devices, which may act to increase transfer, may also decrease similarity. A second possibility is that introducing highly similar (but unimportant) components into a simulation diverts a student's attention from the main topics being trained, thereby causing reduced transfer, as is the case with manipulating the fidelity of motion systems in certain types of flight simulators (Lintern 1987; Swezey 1989).

A recent review by Alessi (1988) devotes considerable attention to debunking the myth that high fidelity necessarily facilitates transfer. After reviewing the literature in the area, Alessi concluded that

transfer-of-training and fidelity are not linearly related but instead may follow an inverted-U-shaped function similar to that suggested by the Yerkes–Dodson law (see Swezey 1978; Welford 1968), which relates performance to stress. According to this view, increases in similarity first cause an increase and then a corresponding decrease in performance, presumably as a function of increasing cognitive load requirements associated with decreased stimulus similarity.

Current issues and problems in transfer span four general areas: (1) measurement of transfer, (2) variables influencing transfer, (3) models of transfer, and (4) application of our knowledge of transfer to applied settings. Research on transfer needs to be conducted with more relevant criterion measures for both generalization and skill maintenance. Hays and Singer (1989) provide a comprehensive review of this domain. A large proportion of the empirical research on transfer has concentrated on improving the design of training programs through the incorporation of learning principles, including identical elements, teaching of general principles, stimulus variability, and various conditions of practice. A critique of the transfer literature conducted by Baldwin and Ford (1988) also indicates that research in the area needs to take a more interactive perspective that attempts to develop and test frameworks to incorporate more complex interactions among training inputs. Many studies examining training design factors, for example, have relied primarily upon data collected using college students working on simple memory or motor tasks with immediate learning or retention as the criterion of interest. Generalizability, in many cases, is limited to short-term simple motor and memory tasks.

3.7. Training Teams and Groups

Because teams are so prevalent, it is important to understand how they function (Swezey and Salas 1992). Teamwork can take on various orientations, including behavioral and cognitive perspectives. Behaviorally oriented views of the teamwork process deal with aspects involved in coordinated events among members that lead to specific functions (e.g., tasks, missions, goals, or actions) that a team actually performs in order to accomplish its required output. Cognitive views of the teamwork domain deal with a team's shared processing characteristics, such as joint knowledge about a task, joint ability to perform aspects of the work, motivation levels, personalities, and thought processes (Salas et al. 1995). The extent to which mental models are shared among team members may help in understanding and training teamwork skills (Cannon-Bowers and Salas 1990). In order for members of a team to coordinate effectively with others, they must share knowledge of team requirements. This, in turn, can help to coordinate a team effectively. Since the range of each individual team member's abilities varies widely, the overall level of competency within a team is often dependent upon shared skills. An individual's ability to complete a team function competently and convey information to other members accurately is a strong influence on the overall team structure and performance.

Swezey et al. (1994) suggest that in order to complete a team task accurately, four things must happen: (1) there must be an exchange of competent information among team members; (2) there must be coordination within the team structure of the task requirements; (3) periodic adjustments must be made to respond to task demands; and (4) a known and agreed-upon organization must exist within the group.

It is important to consider such issues as team size, task characteristics, and feedback use when designing team training programs. It has been shown that team size has a direct influence on the performance and motivation of teams. As the size of the team increases, team resources also increase (Shaw 1976). Due to the increase in information available to larger teams, individual team members have a more readily accessible pool of information for use in addressing team tasks. This in turn can provide increases in creativity, the processing of information, and overall team effectiveness (Morgan and Lassiter 1992). However, the unique aspects associated with larger teams may do more harm than good due to the fact that the increase in size may also pose problems. Various studies (Indik 1965; Gerard et al. 1968) have found that problems in communication and level of participation may increase due to increases in team size. These two issues, when combined, may diminish team performance by placing increased stress on a team in the areas of coordination and communication workload (Shaw 1976).

Task goal characteristics are another important contributor to team performance. Given a task that varies in difficulty, it has been found that goals that appear to be challenging and that target a specific task tend to have a higher motivational impact than those that are more easily obtainable (Ilgen et al. 1987; Gladstein 1984; Goodman 1986; Steiner 1972). According to Ilgen et al. (1987), motivation directs how much time an individual is willing to put forth in accomplishing a team task.

The use of feedback is another factor that influences team motivation and performance. Feedback helps to motivate an individual concerning recently performed tasks (Salas et al. 1992). Researchers concur that the feedback should be given within a short period of time after the relevant performance (Dyer 1984; Nieva et al. 1978). The sequence and presentation of the feedback may also play significant roles in motivation. Salas et al. (1992) have noted that during the early stages of training,

feedback should concentrate on *one* aspect of performance; however, later in time it should concentrate on *several* training components. It has been found that sequencing helps team training in that teams adjust to incorporate their feedback into the task(s) at hand (Briggs and Johnston 1967).

According to Salas and Cannon-Bowers (1995), a variety of methods and approaches are currently under development for use in building effective team training programs. One such technique is the developing technology of team task analysis (Levine and Baker 1991), a technique that, as it matures, may greatly facilitate the development of effective team training. The technology provides a means to distinguish team learning objectives for effective performance from individual objectives and is seen as a potential aid in identifying the teamwork-oriented behaviors (i.e., cues, events, actions) necessary for developing effective team training programs.

A second area is team-performance measurement. To be effective, team-performance measurement must assess the effectiveness of various teamwork components (such as team-member interactions) as well as intrateam cognitive and knowledge activities (such as decision making and communication) in the context of assessing overall performance of team tasks. Hall et al. (1994) have suggested the need for integrating team performance outcomes into any teamwork-measurement system. As team feedback is provided, it is also necessary to estimate the extent to which an individual team member is capable of performing his or her specific tasks within the team. Thus, any competently developed team performance-measurement system must be capable of addressing both team capabilities and individual capabilities separately and in combination.

Teamwork simulation exercises are a third developing technology cited by Salas and Cannon-Bowers (1995). The intent of such simulations is to provide trainees with direct behavioral cues designed to trigger competent teamwork behaviors. Essential components of such simulations include detailed scenarios or exercises where specific teamwork learning objectives are operationalized and incorporated into training.

Salas and Cannon-Bowers (1995) have also identified three generic training *methods* for use with teams; information based, demonstration based, and practice based. The information-based method involves the presentation of facts and knowledge via the use of such standard delivery techniques as lectures, discussions, and overheads. Using such group-based delivery methods, one can deliver relevant information simultaneously to large numbers of individuals. The methods are easy to use and costs are usually low. Information-based methods may be employed in many areas, such as helping teammates understand what is expected of them, what to look for in specific situations, and how and when to exchange knowledge.

Demonstration-based methods are performed, rather than presented, as are information-based methods. They offer students an opportunity to observe behaviors of experienced team members and thus of the behaviors expected of them. Such methods help to provide shared mental models among team members, as well as examples of how one is expected to handle oneself within complex, dynamic, and multifaceted situations (Salas and Cannon-Bowers 1995).

Practice-based methods are implemented via participatory activities such as role playing, modeling, and simulation techniques. These methods provide opportunities to practice specific learning objectives and receive feedback information. With such methods, trainees can build upon previous practice attempts until achieving the desired level(s) of success.

A final category of developmental teamwork technologies, according to Salas and Cannon-Bowers (1995), involves teamwork training implementation strategies. These authors discuss two such strategies: cross-training and team coordination training. In their view, cross-training, training all team members to understand and perform each other's tasks, is an important strategy for integrating inexperienced members into experienced groups. Team coordination training addresses the issue that each team member has specific duties and that those duties, when performed together, are designed to provide a coordinated output. Team coordination training involves the use of specific task-oriented strategies to implement coordination activities and has been successfully applied in the aviation and medical fields.

3.8. Training Evaluation

Training evaluation may serve a variety of purposes, including improving training and assessing the benefits of training. Formative evaluation consists of processes conducted while training is being developed. Summative evaluation consists of processes conducted after training has been implemented.

Because training typically does not remain static (a job's tasks are often modified, replaced, or added), the distinction between formative evaluation and summative evaluation is sometimes blurred (see Goldstein 1993). Formative evaluation focuses on improving training prior to implementation. It may also serve the purpose of assessing benefits of training in a preliminary way. Summative evaluation focuses on assessing the benefits of training to determine how training outcomes improve on-job performance. It may also serve the purpose of improving future training iterations. In terms

of instructional systems design, summative evaluation completes the cycle that began with analysis. Figure 1 shows a simplified version of this cycle.

Both formative and summative aspects of evaluation feed back into the training analysis phase, which showed why training was necessary, the performances that training presumably would change, and the job outcomes that would be affected. Formative evaluation typically includes internal quality checks (such as review by subject matter experts, review against instructional standards, and editing for organization and clarity), as well as pilot testing. Formative evaluation may occur throughout the process shown in Figure 1. Summative evaluation includes assessments of after-training outcomes, both immediately following the conclusion of a training program and at later intervals.

Kirkpatrick (1994) has developed a widely used classification taxonomy of evaluation levels. Table 2 shows these levels and how they apply to both formative and summative evaluation.

Note that pilot testing conducted during formative evaluation should address, at a minimum, levels 1 and 2 of Kirkpatrick's taxonomy. Summative evaluation should address all four levels. Kirkpatrick (1994) has suggested that all four levels must be addressed for evaluation to be useful to organizations. Although using the level 1 evaluation standard as a measure of satisfaction can be useful, using it as an indicator of training effectiveness is misleading. Clark (1982), for instance, showed that about one-third of the time, a negative correlation exists between a learner's end-of-course self-rating and measures of learning.

Level 2 evaluation is obviously beneficial for determining whether training produces the learning it is intended to produce. As discussed above, we recommend criterion-referenced testing as the appropriate source of level 2 data for training (as opposed to education) evaluation. End-of-course criterion-referenced tests are designed to show whether or not trainees can perform adequately on measures of each course objective. In criterion-referenced measurement, the operative question is, "Can trainees perform the required task or not?" Contrast this with norm-referenced testing, which addresses the question, "How do learners' levels of knowledge compare?" In practice, a norm-referenced test could show a percentage of students excelling, while a criterion-referenced test on the same information could show all students as failing to meet certain training standards.

Conducted with a criterion-referenced approach, level 2 evaluation shows what trainees can do at the end of a course, but not what they will do on the job. There are several reasons for this, as noted above. First, there is the issue of retention over time. If learners do not have the opportunity to practice what they have learned in training, retention will decrease. Consequently, for training to be effective, it should be conducted close to the time when trainees need to use what they have learned. Transfer issues, as previously described, may also affect actual job performance and should be carefully considered in training design.

Another reason that level 2 evaluation may not predict how trainees will perform later in time is that outside factors may inhibit application of what is learned. As noted previously, organizations may lack appropriate motivational systems and environmental support for specific behaviors. Thus, if trainees are taught to perform behavior *y* in response to stimulus *x* in training but are required to perform behavior *z* in response to that stimulus on the job, the behavior learned in training will soon be extinguished. Similarly, if employees are taught to use certain tools during training but those tools are absent from the work environment, the tool-related behaviors learned during training will not be used.

Kirkpatrick's level 3 evaluation seeks to measure changes in behavior after training. Because factors other than training may influence later behaviors, measuring these changes successfully may

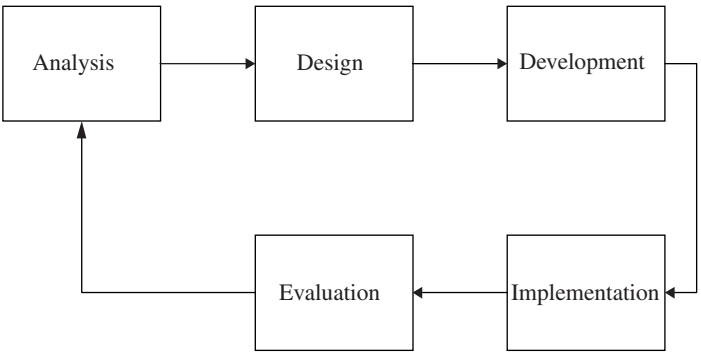

Figure 1 Evaluation's Role in an ISD Model.

TABLE 2 Kirkpatrick's Levels Applied to Formative and Summative Evaluation

Level of Evaluation	Type of Evaluation	
	Formative	Summative
1. Reaction: Participants' reaction to course (customer satisfaction).	"Dog food principle": Even if it's very nutritious, if the dogs don't like it, they won't eat it. Make sure participants are satisfied with the course.	Reactions can be used to distinguish between instructors, setting, audience, and other factors (e.g., are ratings for some instructors consistently higher than for others?).
2. Learning: Change measured at end of course.	Does the course meet its learning objectives? If it doesn't, revise and repilot test until it does.	Use end-of-course measures to determine needs for remediation and for improving future iterations of course.
3. Behavior: Change measured on the job.	Typically not included in formative evaluation.	If the course doesn't change behavior on the job, the investment in development has been wasted. Analyze causes for lack of change. Modify course, motivational factors, and/or environmental factors as necessary.
4. Results: Impact of change on job outcomes.	Typically not included in formative evaluation.	If the behavior change occurs but does not improve the job outcomes it targeted, the training may be flawed and/or external factors may be affecting the outcome. Reanalyze needs.

require an experiment. Table 3 shows an example of an experimental design permitting a level 3 evaluation.

Using the design shown in Table 3, training has been randomly assigned to group B. Baseline performance of both groups is then measured at the same time, before group B receives training. If the assignment is truly random, there should be no significant differences between the performance of trainees in groups A_1 and B_1. At the same point after training, job performance of both groups is again measured. If all other factors are equal (as they should be in random assignment), differences between groups A_2 and B_2 will show the effect of training on job behavior. Depending on the type of measurement, one may use various statistical indices, such as a chi squared test or phi coefficient as a test of statistical significance (see Swezey 1981 for a discussion of this issue.)

This design does not use level 2 evaluation data. However, by modifying the design so that measures of A_1 and B_1 behaviors occur at the end of training (rather than prior to training) and measures of A_2 and B_2 occur later (e.g., at some interval after training), one can use level 2 evaluation data to assess the relative effect of nontraining factors on job performance. In this case (level 2 evaluation), B_1 performance should be significantly higher than A_1 performance. But B_2 performance may not be significantly higher than A_2 performance, depending upon whether nontraining factors inhibit job performance. Again, statistical comparisons are used to determine significance of the effect(s).

TABLE 3 Experimental Design for Level 3 Evaluation

Points of Measurement	Experimental Condition	
	No Training	Training
Before Training	A_1	B_1
After Training	A_2	B_2

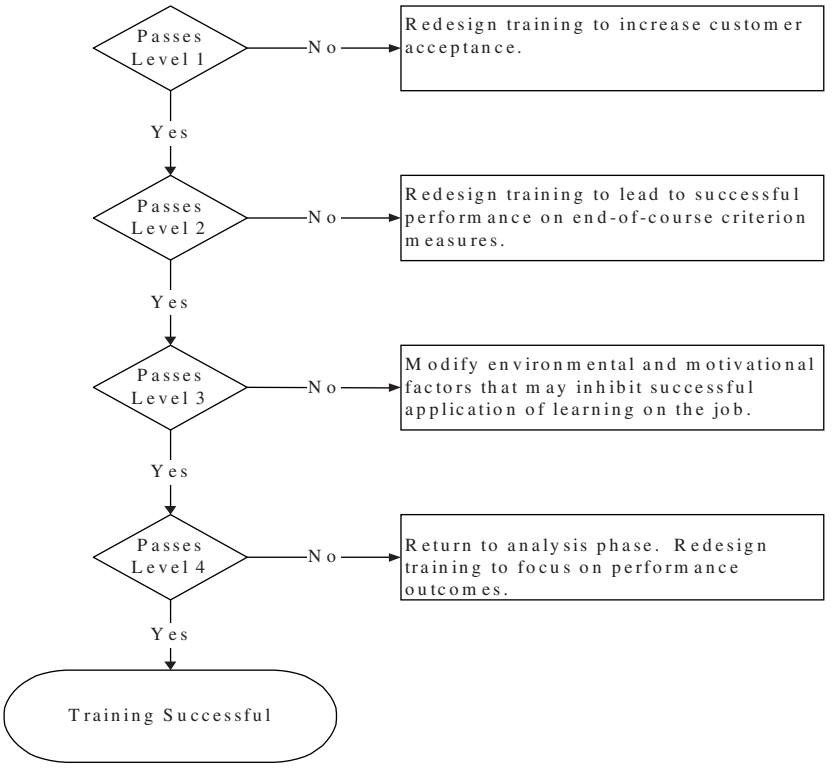

Figure 2 Remedying Failures at Each Level of Evaluation.

Kirkpatrick's level 4 evaluation addresses the basic question, "So what?" Even if evaluation at levels 1 through 3 show positive results, if training does not lead to desired results on job performance, it may not be the proper solution or worth the expense. For example, if training is designed to lead to performance that reduces error rates, and these error rates do not decline adequately, training may not have been the correct solution to the problem situation. Figure 2 provides a brief overview of how to address failure at each of Kirkpatrick's four levels of evaluation.

4. DEVELOPMENT

The distinction between training and development is ill defined. For purposes of this chapter, we define development in organizational contexts as "Plans and activities intended to achieve long-term changes in employees and their organizations." As such, development may include education, training, organizational realignment, values clarification, modifications to feedback and reward systems, mentoring, and a host of other interventions. In this section, we briefly mention a few forms of development in terms of research results.

4.1. Individual Performance Enhancement

In the 1940s and 1950s, much research on individual performance enhancement focused on personality development. By the 1960s, however, it had become clear that a wide variety of personalities could function successfully in nearly all jobs. One of the most widely used psychometric tools in business and industry, the Myers–Briggs Type Indicator (MBTI), purports to measure personality types. However, both Druckman and Bjork (1991) and Pittenger (1993) showed that data obtained via the MBTI have very little predictive validity in terms of job performance. Although research into the predictive value of personality testing continues today, it remains questionable whether development that focuses on personality traits as predictors will lead to significant results with respect to job performance.

Recently, the issue of competencies has also become popular in training circles. Most research on competencies can be divided into two types:

1. Those that address specific job skills, e.g., ''can calibrate a variety of instruments used to measure tensile strength''
2. Those that address traits, (sometimes disguised in behavioral terms), e.g., ''demonstrates the ability to work well with others in a variety of situations''

Although training may be an appropriate development activity for the first type of competency, the second may not benefit from *any* development activity. For development activities to be useful, their outcomes must be clearly specified. If ''works well with others'' is defined in operational terms (e.g., others report that the individual contributes well in team situations), then development activities, such as training, coaching, and mentoring, may be appropriate.

A variety of experiential forms of training are in use as development activities. These range from wilderness survival courses to games and specially designed on-the-job training experiences that focus on an individual's performance. Spitzer (1986) reviews the preparation, conduct, and follow up of a variety of specially designed on-the-job training experiences. Most such experiential approaches have not been validated via careful research. Thiagarajan (1980) also summarizes advantages and disadvantages of games and other forms of experiential learning. He notes that, while experiential learning is often shown to produce the same results as more conventional forms of training, it occasionally leads to poorer skill acquisition. However, he argues that because such experiential techniques are often fun, they may gain trainee acceptance and therefore be a good vehicle for individual skill enhancement. We tend to disagree with this view.

Coaching and mentoring are other methods of performance enhancement used in development situations. In coaching, a coach works with a student during one or more sessions to help the student develop and apply skills on the job. Pearlstein and Pearlstein (1991) present an ISD-based approach to coaching, and Fournies (1987) describes a wide variety of contexts for coaching. Generally, mentoring is a long-term relationship between an experienced and a less-experienced individual that is designed to bring about changes in behavior via counseling, feedback, and a variety of other techniques. Murray (1991) provides an overview of factors and techniques contributing to effective mentoring.

Career planning as a development activity can also be an effective means of enhancing performance. In career planning, individuals and their supervisors and/or human resources departments develop and plan a series of steps to help align individual goals with organizational goals and career progression. These steps may include training and education (either on or off the job), coaching, mentoring, special assignments, and job rotations. Schein (1978) provide a detailed model for career planning. While most employee-assessment systems appear to be a sound basis for individual performance enhancement, their unsuccessful implementation may work against job performance. According to Scherkenbach (1988), Deming's total quality management (TQM) process argues against such systems precisely because poor implementation can cause major roadblocks to success of both individuals and organizations. Since most employee assessment systems are linked to pay decisions, employees who admit to development needs may, in effect, be arguing against raises. This link thus creates both unsuccessful implementations and possible conflicts of interest.

4.2. Organizational Performance Enhancement

Two commonly practiced forms of organizational performance enhancement are management and leadership development and organization development. Management and leadership development focuses on improving organizational outcomes by improving the performance of those responsible for the outcomes. Organization development focuses on developing a total organization, as opposed to some particular aspect(s) of the organization, such as its leadership, management, or employee skills (see Gallessich 1982; Vaill 1971). Pearlstein (1991) argues that leadership development cannot be separated from organization development because leaders cannot be developed outside of the context of organization-wide goals for development.

4.2.1. Management and Leadership Development

Stodgill (1974), in a summary of over 3000 books and articles, found hundreds of definitions of leaders and managers. Some of these define management as focusing on support of organizational activities in their current state, as contrasted with leadership, which focuses on changing an organization to meet new challenges. In this context, a distinction is often made based upon topic areas, with management focusing on basics such as making assignments, delegating, and feedback and leadership focusing on more advanced areas such as communicating vision, establishing shared values, and individual employee empowerment. However, in the context of current organizational challenges, arbitrary distinctions between management and leadership are increasingly less relevant. Vaill (1989) asserts that organizations often find themselves, like kayakers, in ''permanent white water.'' This is even more the case now, with today's greater impacts of increasing globalization and rapidly accelerating technology.

Pearlstein (1992) notes that "Research (on leadership and management) . . . does not show conclusively that any leadership development training approach based on skill-building has led to long-term improvements in organizational functioning. Research does not show conclusively that any leadership development approach based on personal/awareness development or values clarification has led to long-term organizational improvements." Howard and Bray (1988) summarize the research of over 30 years of research on longitudinal management development studies. Complex and surprising results are the rule. For example, interpersonal skills, considered by many assessment centers to be one of the most critical predictors of management success, decline over time for many managers. Worse, managers selected in the 1980s had lower levels of interpersonal skills than those selected in the 1950s. Similarly, Kotter (1982) reports on intensive studies of 15 general managers and concludes that training does not seem as important to leaders' development as do childhood and early work experiences. McCall et al. (1988) summarize the responses of nearly 400 corporate leaders on factors important to their development and note that leaders cited a 12:1 ratio of nontraining to training factors. Finally, Pearlstein (1991) indicates that management and leadership development programs are usually generic, offered out of the context of specific management and leadership jobs, do not last long enough, and focus either on skills or on personal development but not on both.

4.2.2. Organization Development

Organization development (OD) is practiced in many large organizations today. OD practitioners use a form of experimentation called action research, which includes five major phases:

1. Reaching agreement on goals and procedures of the OD activity
2. Designing ways to diagnose needs for organizational change
3. Presenting diagnostic findings in a useful way
4. Using the diagnostic findings to plan an organizational change strategy.
5. Applying the change strategy and evaluating its outcomes

Both Lippitt et al. (1958) and Argyris (1970) provide examples of using this phased approach. The examples have in common behavioral approaches to collecting the data on which to base the change strategies. Pearlstein (1997) provides nine OD principles for those who wish to practice within a human performance technology context:

1. Develop work units (not necessarily the entire organization).
2. Make sure that you are interacting with the appropriate decision maker.
3. Start by reaching agreement on desired outcomes, measurements, roles, and activities.
4. Insist on behavioral measurement, but first listen carefully to the client's statements of values and visions.
5. Make sure that the client considers the impacts of change on individuals, work units, the entire organization, and the larger community of which the organization is a part.
6. Meet with all key players, both individually and in groups.
7. Seek consensus but don't withhold expertise.
8. Give interventions sufficient time to work.
9. Close well with the client by helping to: (a) collect and disseminate summative evaluation data, (b) celebrate organizational successes, and (c) plan next steps.

5. THE FUTURE OF SELECTION, TRAINING, AND DEVELOPMENT

We do not claim to hold a crystal ball; however, some aspects of selection, training, and development are likely to stay the same, while others are likely to change. In our view, those that will stay the same are based on well-established research results and apply independently of increasing globalization and accelerating technological development. Those that will change lack these attributes.

5.1. Selection

Selection tools will likely remain focused on measuring past and current behavior. Some tools that rely on assessing current performance may be slow to change because of difficulties associated with simulating tasks remotely. Many tools will become more widely used over the Internet. That is, organizations will increasingly use the Internet as a means for obtaining information previously gained via application forms, paper-based tests, interviews, and other selection devices. For example, many organizations now use Internet-based application forms that feed candidates' responses in standard formats directly into databases, which are then mined to match candidates' qualifications with job requirements. Similarly, because of globalization, it is likely that selection tools such as application

forms, tests, and interviews will also become increasingly available in multilingual and multicultural versions. Further, simulations and work sample assessments will be increasingly used, also in different culturally oriented and language-based forms.

5.2. Training

The basic development process for training is likely to remain some form of systems-oriented instructional model, although cognitively oriented technologies will increasingly be developed. The well-researched ISD approach has been adapted for use in many cultures and leads to reliable outcomes regardless of the specific type of technology employed. As cognitive approaches become better able to predict factors that build expertise, they will be more frequently used in task analysis. Results may be used to design training that is more useful for ''far transfer'' situations—that is, to tasks relatively dissimilar to those used as examples during training (see Clark 1992). Still, results of cognitive analysis are likely to be used within the context of a systems-oriented instructional model.

Training delivery and administration systems are very likely candidates for change. Computer-based training (CBT), now widely available in CD-ROM format, is increasingly more available in other disk-based formats (e.g., DVD) and on the Internet as Web-based training (WBT). Limitations on processing power, memory, storage, and bandwidth are all decreasing rapidly. This is leading to an increased ability for CBT, regardless of its mode of delivery, to offer high levels of simulation. Streaming audio and streaming video, voice recognition, and other technological advances are rapidly improving simulation fidelity. Similarly, advances in manipulanda (e.g., tactile gloves, aircraft yokes) are also increasing simulation fidelity. The result is that training delivered to remote sites can use both simulation and work sample presentation more effectively.

Other distance learning approaches, such as virtual classrooms, are being used increasingly. Both synchronous (real-time classroom) and asynchronous (classes via forums and message boards) types of distance learning will become widely used. For example, it is likely that organizations will increasingly incorporate university courses directly into work environments. This can be done globally with, for example, Saudi managers taking economics courses offered by Japanese universities.

There are negative aspects to the rapid spread of distance learning techniques. Often media values are emphasized at the expense of sound instructional practice. For example, much CBT available today does not make use of the technology for branching to different points in instruction based upon learner responses. Although the technology for branching has existed since the 1960s (see, e.g., Markle 1969), much CBT available today is linear. Although some argue that learner control (the ability to move through lessons at will) is more important than programmed control, research findings suggest otherwise. Clark (1989), for instance, showed that given a choice of approach (structured or unstructured), CBT users were more likely to choose the alternative least useful for skill acquisition. Novice learners, who may have benefited from a structured approach, often chose an unstructured one, while experts, who could use their advanced ability to explore advantageously, were more likely to choose structured approaches. Similarly, the advance of virtual classrooms in corporate settings may lead to an emphasis on education, as opposed to training. Thus, employees may learn more generalities about topics, at the expense of learning how to perform tasks.

One recent development in training has been slow to evolve. Electronic performance support systems (EPSS), which combine online help, granular training, and expert advice functions, were popularized by Gery (1991). Although used in some corporations today, EPSS use does not seem to be accelerating, possibly because development costs are relatively high. In an EPSS, help is directly available on employee computers. In addition to highly contextual online help, brief, focused training modules are offered when users repeatedly request help on the same topics. Such systems use artificial intelligence techniques, such as algorithms based upon data derived from users' experiences, to offer expert advice. Thus, a user who wanted to advise a consumer on what lumber to purchase for a deck could select an expert advisor function to input the consumer's space requirements and house dimensions, and the computer could immediately provide appropriate sketches and lumber requirements. Such systems can dramatically reduce amounts of time spent in formal training.

5.3. Development

Like training, approaches for individual, management, and leadership development are likely to be offered increasingly on the Internet via virtual classrooms. Since many organizations continue to spend a large amount on development activities, there is little reason to suppose that they will discontinue such expenditures.

CHAPTER 36

Aligning Technological and Organizational Change

ANN MAJCHRZAK
NAJMEDIN MESHKATI
University of Southern California

 Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

The installation of new technology, especially technology involving computers or microprocessors, virtually always involves some change to the organization and its members. Thus, the effective management of technological change must include the effective management of organizational change as well.

In this chapter, conclusions are presented from the literature and recent work by the authors concerning effective management of simultaneous change in technology and organizational design. The objective of this chapter is to impart to the practicing engineer the following four points:

1. There are clear relationships between technological and organizational changes.
2. Introduction of technological change is tantamount to introduction of a technological, organizational, and people (TOP) change.
3. In order to ensure that the full range of TOP options available to any organization is considered in the selection of any single set of TOP changes, the engineer as technology planner must strive to understand the entire set of anticipated TOP changes prior to implementing new technology.
4. Planned change strategies must be thoughtfully applied to facilitate successful progress through the TOP changes.

Technologies of primary interest here are computer-automated production and information technologies because these have received the most research attention in the last decade. Production technologies include computer-automated manufacturing (CAM) and computer-integrated manufacturing (CIM) and their component technologies such as flexible manufacturing cells (FMC), automated guided vehicles, and computer numerical control (CNC) machines. Information technologies include manufacturing resource planning (MRP), computer-aided design (CAD), computer-aided engineering analysis, electronic mail, collaborative technologies, transaction processing technologies such as enterprise resource planning (ERP) systems, supply chain management systems, and electronic commerce.

2. WHY THE TOPIC IS CRITICAL TO INDUSTRIAL ENGINEERS

2.1. Failures of Implementation of New Technology

Accumulated evidence indicates that the implementation of computer-automated technology has not achieved as much success as originally anticipated. The American Production and Inventory Control Society and the Organization for Industrial Research have estimated the failure rate of these technologies to be as high as 75% (Works 1987). In a study in which 55 managers in 41 organizations supplying or using CAM were interviewed, half of the CAM installations were reported as failures (Ettlie 1986). In a study of 95 flexible manufacturing systems in the United States and Japan, the FMSs in the United States were found to be so ineffectively used as to yield little of the flexibility had been achieved in Japan (Jaikumar 1986). Kalb (1987) reports a 30–70% failure rate of computerized manufacturing technologies. One new product-development manager of a large computer manufacturer reported that ''Inadequately implemented new technologies cost our plants up to $1 million a day in unexpected losses.'' A major study of 2000 U.S. firms that had implemented new office systems revealed that at least 40% of these systems failed to achieve the intended results (Long 1989). Gibbs (1994) reports that for every six new large-scale software systems that are put into operation, two others are cancelled, with the average software development project overshooting its schedule by half. The Standish Group in 1995 reported that only 16% of information systems projects were judged to be successful, with 31% outright cancelled (*Wall Street Journal* 1998b). The Standish Group conducted another survey in 1997 of 360 information system professionals and found that 42% of corporate information technology projects were abandoned before completion and 33% were over budget or late (*Computerworld* 1997).

Examples of these failures abound. For example, after spending more than $17 million on a long-anticipated overhaul of Los Angeles's computerized payroll system, the city controller scrapped it (*Los Angeles Times* 1999). The London Ambulance Service computer-aided dispatch system deployed in 1992 was intended to provide an automatic vehicle-locating system, telephone call processing, and allocation buttons for crew to report on current status. The system was pulled because crews couldn't accurately indicate their status and dispatchers couldn't intervene to get the crews to the needed locations (Flowers 1997). The State of California cancelled deployment of an automated child-support system for automatically tracking parents across counties who do not have primary custody of their children after spending $100 million (*Los Angeles Times* 1997). Fox Meyer, once a $5 billion drug-distribution company, was unable to process the huge volume of orders from pharmacies after installing a $65 million ERP system. As a result, it filed for bankruptcy in 1996, was bought in 1997

for just $80 million, and filed a $500 million lawsuit against Andersen Consulting, the implementers of the ERP system (*Information Week* 1998; *Wall Street Journal* 1998b). Oxford Health Plans lost $363 million in 1997 when their new claims-processing system delayed claims processing and client billing (*Wall Street Journal* 1998a; Champy 1998). Computer systems were blamed for delaying the scheduled opening of the first deregulated electricity market in the United States (*Information Week* 1997). Hershey, the nation's largest candy maker, installed a $110 million ERP system in July 1999. Glitches in the system left many distributors and retailers with empty candy shelves in the season leading up to Halloween (*Wall Street Journal* 1999). Whirlpool reported that problems with a new ERP system and a high volume of orders combined to delay shipments of appliances to many distributors and retailers.

These failures are expensive. In an internal document of September 15, 1997, the information systems research firm MetaFax calculated an average yearly loss of $80 billion from a 30% cancellation rate and a $59 billion loss from a 50% over-budget rate. In 1997 alone (before the Y2K inflated IT expenditures), companies spent $250 billion on information technology; a 30–70% failure rate clearly means that billions of dollars are spent with disappointing results (*Wall Street Journal* 1998b). Aside from a disappointing return on investment, the impacts of failed technology investments include:

- Harm to the firm's reputation (where poor implementation gets blamed on the technology vendor or designer)
- Broken trust (where workers are unwilling to go the extra mile the next time)
- Reduced management credibility (because management can't deliver on promises)
- Slower learning curve (leading to crisis management as problems increase with implementation rather than decrease)
- Reduced improvement trajectory (since there is no time to explore opportunities for new technology or new business opportunities for existing technology)

2.2. Why These High Failure Rates?

In one of the first major studies on this problem of implementation, the Congressional Office of Technology Assessment concluded: ''The main stumbling blocks in the near future for implementation of programmable automation technology are not technical, but rather are barriers of cost, organization of the factory, availability of appropriate skills, and social effects of the technologies'' (OTA 1984, p. 94). A few years later, the Manufacturing Studies Board of the National Research Council conducted a study of 24 cases of the implementation of CAM and CIM technologies and concluded: ''Realizing the full benefits of these technologies will require systematic change in the management of people and machines including planning, plant culture, plant organizations, job design, compensation, selection and training, and labor management relations'' (MSB 1986). In a 1986 Yankee Consulting Group marketing survey of CAM and CIM users, the users reported that 75% of the difficulties they experienced with the technologies could be attributable to issues concerned with planning the use of the technology within the context of the organization (Criswell 1988).

Recent evidence continues to support the conclusion that a significant component of the complexity of technological change lies in the organizational changes often experienced. C. Jackson Grayson, Jr., then Chairman of the American Productivity and Quality Center in Houston, Texas, analyzed the 68 applications for the Malcolm Baldrige National Quality Award for 1988 and 1989 and found that a major reason for failing to meet the examination criteria was the neglect of and failure to integrate human and organizational aspects with technology investments (Grayson 1990). Peter Unterweger of the UAW Research Department, after extensive case study visits in the United States and abroad, concluded that the successes of technological implications can be attributable to: (a) hardware playing a subordinate role to organizational or human factors and (b) developing the technical and organizational systems in step with one another (Unterweger 1988). In a study of 2000 U.S. firms implementing new office systems, less than 10% of the failures were attributed to technical failures; the majority of the reasons given were human and organizational in nature (Long 1989). The MIT Commission on Industrial Productivity concluded from their extensive examination of the competitiveness of different American industries: ''Reorganization and effective integration of human resources and changing technologies within companies is the principal driving force for future productivity growth'' (Dertouzos et al. 1989). More recently, in a 1997 survey by the Standish Group of 365 IT executive managers, the top factors identified in application development project failures were poor management of requirements and user inputs (*Computerworld* 1998a). The 1997 MetaFax survey found the reasons for IS failures to include poor project planning and management. In a 1998 *Computerworld* survey of 365 IT executives, the top factors for software development project failures were the lack of user input and changing requirements (*Computerworld* 1998a). A careful study of six failures of information technology projects found that those projects that devoted more effort to

the technology rather than to the organizational issues (such as awareness, training, and changes to organizational procedures) were more likely to fail (Flowers 1997). In short, these failures can be attributed to the inadequate integration of technical with social and organizational factors during the introduction of the technological change, called sociotechnical or TOP (for Technology, Organization, and People) integration. This recognition has led *The Wall Street Journal* to write: ''What's emerging here is a search for a better balance between manpower and computer power'' (1998b, p. 1).

Several cases of failures directly attributable to poor alignment of technology and organizational change can be cited. In one such example (Ciborra and Schneider 1990), a U.S. aircraft instruments plant implemented a computerized MRP system. Ten months into the implementation process, none of the expected gains in efficiency had materialized, despite clearly defined goals and plans, a sound economic evaluation, and a structured implementation plan. The major problem was that there was so much emphasis on following the rules created by the MRP system that clerks often hesitated to override the system's commands even when they knew that the commands did not make sense. Even useful localized innovations with the system, such as shortcuts and new rules of thumb, remained private know-how because localized practices were not sanctioned by management. Learning from mistakes was limited because effective job performance for the system designers was measured by adherence to best technical practice, not to shop-floor reality, and thus the system designers were not willing to have their competence questioned.

As another example, in 1997 Chrysler Financial tossed out a sophisticated financial package bought for the company's financial team. The problem was that the system was incompatible with the company's e-mail system. So the company adopted a less sophisticated approach that was more closely aligned with the way the financial staffers worked: instead of monitoring dealer activity with a 100% computerized system, the company instructed clerks to obtain information from dealers the old-fashioned way—over the phone—and enter the information quickly to make it available to financial staffers who wanted to know which dealers were moving a lot of cars or taking bad loans. According to the project director, the purely computerized solution would have cost many millions of dollars more and taken years to install, but ''by adding some people into the equation, we could get 95% of what we needed'' and take only 90 days to set it up (*Wall Street Journal* 1999, p. A26).

Another example of how advanced technology without correct organizational alignment in the automotive industry failed is presented by *The Economist:*

> [T]he giant Hamtramck plant in Detroit, which makes Cadillacs, is just five years old and heavily automated but ranks among the least competitive plants in the United States. Hamtramck is typical of GM's early efforts to beat the Japanese by throwing truckloads of cash into a new technology. Hamtramck had what is politely called a ''very rough start-up''. Its robots ran wild. Although the problems have now largely been tamed, GM learnt in a joint venture with Toyota that what really mattered in manufacturing was people. (*Economist* 1990).

As another example, British Airways put in a system at airport gates in which the screen was mounted horizontally, low on a desktop. Ticket agents looked down when checking in passengers; as a result, passengers saw only the top of the agent's head. The consultant on the project reported that they did this deliberately so there would be less eye contact and less schmoozing and the lines would be shorter. However, after installation, passengers complained; apparently fliers are naturally anxious and often need a little schmoozing, according to the consultant. The airline moved the screens to eye level (*Computerworld* 1998b).

Similarly, according to a survey of the artificial intelligence industry by *The Economist,* blind introduction of computers in the workplace by an American airline (which prefers to remain nameless) proved that people do not like taking orders from a machine when an expert system was installed to schedule the work of maintenance engineers (*Economist* 1992). The engineers simply rejected the system's plans and the computer system had to be withdrawn. But when, after suitable delay, the airline reintroduced more or less the same system for engineers to use when and if they wanted, it was much better received.

A final example of a project devoting too much attention to the technology side and too little to the organizational side is the London Ambulance system failure. In the formal inquiry on the failure, it was noted that the initial concept of the system was to fully automate ambulance dispatching; however, management clearly underestimated the difficulties involved in changing the deeply ingrained culture of London Ambulance and misjudged the industrial relations climate so that staff were alienated to the changes rather than brought on board. (Flowers 1997).

While much of this information supporting the important role of aligning technology and organizations is anecdotal, there have been several econometric studies of larger samples supporting this claim. A growing body of literature has established strong empirical links among such practices as high-involvement work practices, new technologies, and improved economic performance (MacDuffie 1995; Arthur 1992). Pil and MacDuffie (1996) examined the adoption of high-involvement work practices over a five-year period in 43 automobile assembly plants located around the world, their

technologies (ranging from highly flexible to rigidly integrated), and their economic performance and found that the level of complementary human resource practices and technology was a key driver of successful introduction of high-involvement practices. Kelley (1996) conducted a survey of 973 plants manufacturing metal products and found that a participative bureaucracy (i.e., group-based employee participation that provides opportunities to reexamine old routines) is complementary to the productive use of information technology in the machining process. Osterman (1994) used data on 694 U.S. manufacturing establishments to examine the incidence of innovative work practices, defined as the use of teams, job rotation, quality circles, and total quality management. He found that having a technology that requires high levels of skills was one factor that led to the increased use of these innovative work practices.

To conclude, it should be clear that technological change often necessitates some organizational change. If both organizational and technological changes are not effectively integrated and managed to achieve alignment, the technological change will fail.

3. WHAT ARE THE STUMBLING BLOCKS TO ALIGNMENT?

If the benefits of aligning technology and organizational design are so clear, why isn't it done? We suggest that there are many reasons.

3.1. The Future of Technology Is Probabilistic

The technology S curve has been historically documented as describing technology change over the years (Twiss 1980; Martino 1983). The curve, plotted as the rate of change of a performance parameter (such as horsepower or lumens per watt) over time, has been found to consist of three periods: an early period of new invention, a middle period of technology improvement, and a late period of technology maturity. The technology S curve, however, is merely descriptive of past technology changes. While it can be used for an intelligent guess at the rate of technology change in the future, technology change is sufficiently unpredictable that it cannot be used to predict precisely when and how future change may occur. Fluctuating market demand and/or novelty in the technology base exacerbate the challenge. For example, at Intel, typically at least one third of new process equipment has never been previously used (Iansiti 1999). This probabilistic nature of the technology makes creating aligned technology and organizational solutions difficult because it cannot be known with any certainty what the future organizational-technology solution is likely to be over the long term.

In his study of six information technology project failures, Flowers (1997) concluded that the unpredictability of the technology is a primary complexity factor that contributes to project failure. The more that the technology is at the ''bleeding'' edge, the greater the complexity. Avoiding overcommitment to any one technology or organizational solution, avoiding escalationary behavior where more resources are thrown at the solution-generation process without adequate checks and balances, and maintaining project-reporting discipline in the face of uncertainty are suggested ways of managing the inherent probabilistic nature of technology.

3.2. Some Factors Are Less Malleable Than Others

A series of research studies on the process by which technologies and organizations are adapted when technologies are implemented into an organization have shown that adaptations of both technologies and the organization can occur (Barley 1986; Contractor and Eisenberg 1990; Orlikowski and Robey 1991; Orlikowski 1992; Giddens 1994; Rice 1994; Orlikowski et al. 1995; Rice and Gattiker 1999). However, in reality, some adaptations are less likely to occur because some of these factors tend to be less malleable (Barley 1986; Johnson and Rice 1987; Poole and DeSanctis 1990; Orlikowski 1992; DeSanctis and Poole 1994; Orlikowski and Yates 1994). One of these factors is the existing organizational structure. For example, Barley (1986) found evidence that one factor that tends to be less malleable is the existing power structure in the organization. Barley found that when a medical radiation device was installed into two separate hospitals, the work changed in accordance with the organizational structure, not vice versa. That is, in the hospital where the radiologists had more power in the organizational structure than the technicians, the rift between the two jobs became greater with the new technology. In contrast, in the hospital where technicians and radiologists were not separated hierarchically, the technology was used to share knowledge between the two. Another factor often found to be less malleable is what DeSanctis and Poole (1994) refer to as the ''technology spirit,'' which they define as the intended uses of the technology by the developer or champion who influenced the developer. If the spirit is intended to displace workers, then this spirit is unlikely to be changed during implementation. Research contradicting this assertion has been conducted recently, however (Majchrzak et al. 2000). Moreover, Tyre and Orlikowski (1994) have found that malleability may be temporal, that is, that technologies and structures can be changed, but only during windows of opportunity that may periodically reopen as the technology is used. In their study, the authors found these windows to include new rethinking about the use of the technology or new needs for

the technology that were not originally envisioned. These windows did not stay open for very long; thus, over the long term, some factors may have appeared to be less malleable than others.

In sum, then, a stumbling block to integrating TOP is determining which facets of TOP are malleable to facilitate the alignment; when one facet is not malleable, that puts additional pressure on the remaining facet to conform—a pressure that may not be achievable.

3.3. Alignment Requires a Cross-Functional Definition of the Problem

For a solution to be sociotechnically aligned, changes may be needed in all aspects of the organization, not just that which is under the purview of the industrial engineer or even the manufacturing manager. Changes may be required in the material-handling organization (which may not report to the manufacturing department), the purchasing department, or the human resources department. For example, Johnson and Kaplan (1987), in their study of just-in-time manufacturing, found that those departments that made changes in the incentive systems (a responsibility outside that of the manufacturing manager) were less likely to have implementation problems than companies that did not make such changes. This cross-functional nature of aligned solutions creates the problem that because the solution touches on everyone's responsibilities, it is essentially no one's responsibility (Whiston 1996). Thus, unless an organizational structure is created to explicitly recognize the cross-functional nature of the alignment, a single function—such as the industrial engineer—cannot create the alignment. As a result, resolving a cross-functional problem with a single function becomes difficult, if not impossible.

3.4. Alignment Is Context Specific and Nonrepeatable

A solution that achieves alignment between technology and organization is typically so context specific that it is not likely to be repeatable in its exact form for the next alignment problem that comes along. This is because of the many factors that must be considered in deriving a technology-organization solution. For example, the global introduction of a new technology product typically now requires some modification in each context in which it is introduced either because of the different needs of customers or different service or manufacturing environments (Iansiti 1999) As another example, altering even one technology factor, such as the degree to which the technology can diagnose its own failures, creates the need to change such organizational factors as the amount of skills that workers must have to operate the technology (Majchrzak 1988). As another example, human supervisory control of automated systems—such as is seen in an oil and gas pipeline control center—involves fault diagnosis, error detection and recovery, and safe handling of rare, critical, and nonroutine events and incidents; these activities require very specific system-dependent sets of skills and teamwork (Meshkati 1996).

This context-specific nature of technology-organization solutions contradicts the desire of many managers today to use ''cookie cutter'' or repeatable solutions, believing that such solutions will cost less than solutions tailored to each site (Jambekar and Nelson 1996; Kanz and Lam 1996). In addition, Kahneman et al. (1982) have found that the judgments of people in conditions of uncertainty are governed by the availability heuristic (or bias), whereby people judge the likelihood of something happening by how easily they can call other examples of the same thing to mind. If they have no other examples, they will create connections between examples, even though the connections are tenuous. As a result, they will believe that they have a repeatable solution even though one is not warranted.

For example, when globally implementing ERP systems, managers have a choice whether to roll out a single standardized ERP solution worldwide or to allow some issues (such as user interface screens or data structures) to have localized solutions. Forcing a single standardized implementation world-wide has been the preferred strategy in most implementations because it minimizes the complexity and resources required to accommodate to localized modifications (Cooke and Peterson 1998). However, implementers at Owens-Corning believe that part of their success in their global ERP implementation was attributable to allowing localized solutions, even though it was slightly more complicated in the beginning. They believe that allowing field locations to tailor some aspects of the ERP system not only ensured the buy-in and commitment of field personnel to the ERP project, but also ensured that the ERP system met each and every field location's particular needs.

Thus, another stumbling block to alignment is that alignment solutions are best construed as nonrepeatable and highly contextual—a concept that raises management concerns about the resources required to allow such contextualization.

3.5. Alignment Requires Comprehensive Solutions That Are Difficult to Identify and Realize

A solution aligned for technology and organization is a comprehensive one involving many factors. Today it is widely believed that in addition to strategy and structure, an organization's culture, technology, and people all have to be compatible. If you introduce change in technology, you should

expect to alter your corporate strategy to capitalize on the new capabilities, alter various departmental roles and relations, add personnel with new talents, and attempt to ''manage'' change in shared beliefs and values needed to facilitate use of the new technology. (Jambekar and Nelson 1996, p. 29.5) Despite this need for integration, Iansiti (1999) charges that ''technology choices are too often made in scattershot and reactive fashion, with technology possibilities chosen for their individual potential rather than from their system-level integration.'' Iansiti specifically suggests that only when there is a proactive process of technology integration—''one comprising a dedicated, authorized group of people armed with appropriate knowledge, experience, tools, and structure''—will results be delivered on time, lead times be shorter, resources be adequately utilized, and other performance measures be achieved. In a study of reengineering efforts, Hall et al. (1993) argue that many attempts at reengineering have failed because of a focus on too few of the factors needing to be changed. Instead, for reengineering to work, fundamental change is required in at least six elements: roles and responsibilities, measurements and incentives, organizational structure, information technology, shared values, and skills.

Thus, another stumbling block to alignment is the need to consider all these factors and their relationships. For many managers and industrial engineers, there are too many factors and relationships; as a result, it is far easier to focus mistakenly on only one or a few factors.

3.6. Alignment Involves Long Planning Cycles, Where Observable Results and Knowing Whether You Made the Right Decisions Take Awhile

Years ago, Lawrence and Lorsch (1967) helped us to recognize the importance of the time horizon of feedback from the environment in determining whether strategic and organizational decisions are the right decisions. In their research, they found that some departments had very quick time horizons, such as a manufacturing department that is structured and oriented to obtaining quick feedback from the environment. In contrast are departments with longer time horizons, such as a research and development department, in which the department is organized to expect feedback about their work over a much longer time period. Lawrence and Lorsch further found that these different time horizons of feedback created different needs for organizational structures, performance-monitoring systems, and personnel policies. The technology-development process can be characterized as one that has a long planning cycle so that the time horizon of feedback may be months or years. For example, the average CIM implementation may take up to 3 years to complete; while the implementation of a large ERP system takes at least 18 months. As a result, managers and engineers need to make decisions about the design of the technology-organization solution in the absence of any data from the field. While some of these decisions may be changed later if data from the field indicate a problem in the design, some of these decisions are changeable only at great cost. This creates a bias toward conservativeness, that is, making decisions that minimize risk. As a result, only those factors that decision makers have historical reason to believe should be changed are likely to be changed, increasing the probability of misalignment. Thus, another stumbling block to achieving alignment is the long planning cycle of technology-organizational change, which tends to create a bias against change because learning whether planning decisions are the right ones.

3.7. Alignment Involves Compromises

Given the many factors involved in deriving an aligned solution and the many functions affected by an aligned solution, the final aligned solution is unlikely to be an idealized solution. Rather, the final solution is likely to be the outcome of a series of negotiations among the relevant parties. For example, a labor union may not want to give up the career-progression ladder provided by specialized jobs and embrace cross-functional teamwork; management may not want to give up the decision-making control they enjoy and embrace autonomy among the teams. The process of negotiating these different positions to result in some amicable compromise may be difficult and frustrating, adding to the challenges imposed by alignment.

Information technology, because it tends to break down organizational barriers, turfs, and layers, could face opposition from individuals entrenched in the companies' hierarchy. For example, production planning, inventory control, and quality control will increasingly be under the control of front-line employees, and this will pose a major threat to low-level supervisors and middle managers (Osterman 1989) and may even lead to their extinction (Drucker 1988).

4. HOW CAN TECHNOLOGY PLANNERS PURSUE ALIGNMENT DESPITE THESE DIFFICULTIES?

The difficulties identified in Section 3 are real difficulties not likely to go away with new managers, new technologies, new industrial engineering skills, new organizational designs, or new motivations. Therefore, industrial engineers must identify ways to move past these difficulties. This means taking the difficulties into account when pursuing alignment, rather than ignoring them. Effort then is not

spent on reducing the difficulties per se, but on managing them so that alignment can still be achieved. Below we propose several ways of pursuing alignment in ways that allow technology planners to move past the difficulties.

4.1. Focus Alignment on Business Purpose, Driven by Competitive Need, Not as a Technology Fix to a Localized Problem

The impact of the difficulties identified in Section 3 is often experienced as resistance to change. Managers argue against a technology; workers refuse to intervene to fix the technology; industrial engineers focus solely on the technology, refusing to consider work and job changes. This resistance to change is often a sign that the justification for the technology is weak. Weak justifications are those where the need for the technology is not driven by competitive advantage pursued by the firm. Porter (1985), Schlie and Goldhar (1995), Pine (1993), Goldman et al. (1995), and D'Aveni and Gunther (1994), among others, have emphasized the need for technology choices to be driven by the competitive advantage being pursued by the firm. Yet, as pointed out by Kanz and Lam (1996), traditional strategic management rarely adequately ties technology choices to strategic choices because of a lack of understanding of how technology choices are different from other types of strategic choices (such as new products or cost-cutting strategies). In a two-year study involving over 300 major firms, they found that while 50 executives believed their firms tied improvements in their IT infrastructure to a business strategy, only 10 firms were found to be doing so after a formal assessment. Moreover, while 190 executives believed their overall corporate strategies were driving the methodology for implementing their business plans, less than 20 strategies were actually doing so. The remainder were constrained by limitations in either organizational or IT culture and design (Sweat 1999).

Schlie (1996) offers specific suggestions for identifying how technology choices should be driven by competitive firm needs. He adopts Porter's (1985) strategic planning framework, which suggests that competitive advantage can be derived at any point along a firm's value chain (e.g., inbound logistics, outbound logistics, marketing/sales, procurement, R&D, human resource management, or firm infrastructure). For the point on the value chain that the firm decides to have a competitive advantage, that advantage can be achieved either through cost leadership (i.e., low cost, low price) or differentiation (i.e., uniqueness to the customer). Using this framework, Schlie (1996) suggests that firm management should first decide where in the value chain they will compete, and then how they will use technology to facilitate achieving their competitive advantage. In communicating this to plant personnel, then, justification of both the strategic choices as well as how technology helps the strategic choices is required. Schlie cautions, however, that some technologies can only be adequately justified for some of these strategic choices. He uses as an example the advanced manufacturing technologies CAM and CIM, pointing out that the contribution of these technologies to the competitive advantage of low cost is ambiguous and situation specific. Yet when firms justify their technology expenditures based on direct labor savings, that is precisely what they are suggesting. Thus, difficulties of alignment will not be overcome if the justification for the technology expenditure is suspect from the outset.

While there are many other strategic planning frameworks for integrating technology design choices with strategic choices (e.g., Burgelman and Rosenbloom 1999; Leonard-Barton 1995), the purpose here is not to elaborate the frameworks but to emphasize the need for the technology design choices to be driven by a business strategy—regardless of the framework used—and not by reactive problem solving.

4.2. Recognize the Breadth of Factors and Their Relationships That Must Be Designed to Achieve Alignment

It is apparent from Section 2.2 that the high failure rates of new technologies are due to the lack of alignment among technology and organizational factors. What are these factors? The U.S. industry's initiative on agile manufacturing (documented in Goldman et al. 1995) identified a range of factors, including the production hardware, the procurement process, and the skills of operators. The National Center for Manufacturing Sciences created a program to promote manufacturing firms to assess themselves on their excellence. The assessment contained 171 factors distributed across 14 areas ranging from supplier development to operations, from cost to flexibility, from health and safety to customer satisfaction. In a five-year industry–university collaborative effort funded by the National Center for Manufacturing Sciences, 16 sets of factors were identified that must be aligned (Majchrzak 1997; Majchrzak and Finley 1995), including:

- Business strategies
- Process variance-control strategies
- Norms of behavior

- Strategies for customer involvement
- Employee values
- Organizational values
- Reporting structure
- Performance measurement and reward systems
- Areas of decision-making authority
- Production process characteristics
- Task responsibilities and characteristics
- Tools, fixtures, and material characteristics
- Software characteristics
- Skill breadth and depth
- Information characteristics
- Equipment characteristics

Within each set, 5–100 specific features were identified, with a total of 300 specific design features needing to be designed to create an aligned organizational-technology solution for a new technology. In this five-year study, it was also found that achieving alignment meant that each of these factors needed to be supportive of each other factor. To determine whether a factor was supportive of another factor, each factor was assessed for the degree to which it supported different business strategies, such as minimizing throughput time or maximizing inventory turnover. Supportive factors were then those that together contributed to the same business strategy; inversely, misaligned solutions were those for which design features did not support similar business strategies.

Recognizing this range of factors and their relationships may seem overwhelming; but it can be done. The cross-functional teams and use of CAD technologies for developing the Boeing 777 aircraft present an excellent example of alignment. In designing the 777, Boeing created approximately 240 teams, which were labeled ''design-build teams.'' These teams included cross-functional representatives from engineering design, manufacturing, finance, operations, customer support, maintenance, tool designers, customers, and suppliers (Condit 1994). To communicate part designs, the teams used 100% digital design via the 3D CAD software and the networking of over 2000 workstations. This allowed the suppliers to have real-time interactive interface with the design data; tool designers too were able to get updated design data directly from the drawings to speed tool development. In addition, the CAD software's capability in performing preassembly checks and visualization of parts allowed sufficient interrogation to determine costly misalignments, interferences, gaps, confirmation of tolerances, and analysis of balances and stresses (Sherman and Souder 1996). In sum, the technology of CAD was aligned with the organizational structure of the cross-functional teams.

4.3. Understand the Role of Cultures in Alignment

Culture affects alignment by affecting the change process: changes that support the existing culture are easier to implement successfully than changes that cause the culture to change. At least two types of culture must be considered in designing a technology-organization solution: the national culture of the country and the culture of the organization.

According to Schein (1985), organizational culture is ''a pattern of basic assumptions—invented, discovered, or developed by a given group as it learns to cope with its problems of external adaptation and internal integration—that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel in relation to those problems.'' Kotter and Heskett (1992, p. 4) contend that organizational culture has two levels that differ in terms of their visibility and their resistance to change:

> At the deeper and less visible level, culture refers to values that are shared by the people in a group and that tend to persist over time even when group membership changes. . . . At the more visible level, culture represents the behavior patterns or style of an organization that new employees are automatically encouraged to follow by their fellow employees. . . . Each level of culture has a natural tendency to influence the other.

Operationally, organizational culture is defined as a set of shared philosophies, ideologies, values, beliefs, expectations, attitudes, assumptions, and norms (Mitroff and Kilmann 1984). Cultural norms are the set of unwritten rules that guide behavior (Jackson 1960). Use of this concept allows the capturing of those dimensions of organizational life that may not be visible in the more rational and mechanical aspects of the organization.

Cultures can be characterized not only by their focus but also by their strength (O'Reilly 1989; Beyer 1992). Strong cultures exert greater conformity on organizational members than weak cultures. The stronger the culture, then, the more difficult it will be to implement a technology-organization

alignment that contrasts with that culture. For example, if a knowledge-management repository is installed, workers are unlikely to contribute to the repository if there is a strong culture that encourages independence and heroism (Davenport 1994) Thus, in designing a technology-organization solution, the existing culture of the organization should be carefully considered and, if possible, used to foster the solution.

National culture, according to anthropologists, is the way of life of a people—the sum of their learned behavior patterns, attitudes, customs, and material goods. According to Azimi (1991), the culture of a society consists of a set of ideas and beliefs. These ideas and beliefs should have two principal characteristics or conditions: first, they should be accepted and admitted by the majority of the population; and second, the acceptance of these beliefs and ideas should not necessarily depend upon a scientific analysis, discussion, or convincing argument. Also, national culture, in the context of technology transfer and utilization, could operationally be defined as the ''collective mental programming of peoples' minds'' (Hofstede 1980a).

National culture affects not only the safety but also the success and survival of any technology. National cultures differ on at least four basic dimensions: power distance, uncertainty avoidance, individualism-collectivism, and masculinity-femininity (Hofstede 1980b). Power distance is the extent to which a society accepts the fact that power in institutions and organizations is distributed unequally. It is an indication of the interpersonal power or influence between two entities, as perceived by the less powerful of the two (BCAG 1993). Uncertainty avoidance is the extent to which a society feels threatened by uncertain and ambiguous situations. It also refers to attempts to avoid these situations by providing greater career stability, establishing more formal rules, not tolerating deviant ideas and behaviors, and believing in absolute truths and the attainment of expertise. Individualism is characterized by a loosely knit social framework in which people are supposed to take care of themselves and their immediate families only, while collectivism is characterized by a tight social framework in which people distinguish between in-group and out-group; they expect their in-group members (e.g., relatives, clan, organization) to look after them, and in exchange they owe absolute loyalty to the group. The masculinity dimension expresses the extent to which the dominant values in a society are ''masculine,'' as evidenced by decisiveness, interpersonal directness, and machismo (Johnston 1993). Other characteristics of masculine cultures include assertiveness, the acquisition of money and material goods, and a relative lack of empathy and reduced perceived importance for quality-of-life issues. This dimension can also be described as a measure of the need for ostentatious manliness in the society (BCAG 1993). Femininity, the opposite pole of this continuum, represents relatively lower assertiveness and greater empathy and concern for issues regarding the quality of life.

The four cultural dimensions discussed above also have significant implications for most complex technological systems' performance, reliability, and safety. For instance, according to Helmreich (1994) and Helmreich and Sherman (1994), there is evidence that operators with high power distance and high uncertainty avoidance prefer and place a ''very high importance'' on automation. Furthermore, it is known that the primary purpose of regulations is to standardize, systematize, and impersonalize operations. This is done, to a large extent, by ensuring adherence to (standard and emergency) operating procedures. On many occasions it requires replacing operators' habits with desirable intentions that are prescribed in procedures or enforced by regulations. However, according to several studies, an operator's culturally driven habit is a more potent predictor of behavior than his or her intentions, and there could be occasions on which intentions cease to have an effect on operators' behavior (Landis et al. 1978). This fact places in question the effectiveness of those regulations and procedures that are incompatible with operators' culturally driven habits.

A major, though subtle, factor affecting the safety and performance of a technological system is the degree of compatibility between its organizational culture and the national culture of the host country. It is an inevitable reality that groups and organizations within a society also develop cultures that significantly affect how the members think and perform (Schein 1985).

Demel (1991) and Demel and Meshkati (1989) conducted an extensive field study to explore how the performance of U.S.-owned manufacturing plants in other countries is affected by both the national culture of the host country and the organizational culture of the subsidiary plant. A manufacturing plant division of a large American multinational corporation was examined in three countries: Puerto Rico, the United States, and Mexico. Hofstede's (1980a) Values Survey Module for national culture and Reynolds's (1986) Survey of Organizational Culture were administered. Performance measures (i.e., production, safety, and quality) were collected through the use of secondary research.

The purpose of this investigation was threefold:

1. To determine whether there were any differences among the national cultures of Puerto Rico, the United States, and Mexico
2. To find out whether there were any differences between the organizational cultures of the three manufacturing plants

3. To establish whether there was any compatibility between the organizational culture of the plants and the national culture of the three countries, and examine whether the compatibility (or incompatibility) affected their performance in terms of production yields, quality, safety, and cycle time

Although the results of this study indicate that there are differences among the national culture dimensions of Puerto Rico, the United States, and Mexico, no significant differences were found between the organizational cultures of the three plants. This may be due to selection criteria, by which candidates, by assessment of their behavioral styles, beliefs, and values, may have been carefully screened to fit in with the existing organizational culture, Additionally, socialization may have been another factor. This means that the company may have had in-house programs and intense interaction during training, which can create a shared experience, an informal network, and a company language. These training events often include songs, picnics, and sporting events that build a sense of community and feeling of togetherness. Also, the company may have had artifacts, the first level of organizational culture, such as posters, cards, and pens that remind the employees of the organization's visions, values, and corporate goals and promote the organization's culture.

Therefore, it seems that a ''total transfer'' has been realized by this multinational corporation. Because these manufacturing plants produce similar products, they must obtain uniform quality in their production centers. To gain this uniformity, this company has transferred its technical installations, machines, and organization. Moreover, to fulfill this purpose, the company chooses its employees according to highly selective criteria. Notwithstanding, Hofstede's research demonstrates that even within a large multinational corporation known for its strong culture and socialization efforts, national culture continues to play a major role in differentiating work values (Hofstede 1980a).

There are concepts in the dimensions of organizational culture that may correspond to the same concepts of the dimensions of national culture:

The power distance dimension of national culture addresses the same issues as the perceived oligarchy dimension of organizational culture. They both refer to the nature of decision making; in countries where power distance is large, only a few individuals from the top make the decisions. Uncertainty avoidance and perceived change address the concepts of stability, change, and risk taking. One extreme is the tendency to be cautious and conservative, such as in avoiding risk and change when possible in adopting different programs or procedures. The other is the predisposition to change products or procedures, especially when confronted with new challenges and opportunities—in other words, taking risks and making decisions. Uncertainty avoidance may also be related to perceived tradition in the sense that if the employees have a clear perception of ''how things are to be done'' in the organization, their fear of uncertainties and ambiguities will be reduced. An agreement to a perceived tradition in the organization complements well a country with high uncertainty avoidance. Individualism–collectivism and perceived cooperation address the concepts of cooperation between employees and trust and assistance among colleagues at work. In a collectivist country, cooperation and trust among employees are perceived more favorably than in an individualist country.

The perceived tradition of the organizational culture may also be related to individualism-collectivism in the sense that if members of an organization have shared values and know what their company stands for and what standards they are to uphold, they are more likely to feel as if they are an important part of the organization. They are motivated because life in the organization has meaning for them. Ceremonies of the organizational culture and rewards given to honor top performance are very important to employees in any organization. However, the types of ceremonies or rewards that will motivate employees may vary across cultures, depending on whether the country has a masculine orientation, where money and promotion are important, or a feminine orientation, where relationships and working conditions are important. If given properly, these may keep the values, beliefs, and goals uppermost in the employees' minds and hearts.

Cultural differences may play significant roles in achieving the success of the corporations' performance. The findings of this study could have important managerial implications. First, an organizational culture that fits one society might not be readily transferable to other societies. The organizational culture of the company should be compatible with the culture of the society the company is transferring to. There needs to be a good match between the internal variety of the organization and the external variety from the host country. When the cultural differences are understood, the law of requisite variety can then be applied as a concept to investigate systematically the influence of culture on the performance of the multinational corporations' manufacturing plants. This law may be useful for examining environmental variety in the new cultural settings. Second, the findings have confirmed that cultural compatibility between the multinational corporations' organizational culture and the culture of the countries they are operating in plays a significant role in the performance of the corporations' manufacturing plants.

Therefore, it can be suggested that the decision concerning which management system or method to promote should be based on specific human, cultural, social, and deeply rooted local behavior patterns. It is critical for multinational corporations operating in different cultures from their own to ensure and enhance cultural compatibility for the success of their operations. As a consequence, it

can be recommended that no organizational culture should be transferred without prior analysis and recommendations for adjustment and adaptation to the foreign countries' cultures and conditions. This research has given a clear view of the potential that currently exists for supervising and evaluating cultural and behavioral aspects of organizations as affected by their external environment and their relationship to the performance of the organizations. Culture, both national and organizational, will become an increasingly important concept for technology transfer.

Results showed that while there were differences between the national cultures of the three countries, there were no significant differences between the organizational cultures of the three manufacturing plants. It is noteworthy that the rank order of the performance indicators for these plants was in exact concordance with the rank order of the compatibility between the organizational culture and the national culture of the host country: Mexico had the highest overall cultural compatibility and the highest performance; Puerto Rico had high overall compatibility and the next-highest overall performance; and the United States had the lowest cultural compatibility and the lowest overall performance.

Meshkati has recently studied the concept of a "safety culture." Nuclear reactor operators' responses to nuclear power plant disturbances is shown in Figure 1 (Meshkati et al. 1994, adapted from Rasmussen 1992). The operators are constantly receiving data from the displays in the control

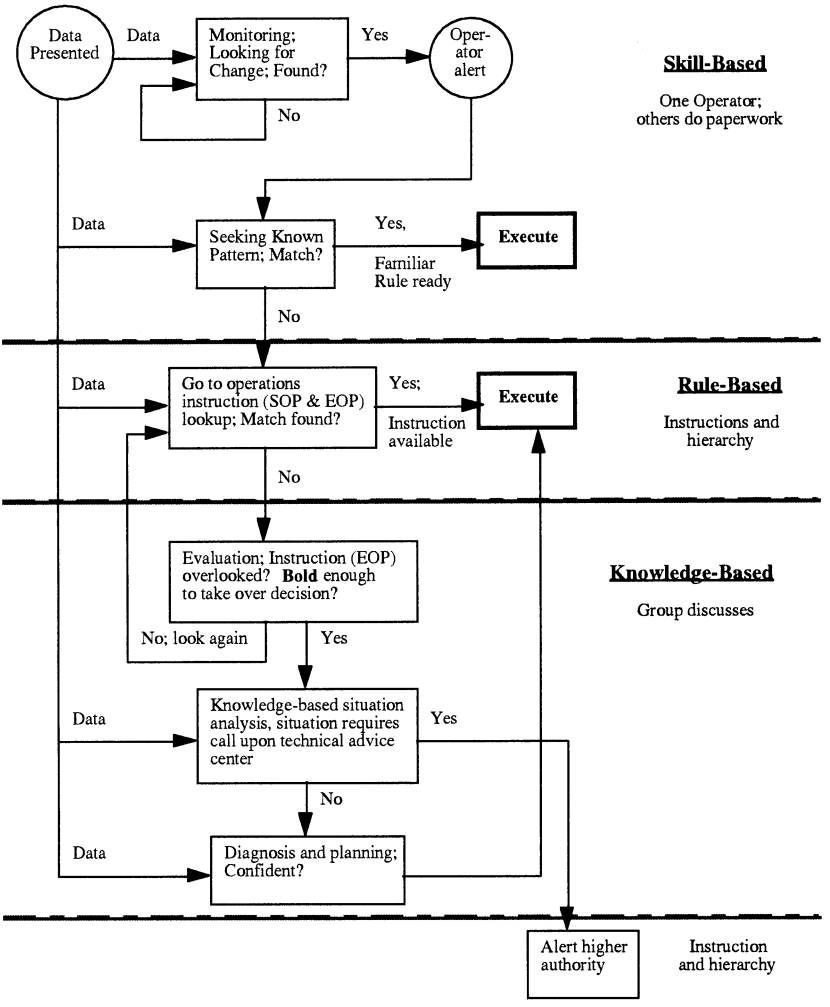

Figure 1 Model for Nuclear Power Plant Operators' Responses to Disturbances. (Adapted from Rasmussen 1992)

room and looking for change or deviation from standards or routines in the plant. It is contended that their responses during transition from the rule-based to the knowledge-based level of cognitive control, especially in the knowledge-based level, are affected by the safety culture of the plant and are also moderated or influenced by their cultural background. Their responses could start a vicious cycle, which in turn could lead to inaction, which wastes valuable time and control room resources. Breaking this vicious cycle requires boldness to make or take over decisions so that the search for possible answers to the unfamiliar situation does not continue unnecessarily and indefinitely. It is contended that the boldness is strongly culturally driven and is a function of the plant's organizational culture and reward system and the regulatory environment. Boldness, of course, is also influenced by operators' personality traits, risk taking, and perception (as mentioned before), which are also strongly cultural. Other important aspects of the national culture include hierarchical power distance and rule orientation (Lammers and Hickson 1979) which govern the acceptable behavior and could determine the upper bound of operators' boldness.

According to the International Atomic Energy Agency, two general components of the safety culture are the necessary framework within an organization whose development and maintenance is the responsibility of management hierarchy and the attitude of staff at all different levels in responding to and benefiting from the framework (IAEA 1991). Also, the requirements of individual employees for achieving safety culture at the installation are a questioning attitude, a rigorous and prudent approach, and necessary communication. However, it should be noted that other dimensions of national culture—uncertainty avoidance, individualism–collectivism, and masculinity–femininity—while interacting with these general components and requirements, could either resonate with and strengthen or attenuate safety culture. For instance, the questioning attitude of operators is greatly influenced by the power distance, rule orientation, and uncertainty avoidance of the societal environment and the openness in the organizational culture of the plant. A rigorous and prudent approach that involves understanding the work procedures, complying with procedure, being alert for the unexpected, and so on is moderated by power distance and uncertainty avoidance in the culture and by the sacredness of procedures, the criticality of step-by-step compliance, and a definite organizational system at the plant. Communication which involves obtaining information from others, transmitting information to others, and so on, is a function of all the dimensions of national culture as well as the steepness and rigidity of the hierarchical organizational structure of the plant.

The nuclear industry shares many safety-related issues and concerns with the aviation industry, and there is a continuous transfer of information between them (e.g., EPRI 1984). Cultural and other human factors considerations affecting the performance of a cockpit crew are, to a large extent, similar to those affecting nuclear plant control room operators. Therefore, it is worth referring briefly to a fatal accident involving a passenger airplane in which, according to an investigation by the U.S. National Transportation Safety Board (NTSB 1991), national cultural factors within the cockpit and between it and the air traffic control tower contributed significantly to the crash. Avianca flight 052 (AV052) (Avianca is the airline of Colombia), a Boeing 707, crashed in Cove Neck, New York, on January 25, 1990, and 73 of the 158 persons aboard were killed. According to the NTSB:

> The NTSB determines that the probable cause of this accident was the failure of the flight crew to adequately manage the airplane's fuel load, *and their failure to communicate an emergency fuel situation to air traffic control* before fuel exhaustion occurred. (NTSB 1991, p. 76, emphasis added)
>
> The word "*priority*" was used in procedures' manuals provided by the Boeing Company to the airlines. A captain from Avianca Airlines testified that the use by the first officer of the word "priority," rather than "*emergency,*" may have resulted from training at Boeing. . . . He stated that these personnel received the *impression* from the training that the words priority and emergency *conveyed the same meaning* to air traffic control. . . . The controllers stated that, although they would do their utmost to assist a flight that requested "priority," *the word would not require a specific response* and that *if a pilot is in a low fuel emergency and needs emergency handling, he should use the word "emergency."* (NTSB 1991, p. 63; emphasis added)

The NTSB concluded:

> The first officer, who made all recorded radio transmissions in English, *never used the word "Emergency,"* even when he radioed that two engines had flamed out, and he did not use the appropriate phraseology published in United States aeronautical publications to communicate to air traffic control the flight's minimum fuel status. (NTSB 1991, p. 75, emphasis added)

Helmreich's (1994) comprehensive analysis of the AV052 accident thoroughly addresses the role of cultural factors. His contention is that

> had air traffic controllers been aware of cultural norms that may influence crews from other cultures, they might have communicated more options and queried the crew more fully regarding the flight status. . . . The possibility that behavior on this [flight] was dictated in part by norms of national culture cannot be dismissed. It seems likely that national culture may have contributed to [the crew's behavior and decision

> making]. . . . Finally, mistaken cultural assumptions arising from the interaction of two vastly different national cultures [i.e., crew and ATC] may have prevented effective use of the air traffic control system. (Helmreich 1994, p. 282)

These conclusions have been corroborated in principle by several other studies: an operator's culturally driven habit is a more potent predictor of behavior than his or her intentions, and there could be occasions on which intentions cease to have an effect on operators' behavior (Landis et al. 1978). This fact brings to question the effectiveness of those (safety-related) regulations and procedures that are incompatible with operators' culturally driven habits.

According to Helmreich (1994):

> In a culture where group harmony is valued above individual needs, there was probably a tendency to remain silent while hoping that the captain would "save the day." There have been reported instances in other collectivist, high power distance cultures where *crews have chosen to die in a crash rather than disrupt group harmony and authority* and bring accompanying shame upon their family and in-group. (Emphasis added)
>
> High Uncertainty Avoidance may have played a role [in this accident] by locking the crew into a course of action and preventing discussion of alternatives and review of the implications of the current course of action. High Uncertainty Avoidance is associated with a tendency to be inflexible once a decision has been made as a means of avoiding the discomfort associated with uncertainty.

Moreover, the importance of the cultural factors vis-à-vis automation in the aviation industry is further highlighted by two recently published studies. Helmreich and Merritt (1998), in their study of national culture and flightdeck automation, surveyed 5705 pilots across 11 nations and report that "the lack of consensus in automation attitudes, both within and between nations, is disturbing." They conclude that there is a need for clear explication of the philosophy governing the design of automation. Most recently, the U.S. Federal Aviation Administration Human Factors Study Team issued a report (FAA 1996). The team identified several "vulnerabilities" in flight crew management of automation and situation awareness that are caused by a number of interrelated deficiencies in the current aviation system, such as "insufficient understanding and consideration of cultural differences in design, training, operations, and evaluation." They recommend a host of further studies, under the title of "Cultural and Language Differences." Moreover, they include pilots' understanding of automation capabilities and limitations, differences in pilot decision regarding when and whether to use different automation capabilities, the effects of training, and the influence of organizational and national cultural background on decisions to use automation.

4.4. Make Organization and Technology Design Choices That Encourage Innovation

The difficulties discussed in Section 3 suggest that even when a comprehensive technology-organization solution is devised, the unpredictability of the process by which technologies and organizational change unfolds will inevitably lead to unplanned events. Simply creating a portfolio of contingency plans is likely to be insufficient because contingencies to cover all unplanned events cannot be identified in advance. Thus, technology-organization solutions are more likely to be successful when they allow for innovation at the individual and group level. That is, even if careful plans have been made for everything from critical technical features for maintainability to redesigned job descriptions and performance-incentive systems, changes to these features, descriptions, and systems should be not only permitted but encouraged as personnel struggle to make the technology suit their work process.

In a careful analysis of six failed information systems developments, Flowers (1997) found that one of the main reasons for failure was an attitude in which failure, or association with failure, was likely to result in scapegoating or possible loss of employment or else have a severe effect upon the careers of the individual or individuals involved. For example, in the report of the inquiry on the failure of the London Ambulance system, the negative effect on the implementation of a senior manager was noted: the senior manager instilled a fear of failure by being very powerful, with a determination not to be deflected off course. Kelley (1996), in a survey of almost 1000 manufacturing plants, found that group-based employee participation mechanisms that supported the reexamination of old routines and taking advantage of informal shortcuts that employees had worked out on their own were complementary—especially in higher technology firms—to the productive use of information technology in the machining process.

Another example of the need for individual and group-level innovation is a recent study of the implementation of a collaborative technology to allow an interorganizational virtual (i.e., distributed across time and location) team to conceptualize and develop a new product. (Majchrzak et al. 2000). The eight-person team was encouraged to indicate the features they wanted in a collaborative technology. They asked for a central repository on a central server that could capture all types of knowledge (from text to drawings), mechanisms for cataloguing the knowledge for easy retrieval later (such as keywords, dates, author identification, and reference links to previous related entries), mechanisms

for being informed when new knowledge relevant to their area of expertise was entered into the knowledge base (e.g., profiling their interests coupled with e-mail notification when an entry fit that profile), ability to link desktop applications interactively to the knowledge base (called hot links), templates for commonly captured knowledge (such as for meeting agendas, meeting minutes, action items, decision rationale), and access anywhere by anyone anytime (24×7 access by team members and managers). A system was developed to these specifications. Then the team was encouraged to develop a set of coordination norms for how to conduct their creative engineering design work virtually using the collaborative technology. They created a new work process that would encourage all members of the team (including suppliers and specialists) and external managers to enter all knowledge asynchronously into the knowledge base and for each member then to comment on the entries as need be. The team worked for 10 months and successfully developed a breakthrough product. What is relevant for this discussion is that while the team had the opportunity to create its own technology and work process at the outset, in the end it changed every single one of its norms and most of the ways in which it used the technology. Thus, while there was careful planning prior to the beginning of the team's work—far more planning than would normally be permitted in many organizations today—the team still found it necessary to make changes. The team was fortunate because it were encouraged and able to make those changes as they became necessary. The technology was designed sufficiently flexibly so that entries could be identified using simple searches rather than the complex navigation tools that they thought they might need. Management was sufficiently flexible that when the team asked them to stop using the technology, they obliged. The team's work process was sufficiently flexible that when asynchronous communication proved insufficient, they were able to add a "meet-me" teleconference line so that all future encounters could be synchronously conducted using both the collaborative technology and the teleconference capability. Thus, the team succeeded not only because there had been careful planning, but because they could also innovate their work process and the technology as problems arose.

Thus, critical to the success of technology-organization alignment is that the technology-organization solution be designed to encourage localized innovation (Johnson and Rice 1987; Rogers 1995), that is, innovation required to make a particular technology-organization solution work in a particular context with a particular set of people. Characteristics of solutions that allow localized innovation include:

4.4.1. Solutions That Enhance, Not Deskill Workers

When workers are deskilled from a technology-organization solution, they do not have the knowledge to be able to intervene when necessary, identify problems, formulate solutions, and then implement the solutions. Thus, solutions must not permit deskilling. Technologies that avoid deskilling are those that allow workers to understand what the technology is doing and how it is doing it and provide workers with ways to intervene in the process to perform the planning, thinking, and evaluation work, leaving the routine work to the technology (Majchrzak 1988). The collaborative technology used by the virtual team members described in Majchrzak et al. (2000) was entirely open, with no hidden formula, hidden menus, or hidden processing; thus, the team was able to evolve the technology to the point where they could it make useful to them. CNC machines that hide processing logic from the operators are examples of technologies that violate this principle and thus inhibit innovation.

4.4.2. Solutions Should Be Human Centered

A broader proposition than that solutions should not deskill workers is that solutions should be human centered, that is, solutions should focus on how people use information, not simply on how to design a better, faster, cheaper machine. Davenport (1994) lists guidelines for designing human-centered information systems:

- Focus on broad information types, rather than on specific computerized data.
- Emphasize information use and sharing rather than information provision.
- Assume transience of solutions rather than permanence.
- Assume multiple rather than single meanings of terms.
- Continue design and reinvention until desired behavior is achieved enterprise wide rather than stopping the design process when it is done or system is built.
- Build point-specific structures rather than enterprise-wide structures.
- Assume compliance is gained over time through influence rather than dictated policy.
- Let individuals design their own information environments rather than attempt to control those environments.

Human-centered automation initiative is a good example of the technologies that attempt to avoid deskilling of human operators (Billings 1996). Loss of situation awareness, which could have been

caused by ''glass cockpit'' and overautomation, have been cited as a major cause of many aviation mishaps (Jentsch et al. 1999; Sarter and Woods 1997). Also, in many cases, because of the aforementioned issues, automation only aggravates the situation and becomes part of the problem rather than the solution. For example, in the context of aviation, automation is even more problematic because it ''amplifies [crew] individual difference'' (Graeber 1994) and ''it amplifies what is good and it amplifies what is bad'' (Wiener 1994). Furthermore, the automated devices themselves still need to be operated and monitored by the very human whose caprice they were designed to avoid. Thus, the error is not eliminated, only relocated. The automation system itself, as a technological entity, has a failure potential that could result in accidents. The problem arises when an automated system fails; it inevitably requires human intervention to fix it in a relatively short time. The same operators who have been out of the loop, may have ''lost the bubble'' (Weick 1990) with respect to cause and effect of the system failure and been deskilled, must now skillfully engage in those very activities that require their contributions to save the day (Meshkati 1996; Roberts and Grabowski 1996).

Deskilling is not necessarily limited to technical skills; blind automation tends to undermine interpersonal skills as well as encourage performance in isolated workstations and ingrains an individualistic culture in the organization. According to an analysis of high-reliability systems such as flight operations on aircraft carriers by Weick and Roberts (1993), a culture that encourages individualism, survival of the fittest, macho heroics, and can-do reactions is often counterproductive and accident prone. Furthermore, interpersonal skills are not a luxury but a necessity in high-reliability organizations.

4.4.3. Solutions That Integrate Across Processes, Not Bifurcate

Technology-organization solutions that create more differentiation between jobs hurt innovation because the problems that arise during implementation are rarely limited to an action that a single person holding a single job can solve. For example, an engineer may not have realized that by speeding up a processing step, she has added a greater queue for inspection, which, if left unresolved, will lead to quicker but more faulty inspections. To solve this problem requires that both quality control and manufacturing work together. For this reason, solutions that are focused on improvements to entire processes—that is, a process-based view of the organization—tend to be more successfully implemented than solutions that are focused on individual functions (Majchrzak and Wang 1996).

4.4.4. Solutions That Encourage Knowledge Recognition, Reuse, and Renewal

Localized innovation can be costly if the solutions themselves are not captured for later potential reuse. That is, if every single context is allowed to experiment through trial and error and generate different ways to handle the problems that arise during solution implementation, and this experimentation is done without the benefit of a knowledge base or technical staff to support knowledge transfer across contexts, the end cost of all the localized solutions can be very high. Thus, each site should have available, and be encouraged to use, a knowledge repository that describes various ways to resolve the different difficulties it is likely to encounter. Moreover, to make such a knowledge repository effective, each context should be encouraged to contribute to the knowledge repository so that future implementations can benefit from their learning (McDermott 1999). For example, a percentage of consultants' pay at Ernst & Young is determined by their contribution to the central knowledge repository (called Ernie) and the uses by other consultants made of their entries.

4.4.5. Solutions Should Decentralize Continuous Improvement

For people to engage in localized innovation, they must both be motivated to do so and have the ability to do it. Motivation can be encouraged by the provision of incentives through reward-and-recognition programs as well as by management offering a consistent message and modeling behavior that everyone should continuously improve what they do. Ability to innovate can be provided through such classic continuous improvement skills as ''five whys,'' Pareto analysis, graphing actual vs. expected outcomes over time, and group problem-solving techniques. Finally, a cycle of continuously evolving on-site experimentation that enables technology and context eventually to ''fit'' should be encouraged (Leonard-Barton 1988). ''Such experimentation can range from scientific investigations of new materials to beta testing a product prototype with potential customers, and from mathematically simulating product performance to studying product aesthetics via physical models'' (Iansiti 1999, p. 3–55). Expecting everyone to become knowledgeable about continuous improvement techniques and then motivating everyone to use those techniques can help to encourage localized innovation.

4.5. Agree on a Change Process for Achieving Alignment

The difficulties identified in Section 3 are better managed when the process by which the technology-organization solution is designed and implemented is an orderly, known, and repeatable process.

People become anxious when they are thrust into chaotic situations over which they have no control and which affect their jobs and possibly their job security and careers (Driver et al. 1993). People are given some sense of control when they know what the process is: how decisions will be made, by whom, and when, and what their role is in the decision-making and implementation process. Sociotechnical systems design suggests the following nine steps in the design and implementation of a technology-organization solution (Emery 1993; Taylor and Felten 1993):

1. Initial scanning of the production (or transformation) system and its environment to identify the main inputs, transforming process, outputs, and types of variances the system will encounter
2. Identification of the main phases of the transformation process
3. Identification of the key process variances and their interrelationships
4. Analysis of the social system, including the organizational structure, responsibility chart for controlling variances, ancillary activities, physical and temporal relationships, extent to which workers share knowledge of each others' roles, payment system, how roles fill psychological needs of employees, and possible areas of maloperation
5. Interviews to learn about people's perceptions of their roles
6. Analysis of relationship between maintenance activities and the transformation system
7. Relationship of transformation system with suppliers, users, and other functional organizations
8. Identification of impact on system of strategic or development plans and general policies
9. Preparation of proposals for change

These nine steps have been created to optimize stakeholder participation in the process, where stakeholders include everyone from managers to engineers, from suppliers to users, from maintainers to operators. A similar process is participative design (Eason 1988; Beyer and Holtzblatt 1998), tenets of which include:

- No one who hasn't managed a database should be allowed to program one.
- People who use the system help design the infrastructure.
- The best information about how a system will be used comes from in-context dialogue and role playing.
- Prototyping is only valuable when it is done cooperatively between users and developers.
- Users are experts about their work and thus are experts about the system; developers are technical consultants.
- Employees must have access to relevant information, must be able to take independent positions on problems, must be able to participate in all decision making, must be able to facilitate rapid prototyping, must have room to make alternative technical and/or organizational arrangements, must have management support but not control, must not have fear of layoffs, must be given adequate time to participate, and must be able to conduct all work in public.

The participative design process first involves establishing a steering committee of managers who will ultimately be responsible for ensuring that adequate resources are allocated to the project. The steering committee is charged with chartering a design team and specifying the boundaries of the redesign effort being considered and the resources management is willing to allocate. The design team then proceeds to work closely with the technical staff first to create a set of alternative organizational and technical solutions and then to assess each one against a set of criteria developed with the steering committee. The selected solutions are then developed by the design and technical personnel, with ever-increasing depth. The concept is that stakeholders are involved before the technology or organizational solutions are derived and then continue to be involved as the design evolves and eventually makes the transition to implementation (Bodker and Gronbaek 1991; Clement and Van den Besselaar 1993; Kensing and Munk-Madsen 1993; Damodaran 1996; Leonard and Rayport 1997).

Both the participative design and STS processes also focus on starting the change process early. Typically, managers wait to worry about alignment after the technology has been designed, and possibly purchased. Because too many organizational and other technology choices have now been constrained, this is too late (Majchrzak 1988). For example, if the data entry screens for an enterprise resource-planning system are designed not to allow clerks to see the next steps in the data flow, and the organizational implications of this design choice have not been considered in advance, clerks may well misunderstand the system and input the wrong data, leading to too many orders being sent to the wrong locations. This is what happened at Yamaha. If the enterprise resource-planning system had been designed simultaneously with the jobs of clerks, then the need to present data flow information would have been more apparent and the costly redesign of the user interface would not have

been required. Thus, starting the change process before the technology has been designed is critical to achieve alignment.

Finally, a change process must include all best practices of any project management structure, from metrics and milestones to skilled project managers and contract administration. Too often, the implementation of a technology-organization solution is not given the organizational sanction of a project and instead is decomposed into the various functional responsibilities, with the integration being assigned to somebody's already full plate of responsibilities. A project manager is needed who is responsible for the entire life cycle, from design to implementation to use, and whose performance is based on both outcome metrics (e.g., the extent to which the solution contributed to the business objectives) and process metrics (e.g., did people involved in the design find that their time was well spent?). The project manager needs to report to a steering committee of representatives from each stakeholder community, and the steering committee should hold the program manager accountable to following best-practice project-management principles such as

1. Clear descriptions of specifications and milestones that the solution must meet
2. Risk identification, tracking, and mitigation
3. Early and iterative prototyping with clear testing plans including all stakeholders
4. A formal process for tracking requests for changes in specifications

Finally, given the key role played by the project manager, the job should not be given to just anyone. While small technology-organizational solutions might be handled by an inexperienced project manager, provided there is some formal mentoring, the larger the project, the greater the need for experience. With larger projects, for example, experience is required in contract administration (e.g., devising contracts with service providers that offer them the type of incentives that align their interests with yours), coordination of distributed teams, managing scope creep, and balancing conflicts of interests. These skills are not specific to a technology; but they are specific to project management expertise. The Conference Board, for example, found that problematic enterprise resource planning installations were attributable to the use of poor project-management principles that were specific not to the technology but rather to the scale of the change required (Cooke and Peterson 1998). Thus, a planned change process is critical to the ability to overcome difficulties of alignment.

4.6. Use Decision Aids to Enhance Internal Understanding of Technology-Organizational Alignment

A final recommendation for managing the difficulties of alignment is to use computerized decision aids that have a sufficient knowledge base to offer guidance on how to align technology and organizational options under various contexts. In this way, a company can reduce its reliance on outside consultants while it iteratively strives for better and better alignment. Pacific Gas & Electric seemed to appreciate the need to take technology and organizational development in-house, according to the *Wall Street Journal* (1998b), when it decided to use a team of 300 company employees in its $200 million, four-year effort to rebuild the company's aging computer system. Big-name consulting firms were eschewed, in favor of small consulting firms, but only in supporting roles. As with any simulation package used in industrial engineering, such a decision aid should allow what-if modeling, that is, the ability to try out different technology-organizational solutions and see which are more likely to achieve the desired outcomes at the least cost. Such a decision aid should also incorporate the latest best practices on what other firms have been able to achieve when aligning their organizations and technologies. Finally, such a decision aid should help the firm to conduct a cross-functional comprehensive assessment of the current alignment state of the firm and compare it to the to-be state to identify the high-priority gaps that any new solution should resolve. In this section, we describe two decision aids, TOP Modeler (www.topintegration.com) and iCollaboration software (www.adexa.com).

4.6.1. TOP Modeler

TOP Modeler is a dynamic organization analysis, design, and reengineering tool (Majchrzak and Gasser 2000). TOP Modeler uses a flexible, dynamic modeling framework to deliver a large, well-validated base of scientific and best-practice knowledge on integrating the technology, organizational, and people (TOP) aspects of advanced business enterprises. The current focus of TOP Modeler's knowledge base is advanced manufacturing enterprises, although it can be expanded to other types of enterprises. TOP Modeler's knowledge base was developed with a $10 million, five-year investment of the U.S. Air Force ManTech program, the National Center for Manufacturing Sciences, Digital Equipment Corporation, Texas Instruments, Hewlett-Packard, Hughes, General Motors, and the University of Southern California.

Users have the choice of using TOP Modeler to evaluate their current organization or evaluate their alternative "to-be" future states. Users do this by describing their business strategies and being

informed by TOP Modeler of an ideal organizational profile customized to their business strategies. Then users can describe features of their current or proposed future organization and be informed by TOP Modeler of prioritized gaps that need to be closed if business strategies are to be achieved. There are three sets of business strategies contained in TOP Modeler: business objectives, process variance control strategies, and organizational values. TOP Modeler also contains knowledge about the relationships among 11 sets of enterprise features, including information resources, production process characteristics, empowerment characteristics, employee values, customer involvement strategies, skills, reporting structure characteristics, norms, activities, general technology characteristics, and performance measures and rewards.

The TOP Modeler system has a graphical, interactive interface; a large, thorough, state-of-the-art knowledge representation; and a flexible system architecture. TOP Modeler contains a tremendous depth of scientific and best-practice knowledge—including principles of ISO-9000, NCMS's Manufacturing 2000, etc.—on more than 30,000 relationships among strategic and business attributes of the enterprise. It allows users to align, analyze, and prioritize these attributes, working from business strategies to implementation and back. The user of TOP Modeler interacts primarily with a screen that we call the ferris wheel. This screen provides an immediate, intuitive understanding of what it means to have TOP integration in the workplace: TOP integration requires that numerous different aspects of the workplace (e.g., employee values, information, and responsibilities for activities) must all be aligned around core organizational factors (e.g., business objectives) if optimum organizational performance is to be achieved.

TOP Modeler has been used in over 50 applications of organizational redesign, business process redesign, or implementation of new manufacturing technology. The companies that have used it have ranged from very small companies to very large companies, located in the United States, Brazil, and Switzerland. Some of the uses we have been informed about include:

- Use by government-sponsored manufacturing consultants (e.g., Switzerland's CCSO) to help small companies develop strategic plans for restructuring (in one case, the tool helped the consultant understand that the company's initial strategic plan was unlikely to succeed until management agreed to reduce the amount of variation that it allowed in its process).
- Use by large software vendors (e.g., EDS) to help a company decide to not relocate its plant from one foreign country to another (because the expense of closing the "gaps" created by the move was likely to be too high).
- Use by a large manufacturing company (General Motors) to decide whether a joint venture plant was ready to be opened (they decided on delaying the opening because the tool helped to surface differences of opinion in how to manage the workforce).
- Use by a small manufacturing company (Scantron) to decide whether its best practices needed improving (the tool helped the company to discover that while it did indeed have many best practices, it needed to involve the workforce more closer with the supplier and customer base, an action the company subsequently took).
- Use in a large technology change effort at a large manufacturing company (Hewlett-Packard) to help identify the workforce and organizational changes needed for the new production technology to operate correctly (resulting in a substantial improvement in ramp-up time when the new product and production process was introduced).
- Use by a redesign effort of a maintenance crew (at Texas Instruments) to determine that the team-based approach they had envisioned needed several important improvements prior to start-up.
- Use by a strategic planning committee at a large manufacturing company to identify areas of misalignment among elements of a new strategic plan (in this case between quality and throughput time).
- Use by a manufacturing division manager to verify his current business strategy, which had been given to him by his group manager. As a consequence of using TOP Modeler, he discovered that he had agreed to a business objective of new product development without having the authority over the necessary people, skills, and other resources to deliver on that objective. He went back to his group manager to renegotiate these resources.

These are just a few examples of the uses made of TOP Modeler. We believe that with a decision aid, the difficulties of achieving alignment are substantially reduced.

4.6.2. iCollaboration Tool for Technology-Organizational Realignment

Another powerful decision aid for the (intra- and interenterprise) technology-organization alignment that is currently being used by many companies in different industries is the state-of-the-art, Internet-enabled Adexa company's iCollaboration software (www.adexa.com). These manufacturing and ser-

vice industries include electronics, semiconductor, textile and apparel, and automotive. Adexa tools provide a continuous and dynamic picture of a manufacturing enterprise supply chain and operational status at all times.

iCollaboration software suite enables users to dynamically address and monitor operational planning, materials management, order management and request for quotes (RFQs), strategic and operational change propagation, new product management, collaborative customer and demand planning, and customer satisfaction.

The main feature of the iCollaboration suite include:

1. An integrated/synchronized set of supply chain and operations planning tools that cover the strategic planning (facilities, products, supplies
2. Supply chain planning (sourcing, making, storing)
3. Material and capacity planner; detailed make and deliver, factory planning
4. Reactive dynamic scheduler shop-floor scheduling, dispatch lists

Figure 2 shows a conceptual architecture of Adexa iCollaboration suite and how it interfaces both intra- and interenterprise. The following is a review of some specific areas, examples, and improvements where the iCollaboration tool could help the enterprise in systematic integration of technology into an organizational setting.

4.6.2.1. Operational Planning Operational planning in this context encompasses all the activities: forecasting, demand planning, sourcing, production planning, and shipping. The strategic plan should be aligned with the tactical and operational so that every decision at all levels is consistent; any deviations should be immediately relayed and approved or rejected. The supply chain planner (SCP) and the global strategic planner (GSP) tools create strategic plans that are feasible at lower levels, thus eliminating/minimizing unnecessary monitoring. Each planner (demand, materials, production, etc.) is working from the most current plans and has visibility into what is possible, which leads to linear-empowered organizations. Every change in market demand or supply chain problem is immediately reflected and visible, allowing an optimal replan based on prevalent situations. Materials, manufacturing resources, skills, and shippers all operate in synch, thus eliminating expeditors and facilitators. The GSP, SCP, material and capacity planner (MCP), collaborative demand planner (CDP), collaborative supply planner (CSP), and collaborative enterprise Planner (CEP) tools enable

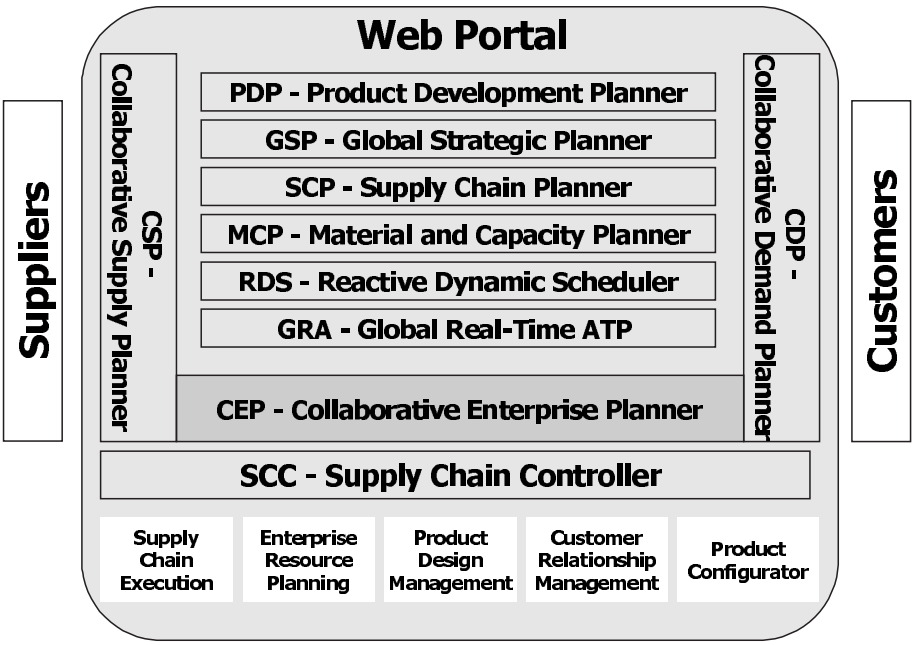

Figure 2 The Architecture of the iCollaboration Tool.

the management to align its organizations and coordinate functions (e.g., centralized vs. decentralized planning, ability to manage customer or product lines by one person or department) effectively to meet its business goals.

4.6.2.2. Materials Management The materials organization or individual responsible for raw materials, subassembly suppliers, feeder plants, and finished goods management needs full visibility into all requirements and changes as they happen. Based on the enterprise, these functions may be aligned by product family, facility, or material type. The material managers have access to the latest long-term forecasts and plans, any market changes, order status and changes, effectivities, part substitutions, and all specific rules as they apply to the vendor or supplier, and the latest company rules regards products, materials, customers, or priorities. The enterprise is thus free to align the organization to achieve lowest inventories, lowest material-acquisition costs, best vendor contracts (reduced set of reliable suppliers, quality, etc.), effective end-of-life planning, and reduced obsolescence.

4.6.2.3. Order Management and Request for Quotes (RFQs) An organization, which is responsible for the first line of attack on responding to RFQs, order changes, new orders, new customers, should be able to respond rapidly and accurately to delivery capability and costs. More importantly, the response should be based on the current plant loads and reflects the true deliverable lead times and capabilities.

4.6.2.4. Strategic and Operational Change Propagation As is the norm, strategies and operational activities change for various internal or external reasons. Most organizations without access to the right technology manage this change by incurring high costs in terms of additional people both to convey the message of change and to manage and monitor. Visibility and instant change propagation in either direction allow enterprises to respond only when necessary, and they are guided by a system-oriented decision so that their responses are optimal and effective immediately.

4.6.2.5. New Product Management New product development, engineering, materials, sales, and production functions require seamless collaboration. Business processes that take advantage of these functionalities can be implemented so that new product introduction is as much a part of day-to-day operations as the making and delivery of current products. There may not necessarily be a need for any special organizations or staffing to meet new product introductions. These products become akin to new demands on resources; and in fact, with the added visibility and speed of change propagation, the enterprise can develop better-quality products and more of them. This can be done because an enterprise utilizing a tool such as iCollaboration can easily try out more ideas and functions simultaneously, which increases the ability of the enterprise to ramp up production faster

4.6.2.6. Collaborative Customer/Demand Planning The CDP tool allows the customer-facing individuals to evaluate and analyze the demands by sales organizations, geography, product managers, and manufacturing and product planners to interact and control all activities seamlessly and consistent with enterprise goals of maximizing profitability and related corporate strategies. The application of this tool may result in the synchronization among the entire sales and customer relationship teams, in conjunction with customer relationship management (CRM) integration, which would produce customer satisfaction.

4.6.2.7. Customer Satisfaction Customer satisfaction, as measured by product delivery due date performance, accurate order fill rate, response to quotes, and response to changes in orders, can be significantly enhanced by creating an empowered customer facing organization that is enabled and empowered. It should be noted that this issue is one of the most critical determinants of success for today's e-commerce businesses. With the iCollaboration tools, an organization can create customer-facing organizations that may be aligned with full customer responsibility, product responsibility, order responsibility, or any combination of those. These organizations or individuals are independent, do not have to call someone, and yet are in synch with all other supporting organizations.

5. CONCLUSIONS

A review of possible decisions leaves a long list of do's and don'ts for implementing new technology. Some of the more important ones are:

- Don't regard new technology and automation as a quick fix for basic manufacturing or human resource problems; look to the firm's entire human–organization–technology infrastructure as the fix.
- Don't assume that human resource problems can be resolved after the equipment is installed; some of the problems may have to do with the specific equipment selected.

- Do expect that multiple different configurations of matches of human–organization–technology infrastructure elements are equally effective as long as the organization can undergo all the needed changes.
- Do expect to redesign jobs of operators, technical support staff, and supervisors.
- Do involve marketing staff in resources planning.
- Don't look for broad-brush deskilling for skill upgrading of the workforce with new technology; rather, some new skills will be required and others will no longer be needed.
- Don't make direct labor the prime economic target of new technology; the displacement of direct labor is only a small part of the economic benefit of the new technology.
- Do perform a training-needs analysis prior to any employee training relating to the implementation of the new technology; do expect a substantial increase in training cost.
- Do expect that the union–management relationship will change dramatically.
- Do begin facing the dilemma of changing the organizational structure to meet both coordination and differentiation needs.
- Do expect resistance; begin convincing managers and the workforce of the need for change before installing the new technology.
- Do use a multidisciplinary project team to implement any new technology in the workplace.
- Do assess and incorporate all aspects of new technology in the implementation decision making, such as social and environmental impacts.
- Do ensure a thorough understanding of the dimensions of local national culture.
- Do ascertain a determination of the extent of national culture match with those of organizational culture of the technological system (to be implemented).
- Do ensure that the effects of cultural variables on the interactions between human operators and automation in control centers of technological systems are fully considered.

The foregoing ideas concerning technology alignment with organization are of paramount importance for the companies in this emerging era of e-commerce and e-business, which is the ideal test bed for the full implementations of these ideas. The new industrial revolution being precipitated by the advent of the e-commerce phenomenon is probably the most transformative event in human history, with the far-reaching capability to change everything from the way we work to the way we learn and play. The e-commerce industry has empowered customers more than ever and has further required seamless coordination and information exchange among inter- and intraorganizational units responsible for dealing with customers and suppliers. For instance, Dell Computer, a pioneer and a harbinger of the e-commerce industry, has created a fully integrated value chain that allows for a three-way information partnership with its suppliers and customers, thereby improving efficiency and sharing the benefits across the entire chain. (*Economist* 1999). Product managers, manufacturing, and product planners need to interact and control all activities seamlessly with full transparency to the customer. This holistic approach necessitates the utmost efficiency of the entire production life cycle and eventually requires addressing all environmental impacts of e-business.

The new world order for business and industry mandates that technology implementation be comprehensive and must encourage continuous evolution and that it needs tools to help the process of implementation.

Acknowledgments

Najmedin Meshkati would like to acknowledge the contributions of his former USC graduate student and research assistant, Ms. Gail Demel, for the cross-cultural study, undergraduate student Mr. Joseph Deato for his review and analysis of the material, and Dr. Cyrus K. Hadavi of Adexa for providing insightful information on enterprise resource planning and iCollaboration.

CHAPTER 37

Teams and Team Management and Leadership

François Sainfort
Georgia Institute of Technology

Alvaro D. Taveira
University of Wisconsin-Whitewater

Neeraj K. Arora
National Cancer Institute

Michael J. Smith
University of Wisconsin-Madison

This chapter examines the state of the research and practice on teamwork. We review and present main guidelines for the choice of teams, the effective utilization of teams in organizations, as well as available approaches to assess team outcomes. The impacts of teams on different segments of the organizations and future challenges for research and practice are discussed.

1. INTRODUCTION

Teamwork has been recommended as an organizational design feature for many years, as a way to improve productivity, quality, and employee satisfaction (Lawler and Mohrman 1987). This is especially true in today's organizational environment, with increased global competition and a more demanding workforce (Katzenbach and Smith 1993). The increased attention to teams has become widespread particularly in the context of total quality management (TQM) or quality improvement (QI), which relies heavily on teamwork (Dean and Bowen 1994; Deming 1986).

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

Teamwork represents one form of work organization that can have large positive and/or negative effects on the different elements of the work system and on human outcomes, such as performance, attitudes, well being, and health. Conceiving work as a social system and advocating the necessity of both technical and social performance optimizations as necessary for organizational effectiveness, the sociotechnical theory provides several arguments and examples supporting teamwork. The germinal study, which gave the essential evidence for the development of the sociotechnical field, was a team experience observed in the English mining industry during the 1950s. In this new form of work organization, a set of relatively autonomous work groups performed a complete collection of tasks interchanging roles and shifts and regulating their affairs with a minimum of supervision. This experience was considered a way of recovering the group cohesion and self-regulation concomitantly with higher level of mechanization (Trist 1981). The group had the power to participate in decisions concerning work arrangements, and these changes resulted in increased cooperation between task groups, personal commitment from the participants, and reduction in absenteeism and the number of accidents.

A GM assembly plant located in Fremont, California was considered until 1982, the year it ended operations, the worst plant in the GM system and in the auto industry as whole. For years, the plant presented dismay levels of quality, low productivity, and prevalent problems of absenteeism and turnover. The plant was reopened two years later under a new joint venture with Toyota. Changes focusing primarily on the relationship between workers and management, the organizational structure, and the widespread use of teamwork transformed the plant in one of the most productive ones of the GM system, with high levels of employee satisfaction and very low levels of absenteeism (Levine, 1995).

Examples like those above illustrate the advantages of using teams to perform a variety of organizational assignments and tasks. Supporters of teamwork have promoted teamwork on many grounds, highlighting its potential for increased productivity, quality, job satisfaction, organizational commitment, and increased acceptance of change, among others. Teamwork is the preferred strategy to increase employee involvement in the workplace. Indeed, terms such as *participatory management, employee involvement,* and participation are frequently equated with teamwork. According to Lawler (1986), employee involvement affects five major determinants of organizational effectiveness: motivation, satisfaction, acceptance of change, problem solving, and communication. Lawler states that employee involvement can create a connection between a particular level of performance and the perception of a favorable consequence. Involvement in teams can provide rewards beyond those allocated by the organization, such as money and promotion: it can supply intrinsic rewards, that is, accomplishment, personal growth, and so on. Similarly, Lawler argues that allowing people to participate in the definition of the procedures and methods utilized in their daily activities is an effective way to improve those methods and can motivate employees to produce a better-quality job. Teams also can ease the process of implementation of organizational changes and avoid the ''not-invented-here'' perception and create commitment with the implementation of change.

It has been argued that in many circumstances the effort of a group of people generates effective solutions that would not be produced by the same individuals working independently. This superior outcome would result not only from the greater pooled knowledge available to the group members, but also from the interaction process among them, from the mutual influence on each other's thinking. This process has been termed *collective intelligence* (Wechsler 1971) and refers to a mode of cooperative thinking that goes beyond simple collective behavior. Finally, system reliability is also assumed to improve through employee participation since it increases the human knowledge variety and enables the workers to understand their role in making the system more efficient and safer.

While there are a number of positive elements associated with teamwork in general, there are also some potential negative elements. Furthermore, these elements are not constant but rather depend on the type of team as well as the organizational environment in which teams operate. In the next section, we propose a typology of teams, review key characteristics of teams, and address the issue of designing teams.

2. TEAMS: TYPES, CHARACTERISTICS, AND DESIGN

2.1. Types of Teams

Sundstrom et al. (1990, p. 120) have defined work teams as ''interdependent collections of individuals who share responsibility for specific outcomes for their organizations.'' Teams can vary a great deal in the way they are designed, managed, and implemented. Various forms of teamwork have been proposed and applied, from temporary teams (e.g., ad hoc committees, quality improvement teams, project teams) to permanent teams (e.g., manufacturing crews, maintenance crews). Temporary teams are usually set up when some problem occurs or some change needs to be implemented and/or to better manage the change process. Teams also vary greatly in terms of the amount of autonomy and authority they have. For example, manager-led teams have responsibility only for the execution of work (Medsker and Campion 1997). On the other hand, self-managed teams can have a large amount

of autonomy and decide on issues such as work organization and performance monitoring. Somewhere in between, semiautonomous work groups will experience limited degrees of autonomy and decision making over such issues. Finally, teams vary significantly in terms of the task or the nature of work to be performed. Sundstrom et al. (1990) propose four broad categories of work team applications: (1) advice and involvement, (2) production and service, (3) projects and development, and (4) action and negotiation.

2.2. Characteristics of Teams

Lawler (1986) lists the following characteristics of work teams: membership, work area coverage, training, meetings, supervision, reward systems, decision-making responsibility, installation process, and size. Sundstrom et al. (1990) have proposed that work team effectiveness is dynamically interrelated with organizational context, boundaries and team development. Hackman (1987) has proposed a normative model of group effectiveness. The model identifies three process criteria: effort, knowledge, and the appropriateness of task performance strategies. Increases in these three criteria, given task configurations, should improve the overall effectiveness of the group. According to Hackman (1987), the basic levers to change the process criteria are group design, organizational context, and synergy.

2.3. Team Design

For the design of work groups, three different levels of criteria need to be considered. First, global issues on strategy selection need to be defined—that is, decisions regarding the appropriateness of teamwork for the situation at hand, what type of team would be most adequate, and the amount of authority/autonomy granted to the team need to be made. Second, the specifics of the group design and mechanics need to be decided upon, including matters of size and composition/membership, work area coverage or tasks, and coordination. Finally, in agreement with team members, issues related to the team performance and duration need to be defined. This includes reward systems, duration, and performance/effectiveness assessment, all issues that are determinant in making continuation, change, or termination decisions throughout the life of the team.

Decisions at the strategic level are critical and difficult to make. The adequacy of teamwork for a given situation can be assessed through criteria depicted in Tables 3 and 4 in Medsker and Campion (2000) (Chapter 33 of this Handbook). As proposed by Medsker and Campion, Table 3 summarizes advantages and disadvantages of team design as compared to individual job design. Table 4 in Medsker and Campion proposes a list of systematic questions for which affirmative answers support the use of teamwork for the situation at hand. The choice of the appropriate type of team depends on the application but also on the risks and opportunities offered by the different team configurations, as shown in Table 1. The next decision is on amount of authority/autonomy provided to the group. This decision is difficult to make and depends on other characteristics such as the organizational

TABLE 1 Risks and Opportunities for Work Teams

Teams	Risks	Opportunities
Top management teams	Underbounded; absence of organizational context	Self-designing; influence over key organizational conditions
Task Forces	Team and work both new	Clear purpose and deadline
Professional support groups	Dependency on others for work	Using and honing professional expertise
Performing groups	Skimpy organizational supports	Play that is fueled by competition and/or audiences
Human service teams	Emotional drain; struggle for control	Inherent significance of helping people
Customer service teams	Loss of involvement with parent organization	Bridging between parent organization and its customers
Production teams	Retreat into technology; insulation from end users	Continuity of work; ability to home both the team design and the product

Adapted from J. R. Hackman, ''Creating More Effective Work Groups in Organizations,'' in *Groups That Work* (*And Those That Don't*), J. R. Hackman, Ed., copyright © 1990 Jossey-Bass, Inc., a subsidiary of John Wiley & Sons, Inc. Reprinted by permission.

culture, the nature of the team's tasks, the skills and knowledge of the team members, and the training received and to be received. Such a decision has important implications for management and employee involvement, which will be addressed in Section 6.

Decisions at the tactical level, that is, the specifics of the group design and mechanics are usually easier to make and are negotiated with team members. This includes matters of size and composition/membership, work area coverage or tasks, and coordination mechanisms. For many teams, the optimal size is difficult to determine. In fact, a variety of factors may affect team size. Obviously the primary factor is the size and scope of a required project or set of tasks. However, several other factors can influence team size (it should be noted that all factors are not necessarily applicable to all types of teams). Factors affecting team size include:

- Amount of work to be done
- Amount of time available to do the work
- Amount of work any one person can do in the available time
- Differentiation of tasks to be performed in sequence
- Number of integrated tasks required
- Balancing of tasks assignments
- Cycle time required
- Variety of skills, competences, knowledge bases required
- Need for reserve team members
- Technological capabilities

Finally, at the third level, decisions regarding team performance and duration should be negotiated and made prior to engaging teamwork. Section 5 provides a comprehensive, structured list of variables affecting and/or defining team performance. Such characteristics can be used to develop a system to measure and monitor team performance over time.

As mentioned above, teams are widely used in today's organizational environment, with increased global competition and a more demanding workforce (Katzenbach and Smith 1993). The next section describes two important current applications of teamwork.

3. QUALITY IMPROVEMENT AND PARTICIPATORY ERGONOMICS TEAMS

Teamwork has been the backbone of quality improvement. More recently, teamwork has been used in the context of participatory ergonomics (PE). However, while QI teams primarily focus on activities related to identifying, designing, and implementing improvements in both work processes and products/services, PE teams primarily focus on improvement of working conditions. The following sections review the state of the art for both applications of teamwork.

3.1. Teams in the Context of Quality Improvement

Employee participation, particularly through teamwork, is one of the essential foundations of QI. Different from many other management approaches that present teamwork effectiveness as contingent to several aspects, QI supports the use of teams without any specific provisions (Dean and Bowen 1994).

A variety of quality-related teams can exist within organizations. Kano (1993) categorizes teams into three types: (1) functional teams, which are ongoing voluntary problem-solving groups made up of workers in the same workplace; (2) quality building-in-process teams, in which a set of related jobs are shared, with the goal of building quality into a product during the assembling process; and (3) task/project teams, which are ad hoc groups comprised of staff or line managers, who disband once the task is completed.

Quality circle (QC) is one of the most widely discussed and adopted forms of teamwork (Cotton 1993). QCs are project/problem-solving teams that have been defined as small groups of volunteers from the same work area who meet regularly to identify, analyze, and solve quality-related problems in their area of responsibility (Wayne et al. 1986). These groups usually consist of 8 to 10 employees who meet on a regular basis, such as one hour per week. In many QCs, the supervisor is designated as the circle leader. Formal training in problem-solving techniques is often a part of circle meetings.

The claimed benefits of QCs include quality and cost awareness; reduction in conflict and improved communications; higher morale, motivation, and productivity; and cost savings (Head et al. 1986). The effect of this type of teamwork on employee attitudes is assumed to be the primary reason for their success (Head et al. 1986). Marks et al. (1986) propose that QC participation will lead to enriched jobs, with employees experiencing work as more meaningful, obtaining greater knowledge

of the results of their work, and gaining a greater sense of responsibility. Enriched jobs are the result of increased skill variety, task identity, task significance, autonomy, and feedback (Hackman and Oldham 1980). These job characteristics may then be related to outcomes that include higher job satisfaction and motivation.

Teamwork can enrich jobs through different mechanisms. Skill variety can be increased from both project activity and one's role within the team. Activities such as data collection and analysis, problem solving, presenting information to groups, and group decision making are key elements in quality-related teamwork, which may not be part of workers' daily routines. Team projects can typically be expected to increase the variety of stimuli to which employees are exposed (Rafaeli 1985).

An essential element of quality-related teamwork is providing feedback to participants (Head et al. 1987). Feedback may be provided through data collection conducted by the team. Interaction within the group and with outside groups (e.g., management, customers) is another potential source of feedback. Team activity increases the frequency of communication among coworkers and supervisors, and may include those outside of the team as well (Buch and Raban 1990; Rafaeli 1985; Marks et al. 1986).

At the team level, the worker may experience a degree of control that is higher than one would expect at the individual level. Autonomy is actually expected to increase among quality team members (Head et al. 1987; Rafaeli 1985). Teams may have control over the content and sequence of activities. In addition, team members may be given control over specific tasks within the group, such as data collection and analysis.

However, the data regarding these hypothesized relationships are somewhat inconsistent. Marks et al. (1986) found that QC participation in a manufacturing firm influenced work attitudes that were directly related to QC involvement: participation, decision making, group communication, worthwhile accomplishments, and enhancing the opportunities and skills needed for advancement. There was no improvement found in job challenge, personal responsibility, and overall job satisfaction. Rafaeli (1985), in a study of QCs in a manufacturing firm, did find QC involvement to be related to the job dimension of task variety, but not to autonomy. In addition, Rafaeli found no relationship between QC involvement and job satisfaction. Head et al. (1986) also studied QC participation in a manufacturing setting, and found no significant differences on any of the core job dimensions, nor in satisfaction or motivation measures. While Mohrman and Novelli (1985) did find improvements in job satisfaction for warehouse employees, there were then decreases in satisfaction after one year. Nonparticipants were significantly lower in feedback and involvement in decision making. Buch and Raban (1990) reported improvements in QC members' perceptions of certain job dimensions, such as autonomy and communication. However, they did not find any difference between members and nonmembers in overall job satisfaction. Finally, Jennings (1988) found QC participation to be related to negative outcomes, namely role conflict and stress.

These conflicting results may be due to the time period in which the different studies were conducted. Longitudinal studies of QCs have shown a consistent pattern of diminishing effects over time. Griffin (1988) found increases in both job satisfaction and organizational commitment for the first one and a half years of a QC program in a manufacturing plant, which were followed by decreases in these measures over a three-year period. Mohrman and Novelli (1985) found a similar pattern of results for job satisfaction. In a qualitative study of manufacturing and banking organizations, Doherty et al. (1989) found an increase, followed by a decrease, in perceived communication, participation, and employee/management relations for a team suggestion program.

The patterns from longitudinal studies indicate that QCs might not have lasting effects. Perhaps long-lasting attitudinal changes should not be expected from a program that accounts for such a small proportion of employees' total work time (Wood et al. 1983). Overall, studies of QCs seem to show a slight impact on satisfaction and commitment. Cotton (1993) argues that direct, teamwork-related attitudes, such as perceptions of influence, are more affected by QCs, while general attitudes, such as job satisfaction and organizational commitment, are less affected.

It has been suggested that, in order to obtain greater benefits, teamwork should be part of a more comprehensive program (Head et al. 1986). Quality circles are a parallel structure in the organization and may not have the authority or resources to affect change (Lawler and Mohrman 1987). QCs may not be related to the day-to-day work done in organizations, and nonparticipants may feel left out, resulting in a negative backlash (Lawler 1986). Demands may be increased for both participants and nonparticipants. For participants, there are the additional duties of going to team meetings and training sessions, while nonparticipants may occasionally have to fill in for participants who are away from their jobs. The main drawback with QCs, according to Lawler and Mohrman (1987), is that they are not well integrated into the organization, in terms of management philosophy, technical and organizational redesign, personnel policies, and training.

Quality improvement (QI) uses quality teams that are similar to QCs in that they address specific problem areas, employ statistical tools, provide group process and problem-solving training to team members, and use team facilitators. Both QCs and QI teams use the PDCA cycle (Plan, Do, Check,

Act) and the QC Story (i.e., seven-step problem-solving method) as their primary problem-solving methodologies. However, there are differences in the context of quality teams under QI that may result in better integration within the organization.

Carr and Littman (1993) identify several differences between QI teams and QCs. QCs are often limited to employees and front-line supervisors, while QI teams include members from management as well. Involving management in quality teams can reduce management resistance and fear. QCs in general have a more limited focus than QI teams in both issues addressed and composition of teams. While QCs generally include only the members of a specific work area, QI teams may be cross-functional, including members from different units within the organization. Teams such as this can deal with broader organizational issues and can implement solutions that are more likely to be accepted and effective since more stakeholders are involved. Teams under QI have the potential for a high degree of integration into the organization through greater involvement of management and the existence of more broadly based teams.

3.2. Participatory Ergonomics

Perhaps one the fastest-growing applications of teamwork has been in the field of ergonomics. The use of teams to evaluate, design, and implement jobs and workstations is relatively recent but has met widespread acceptance. A clear indication of this trend is the growing number of submissions on the topic in most national and international ergonomics conferences and the inclusion of employee participation as one of the basic requirements in the proposed OSHA Ergonomics Standard (OSHA 1999).

Participatory ergonomics can be understood as a spinoff of the activity of quality-related teams focusing on working conditions. Noro and Imada created the term *participatory ergonomics* (PE) in 1984 with the main assumption that ergonomics is bounded by the degree to which people are involved in conducting this technology. According to Imada (1991), PE requires users (the real beneficiaries of ergonomics) to be directly involved in developing and implementing ergonomics. Wilson (1995) more recently proposed a more comprehensive definition of PE as ''the involvement of people in planning and controlling a significant amount of their own work activities, with sufficient knowledge and power to influence both processes and outcomes in order to achieve desirable goals.''

Imada (1991) points out three major arguments in support of worker involvement in ergonomics. First, ergonomics being an intuitive science, which in many cases simply organizes the knowledge the workers are already using, it can validate the workers' accumulated experience. Second, people are more likely to support and adopt solutions they feel responsible for. Involving users/workers in the ergonomic process has the potential to transform them into makers and supporters of the process rather than passive recipients. Finally, developing and implementing technology enables the workers to modify and correct occurring problems continuously.

Participatory ergonomics can be an effective tool for disseminating ergonomic information allowing for the utilization of this knowledge in a company-wide basis. It is evident that professional ergonomists will not be available to deal with all the situations existent in an entire organization and that there is a need to motivate, train, and provide resources to workers to analyze and intervene in their work settings.

Participatory ergonomics sees end users' contributions as indispensable elements of its scientific methodology. It stresses the validity of simple tools and workers' experience in problem solution and denies that these characteristics result in nonscientific outcomes. Employees or end users are in most situations in the best position to identify the strengths and weaknesses of the work situations. Their involvement in the analysis and redesign of their workplace can lead to better designs as well as increase their and the company's knowledge on the process.

This approach stresses the relevance of ''small wins'' (Weick 1984), a series of concrete, complete, implemented contributions that can construct a pattern of progress. The nature of these small victories allows the workers to see the next step, the next improvement, and it constitutes a gradual, involving movement towards organizational change. Participatory ergonomics is seen occasionally either as method to design and implement specific workplace changes or a work organization method in place regardless of the presence of change. Wilson and Haines (1997) argue that the participatory process is in itself more important than the focus of that participation since a ''flexible and robust'' process may support the implementation of any change.

Participatory ergonomics emphasizes self-control and self-determination and provides workers more control over their working conditions. This approach also offers potential for reduced job strain through increased social interaction and support. In fact, worker involvement has been shown to be the most common feature among effective stress-management programs (Karasek 1992).

Participatory ergonomics has been implemented through a variety of different organizational approaches and team designs, and no clear unifying model has been proposed or seems likely to be achieved (Vink et al. 1992). Liker et al. (1989) describe six different models of participation based on either direct or representative participation and on different levels of worker input. Wilson and

Haines (1997) describe seven dimensions of participatory ergonomics, characterizing the level of participation (e.g., workstation, organization), focus (e.g., product, workstation, job), purpose (e.g., design, implementation), timeline (e.g., continuous, discrete), involvement (e.g., direct, representative), coupling (e.g., direct, remote), and requirement (e.g., voluntary, necessary).

The tools employed in participatory ergonomics clearly reflect the importance given to the simplicity and meaningfulness of the methods. Group processes follow procedures that mirror those used in quality-related teams. The most common techniques utilized are also derived from QI applications, including Pareto analysis, brainstorming, cause-and-effect diagram, flowcharts, and several forms of displaying quantitative information. Other tools for observation, time measurement, workstation analysis, and problem solving have been developed to address the needs of teams working on ergonomic issues. See Noro and Imada (1991) and Wilson and Haines (1997) for a more complete account of available methods.

Participatory ergonomics is a main feature of most successful ergonomic programs, as emphasized in the National Institute for Occupational Safety and Health's (NIOSH) elements of ergonomics programs (Cohen et al. 1997). This approach has been increasingly common among interventions aimed at improving productivity and reducing both physical and mental workloads. Successful applications of PE have been reported in many industries, including meatpacking (Garg and Moore 1997), health care (Evanoff et al. 1999), automotive (Joseph 1986; Orta-Anes 1991; Keyserling and Hankins 1994), office work (Vink et al. 1995; Haims and Carayon 1998), and agriculture (Sutjana et al. 1999).

Even though the potential benefits are significant, PE faces the same difficulties as do other teamwork initiatives discussed elsewhere in this chapter. Difficulties for the successful implementation of PE include lack of commitment from management and its use as decoy for other purposes such as undermining the union or reducing management influence (Day 1998). The skeptical stance of management regarding the need for ergonomic improvement, the lack of worker awareness of ergonomic deficiencies, and labor management conflict are also highlighted as possible hurdles for PE development (Vink et al. 1992).

4. KEY SUCCESS FACTORS FOR EFFECTIVE TEAMS

Teamwork is not a simplistic, mechanistic work organization technique that can be applied easily with immediate results. To the contrary, it can be a complex management approach that demands well-planned support in all its phases to be effective. Teamwork is not a panacea and is not suitable to all organizational contexts.

Some basic insights into the suitability of teams can be derived from Kanter's (1983) thoughts on participatory management. *Mutatis mutandis,* the use of teamwork (participation) is appropriate for situations related to staying ahead of change, gaining new sources of expertise, involving all who know something about the subject, achieving consensus in controversial matters, building commitment, dealing with problems belonging to no one by organizational assignment, balancing vested interests, avoiding hasty decisions, handling conflicting views, and developing and educating people through their participation. On the other hand, teamwork can be inadequate when a solution for the problem is already available, when nobody really cares about the issue, and when there is no time for discussion.

Kanter (1983) suggests that for participation to be effective, the following elements are required: leadership (particularly for the initiation of the process), a clearly designed management structure, assignment of meaningful and feasible tasks with clear boundaries and parameters, a time frame, scheduling of reports and accountability, information and training for participants, recognition and rewards for teams' efforts (extrinsic rewards), delegation of control but no abdication of responsibility, and a clear process of formation of the participatory groups as well as their evolution and ending and the transfer of learning from them.

Management support has been widely recognized as the fundamental condition for the implementation of teamwork initiatives (Carr and Litman 1993; Hyman and Mason 1995; Kocham et al. 1984). Without continued support and commitment from management, team efforts are doomed to failure. The role of top management is to initiate the teamwork process, setting up policy and guidelines, establishing the infrastructure for team functioning, providing resources, promoting participation, guidance, and cooperation, and assigning a meaningful and feasible task. Tang et al. (1991) report a relationship between upper-management attendance and team members' participation and between middle-management attendance and teams' problem-solving activities. In a study of 154 QC applications from 1978 to 1988, Park and Golembiewski (1991) found middle-management attitude to be the strongest predictor of team success. Employees who are involved in team projects that receive low levels of management support may become frustrated due to lack of resources and cooperation. This may in turn result in negative attitudes, not only towards the project itself, but also towards the job and organization.

Hackman (1990) points out that unclear or insufficient authority or mandate, which relate to the lack of support from top management, are critical impediments to team achievement. Hackman indicates some consequential issues for teams with regard to group authority. First, the team needs to have authority to manage its own affairs. Second, teams need a stable authority structure. Finally, the timing and substance of interventions by authoritative figures. Interventions by authoritative figures can be most effective as the beginning of team development and can be particularly harmful if done on concerns that the group sees as theirs.

For ad hoc teams in particular, the clarity and importance of the team charge also play an important role in the definition and achievement of success. The team charge should be specific and relevant from the participants' and organization's perspectives.

Time limits are powerful organizing factors that shape team performance, particularly for ad hoc teams (Gersick and Davis-Sacks 1990). The available time guides the pace of work and the selection of strategies employed by teams. The lack of clear timelines can cause problems for teams making adopted strategies inadequate and impacting negatively the members' motivation. Time landmarks can in some situations be provided to the team through other avenues, such as a training delivery schedule (Taveira 1996).

The careful definition of team composition is emphasized as an essential aspect of team success in the literature (Carr and Littman 1993; Larson and LaFasto 1989; Scholtes 1988; Kanter 1983). These authors indicate that the absence of members with key expertise or critical organizational linkages can be a sticking point for teams. Both technical and organizational aspects need to be observed in team composition.

The team leader role is essential as an external linkage between the group and upper management, as a promoter of involvement, and as a coordinator and facilitator of communication inside the group (Taveira 1996; Scholtes 1988). Another facet of the team leader's position, serving as a role model, is highlighted by Bolman and Deal's (1992) symbolic tenet: ''example rather than command holds a team together.'' The diligence of the leader in his effort of coordinating and supporting the team can motivate members to volunteer for work assignments and ease the distribution of assignments.

Training is considered to be the one of the most essential resource for team success. It can provide fundamental principles and procedures for its functioning. Training can impart ground rules, guidelines for internal and external communication, and favored ways to make decisions. Training sessions can provide opportunities to discuss and learn with other teams and be conducive to a perception of support and predictability about oncoming tasks and group development. It can introduce the team to a number of procedures and behaviors that enhance communication and involvement (Taveira 1996). Training in problem solving, data collection and analysis, and group decision making is necessary for employees to fully contribute to the group process.

Training is seen as fundamental for giving the team structure for a sound internal process (Hackman 1990). In the specific case of ''one-project'' teams, where a nonroutine task is undertaken by a new mix of people, training may be critical. Since such groups are unlikely to have established routines for coordinating members' efforts or for determining how work and influence will be distributed among them, training may provide vital guidelines (Gersick and Davis-Sacks 1990).

Moreland and Levine (1992) define commitment as an emotional bond between a person and a group. These authors point out two prevalent theories on commitment: (1) people are committed to a group insofar as it generates more rewards and fewer costs than do other groups to which they already belong or that they could join; (2) commitment depends primarily on how important a group is to someone's social identity. This second theory implies that a need for self-enhancement leads people to feel more committed to groups that seem more successful. A logical extension could be that early success increases the member's commitment to the group.

Correspondingly, Hackman (1990) asserts that groups that begin well and achieve some early wins often trigger a self-sustained upward trend in performance. Hackman delineates a two-factor hypothesis in this regard. The first factor is the quality of the group's initial design, and the second is the occurrence of positive or negative events that trigger the spiral.

Consensus is frequently referred to as the preferred decision-making strategy for teams. Shared definitions of consensus and clear procedures to put this mode of decision making in place are needed. Consensus is defined by Scholtes (1988) as a process of finding a proposal that is acceptable enough that all members can support it and no member opposes to it. Consensus requires time and active participation from team members (Carr and Littman 1993). It demands mutual respect (listening), open-mindedness, and effort at conflict resolution.

Amason et al. (1995) characterize the management of conflicts as ''the crux of team effectiveness.'' They assert that effective teams manage conflict in a way that contributes to its objective. Less-effective teams either avoid conflict, which leads to compromised decisions, or let it seriously disrupt the group process. The authors divide conflict into two types of cognitive and affective. Cognitive conflict focuses on the substance of the issues under discussion. Examination, comparison, and conciliation of opinions characterize it. Cognitive conflict is useful because it invites team members to consider their perspectives from different angles and question underlying assumptions. It can improve members' understanding and commitment to the team's objectives. Affective conflict focuses on

disagreements on personal matters and contributes to distrust, bitterness, cynicism, and indifference among team members. Amason et al. believe that task orientation, an inclusive strategy, and open communications are the key elements in fostering cognitive conflict, while avoiding affective conflict.

Nemeth (1992), analyzing the role of dissent on groups, highlights the importance of a vocal minority. According to Nemeth, the expression of disagreeing views, even when they are wrong, encourages attention and thought processes that enable the identification of new facts and solutions and promotes the quality of group decision making and performance. Disagreement may preclude precipitated action (Kanter 1983) and the occurrence of ''groupthink'' (Janis 1982), in which alternative courses of action are not considered. Minority views stimulate divergent thought processes, adoption of multiple perspectives, and the use of multiple strategies for problem solution.

Gersick and Davis-Sacks (1990) postulate that the challenge of the group is to find the correct equilibrium of independence from and sensitivity to outsiders. The authors add that balancing the relationship between the team and the outside context becomes more complicated when outsiders have dissimilar expectations. The team's composition also influences this balancing since it represents a specific aggregate of dispositions toward, and information about, those stakeholders.

References can be found in the literature to the idea that styles of participatory management should match the organizational culture. Locke et al. (1986) state that the ''manager's natural style of leadership'' (including decision making, autonomy, and employee control) must also be considered. Similarly, the goals of participatory management should be matched with employee knowledge, skills, and ability. Assessment of the organization's characteristics and needs concerning the implementation of participatory management is fundamental. Particularly, a careful training plan must be developed aimed at motivating and preparing people for teamwork.

Additionally, that an organization that has historically promoted from within and has good employee relations may benefit from more from teamwork than an organization that has high employee turnover rates and does not invest in long-term development of human resources.

There may be other drawbacks to participation in teams. Divided loyalties between the group and the organizational segments to which the members belong may result in peer pressure against participation. Coercion and retaliation against team members by management is a possibility. Members may also be frustrated if team recommendations are not acted upon or if their efforts are not recognized by top management.

Duffy and Salvendy (1997, 1999) using a survey of 103 electronic component manufacturers using concurrent engineering, reached conclusions extremely consistent with the experience of groups working in other organizational contexts. Their findings confirmed the importance of team members' proximity for success in product development and concurrent engineering efforts. Physical proximity increases communication frequency, and teams are likely to be more successful if they communicate more frequently. Successful group work was found to be dependent on a reward structure that reflects group achievement as well as individual achievement. Team size, problem-solving effectiveness, and technical training were also found to contribute to success. The perceived value of communication between different concurrent engineering functions/roles was found to be significantly related to quality of communication and concurrent engineering success.

The implementation of teamwork demands organizational resources, not only in financial terms, but also in time and organizational effort required for planning, training, meetings, and other activities. Therefore, resources must be allocated, and contrary to what some believe, effective teamwork is not free, and spontaneity is not the only driving force behind it.

5. TEAM EFFECTIVENESS

Team performance can be approached in many ways. The following model (developed specifically for QI teams) adopts a systems perspective to conceptualizing team performance by classifying the various factors affecting or related to performance into three broad categories derived from the structure–process–outcome paradigm espoused by Donabedian (1992). The model is displayed in Figure 1 and discussed in detail below. While it was developed in the context of quality improvement, many or all of its elements apply to other teams as well.

5.1. Structure Variables

Structure variables are the contextual parameters that may impact team processes and outcomes. We identified the following three dimensions within which the different structure variables could be classified: organizational characteristics, team characteristics, and task characteristics.

5.1.1. Organizational Characteristics

Researchers have discussed the impact of several organizational variables on project outcomes. Three factors stand out: top-management support, middle-management support, and sufficiency of resources.

- *Top-management support* of project teams has been stressed in terms of the extent to which the management encourages the team, provides constructive feedback, actively champions the pro-

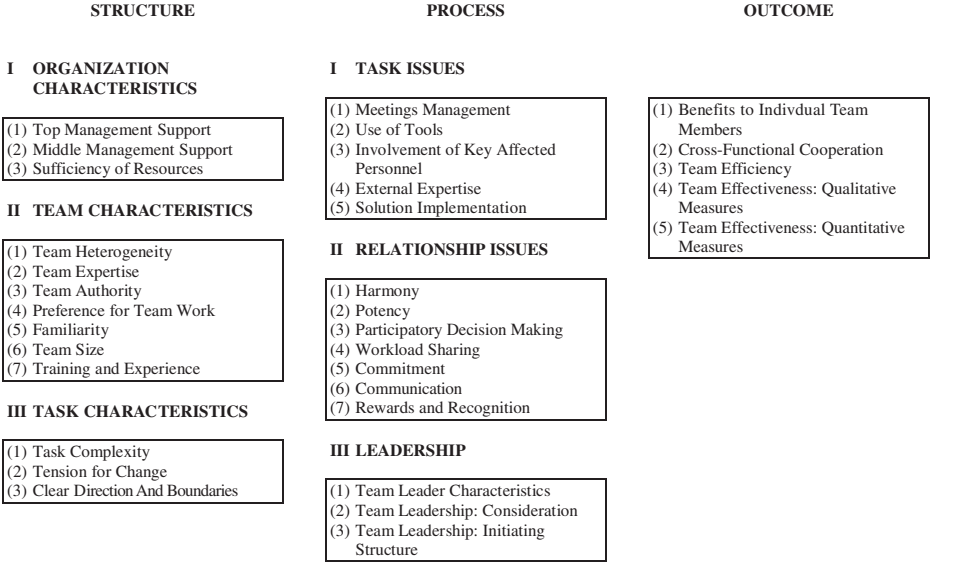

Figure 1 Model of Team Effectiveness.

ject, regularly reviews the team's progress, and rewards the team for its performance (Waguespack 1994; Mosel and Shamp 1993; McGrath 1964; Smith and Hukill 1994; Van de Ven 1980; CHSRA 1995; Rollins 1994).

- *Middle-management support* is deemed important for successful QI team performance because team members need to be given time off by their supervisors from their routine jobs to work on team issues (Gladstein 1984; Davis 1993). Team members have often reported difficulty in obtaining permission from their supervisors to attend team meetings (CHSRA 1995). Indeed, lack of encouragement and recognition and inadequate freedom provided by supervisors has been shown to contribute to delays in successful completion of projects (Early and Godfrey 1995).
- *Sufficiency of resources,* although an aspect of top-management support, has been so consistently linked with project outcome that it warrants separate discussion. Availability of adequate training, access to data resources, ongoing consulting on issues related to data collection, analysis, and presentation, adequate allocation of finances, and availability of administrative support are some of the resources cited as important in studies on team effectiveness (Mosel and Shamp 1993; Levin 1992; Smith and Hukill 1994; Early and Godfrey 1995; Gustafson et al. 1992; Nieva et al. 1978; CHSRA 1995).

5.1.2. Team Characteristics

Team characteristics, or group composition, has received significant attention in studies on team effectiveness. We identified the following seven distinct aspects of team composition that are likely to impact QI team performance: team heterogeneity, team expertise, team authority, preference for teamwork, familiarity, team size, and quality-improvement training and expertise.

- *Team heterogeneity* refers to the mix of personalities, attitudes, skills, background, abilities, rank, and experience among team members. Several studies have discussed the significant impact of team heterogeneity on team effectiveness (Guzzo and Dickson 1996; Campion et al. 1993; Morgan and Lassiter 1992; Salas et al. 1992).
- *Team expertise* assesses the team's ability to solve the assigned problem. A QI team would possess the expertise required to complete a project successfully if it included members who had expert knowledge of the functional area under study as well as adequate training and experience in the methods of quality improvement. In particular, studies show that successful teams have adequate representation of all departments affected by the process under study,

especially the process owners who have intimate knowledge of the process. In addition, successful teams also include members with prior QI teamwork experience (Rollins et al. 1994; Flowers et al. 1992; Johnson and Nash 1993; CHSRA 1995).

- *Team authority* assesses the relative power of the team within the organization that would facilitate the completion of the project efficiently and successfully. For instance, Gustafson et al. (1992) suggest that the reputation of the team leader and other team members among the affected parties significantly impacts the implementation success of solutions. Involvement of people in a position of authority on the team, such as department heads, and inclusion of opinion leaders, i.e., people whose opinions are well respected by the affected parties, helps in overcoming resistance to change and eases the process of solution implementation (CHSRA 1995; Davis 1993; Nieva et al. 1978; Rollins et al. 1994).
- *Preference for teamwork* is another important element of team composition. Campion et al. (1993) cite research that shows that employees who prefer to work in teams are likely to be more satisfied and effective as members of a team.
- *Familiarity* among team members may lead to improved group dynamics and hence better team effectiveness. Team members who are more familiar with each other may be more likely to work together better and exhibit higher levels of team performance (Misterek 1995).
- *Team size* has been found to have an important effect on team performance (Morgan and Lassiter 1992). Although larger teams result in increased resources, which may lead to improved team effectiveness, they may also lead to difficulties in coordination and reduced involvement of team members (Campion et al. 1993; Morgan and Lassiter 1992). Campion et al. (1993) suggest that teams should be staffed to the smallest number needed to carry out the project.
- *Quality-improvement training and experience* of team members has also been shown to affect the outcome of QI projects significantly. Although it features as an aspect of overall team expertise, we consider it important enough in the context of QI project teams to discuss separately. Case studies of successful QI teams show that most of the members of the teams had either participated on other QI projects or at least received some form of prior QI training, such as familiarity with the common QI tools and group processes (CHSRA 1995).

5.1.3. Task Characteristics

Task characteristics are factors that are specific to the problem assigned to the project team. We classify the various task characteristics deemed important in previous research studies into three categories:

1. *Task complexity* has been studied at two levels: (a) as a measure of the complexity of the process being studied, e.g., number of departments affected by the process (CHSRA 1995; Misterek 1995), the difficulty of measuring the process quantitatively (Davis 1993; Juran 1994); and (b) as a measure of the complexity of the goals assigned to the team, e.g., scope of the project, number of goals to be accomplished (Juran 1994).
2. *Tension for change* assesses the importance, severity, and significance of the project. Greater tension for change leads to higher motivation for solving the problem (Juran 1994; Gustafson et al. 1992; Van de Ven 1980). In order to be successful, projects should (a) be selected based on data-driven evidence of the existence of the problem (Mosel and Shamp 1993; Rollins et al. 1994; CHSRA 1995); (b) focus on processes that are a cause of dissatisfaction among the process owners (Gustafson et al. 1992); and (c) be considered important areas for improvement by management (Mosel and Shamp 1993).
3. *Clear directions and boundaries* refer to the extent to which management provides the team with a clear mandate. The clarity with which management describes the problem, its requirements, and project goals and explains the available team resources and constraints has been discussed as directly affecting team processes and outcomes (Misterek 1995; Levin 1992; Gustafson et al. 1992; Fleishman and Zaccaro 1992).

5.2. Process Variables

Mosel and Shamp (1993) and Levin (1992) classify process variables into two core dimensions: (1) task or project dimension, which consists of processes that are directly related to solving the assigned problem, such as use of QI tools, efficient planning of meetings, and solution generation and implementation, and (2) relationship or socioemotional dimension, which deals with the dynamics and relationships among team members, such as communication and harmony. Since team leadership impacts both task and relationship issues, we consider it separately as a third dimension of process variables. We discuss these three dimensions of process variables next.

5.2.1. Task Issues

The following five task variables have been shown to impact team outcomes and other team processes:

1. Efficient *meetings management* has been shown to result in sustained member involvement and improved overall efficiency with which the team solves the problem (CHSRA 1995). In particular, the advantages of mutually establishing team norms up front (such as meeting times, frequency, and length), and advanced planning of meeting agenda and assignment of responsibility to members for specific agenda items have been highlighted (Davis 1993; Juran 1994).
2. *Quality-improvement tools* aid the team at various stages of the project. Effective use of tools has been shown to help teams keep track of their activities, clarify understanding of the system, help identify problems and solution, help maintain focus, and aid in decision making and data collection and analyses (Plsek 1995; Scholtes 1988; CHSRA 1995; Levin 1992).
3. *Involvement of key personnel,* especially those who are directly affected by the process being studied, significantly improves the chances of success of a QI project (Gustafson et al. 1992). For instance, involvement of process owners during the various stages of problem exploration, solution design, and implementation results in a better understanding of the problem by the team and leads to solutions that are more likely to be accepted and implemented smoothly (Rollins et al. 1994; CHSRA 1995; Van de Ven 1980).
4. *External expertise* refers to sources outside the organization that may be helpful to the team during the various stages of the project. For instance, comparison of current levels of performance with industry standards often helps in providing data-based evidence of the severity of the problem, thereby resulting in increased management support (CHSRA 1995). Networking with other organizations that have successfully solved similar problems and identifying benchmarks helps teams develop successful solutions (Gustafson et al. 1992). Examples of other sources of external expertise that can help teams better understand the problem, and design effective solutions include literature, consultants, and clearinghouses (Rollins et al. 1994; CHSRA 1995).
5. Poor *solution implementation* not only may lead to significant delays in completion of a project (Early and Godfrey 1995) but may also result in the failure of the team's solutions in resulting in any substantial improvement (Gustafson et al. 1992). In order to implement its solutions successfully, the team needs to get buy-in from the process owners (Juran 1994; Rollins et al. 1994; Gustafson et al. 1992; Johnson and Nash 1993; CHSRA 1995). In order to evaluate and demonstrate the advantages of their solutions, the team needs to develop easy to measure process and outcome variables and must have in place a well-designed data-collection strategy (Juran 1994; CHSRA 1995). In addition, feedback from the process owners should be obtained to facilitate further improvement of the process (Gustafson et al. 1992).

5.2.2. Relationship Issues

The relationship-based variables that have been shown to impact a team's performance are as follows:

- Team *harmony* refers to the ability of team members to manage conflict and work together as a cohesive unit. The extent to which team members cooperate with one and other and work well together has been shown to affect team outcomes positively (Misterek 1995; Guzzo and Dickson 1996; Mosel and Shamp 1993).
- Team *potency* has been defined as a team's collective belief that it can be effective (Guzzo and Dickson 1996). It is similar to Bandura's (1982) notion of self-efficacy. Campion et al. (1993) have demonstrated a positive relationship between team potency and outcomes such as team productivity, effectiveness, and team member satisfaction.
- *Participatory decision making (PDM)* refers to involvement of all team members on important team decisions. Participation in decisions results in an increase in members' sense of responsibility and involvement in the team's task (Campion et al. 1993). PDM style has been shown to be a common characteristic of successful QI teams (CHSRA 1995; Scholtes 1988).
- *Workload sharing,* similar to PDM, ascertains the extent of balanced participation among members of a team. Teams where most of the members contribute equally to the work have been shown to be more productive and successful (CHSRA 1995; Campion et al. 1993; Scholtes 1988).
- *Commitment* of team members to the team's goals is one of the driving forces behind effective teams (Waguespack 1994). Successful QI teams have reported member motivation and commitment to improve the process as being a critical factor in their success (CHSRA 1995).
- *Communication* is a critical component of teamwork because it serves as the linking mechanism among the various processes of team functioning (Rosenstein 1994). For instance, Davis (1993)

discusses the impact of open communications among members of a QI team on team member commitment. Studies have also demonstrated a positive association between open communication and team performance and team member satisfaction (Gladstein 1984; Campion et al. 1993).

- *Rewards and recognition* help motivate team members and enhance their commitment to team goals (CHSRA 1995). Levin (1992) suggests that formally celebrating the achievement of various project milestones helps a QI team maintain its momentum, motivation, and enthusiasm for accomplishing the project successfully.

5.2.3. Leadership

The impact of team leadership on team performance has been extensively researched. The role of a team leader is to provide direction, structure, and support to other team members (Dickinson et al. 1992). The behavior and competence of the team leader has been shown to affect significantly both team processes and outcomes (CHSRA 1995; Mosel and Shamp 1993). Rosenstein (1994) divides leadership into two distinct but correlated behaviors:

1. *Consideration,* which focuses more on the relationship-based team processes, e.g., the extent to which the team leader facilitates open communication among team members
2. *Initiating structure,* which focuses more on the task-oriented team processes, e.g., the ability of the team leader to plan and coordinate the team's activities capably.
3. In addition to these two behavioral factors, researchers have also emphasized the team leader's *overall characteristics,* such as skills and commitment (Smith and Hukill 1994; Juran 1994). We therefore evaluate the dimension of leadership on all three factors.

5.3. Outcome Variables

Outcome variables constitute the results of the team's performance. We identified four different outcome variables that have been the focus of existing research studies on team performance: benefits to individual team members, cross-functional cooperation, team efficiency, and team effectiveness.

1. *Benefits to individual team members* assesses the influence of the team experience on individual team members (Hackman 1987). Increased job satisfaction, a feeling of accomplishment, and a more problem-focused approach to the daily work are some of the benefits that members derive as a result of participating on teams (Juran 1994; Campion et al. 1993).
2. Improvement in *cross-functional cooperation* is a very common positive outcome of successful QI team efforts (CHSRA 1995). Studies have shown that participation in QI teams by members of different departments often results in the development of mutual trust and respect across departments and a greater understanding of the system, which leads to improved interdepartmental cooperation and communication (Rollins et al. 1994; Juran 1994).
3. The output of the team's effort is measured both in terms of efficiency and effectiveness. *Team efficiency* assumes importance because organizations implementing TQM often complain about the time required to experience significant improvement (Early and Godfrey 1995). In a study of causes of delays in completing QI projects, Early and Godfrey (1995) report that up to 62.8% of the total time taken by the teams could have been avoided. Team productivity has also been a key outcome measure in studies of various other work groups (e.g., Campion et al. 1993).
4. *Team effectiveness* can be assessed by both qualitative and quantitative measures (Landy and Farr 1983; Guzzo and Dickson 1996). Qualitative measures are more subjective and judgmental, such as ratings that require individuals to evaluate the performance of the team (e.g., Campion et al. 1993). Quantitative measures, on the other hand, are objective and nonjudgmental, such as reduction in length of stay, dollars saved, and reduction in error rate (e.g., CHSRA 1995).

6. IMPACT OF TEAMS

Teamwork represents one form of work organization that can have large positive and/or negative effects on the different elements of the work system and on human outcomes, such as performance, attitudes, well being, and health. Given the variety of team characteristics and organizational settings, it is likely that the impact of teamwork on the work system will be highly variable. Some teams may provide for positive characteristics, such as increased autonomy and more interesting tasks, whereas other teams may produce production pressures and tightened management control (Lawler 1986). One important issue in team design is the degree of authority and autonomy (Medsker and Campion 1997; Goodman et al. 1988). It is, therefore, important to examine the impact of teamwork on the task and organizational elements of the work system. Tasks performed by teams are typically of

different nature of tasks performed by individual employees. Understanding the physical and psychosocial characteristics of the tasks performed by the team and the members of the team is highly significant for ergonomists. Teams can provide opportunities for reducing the physical and psychosocial repetitiveness of tasks performed by individual employees. This is true only if employees have sufficient training on the different tasks and if rotation among tasks occurs. In some instances, the increased authority and autonomy provided to teams may allow employees to influence their work rhythms and production schedules. This may have beneficial physical impact if adequate work–rest schedules are used. On the other hand, members of the team may work very hard at the beginning of the shift in order to rest at the end of the day. This overload at the beginning of the shift may have some physical health consequences, such as cumulative trauma disorders. A more balanced workload over the entire shift is preferred. In other instances, teamwork has been accompanied by tightened management control (Barker 1993) and electronic and peer surveillance (Sewell 1998). In conclusion, the impact of teamwork on work organization and ergonomics is largely undetermined and depends on a range of factors. However, teamwork can provide many opportunities to improve elements of the work system.

6.1. Impact on Management

The upper managerial levels of organizations have been traditionally targeted in the efforts to sell teamwork. For these management segments, the benefits would come in improvements to the whole organization success and the possibility of spending more time working at the strategic level once the daily decisions can be undertaken by the employee teams. However, one group whose needs are frequently overlooked when implementing employee involvement programs is the middle managers or supervisors. Because the supervisors are a part of management, it is often assumed that they will buy into the philosophies adopted by upper management. Otherwise, according to studies by Klein (1984), even though 72% of supervisors view participation programs as being good for the company and 60% see them as good for employees, less than 31% view them as beneficial to themselves. This perspective is clearly portrayed by Kanter (1983): ''participation is something the top orders the middle to do for the bottom.'' Concerns among supervisors relate to job security, job definition, and additional work created to implement these programs (Klein 1984). A common fear is that employee participation would take supervisors out of the chain of command. Supervisors typically have attained their positions via promotions intended to reward them for outstanding performance as a worker. Sharing their supervisory tasks can be seen as a loss of status to less-deserving workers. Support from first-line supervisors is essential for success of overall participation programs. Some successful experiences in obtaining this support have included the introduction of presentations to upper management, by supervisors, about teamwork activities and creation of teams for forepersons themselves (Harrison 1992).

6.2. Impact on Employees

It is considered that today's better trained and educated workers have expectations greater than basic pay, benefits, and a safe place to work. According to Lawler (1986), these enlarged expectations include participating in meaningful decisions. On the other side, potential problems from the employee perspective need to be addressed. The literature on the subject of employee involvement has dedicated much less emphasis on the problems than on the benefits. Indeed, when these problems are discussed, they are almost always seen from the perspective of the organization and its management. Very little has been written about the problems from the workers' standpoint.

Regarding the negative consequences of teamwork experienced by workers, Baloff and Doherty (1988) state that it can be very disruptive, especially during the crucial start-up period of employee involvement. These authors classify the negative consequences into three categories. First, participants may be subjected to peer-group pressure against what is perceived as collaboration with management in ways that endanger employees' interests. Second, the participants' manager may attempt to coerce them during the group activity, or they may retaliate against the participants if the results of their involvement displease them. Third, participants may have difficulty adapting psychologically at the end of a highly motivating participation effort if they are thrust back into narrow, rigidly defined tasks. Lawler (1986) expresses similar concern about some types of participation that do not match the overall structure of organization and inevitably will produce frustrated expectations among the workers.

On the more negative side of the spectrum of the assessments on teams, Parker and Slaughter (1994, 1988) see them as a way of undermining the union and exploiting workers. Team concept is seen as part of ''management by stress,'' whereby production is speeded up and management actually exerts *more* control on employees. According to these authors the ''work rationalization'' that used to be done by management is being made now by the employees themselves. The authors point out that peer pressure related to this kind of involvement is even more restrictive than the hierarchy itself. They state that there are several myths about teamwork, that the team concept involves: job security, increased productivity, more control by workers, working smarter not harder, workers with more

skills, stronger unions, and feeling of teamwork in the shop floor. The authors conclude that teams themselves are not harmful, but rather the way management has put them into practice and the underlying motivations.

All in all, however, if teamwork is properly chosen as a form of work design and if teams are well designed and managed, teamwork can effectively improve productivity, quality, and employee satisfaction.

CHAPTER 38
Performance Management

MARTIN P. FINEGAN
KPMG

DOUGLAS K. SMITH
Author and Consultant

1. INTRODUCTION

This chapter is about performance management. Performance relates to the measurable outcomes or results achieved by an organization. Management relates to the actions or activities an organization deploys to improve its desired outcomes. This chapter focuses on three major themes:

1. Key ideas organizations have found helpful in dealing with powerful and fundamental forces of change at work in the world

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

2. How goal setting and metrics can improve performance at the individual, team, working-group and organizational-unit levels
3. How the formal and informal aspects of an organization each contribute to managing performance in a world of change

We have grounded this chapter in our own extensive experience as well as the writings of leading commentators. Our objective is to provide readers with a blend of best practices. In particular, we seek to avoid—and advise readers to avoid—selecting any single approach to performance management as "the best and only." Rather, we promote a "both/and" view of the world, in which readers carefully craft that blend of approaches that best fits the needs and challenges ahead of them. This contrasts with the far too dominant "either/or" mindset that maintains, incorrectly, that performance is best managed by selecting a single comprehensive approach through some debate grounded in the proposition that either approach A or approach B is best. In our experience, it usually turns out that both approach A and approach B are relevant to the challenge of managing performance in a changing world.

This chapter concentrates on providing guidance that can be applied, practiced, and perfected by any individuals and teams in any organization. The concepts and techniques we put forward do not depend on senior-management support. We do not attempt to put forward a comprehensive performance-management system model. Our focus is on performance in an environment of change and on how individuals, teams, and groups can significantly improve their mindsets and approaches to improving performance. You and your colleagues can begin to make a performance difference tomorrow for yourself and your organizations. We will provide some ideas and perspectives on formal aspects to integrating performance management and to formal top-management-driven approaches to change. But by and large, our ideas are for you, and you can use them wherever you sit in an organization and on whatever performance challenge arises.

2. THE CHANGE IMPERATIVE

After summarizing the fundamental forces of change that so often determine the nature of today's performance challenges, this section reviews a series of key concepts and ideas useful in managing performance itself. These include:

- The balanced scorecard: a change in what performance means and how its is measured
- New mental assumptions for managing performance and change
- Disciplines of learning and performing organizations
- Work as process and competition as time based
- Characteristics of high performance organizations
- The trend toward impermanent organizations and alliances

2.1. Forces of Change

If you are young enough, the world of change is all you have. For others, managing performance is very different today than in years past. Regardless of your age and experience, you should have a picture of the fundamental forces at work that shape and determine the challenges ahead of yourselves and your organizations. One of our favorite frameworks comes from John Kotter, a professor at Harvard Business School. Figure 1 shows Professor Kotter's summary of the economic and social forces driving the need for major change.

These forces are fundamental because they will not be going away any time soon and many market responses to them are irreversible. Globalization and internet technologies are but two examples of changes with permanent and lasting impact.

New market and competitive pressures represent both danger and opportunity. Organizations everywhere are attempting to capitalize on the opportunities and to mitigate their risks from the dangers. The economic headline stories we read about and listen to every day are all in some way responses or reactions (or the lack thereof) to the fundamental forces.

Frameworks like Kotter's help and encourage readers to look at the external environment for the drivers of change. They give clues as to what is important, how organizations might adapt and lead and, if probed, possible clues about what's around the corner. Naturally, organizations must continue to look at themselves as well. But far too many organizations under perform as a result of only looking inward for both the causes and solutions to better performance. The ability to understand change and adapt to it more quickly than others is among the most important dimensions of managing performance for organizations to master as we enter the 21st century.

Figure 1 Economic and Social Forces Driving the Need for Major Change in Organizations. (Adapted from Kotter 1996)

2.2. A Changing View of Performance Itself: The Balanced Scorecard

The forces of change have altered what performance itself means. Gone are the days when financial results were all that mattered. In today's world, organizations must deliver a combination of financial and nonfinancial performance outcomes. Readers who do not understand the new scorecard of performance will fall into the three main traps of a financial-only approach to performance management:

1. *Unsustainability:* Achieving sustained organizational performance demands outcomes and results that benefit all of the constituencies that matter. Shareholders provide opportunities and rewards to people of the enterprise to deliver value to customers, who generate returns to shareholders, who in turn provide opportunities to the people of the organization, and so on. If you substitute citizens or beneficiaries for customers of the enterprise, you can apply this concept to profit and not-for-profit organizations. Focusing solely on financial measures will create shortfalls in customer service, employee satisfaction, or product/process quality. The wise executive looks at financial measures as lagging measures and seeks other more direct measures of contributing performance to serve as leading measures.
2. *Demotivation:* Executives at the top are motivated by performance measures because they also receive big paydays from achieving them. But today's competitive environment requires tremendous energy and contribution from people throughout the organization. For most people in the organization, financial measures are a too-distant indicator of success or failure, to which many have contributed. Concentrating solely on the financial dimension of measurement is not motivating. It can go further toward being demotivating if people suspect that leaders are concentrating on financial measures out of self-interest.
3. *Confusion:* People need to see how and why their contributions make a difference. Financial goals alone will not reach or connect with very many individuals or groups. These people can become confused and resort to activity-based goals to fill their void.

This new scorecard was first popularized by Kaplan and Norton (1995). All organizations have multiple constituencies such as shareholders, customers, employees, and strategic partners. Each of these constituencies has performance needs and concerns that must be met if the organization hopes to survive and thrive. Kaplan and Norton's scorecard emphasizes the need to convert an organization's

strategy into a series of linked performance metrics and outcomes across a 4D logic that suggests that a firm's financial results directly arise from results that matter to customers, which in turn arise from results of internal processes, which in turn arise from results that matter to the people of the organization in terms of learning and growth.

Smith (1999) fundamentally improved on Kaplan and Norton's thinking by suggesting that the balanced scorecard can be both more balanced and more integrated by replacing the linear logic of people-to-process-to-customer-to-shareholder with a reinforcing, integrated logic wherein results for each constituency both leads and lags results for others. Accordingly, managing performance in a sustainable way looks more like Figure 2, which depicts a philosophy for never-ending success.

When viewed in this way, financial and nonfinancial goals all reinforce and link to one another. Moreover, the goals support a narrative or story of success that will not fall victim to unsustainability, demotivation, and confusion.

2.3. New Mental Assumptions for Mastering Performance and Change

Managing both financial and nonfinancial performance in a world of change demands that readers know how to manage change. Having said that, the first and foremost principle of managing change (see Smith 1996) is to keep *performance* the primary objective of managing change, not *change*. Far too many people and organizations do the opposite. If readers are to avoid this trap, they must work hard to connect real and sustainable performance achievements to the changes underway in their organizations.

With clear and compelling performance objectives in mind, readers must avoid a variety of world-views that do not respond to the challenges at hand in today's fast moving world. Kanter (1983) foresaw many of the new and different ways for people and organizations to picture and respond to change. She called for a ''necessary shift from segmentalist to integrative assumptions.'' Today, we might paraphrase her thoughts as shifting from ''stovepipe'' to ''horizontal'' views of work and organization (see Smith 1996). Here are what Kanter described as ''old'' vs. ''new'' assumptions:

- *Old assumption #1:* Organizations and their subunits can operate as closed systems, controlling whatever is needed for their operation. They can be understood on their own terms, according to their internal dynamics, without much reference to their environment, location in a larger social structure, or links to other organizations or individuals.
- *Old assumption #2:* Social entities, whether collective or individual, have relatively free choice, limited only by their own abilities. But since there is also consensus about the means as well as the ends of these entities, there is clarity and singularity of purpose. Thus, organizations can have a clear goal; for the corporation, this is profit maximization.

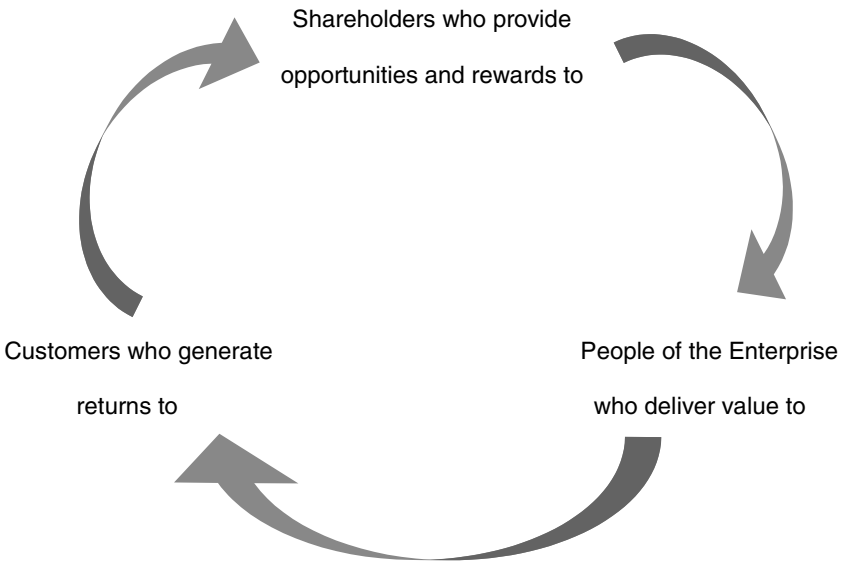

Figure 2 The Performance Cycle. (Adapted from Smith 1999)

- *Old assumption #3:* The individual, taken alone, is the critical unit as well as the ultimate actor. Problems in social life therefore stem from three individual characteristics: *failure of will* (or inadequate motivation), *incompetence* (or differences in talent), and *greed* (or the single-minded pursuit of self interest). There is therefore little need to look beyond these individual characteristics, abilities, or motives to understand why the coordinated social activities we call institutional patterns do not always produce the desired social goods.
- *Old assumption #4:* Differentiation of organizations and their units is not only possible but necessary. Specialization is desirable for both individuals and organizations; neither should be asked to go beyond their primary purposes. The ideal organization is divided into functional specialties clearly bounded from one another, and managers develop by moving up within a functional area.

Here are the new assumptions that Kanter puts forward as alternatives that are more responsive to the external pressures in our changing world:

- *New assumption #1:* Organizations and their parts are in fact open systems, necessarily depending on others to supply much of what is needed for their operations. Their behavior can best be understood in terms of their relationships to their context, their connections—or nonconnections—with other organizations or other units.
- *New assumption #2:* The choices of social entities, whether collective or individual, are constrained by the decisions of others. Consensus about both means and ends is unlikely; there will be multiple views reflecting the many others trying to shape organizational purposes. Thus, singular and clear goals are impossible; goals are themselves the result of bargaining processes.
- *New assumption #3:* The individual may still be the ultimate—or really the only—actor, but the actions often stem from the context in which the individual operates. Leadership therefore consists increasingly of the design of settings that provide tools for and stimulate constructive, productive individual actions.
- *New assumption #4:* Differentiation of activities and their assignment to specialists is important, but coordination is perhaps even more critical a problem, and thus it is important to avoid overspecialization and to find ways to connect specialists and help them to communicate.

The contrast between old and new is sharp. In the old-assumption world, the manager was in control of both the external and the internal. In the new assumption-based world, uncertainty dominates and the need to be fluid and lead by influence rather than control has become the norm. An organization cannot become a strong 21st-century performer if it remains dominated by the old assumptions. It will not be able to change to adapt to new market needs, new technologies, or new employee mindsets. The old model is too slow and costly because it produces unnecessary hierarchy and unneeded specialization.

It takes a very different mindset and perspective to thrive in a world dominated by the new assumptions. One cannot be successful at both in the same ways. Success in each requires a different mental model.

2.4. Disciplines of the Performing and Learning Organization

A variety of new mental models and disciplines have arisen in response to the shifting assumptions so well described by Kanter. Peter Senge is perhaps best known for triggering the search for new disciplines. He suggests five disciplines that distinguish the learning organization from old-world organizations that do not learn (or perform) (Senge et al. 1992):

- *Personal mastery:* learning to expand personal capacity to create the results we most desire and creating an organizational environment that encourages all of its members to develop themselves toward the goals and purposes they choose.
- *Mental models:* reflecting upon, continually clarifying, and improving our internal pictures of the world and seeing how they shape our actions and decisions.
- *Shared vision:* building a sense of commitment in a group by developing shared images of the future we seek to create and the principles and guiding practices by which we hope to get there.
- *Team learning:* transforming conversational and collective thinking skills so that groups of people can reliably develop intelligence and ability greater than the sum of individual members' talents.
- *Systems thinking:* a way of thinking about, and a language for describing and understanding, the forces and interrelationships that shape the behavior of systems. This discipline helps us see how to change systems more effectively and to act more in tune with the larger processes of the natural and economic world.

Each of these disciplines requires a commitment to practice to improve our views and skills in each area. Critically, readers who seek to master these disciplines must do so with an eye on performance itself. Readers and their organizations gain nothing when efforts seek to make people and organizations become learning organizations in the absence of a strong link to performance. Organizations must be both learning and performing organizations.

2.5. Work as Process and Competition as Time Based

Innovation, quality, and continuous improvement have emerged as primary challenges for organizations to apply learning and performance disciplines in the face of change. Innovation draws on and responds to the technological drivers so present in today's world. But innovation also applies to nontechnological challenges. Indeed, for at least the past two decades, competitive success has gone to those who add value to products and services through information, technology, process improvement, and customer service. They must continually ask themselves how to do better and how to do it faster. The old-world adage of "if it ain't broke, don't fix it" has been replaced by "if it ain't broke, fix it!"

At the heart of this reality is quality and continuous improvement. Quality measures itself from the eyes of the customer and views all work as process. Performance of processes is measured by defects as defined by customers, whether internal or external. Defects themselves have many dimensions. But, with the publication of *Competing against Time* (Stalk and Hout 1990), organizations throughout the world were put on notice that speed was now a reality of success. Whether internal or external, customers want error- and defect-free products and services and they want them *fast*. Or, we should say, *faster*. Organizations who master innovation, quality, and continuous improvement never settle for today's results. They continually seek to improve and do so by setting and meeting goals for reducing defects and errors and increasing speed of processes.

2.6. High-Performance Organizations

Many commentators have concluded that organizations cannot succeed in this new world without a fundamentally different set of characteristics. Figure 3 shows contrasting lists of characteristics from a survey of writers, thinkers, and executives.

Traditional	*High Performance*
• Internally driven design	• Customer and environmentally focused design
• Highly controlled fractionated units	• Empowered and autonomous units
• Ambiguous requirements	• Clear direction and goals
• Inspection of errors	• Control of variance at the source
• Technical system dominance	• Socio-technical integration
• Limited information flow	• Accessible information flow
• Fractionated, narrow jobs	• Enriched and shared jobs
• Controlling and restrictive human resources practices	• Empowering human resources practices
• Controlling management structure, process, and culture	• Empowering management structure, process, and culture
• Static designs dependent on senior management redesign	• Capacity to reconfigure

Figure 3 Contrasting Traditional and High-Performance Organizations. (*Source:* Nadler et al. 1992)

High-Performing Organizations	*Low-Performing Organizations*
• Informal	• Rank is right
• Experimental	• Little risk taking
• Action-oriented	• Formal relationships
• High cooperation	• Privileges and perks
• Low defensiveness	• Many status symbols
• High levels of trust	• Rules rigidly enforced
• Little second-guessing	• Slow action / great care
• Few trappings of power	• Much protective paperwork
• High respect for learning	• Decision making at the top
• Few rules and high flexibility	• High levels of fear and anxiety
• Low levels of anxiety and fear	• Your problem is yours, not ours
• Empowered team members	• Well-defined chain of command
• Failures seen as problems to solve	• Learning limited to formal training
• Decisions made at the action point	• Many information-giving meetings
• People easily cross organizational lines	• Trouble puts people on defensive
	• Little problem solving below top
• Much informal problem solving	• Crossing organizational lines
• Willingness to take risks	forbidden

Figure 4 High-Performing vs. Low-Performing Team Characteristics. (*Source:* Synectics, Inc.)

Synectics, an innovation firm, has captured the above list in a slightly different way. Figure 4 contrasts the spirit of innovation in high-performing vs. low performing organizations.

2.7. The Impermanent Organization

Finally, we wish to comment on the trend toward impermanent organizations and alliances. More and more often, organizations respond to performance and change challenges by setting up temporary alliances and networks, both within and beyond the boundaries of the formal organization. It could turn out that this model of the temporary organization and alliance formed to bring a new innovation to market will in fact become the norm. Some have suggested this as one very viable scenario, which Malone and Laubacher (1998) dub the ''e-Lance economy.'' Malone and Laubacher put forward the idea of many small temporary organizations forming, reforming, and recombining as a way of delivering on customer needs in the future. While they concede that this may be an extreme scenario, it is not an impossible one. Their research is part of an ongoing and significant series of projects at MIT around the 21st-century organization. Another research theme is the continued importance of process management in the future, putting processes alongside products in terms of performance-management importance. One view is certain: 20 years from now, very different business models than the ones we know today will have become the norm.

3. PERFORMANCE SUCCESS: GOAL SETTING AND METRICS

Let's first look at a few fundamental flaws in how many organizations approach performance. As stressed by Smith (1999), ''Performance begins with focusing on outcomes instead of activities.'' Yet most people in most organizations do the reverse. With the exception of financial results, most goals

are activity based instead of outcome based. Such goals read like ''develop plans to reduce errors'' or ''research what customers want.'' These are activities, not outcomes. They do not let the people involved know when they have succeeded, or even how their efforts matter to their own success and that of their organizations.

3.1. Performance Fundamentals and Obstacles

A variety of obstacles and bad habits explain this misplaced emphasis on activities instead of outcomes. At their root lie the old assumptions, financial-focus, internal orientation, and silo organization models we reviewed above. These obstacles and bad habits include:

3.1.1. Natural Human Anxieties

Most people get nervous about the specificity with which their personal success or failure will be measured. We like some flexibility to say we did the right things and that any lack of desired outcome is due to extenuating circumstances. A common tactic is to declare any outcome outside our complete control as unachievable. The problem with this is that for most people in an organization this leaves a narrow set of activities. The further you are from the front line to the customer, the more tempting and common this tactic becomes.

3.1.2. Difficulty Expressing Nonfinancial Outcomes

It is not easy to state nonfinancial goals in an outcome-based fashion. Yet so many performance challenges are first and best measured in nonfinancial ways. It is hard work and personally risky to move beyond the goal of completing the activities and expose your performance to a measure of how effective that activity is where it counts, in the eyes of customers, employees, and strategic partners. The basic anxiety and aversion to setting real outcomes as goals will always be around, particularly when new and different challenges confront us. A key to success is to control the anxiety rather than letting it control you.

3.1.3. Flawed Assumptions

In many instances, people falsely assume performance outcome-based goals exist when they don't. People in organizations, especially the ones who have achieved a degree of success, often claim they already know what the critical outcomes are and how to articulate them, when in reality they don't. Or people will elude the responsibility to state outcomes by claiming the outcomes themselves are implied in the activities or plans afoot. Or they will refer to the boss, expecting he or she has it all under control. All of these excuses are mere ruses to avoid the responsibility to specifically and expressly articulate the outcomes by which any effort can be monitored for success.

3.1.4. The Legacy of Financial Management

The financial scorecard has dominated performance business measurement in the modern corporation. As reviewed in the Section 1, the financial-only approach to performance management fails to account for performance outcomes that matter to customers, employees, and strategic partners. It produces organizational cultures that are short-term focused and have difficulty breaking out of the silo approach to work. Why? Because functional organizations are uniquely suited to cost accounting. With the introduction of activity-based accounting by Cooper and Kaplan, organizations were given the chance to move toward a process view of work and still keep their numbers straight. That can help, but it is not enough. Until organizations seriously set and achieve outcome-based goals that are both financial and nonfinancial and link to one another, those organizations will continue to manage performance suboptimally.

3.1.5. The Intrusive Complexity of the Megaproject or Megaprogram

Also standing in the way of outcome-based performance management is the grand illusion of a complete solution to a firm's information systems. The promise of information technology systems that provide organizations with an integrated approach to transaction management and performance reporting has been a major preoccupation of management teams ever since computers, and personal computers in particular, have become both accessible and affordable (most recently in the form of enterprise resource planning [ERP] systems).

SAP, Oracle, and PeopleSoft are a few of the more popular ERP software providers who have experienced phenomenal success in the 1990s. While the drive to implement new systems was accelerated by the now-infamous Y2K problem, the promise of integrated and flexible information flow throughout an organization had great appeal. These systems were also very much a part of the broader ''transformation'' programs that many organizations were pursuing at the same time. Many comprehensive transformation frameworks and methodologies that have emerged over the past decade were

built on the success that business process reengineering had in the early 1990s. These programs redesigned the people, process and technology of an organization to bring about the performance promise of transformation. Reengineering programs require at least two years to complete and are delivered through massive teams following very detailed methodology scripts. Completing the activities alone is often exhausting and risky. But their promised paybacks are huge, ranging from industry leadership to a chance to survive (and hopefully thrive once again).

Because of the long timeframes associated with the effort and with being able to see the reward, the value received from the effort is difficult to measure. There is a time lag between the team's implementation activities and the outcome. This is true of many things strategic. Consulting teams (and executive sponsors) are often onto their next assignments long before outcomes can be realized as they were defined in the business case.

A focus on performance outcomes for strategic initiatives most often gets lost or mired in the operational systems that are used in most companies. These systems are designed to support the tactics of an organization, which are very often bounded by the time cycles inherent in the formal budgeting and planning systems. All of these realities overwhelm the manager trying to create performance change. The bigger and more complex the organization, the more complicated the improvement of formal performance-management systems.

Many of the large consulting firms (certainly the ones showing annual growth rates in the 30–35% range during the past decade) play to the formal side of organization performance, bringing frameworks and methodologies that require large consulting teams that provide comprehensive solutions to performance management. At the same time, many corporate executives and managers are in need of ''having it all integrated'' for the promise of accelerated decision making and improved information flow.

Each of these goals has merit and the results can provide large payback. The problem is that in far too many situations, the payoff does not come because of the sheer complexity of the solutions. Much of the implementation cost and business case payback for these endeavors deals with taking activities out of the process. With the advent of the Internet, completely new business models are being pursued for connecting products or services with customers. The sheer size and cost of these approaches require a focus on the formal systems.

So to the list of obstacles to making performance measurable we add this significant pressure to focus on large, complex projects. As consulting firms and their clients have gained experience with ''transformation'' over the past decade, they have added more emphasis on the informal systems and the people aspect of change. However, their business models still require large teams that will continue to have a bias toward changing the formal systems rather than working at the informal.

3.2. Overcoming the Obstacles: Making Performance Measurable

So what can you do to overcome this formidable list of obstacles? Getting focused on performance outcomes rather than activities is the place to begin. But it is not enough on its own. You will need more to sustain your focus. There are three additional aspects to performance management:

1. Picking relevant and specific metrics
2. Using the ''four yardsticks''
3. Articulating SMART goals

Let's take a brief look at the most important aspects behind each of these attributes.

3.2.1. Picking Relevant and Specific Metrics

Sometimes metrics are obvious; other times, the best measures seem elusive. Revenues, profits, and market share are universally recognized as effective metrics of competitive superiority and financial performance. But no universally recognized measures have emerged for such challenges as customer satisfaction, quality, partnering with others, being the preferred provider, innovation, and being the best place to work. Management teams must learn to avoid getting stuck because of the absence of an already accepted standard of measure. They must be willing to work together to pick measures that make sense for their particular challenges.

A good set of measures will have a proper blend of qualitative and quantitative metrics. Consider a company's aspirations to build partnering relationships with key suppliers or customers. Certain threshold goals for the amount of business conducted with each potential partner can provide quantitative and objective performance outcomes. However, it is easy to imagine an outcome where these measures are met but a true partnering relationship is not achieved. Partnership implies a variety of subjective and qualitative characteristics such as trust, consulting each other on critical matters, sharing knowledge, and relying on each other for difficult challenges. Using metrics around these important outcomes will require special candor and honesty from both partners to track behaviors,

learn from results, and motivate improvement for both parties in the relationship. Using these types of subjective measures is acceptable and may in fact provide superior results. But you must understand the difficulties associated with such use and overcome them.

Here are several additional pieces of guidance about selecting measures that, while obvious, are often sources of frustration.

- Many metrics require extra work and effort. This will be true for almost all measures that do not already exist in an organization. So if the challenge is new, the best measures will most likely also be new.
- If the measure is new, you will not have a baseline. Organizations and managers must be willing to use their gut feeling as to their baseline performance level. Researching ranges of normal or best-in-class measures can give clues. It is not important to be exact, only to have a sufficient measure to allow the group to move.
- Some measurement criteria will demand contributions from people or groups who are not under your control or authority. In fact, most serious challenges in an organization will require all or many departments to contribute. It will take extra work to get all groups or departments aligned with both the goals and the measures.
- Some metrics are leading indicators of success, while others are lagging indicators. Revenues, profits, and market share are common examples of lagging indicators and therefore are routinely overused. Leading indicators must also be developed to get at the drivers behind the financial success.

The key is to work hard enough at it to make good measurement choices and then stick with them long enough to learn from them. Organizations and managers must overcome the anxieties and frustrations that come with outcome-based performance measures and learn how to select and use the best measures. The following section on the four yardsticks can help you become increasingly comfortable in choosing and sticking with the best measures of progress.

3.2.2. Using the Four Yardsticks

All performance challenges are measurable by some combination of the following:

- Speed/time
- Cost
- On-spec/expected quality
- Positive yields

The first two are quantitative and objective and the second two a blend of objective/subjective and quantitative/qualitative. Becoming adept at the use of these yardsticks will take you a long way toward overcoming the anxieties and obstacles inherent in performance outcome-based goals.

3.2.2.1. Speed/Time Process management is the most common application of this metric. We use it anytime we need to measure how long it takes to complete some activity or process. It is one of the measures that usually requires extra work. Most processes in an organization cross multiple department boundaries, but not neatly. The extra work comes in the need to be specific about beginning and ending points. The scope you place on the process end points will depend on your goal and level of ambition behind the process. For example, an order-generation and fulfillment process that is designed to be both the fastest and totally customer-driven will need to go beyond receipt of delivery and include process steps that measure your customers' use and satisfaction levels. If the process you want to measure is complex, you also must define the specific steps to the process so that you will understand where to concentrate efforts and where your efforts are paying off.

There are six choices you need to make when applying a speed/time metric:

1. What is the process or series of work steps you wish to measure?
2. What step starts the clock?
3. What step stops the clock?
4. What unit of time makes the most sense?
5. What number and frequency of items going through the process must meet your speed requirements?
6. What adjustments to roles and resources (e.g., systems) are needed to do the work of measurement and achieve the goals?

Some of the more fundamental processes in organizations in addition to order fulfillment include new product/service development and introduction, customer service, integrated supply chain, and the hiring/development/retention of people.

3.2.2.2. Cost Cost is clearly the most familiar of the four yardsticks. But here too we can point to nuances. Historically, organizations have focused mostly on the unit costs of materials or activities. These units paralleled organization silo structures. This approach to costing still makes sense for certain functionally sensitive performance challenges. On the other hand, many of today's process-based performance challenges demand the use of activity-based costing instead of unit costing.

3.2.2.3. On-Spec/Expected Quality Product and service specifications generally derive from production, operational, and service-level standards, legal and regulatory requirements, and customer and competitive demands. Another way of viewing specifications is through a company's value proposition, which includes the functions, features, and attributes invested in a product or service in order to win customer loyalty. Some dimensions of quality are highly engineered and easily defined and measured. Others can become abstract and very hard to measure unless the specifications are stated and well defined.

This is key when using this family of metrics. When customer expectations are unknown or poorly defined, they cannot be intentionally achieved. You cannot set or achieve goals related to aspects of performance that you cannot even define. The approach to quality and continuous improvement reviewed above therefore, emphasizes the need to let the customer define quality, to consider any deviation from that a defect, and to set specific goals about reducing defects on a continual basis.

3.2.2.4. Positive Yields This final yardstick category is designed to deal with more abstract or unknown dimensions to customer expectations. It is also a catch-all category whose measures reflect positive and constructive output or yield of organizational effort. Yields are often prone to subjective or qualitative measures, and their purpose is to get at the measurement of newer performance challenges such as alliances or strategic partnering, ''delighting customers'' or core competencies. While it is hard to reduce these aspirations to specific or quantifiable measurement, the subjective or qualitative measures in this area can be very effective as long as they can be assessed and tracked with effective candor and honesty. (Note how this brings us back to Kanter's ''new assumptions'' and Synectics' high-performance organization attributes.)

Good performance goals nearly always reflect a combination of two or more of the four yardsticks. Moreover, the first two yardsticks (speed/time and cost) measure the effort or investment *put into* organizational action, while the second two (on-spec/expected quality and positive yields) measure benefits you *get out of* that effort or investment. The best goals typically have at least one performance outcome related to effort put in and at least one outcome related to the benefits produced by that effort.

3.2.3. Articulating SMART Performance Goals

People setting outcome-based goals can benefit from using the SMART acronym as a checklist of items that characterize goals that are specific, relevant, aggressive yet achievable, relevant to the challenge at hand, and time bound. Thus, goals are SMART when they are:

- *Specific:* Answers questions such as ''at what?'' ''for whom?'' and ''by how much?''
- *Measurable:* Learning requires feedback, which requires measurement. Metrics might be objective or subjective, as long as they are assessable.
- *Aggressive* (yet *Achievable*): Each ''A'' is significant. *Aggressiveness* suggests stretch, which provides inspiration. *Achievable* allows for a more sustained pursuit because most people will not stay the course for long if goals are not credible. Setting goals that are both aggressive and achievable allows people and organizations to gain all the advantages of stretch goals without creating illusions about what is possible.
- *Relevant:* Goals must relate to the performance challenge at hand. This includes a focus on leading indicators, which are harder to define and riskier to achieve than the more commonly relied-on lagging indicators around financial performance (i.e. revenue, profits).
- *Time bound:* The final specific measure relates to time and answering the question ''by when?'' You cannot define success without knowing when time is up.

4. COMBINING THE FORMAL AND INFORMAL ORGANIZATIONS: THE CHALLENGE OF ALIGNMENT IN A FAST-CHANGING WORLD

Organizations can hardly be called organized if people throughout them are pursuing goals that are random, unaligned, and conflicting. Managing performance, then, must include an effort to align

goals, both against performance challenges and across the various parts of the organization (and increasingly, effort beyond the organization itself, e.g., by strategic partners). Until a decade ago, alignment was considered a simple task, one conducted mostly at budgeting and planning time to be certain all the numbers added up. Today, alignment is far more subtle and challenging. To meet that challenge, readers must be certain they are paying attention to only the relevant challenges, the relevant metrics, and the relevant parts of both the formal and the informal organization.

The formal organization equates to formal hierarchy. It reflects the official directions, activities, and behavior that leaders want to see. The informal organization relates to the actual organizational behavior. It reflects the behaviors that individuals and teams exhibit regardless of official leadership. Both are necessary for truly successful performance management and both are real in contributing to outcomes. Readers will fall into a trap if they worry only about alignment among the official, formal organization.

4.1. Identifying the Working Arenas That Matter to the Challenge at Hand

To avoid that trap, readers need to learn about ''working arenas,'' which consist of any part of an organization, whether formal or informal, and whether inside the organization or beyond it (e.g., strategic partner), where work happens that matters to performance. Working arenas are where people make performance happen. They include and go well beyond any single individual's job. Today's organizations exhibit much more variety in how work gets structured, as Figure 5 shows.

A real shift has occurred from hierarchy-based work structures to more horizontal and open work structures. This reinforces our message earlier about the pace of change and how it forces us to consider these newer forms of structuring work to create connection and speed. That is exactly what you and your colleagues need to do with your performance goals—create connections so that you can increase your speed during implementation. The absolute is that you must set outcome-based goals that fit all the relevant working arenas, not just the jobs, of the people who must achieve those goals.

Fit is not a new concept. It has been attached for a long time to the time-honored managerial maxim that formal accountability matches formal responsibility. However, today this maxim is impossible to apply. Performance challenges have too much overlap across formal structures. And they change far too often to live within any set of formal control processes around all we do. Instead, you should apply a new version of fit—where accountability for outcome-based goals must fit the working arenas of those involved in achieving the goals. The right column in Figure 5 implies both formal (departments, businesses, jobs) and informal (teams, initiatives, processes) working arenas. Fit still makes sense; it just needs to cover a broader spectrum of how work actually gets done. Our argument is that more and more high-performing organizations are learning to apply fit to a broader array of

1950s ➔ 1980s	1990s ➔ 21st century working arenas
• Jobs	• Processes
• Departments	• Teams
• Functions	• Joint ventures
• Projects	• Projects
• Business	• Initiatives
• Corporate headquarters	• Task forces
	• Businesses
	• Alliances
	• Programs
	• Communities of practice
	• Centers of excellence
	• Etc.

Figure 5 Working Arenas: Past and Future. (*Source:* Smith 1999)

informal approaches. It's still all about being effective and efficient—but with greater speed and nimbleness.

The concept of working arenas can help you divide up work in ways that include but go beyond the formal job–department–function–business model. It frees you to ask a critical series of six questions that make it easier to apply performance-based outcome goals, including:

1. What is the performance challenge at hand?
2. What outcomes would indicate success at this challenge?
3. What are the working arenas relevant to this challenge?
4. To which of those working arenas do I (or we) contribute?
5. What metrics make the most sense for these working arenas?
6. What SMART outcome-based goals should we set and pursue for each of these working arenas?

If you were to think through any specific performance challenge in your organization, several patterns would emerge. First, most people contribute to only two or three working arenas at any one time. Second, most contributions come first and foremost in the context of the individual or the team. Third, without identifying the working arena that makes the most sense for any given performance challenge, it is hard for people to confidently believe they are organized for success.

4.2. Using Logic to Achieve Alignment across the Relevant Working Arenas

In the silo or pyramid model of organization that dominated for most of the 20th century, alignment was a matter of adding up costs and revenues to be certain that budgets and plans made sense. Given the entirely formal character of organizations and the relatively small number of working arenas (see Figure 5), this made sense. However, in the fast-moving, flexible, ''real'' world of today, there are far too many different kind of working arenas, far too many different kind of performance challenges, and (as we discussed in Section 3.2), far more kinds of metrics for success. Budgeting- and planning-driven approaches to alignment that focus solely on being sure the numbers add up do not work in this world.

Instead, readers must get comfortable with two approaches to alignment, quantitative and qualitative. Both of these are logical. If a team is working to increase the speed of a critical process such as new product development, they might measure success by speed and quality. Those metrics will not add up or roll up to quantitatively support the entire business's revenue and profit goals. But those metrics do logically reinforce the entire business's strategy to grow through innovation. In the new world of alignment, then, it is most critical to ask whether the outcome-based goals set across a relevant series of working arenas are logically aligned, not just arithmetically aligned.

Table 1 lists many of today's most compelling performance challenges and suggests whether readers will find it easier to discover logical alignment quantitatively, qualitatively, or through some combination of both.

TABLE 1 Aligning Performance Challenges

Today's Performance Challenges	Quantitative Alignment	Qualitative Alignment
Core competencies		X
Customer service	X	X
Diversity	X	X
Electronic commerce	X	
Growth	X	
Innovation	X	X
Mergers/acquisitions	X	X

4.3. Leadership of Both the Formal and Informal Organization During Periods of Change

Leaders who must manage performance in the face of change will be more likely to succeed if they attend to both the formal and informal aspects of the organization. Those who focus solely on the formal, official organization will fail. Not only will they fall into the trap of believing that formal goal alignment is in place so long as the financial numbers add up, but they will also fail to address the most critical performance-management challenge of all: how to get existing employees and managers to take the risk to do things differently.

When performance itself depends on lots and lots of existing people learning new skills, behaviors and working relationships, leaders are faced with behavior-driven change. By contrast, if a new strategy or direction can be accomplished based on existing skills, then leaders are faced with decision-driven change. Many of the old assumptions reviewed in Section 2 work better for decision-driven change than for behavior-driven change. However, an ever-increasing number of performance challenges now require leaders to master the disciplines for managing behavior-driven change.

Here are four questions that will help you tell the difference between decision-driven and behavioral-driven change:

1. Does all or any significant part of your organization have to get very good at one or more things that it is not good at today?
2. Do lots of already employed people have to change specific skills, behaviors, and/or working relationships?
3. Does your organization have a positive record of success with changes of the type you are considering?
4. Do those people who must implement the new decisions and directions understand what they need to do and urgently believe the time to act is now?

If the answer is no to the first two questions and yes to the second two, you can employ a decision-driven change approach. If the answer is yes to the first two questions and no to the second two, you are facing behavior-driven change.

If you do face decision-driven change, we suggest following the following best practices (Kotter 1996):

1. Establishing a sense of urgency
   - Examining the market and competitive realities
   - Identifying and discussing crises, potential crises, or major opportunities
2. Creating the guiding coalition
   - Putting together a group with enough power to lead the change
   - Getting the group to work together like a team
3. Developing a vision and strategy
   - Creating vision to help direct the change effort
   - Developing strategies for achieving that vision
4. Communicating the change vision
   - Using all available avenues to communicate vision constantly
   - Having the guiding coalition role model the behavior expected of employees
5. Empowering broad-based action
   - Getting rid of obstacles
   - Changing systems or structures that undermine the change vision
   - Encouraging risk taking and nontraditional ideas, activities, and actions
6. Generating short-term wins
   - Planning for visible improvements in performance, or ''wins''
   - Creating those wins
   - Visibly recognizing and rewarding people who made the wins possible
7. Consolidating gains and producing more change
   - Using increased credibility to change all systems, structures, and policies that don't fit together and don't fit the transformation vision
   - Hiring, promoting, and developing people who implement the change vision
   - Reinvigorating the process with new projects, themes, and change agents

8. Anchoring new approaches in the culture
   - Creating better performance through customer- and productivity-oriented behavior, more and better leadership, and more effective management
   - Articulating the connections between new behaviors and organizational success
   - Developing means to ensure leadership development and succession.

If, however, you are confronted with behavior-driven change, Kotter's transformational leadership approaches will not necessarily work. Indeed, as extensively discussed in Smith (1996), study after study shows that up to four out of five change efforts either fail or seriously suboptimize. And the root cause of these failures lie in leaders who follow decision-driven approaches like those suggested by Kotter when, in fact, they face behavior-driven change.

Managing performance through a period of behavior-driven change demands a different approach. Here is a series of best practices:

1. Keep performance, not change, as the primary objective of behavior and skill change.
2. Focus on continually increasing the number of people taking responsibility for their own performance and change.
3. Ensure that each person always knows why his or her performance and change matter to the purpose and results of the whole organization.
4. Put people in a position to learn by doing and provide them with the information and support needed just in time to perform.
5. Embrace improvisation; experiment and learn; be willing to fail.
6. Use performance to drive change whenever demanded.
7. Concentrate organization designs on the work people do, not on the decision-making authority they have.
8. Create and focus your two scarcest resources during behavioral-driven change—energy and meaningful language.
9. Harmonize and integrate the change initiatives in your organization, including those that are decision driven as well as behavior driven.
10. Practice leadership based on the courage to live the change you wish to bring about—walk the talk.

Please take these and practice. Get others to try. They will make a huge and lasting difference for you personally and for your organizations.

4.4. Bringing It All Together

We will close with a few suggestions on how your organization can put it all together into an integrated performance outcomes-management system. The concepts, frameworks, and techniques presented in this chapter can be deployed to establish an outcomes-management system in your organization. The objective is performance. You should seek to establish a system and set of practices to help the people of your enterprise routinely set and update the SMART outcome-based goals that matter most to success as well as to choose which management disciplines to use to achieve their goals. The outcomes-management system will enable everyone to see how the goals in your organization fit together and make sense from a variety of critical perspectives, from top management (the whole) to each small group, working arena, and performance challenge and each individual throughout the organization.

Figure 6 presents an overview of the design of what a business outcomes-management system might look like.

Figure 6 summarizes the skeletal design of an outcomes-management system for any single business. It brings visibility to the outcomes that matter most to customers, shareholders, and people of the business. It then links these outcomes to the most critical functions, processes, and initiatives that contribute to overall success. This design can be extended to the multibusiness corporation and can be driven down through the organization to every critical shared service or working arena that is critical to success. See Smith (1999) for more illustrations of how this cascading performance outcomes-management system model can work.

An integrated performance model requires that you create the critical linkages, bring visibility to the interdependencies among working arenas, and drive performance through aggressive planning and execution. But avoid the trap of spending all the organization energy around the activity of creating the integrated plan. Make sure you remember the paramount rule: focus on performance outcomes, not activity.

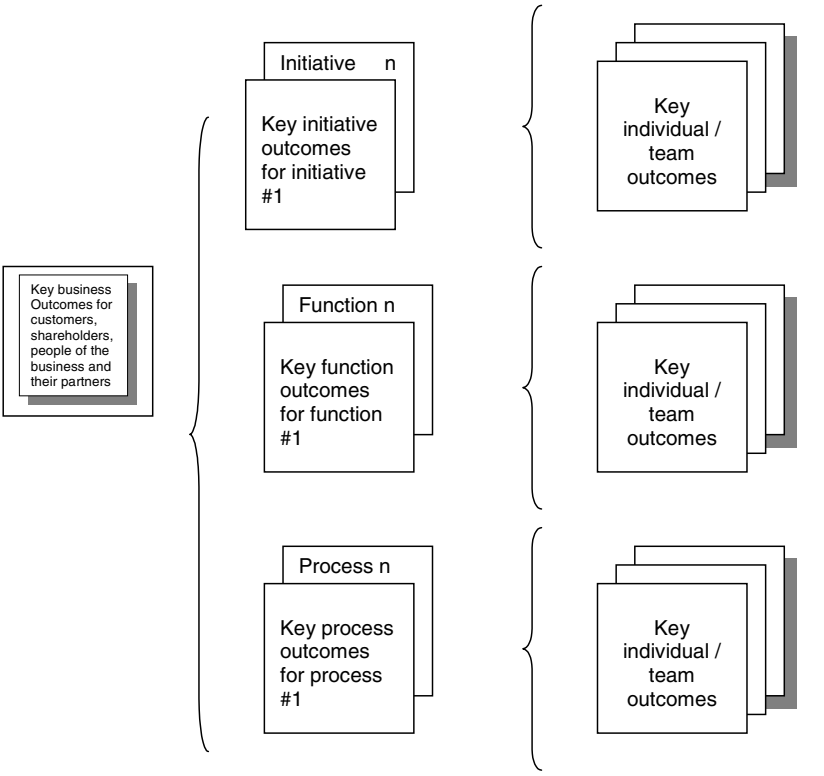

Figure 6 Business Outcomes Management System: Design. (Adapted from Smith 1999)

5. CONCLUDING THOUGHTS

We have presented a view of how organizations should view performance in order to improve it. We recommend that you combine the approaches that effect the formal and informal systems in an organization. Success comes not from a single program, slogan, or initiative, but from working the total picture.

We have covered a lot of ground around our original three themes: change, measurement, and combining informal and formal organizational approaches to achieve performance success. We have tried to share with you our experiences and to give you ideas and techniques that will enhance your perspectives on performance management and will also allow you try new things today. We hope we have succeeded.

CHAPTER 39
Cognitive Tasks

TOM KONTOGIANNIS
Technical University of Crete

1. INTRODUCTION

In any purposeful human activity there is a blend of physical components or manipulations and cognitive components, such as information processing, situation assessment, decision making, and planning. In many tasks, however, the cognitive components are more demanding and crucial for the task performance than the physical components. We call these tasks *cognitive*. Design, managerial and production planning, computer programming, medical diagnosis, process control, air traffic control, and fault diagnosis in technological systems are typical examples of cognitive tasks.

Traditionally, cognitive tasks have been carried out by white-collar workers, middle and upper cadres of enterprises, as well as several freelance professionals. With the advent of information technology and automation in modern industrial settings, however, the role of blue-collar workers has changed from manual controllers to supervisors and diagnosticians. In other words, developments in technology are likely to affect the requirements about knowledge and skills and the way operators interact with systems. Consequently, cognitive tasks abound in modern industries.

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

In view of these changes in cognitive and collaborative demands, ergonomics must play a crucial role in matching technological options and user requirements. *Cognitive ergonomics* or *cognitive engineering* is an emerging branch of ergonomics that places particular emphasis on the analysis of cognitive processes—for example, diagnosis, decision making, and planning—required of operators in modern industries. Cognitive ergonomics aims to enhance performance of cognitive tasks by means of several interventions, including:

- User-centered design of human–machine interaction
- Design of information technology systems that support cognitive tasks (e.g., cognitive aids)
- Development of training programs
- Work redesign to manage cognitive workload and increase human reliability

Successful ergonomic interventions in the area of cognitive tasks require a thorough understanding not only of the demands of the work situation, but also of user strategies in performing cognitive tasks and of limitations in human cognition. In some cases, the artifacts or tools used to carried out a task may impose their own constraints and limitations (e.g., navigating through a large number of VDU pages), which add up to the total work demands. In this sense, the analysis of cognitive tasks should examine the interaction of users both with their work environment and with artifacts or tools; the latter is very important as modern artifacts (e.g., control panels, electronic procedures, expert systems) become increasingly sophisticated.

As a result, this chapter puts particular emphasis on how to design man–machine interfaces and cognitive aids so that human performance is sustained in work environments where information may be unreliable, events be difficult to predict, goals have conflicting effects, and performance be time constrained. Other types of situations are also considered, as they entail performance of cognitive tasks. Variations from everyday situations are often associated with an increase in human errors as operators are required to perform several cognitive tasks, such as detecting variations, tailoring old methods or devising new ones, and monitoring performance for errors. Sections 2 and 3 introduce human performance models that provide the basic framework for a cognitive analysis of the work environment, artifact constraints, and user strategies. Design principles and guidelines derived from these models are also presented in these sections. Section 4 describes the methodology of cognitive task analysis. Finally, Section 5 discusses two case studies presenting the cognitive analysis carried out for the design of cognitive aids for complex tasks.

2. MODELS OF HUMAN COGNITION AND DESIGN PRINCIPLES

Models of human cognition that have been extensively used in ergonomics to develop guidelines and design principles fall into two broad categories. Models in the first category have been based on the classical paradigm of experimental psychology—also called the behavioral approach—focusing mainly on information-processing stages. Behavioral models view humans as ''fallible machines'' and try to determine the limitations of human cognition in a neutral fashion independent from the context of performance, the goals and intentions of the users, and the background or history of previous actions. On the other hand, more recent models of human cognition have been developed mainly through field studies and the analysis of real-world situations. Quite a few of these cognitive models have been inspired by Gibson's (1979) work on ecological psychology, emphasizing the role of a person's intentions, goals, and history as central determinants of human behavior.

The human factors literature is rich in behavioral and cognitive models of human performance. Because of space limitations, however, only three generic models of human performance will be presented here. They have found extensive applications. Section 2.1 presents a behavioral model developed by Wickens (1992), the human information-processing model. Sections 2.2 and 2.3 present two cognitive models, the action-cycle model of Norman (1988) and the skill-, rule-, and knowledge-based model of Rasmussen (1986).

2.1. The Human Information-Processing Model

2.1.1. The Model

The experimental psychology literature is rich in human performance models that focus on how humans perceive and process information. Wickens (1992) has summarized this literature into a generic model of information processing (Figure 1). This model draws upon a computer metaphor whereby information is perceived by appropriate sensors, help-up and processed in a temporal memory (i.e., the working memory or RAM memory), and finally acted upon through dedicated actuators. Long-term memory (corresponding to a permanent form of memory, e.g., the hard disk) can be used to store well-practiced work methods or algorithms for future use. A brief description of the human information-processing model is given on page 1015.

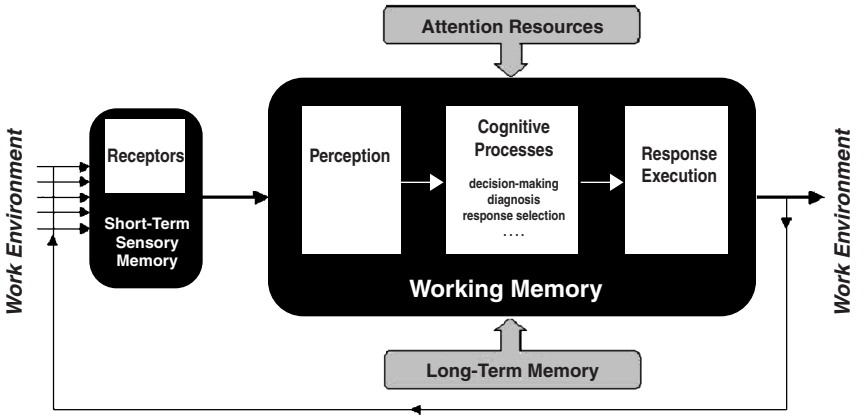

Figure 1 The Human Information-Processing Model. (Adapted from Wickens 1992)

Information is captured by sensory systems or receptors, such as the visual, auditory, vestibular, gustatory, olfactive, tactile, and kinesthetic systems. Each sensory system is equipped with a central storage mechanism called short-term sensory store (STSS) or simply *short-term memory*. STSS prolongs a representation of the physical stimulus for a short period after the stimulus has terminated. It appears that environmental information is stored in the STSS even if attention is diverted elsewhere. STSS is characterized by two types of limitations: (1) the storage capacity, which is the amount of information that can be stored in the STSS, and (2) the decay, which is how long information stays in the STSS. Although there is strong experimental evidence about these limitations, there is some controversy regarding the numerical values of their limits. For example, experiments have shown that the short-term visual memory capacity varies from 7 to 17 letters and the auditory capacity from 4.4 to 6.2 letters (Card et al. 1986). With regard to memory decay rate, experiments have shown that it varies from 70 to 1000 msec for visual short-term memory whereas for the auditory short-term memory the decay varies from 900 to 3500 msec (Card et al. 1986).

In the next stage, perception, stimuli stored in STSS are processed further, that is, the perceiver becomes conscious of their presence, he/she recognizes, identifies, or classifies them. For example, the driver first sees a ''red'' traffic light, then detects it, recognizes that it is a signal related to the driving task, and identifies it as a stop sign. A large number of different physical stimuli may be assigned to a single perceptual category. For example, a, A, **a**, *a* and the sound ''a'' all generate the same categorical perception: the letter ''a.'' At the same time, other characteristics or dimensions of the stimulus are also processed, such as whether the letter is spoken by a male or female voice, whether it is written in upper- or lowercase, and so on.

This example shows that stimulus perception and encoding is dependent upon available attention resources and personal goals and knowledge as stored in the long-term memory (LTM). This is the memory where perceived information and knowledge acquired through learning and training are stored permanently. As in working memory, the information in long-term memory can have any combination of auditory, spatial, and semantic characteristics. Knowledge can be either procedural (i.e., how to do things) or declarative (i.e., knowledge of facts). The goals of the person provide a workspace within which perceived stimuli and past experiences or methods retrieved from LTM are combined and processed further. This workspace is often called working memory because the person has to be conscious of and remember all presented or retrieved information. However, the capacity of working memory also seems to be limited. Miller (1956) was the first to define the capacity of working memory. In a series of experiments where participants carried out absolute judgment tasks, Miller found that the capacity of working memory varied between five and nine items or ''chunks''* of information when full attention was deployed. Cognitive processes, such as diagnosis, decision making, and planning, can operate within the same workspace or working memory space. Attention is the main regulatory mechanism for determining when control should pass from perception to cognitive processes or retrieval processes from LTM.

*The term *chunk* is used to define a set of adjacent stimulus units that are closely tied together by associations in a person's long-term memory. A chunk may be a letter, a digit, a word, a phrase, a shape, or any other unit.

At the final stage of information processing (response execution), the responses chosen in the previous stages are executed. A response can be any kind of action, such as eye or head movements, hand or leg movement, and verbal responses. Attention resources are also required at this stage because intrinsic (e.g., kinesthetic) and/or extrinsic feedback (e.g., visual, auditory) can be used to monitor the consequences of the actions performed.

A straightforward implication of the information-processing model shown in Figure 1 is that performance can become faster and more accurate when certain mental functions become ''automated'' through increased practice. For instance, familiarity with machine drawings may enable maintenance technicians to focus on the cognitive aspects of the task, such as troubleshooting; less-experienced technicians would spend much more time in identifying technical components from the drawings and carrying out appropriate tests. As people acquire more experience, they are better able to time-share tasks because well-practiced aspects of the job become automated (that is, they require less attention and effort).

2.1.2. Practical Implications

The information-processing model has been very useful in examining the mechanisms underlying several mental functions (e.g., perception, judgment, memory, attention, and response selection) and the work factors that affect them. For instance, signal detection theory (Green and Swets 1988) describes a human detection mechanism based on the properties of response criterion and sensitivity. Work factors, such as knowledge of action results, introduction of false signals, and access to images of defectives, can increase human detection and provide a basis for ergonomic interventions. Other mental functions (e.g., perception) have also been considered in terms of several processing modes, such as serial and parallel processing, and have contributed to principles for designing man–machine interfaces (e.g., head-up displays that facilitate parallel processing of data superimposed on one another). In fact, there are several information-processing models looking at specific mental functions, all of which subscribe to the same behavioral approach.

Because information-processing models have looked at the mechanisms of mental functions and the work conditions that degrade or improve them, ergonomists have often turned to them to generate guidelines for interface design, training development, and job aids design. To facilitate information processing, for instance, control panel information could be cast into meaningful chunks, thus increasing the amount of information to be processed as a single perceptual unit. For example, dials and controls can be designed and laid out on a control panel according to the following ergonomic principles (Helander 1987; McCormick and Sanders 1987):

- *Frequency of use* and *criticality:* Dials and controls that are frequently used, or are of special importance, should be placed in prominent positions, for example in the center of the control panel.
- *Sequential consistency:* When a particular procedure is always executed in a sequential order, controls and dials should be arranged according this order.
- *Topological consistency:* Where the physical location of the controlled items is important, the layout of dials should reflect their geographical arrangement.
- *Functional grouping:* Dials and controls that are related to a particular function should be placed together.

Many systems, however, fail to adhere to these principles—for example, the layout of stove burner controls fails to conform to the topological consistency principle (see Figure 2). Controls located beside their respective burners (Figure 2[*b*] and 2[*d*]) are compatible and will eliminate confusions caused by arrangements shown in Figure 2(*a*) and 2(*c*).

Information-processing models have also found many applications in the measurement of mental workload. The limited-resource model of human attention (Allport 1980) has been extensively used to examine the degree to which different tasks may rely upon similar psychological resources or mental functions. Presumably, the higher the reliance upon similar mental functions, the higher the mental workload experienced by the human operator. Measures of workload, hence, have tended to rely upon the degree of sharing similar mental functions and their limited capacities.

Information-processing models, however, seem insufficient to account for human behavior in many cognitive tasks where knowledge and strategy play an important role. Recent studies in tactical decision making (Serfaty et al. 1998), for instance, have shown that experienced operators are able to maintain their mental workload at low levels, even when work demands increase, because they can change their strategies and their use of mental functions. Under time pressure, for instance, crews may change from an explicit mode of communication to an implicit mode whereby information is made available without previous requests; the crew leader may keep all members informed of the ''big picture'' so that they can volunteer information when necessary without excessive communications. Performance of experienced personnel may become adapted to the demands of the situation,

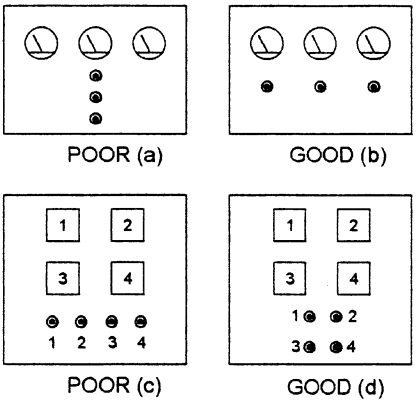

Figure 2 Alternative Layouts of Stove Burner Controls.

thus overcoming high workload imposed by previous methods of work and communication. This interaction of expert knowledge and strategy in using mental functions has been better explored by two other models of human cognition that are described below.

2.2. The Action-Cycle Model

2.2.1. The Model

Many artifacts seem rather difficult to use, often leading to frustrations and human errors. Norman (1988) was particularly interested in how equipment design could be benefit from models of human performance. He developed the action-cycle model (see Figure 3), which examines how people set themselves and achieve goals by acting upon the external world. This action–perception cycle entails two main cognitive processes by which people implement goals (i.e., execution process) and make further adjustments on the basis of perceived changes and evaluations of goals and intentions (i.e., evaluation process).

The starting point of any action is some notion of what is wanted, that is, the goal to be achieved. In many real tasks, this goal may be imprecisely specified with regard to actions that would lead to the desired goal, such as, "I want to write a letter." To lead to actions, human goals must be transformed into specific statements of what is to be done. These statements are called intentions. For example, I may decide to write the letter by using a pencil or a computer or by dictating it to my secretary. To satisfy intentions, a detailed sequence of actions must be thought of (i.e., planning) and executed by manipulating several objects in the world. On the other hand, the evaluation side of

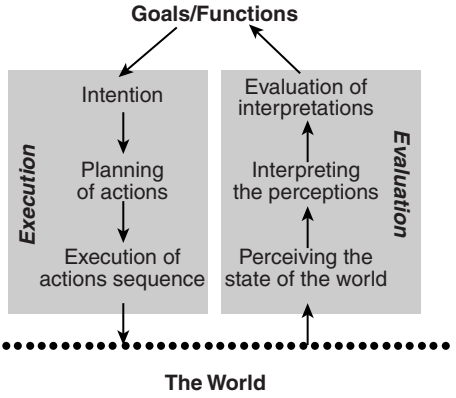

Figure 3 The Action-Cycle Model. (Adapted from Norman 1988)

things has three stages: first, perceiving what happened in the world; second, making sense of it in terms of needs and intentions (i.e., interpretation); and finally, comparing what happened with what was wanted (i.e., evaluation). The action-cycle model consists of seven action stages: one for goals (forming the goal), three for execution (forming the intention, specifying actions, executing actions), and three for evaluation (perceiving the state of the world, interpreting the state of the world, evaluating the outcome).

As Norman (1988, p. 48) points out, the action-cycle model is an approximate model rather than a complete psychological theory. The seven stages are almost certainly not discrete entities. Most behavior does not require going through all stages in sequence, and most tasks are not carried out by single actions. There may be numerous sequences, and the whole task may last hours or even days. There is a continual feedback loop, in which the results of one action cycle are used to direct further ones, goals lead to subgoals, and intentions lead to subintentions. There are action cycles in which goals are forgotten, discarded, or reformulated.

2.2.2. The Gulfs of Execution and Evaluation

The action-cycle model can help us understand many difficulties and errors in using artifacts. Difficulties in use are related to the distance (or amount of mental work) between intentions and possible physical actions, or between observed states of the artifact and interpretations. In other words, problems arise either because the mappings between intended actions and equipment mechanisms are insufficiently understood, or because action feedback is rather poor. There are several *gulfs* that separate the mental representations of the person from the physical states of the environment (Norman 1988).

The *gulf of execution* reflects the difference between intentions and allowable actions. The more the system allows a person to do the intended actions directly, without any extra mental effort, the smaller the gulf of execution is. A small gulf of execution ensures high usability of equipment. Consider, for example, faucets for cold and hot water. The user intention is to control two things or parameters: the water temperature and the volume. Consequently, users should be able to do that with two controls, one for each parameter. This would ensure a good mapping between intentions and allowable actions. In conventional settings, however, one faucet controls the volume of cold water and the other the volume of hot water. To obtain water of a desired volume and temperature, users must try several combinations of faucet adjustments, hence losing valuable time and water. This is an example of bad mapping between intentions and allowable actions (a large gulf of execution).

The *gulf of evaluation* reflects the amount of effort that users must exert to interpret the physical state of the artifact and determine how well their intentions have been met. The gulf of evaluation is small when the artifact provides information about its state that is easy to get and easy to interpret and matches the way the user thinks of the artifact.

2.2.3. Using the Action-Cycle Model in Design

According to the action-cycle model, the usability of an artifact can be increased when its design bridges the gulfs of execution and evaluation. The seven-stage structure of the model can be cast as a list of questions to consider when designing artifacts (Norman 1988). Specifically, the designer may ask how easily the user of the artifact can:

1. Determine the function of the artifact (i.e., setting a goal)
2. Perceive what actions are possible (i.e., forming intentions)
3. Determine what physical actions would satisfy intentions (i.e., planning)
4. Perform the physical actions by manipulating the controls (i.e., executing)
5. Perceive what state the artifact is in (i.e., perceiving state)?
6. Achieve his or her intentions and expectations (i.e., interpreting states)
7. Tell whether the artifact is in a desired state or intentions should be changed (i.e., evaluating intentions and goals)

A successful application of the action-cycle model in the domain of human–computer interaction regards direct manipulation interfaces (Shneiderman 1983; Hutchins et al. 1986). These interfaces bridge the gulfs of execution and evaluation by incorporating the following properties (Shneiderman 1982, p. 251):

- Visual representation of the objects of interest
- Direct manipulation of objects, instead of commands with complex syntax
- Incremental operations that their effects are immediately visible and, on most occasions, reversible

The action-cycle model has been translated into a new design philosophy that views design as knowledge in the world. Norman (1988) argues that the knowledge required to do a job can be distributed partly in the head and partly in the world. For instance, the physical properties of objects may constrain the order in which parts can be put together, moved, picked up, or otherwise manipulated. Apart from these physical constraints, there are also cultural constraints, which rely upon accepted cultural conventions. For instance, turning a part clockwise is the culturally defined standard for attaching a part to another while counterclockwise movement usually results in dismantling a part. Because of these natural and artificial or cultural constraints, the number of alternatives for any particular situation is reduced, as is the amount of knowledge required within human memory. Knowledge in the world, in terms of constraints and labels, explains why many assembly tasks can be performed very precisely even when technicians cannot recall the sequence they followed in dismantling equipment; physical and cultural constraints reduce the alternative ways in which parts can be assembled. Therefore, cognitive tasks are more easily done when part of the required knowledge is available externally—either explicit in the world (i.e., labels) or readily derived through constraints.

2.3. The Skill-, Rule-, and Knowledge-Based Model

2.3.1. The Model

In a study of troubleshooting tasks in real work situations, Rasmussen (1983) observed that people control their interaction with the environment in different modes. The interaction depends on a proper match between the features of the work domain and the requirements of control modes. According to the skill-, rule-, and knowledge-based model (SRK model), control and performance of human activities seem to be a function of a hierarchically organized control system (Rasmussen et al. 1994). Cognitive control operates at three levels: skill-based, or automatic control; rule-based, or conditional control; and knowledge-based, or compensatory control (see Figure 4).

At the lowest level, skill-based behavior, human performance is governed by patterns of preprogrammed behaviors represented as analog structures in a time–space domain in human memory. This mode of behavior is characteristic of well-practiced and routine situations whereby open-loop or feedforward control makes performance faster. Skill-based behavior is the result of extensive practice where people develop a repertoire of cue–response patterns suited to specific situations. When a familiar situation is recognized, a response is activated, tailored, and applied to the situation. Neither any conscious analysis of the situation nor any sort of deliberation of alternative solutions is required.

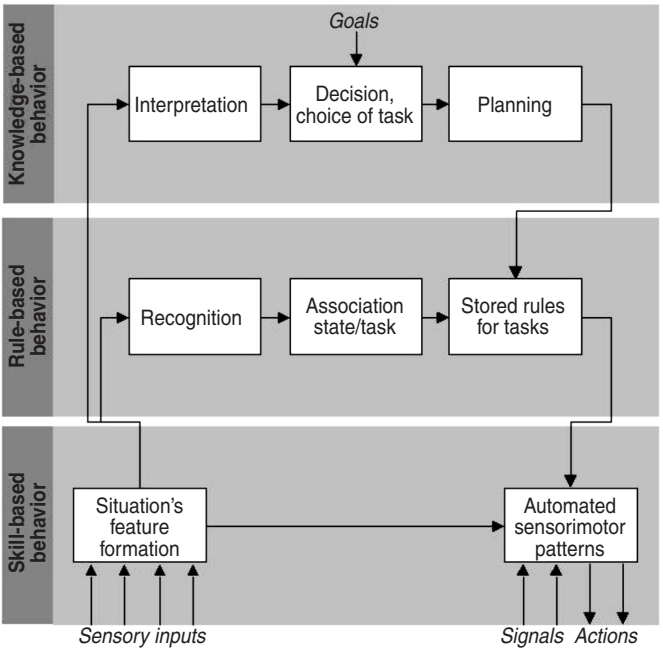

Figure 4 The Skill-, Rule-, and Knowledge-Based Model. (Adapted from Rasmussen 1986)

At the middle level, rule-based behavior, human performance is governed by conditional rules of the type:

$$\textit{if} \quad \langle \text{state } X \rangle \quad \textit{then} \quad \langle \text{action } Y \rangle$$

Initially, stored rules are formulated at a general level. They subsequently are supplemented by further details from the work environment. Behavior at this level requires conscious preparation: first recognition of the need for action, followed by retrieval of past rules or methods and finally, composition of new rules through either self-motivation or through instruction. Rule-based behavior is slower and more cognitively demanding than skill-based behavior. Rule-based behavior can be compared to the function of an expert system where situations are matched to a database of production rules and responses are produced by retrieving or combining different rules. People may combine rules into macrorules by collapsing conditions and responses into a single unit. With increasing practice, these macrorules may become temporal–spatial patterns requiring less conscious attention; this illustrates the transition from rule-based to skill-based behavior.

At the highest level, knowledge-based behavior, performance is governed by a thorough analysis of the situation and a systematic comparison of alternative means for action. Goals are explicitly formulated and alternative plans are compared rationally to maximize efficiency and minimize risks. Alternatives are considered and tested either physically, by trial and error, or conceptually, by means of thought experiments. The way that the internal structure of the work system is represented by the user is extremely important for performance. Knowledge-based behavior is slower and more cognitively demanding than rule-based behavior because it requires access to an internal or mental model of the system as well as laborious comparisons of work methods to find the most optimal one.

Knowledge-based behavior is characteristic of unfamiliar situations. As expertise evolves, a shift to lower levels of behavior occurs. This does not mean, however, that experienced operators always work at the skill-based level. Depending on the novelty of the situation, experts may move at higher levels of behavior when uncertain about a decision. The shift to the appropriate level of behavior is another characteristic of expertise and graceful performance in complex work environments.

2.3.2. Using the SRK Model

The SRK model has been used by Reason (1990) to provide a framework for assigning errors to several categories related to the three levels of behavior. Deviations from current intentions due to execution failures and/or storage failures, for instance, are errors related to skill-based behavior (slips and lapses). Misclassifications of the situation, leading to the application of the wrong rule or incorrect procedure, are errors occurring at the level rule-based behavior. Finally, errors due to limitations in cognitive resources—"bounded rationality"—and incomplete or incorrect knowledge are characteristic of knowledge-based behavior. More subtle forms of errors may occur when experienced operators fail to shift to higher levels of behavior. In these cases, operators continue skill- or rule-based behavior although the situation calls for analytical comparison of options and reassessment of the situation (e.g., knowledge-based processing).

The SRK model also provides a useful framework for designing man–machine interfaces for complex systems. Vicente and Rasmussen (1992) advance the concept of ecological interfaces that exploit the powerful human capabilities of perception and action, at the same time providing appropriate support for more effortful and error-prone cognitive processes. Ecological interfaces aim at presenting information "in such a way as not to force cognitive control to a higher level than the demands of the task require, while at the same time providing the appropriate support for all three levels" (Vicente and Rasmussen 1992, p. 598). In order to achieve these goals, interfaces should obey the following three principles:

1. *Support skill-based behavior:* The operator should be able act directly on the display while the structure of presented information should be isomorphic to the part–whole structure of eye and hand movements.
2. *Support rule-based behavior:* The interface should provide a consistent one-to-one mapping between constraints of the work domain and cues or signs presented on the interface.
3. *Support knowledge-based behavior:* The interface should represent the work domain in the form of an abstraction hierarchy* to serve as an externalized mental model that supports problem solving.

*Abstraction hierarchy is a framework proposed by Rasmussen (1985; Rasmussen et al. 1994) that is useful for representing the cognitive constraints of a complex work environment. For example, the constraints related to process control have been found to belong to five hierarchically ordered levels (Vicente and Rasmussen 1992, p. 592): the purpose for which the system was designed (functional purpose); the intended causal structure of the process in terms of mass, energy, information, or value flows (abstract purpose); the basic functions that the plant is designed to achieve (generalized function); the characteristics of the components and the connections between them (physical function); and the appearance and special location of these components (physical form).

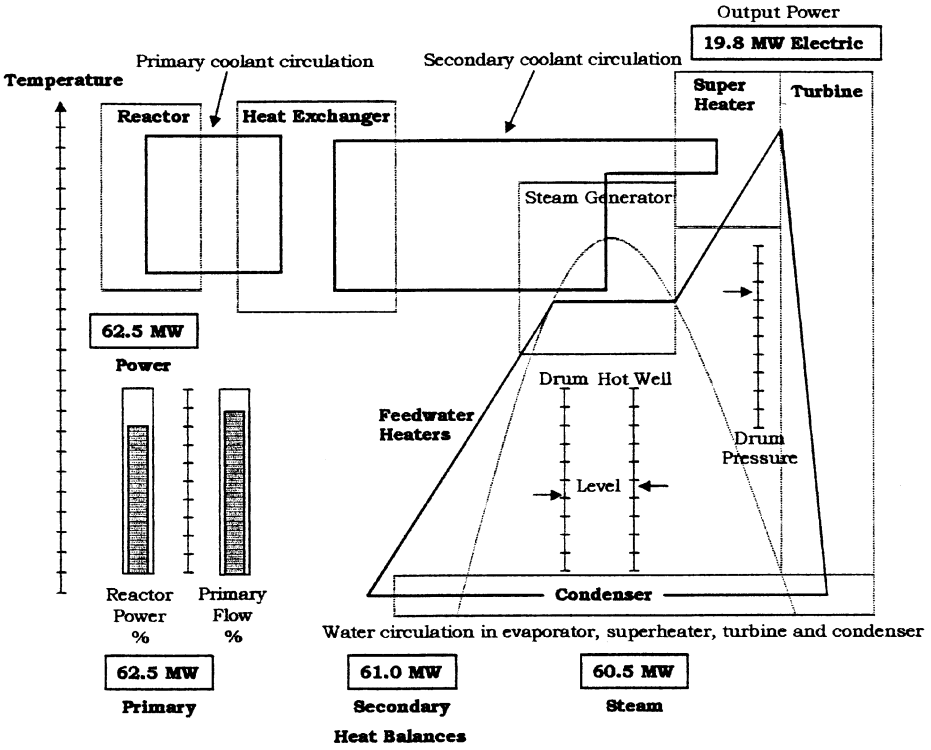

Figure 5 An Ecological Interface for Monitoring the Operation of a Nuclear Power Plant (From Lindsay and Staffon 1988, by permission. Work performed for U.S. Department of Energy at Argonne National Laboratory, Contract No. W-31,109-ENG-38)

An example of an ecological interface that supports direct perception of higher-level functional properties is shown in Figure 5. This interface, designed by Lindsay and Staffon (1988), is used for monitoring the operation of a nuclear power plant. Graphical patterns show the temperature profiles of the coolant in the primary and secondary circulation systems as well as the profiles of the feedwater in the steam generator, superheater, turbine, and condenser. Note that while the display is based on primary sensor data, the functional status of the system can be directly read from the interrelationships among data. The Rankine cycle display presents the constraints of the feedwater system in a graphic visualization format so that workers can use it in guiding their actions; in doing this, workers are able to rely on their perceptual processes rather than analytical processes (e.g., by having to solve a differential equation or engage in any other abstract manipulation). Plant transients and sensor failures can be shown as distortions of the rectangles representing the primary and secondary circulation, or as temperature points of the feedwater system outside the Rankine cycle. The display can be perceived, at the discretion of the observer, at the level of the physical implications of the temperature readings, of the state of the coolant circuits, and of the flow of the energy.

3. DIAGNOSIS, DECISION MAKING AND ERGONOMICS

After this brief review of behavioral and cognitive models, we can now focus on two complex cognitive processes: diagnosis and decision making. These cognitive processes are brought into play in many problem-solving situations where task goals may be insufficiently specified and responses may not benefit from past knowledge. These characteristics are common to many problem-solving scenarios and affect how people shift to different modes of cognitive control. Problem solvers may use experiences from similar cases in the past, apply generic rules related to a whole category of problems, or try alternative courses of actions and assess their results. In other words, optimizing problem solving on the basis of knowledge-based behavior may be time consuming and laborious. People tend to use several heuristics to regulate their performance between rule-based and knowledge-based processing. This increases task speed but may result in errors that are difficult to recover from.

In following, we present a set of common heuristics followed by experienced diagnosticians and decision makers, potential biases and errors that may arise, and finally ergonomic interventions how to support human performance.

3.1. Diagnosis

Diagnosis is a cognitive process whereby a person tries to identify the causes of an undesirable event or situation. Technical failures and medical problems are two well-known application areas of human diagnosis. Figure 6 presents some typical stages of the diagnosis process. Diagnosis starts with the perception of signals alerting one to a system's failure or malfunction. Following this, diagnosticians may choose whether to search for more information to develop a mental representation of the current system state. At the same time, knowledge about system structure and functioning can be retrieved from the long-term memory. On the basis of this evidence, diagnosticians may generate hypotheses about possible causes of the failure. Pending upon further tests, hypotheses may be confirmed, completing the diagnosis process, or rejected, leading to selection of new hypotheses. Compensation for failures may start when the diagnostician feels confident that a correct interpretation has been made of the situation.

Fault diagnosis is a demanding cognitive activity whereby the particular diagnostic strategy will be influenced by the amount of information to be processed in developing a mental model of the situation, the number of hypotheses consistent with available evidence, and the activities required for testing hypotheses. In turn, these factors are influenced by several characteristics of the system or the work environment, including:

- The number of interacting components of the system
- The degrees of freedom in the operation of the system
- The number of system components that can fail simultaneously
- The transparency of the mechanisms of the system

Time constraints and high risk may also add up, thus increasing the difficulty of fault diagnosis. A particularly demanding situation is dynamic fault management (Woods 1994), whereby operators have to maintain system functions despite technical failures or disturbances. Typical fields of practice

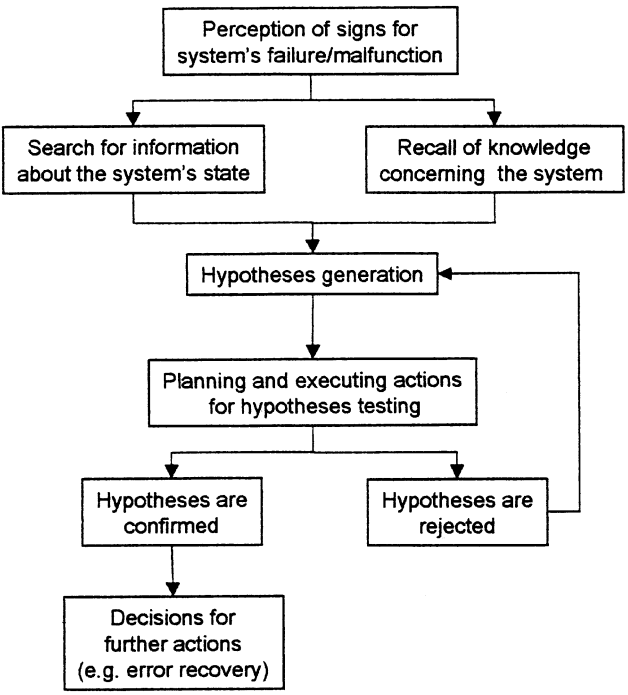

Figure 6 Typical Processes in Fault Diagnosis.

where dynamic fault management occurs are flight deck operations, control of space systems, anesthetic management, and process control.

When experienced personnel perform fault diagnosis, they tend to use several heuristics to overcome their cognitive limitations. Although heuristics may decrease mental workload, they may often lead to cognitive biases and errors. It is worth considering some heuristics commonly used when searching for information, interpreting a situation, and making diagnostic decisions.

Failures in complex systems may give rise to large amounts of information to be processed. Experienced people tend to filter information according to its informativeness—that is, the degree to which it helps distinguish one failure from another. However, people may be biased when applying heuristics. For instance, diagnosticians may accord erroneous or equal informative value to a pattern of cues (''as-if'' bias: Johnson et al. 1973). In other cases, salient cues, such as noises, bright lights, and abrupt onsets of intensity or motion, may receive disproportionate attention (salience bias: Payne 1980).

Diagnosis may be carried out under psychological stress, which can impose limitations in entertaining a set of hypotheses about the situation (Rasmussen 1981; Mehle 1982; Lusted 1976). To overcome this cognitive limitation, experienced diagnosticians may use alternative strategies for hypothesis generation and testing. For instance, diagnosticians may start with a hypothesis that is seen as the most probable one; this probability may be either subjective, based on past experience, or communicated by colleagues or the hierarchy. Alternatively, they may start with a hypothesis associated with a high-risk failure, or a hypothesis that can be easily tested. Finally, they may start with a hypothesis that readily comes to mind (availability bias: Tversky and Kahneman 1974).

Another heuristic used in diagnosis is anchoring, whereby initial evidence provides a cognitive anchor for the diagnostician's belief in this hypothesis over the others (Tversky and Kahneman 1974). Consequently, people may tend to seek information that confirms the initial hypothesis and avoid any disconfirming evidence (Einhorn and Hogarth 1981; DeKeyser and Woods 1990). This bias is also known as cognitive tunnel vision (Sheridan 1981).

Finally, Einhorn and Hogarth (1981), Schustack and Sternberg (1981), and DeKeyser and Woods (1990) describe situations where diagnosticians tend to seek—and therefore find—information that confirms the chosen hypothesis and to avoid information or tests whose outcomes could reject it. This is known as confirmation bias. Two possible causes for the confirmation bias have been proposed: (1) people seem to have greater cognitive difficulty dealing with negative information than with positive information (Clark and Chase 1972); (2) abandon a hypothesis and reformulating a new one requires more cognitive effort than does searching for and acquiring information consistent with the first hypothesis (Einhorn and Hogarth 1981; Rasmussen 1981).

3.2. Decision Making

Decision making is a cognitive process whereby a person tries to choose a goal and a method that would stabilize the system or increase its effectiveness. In real-world situations, goals may be insufficiently defined, and thus goal setting becomes part of decision making. Furthermore, evaluation criteria for choosing among options may vary, including economic, safety, and quality considerations. In such cases, optimizing on most criteria may become the basis for a good decision. Managerial planning, political decisions, and system design are typical examples of decision making.

Traditional models of decision making have adopted a rational approach that entailed:

1. Determining the goal(s) to be achieved and the evaluation criteria
2. Examining aspects of the work environment
3. Developing alternative courses of action
4. Assessing alternatives
5. Choosing an optimal course of action

Rational models of decision making view these stages as successive; however, in real fields of practice their sequence may change (Marmaras et al. 1992; Klein 1997; Dreyfus 1997) as a function of several factors in the work environment.

Factors that could influence the difficulty of decision making include:

- The amount of information that the decision maker has to consider
- The uncertainty of available information
- The dynamic nature of the work environment
- The complexity of evaluation criteria
- The alternative courses of action that can be developed
- The time constraints imposed on the decision maker
- The risk related to possible decisions

To overcome limitations in human cognition, experienced decision makers may use a number of heuristics. As in diagnosis, heuristics may allow decision makers to cope with complexity in real-world situations but on the other hand, they may lead to cognitive biases and errors. For instance, decision makers may use information selectively and make speculative inferences based on limited data. Hayes-Roth (1979) has called this heuristic ''opportunistic thinking,'' which is similar to Simon's (1978) concept of ''satisfying and search cost''; in other words, decision makers may pursue a trade-off between seeking more information and minimizing the cost in obtaining information. Although this strategy can simplify decision making, important data may be neglected, leading to erroneous or suboptimal decisions.

To cope with complexity and time pressure, decision makers tend to acquire sufficient evidence to form a mental representation of the situation and examine a rather limited set of alternative actions (Marmaras et al. 1992). Instead of generating a complete set of alternatives at the outset and subsequently performing an evaluation based on optimizing several criteria, decision makers may start with an option that has been incompletely assessed. This heuristic could be attributed to the fact that experienced decision makers possess a repertoire of well-practiced responses accessed through recognition rather than conscious search (Simon 1978). Limited consideration of alternatives, however, can lead to ineffective practices. For instance, if the situation at hand differs in subtle ways from previous ones, suboptimal solutions may be adopted. Furthermore, in domains such as system design and managerial planing, new innovative solutions and radical departures may be of great advantage.

In dynamic systems, the distinguishing features of a situation may change over time and new events may add up. Operators should reflect on their thinking and revise their assessment of the situation or their earlier decisions in order to take account of new evidence, interruptions, and negative feedback (Weick 1983; Schon 1983; Lindblom 1980). Under stress, however, experienced decision makers may fixate on earlier decisions and fail to revise them at later stages. Thinking/acting cycles may compensate to some extent for cognitive fixation on earlier decisions. That is, initial decisions can be effected on the basis of related experiences from similar situations, but their suitability can be evaluated after the first outcomes; in this way, decision makers can undertake corrective actions and tailor earlier decisions to new circumstances.

3.3. Supporting Diagnosis and Decision Making

To overcome these weaknesses of human cognition, many engineering disciplines, such as artificial intelligence, operations research, and supervisory control, have pursued the development of stand-alone expert systems that support humans in diagnosis and decision making. Although these systems have made a significant contribution to system design, their performance seems to degrade in unfamiliar situations because humans find it rather awkward to cooperate. Operators are forced to repeat the whole diagnostic or decision-making process instead of taking over from the computer advisor. There is a need, therefore, to develop cognitive advisors that enhance the cognitive processes of operators rather than to construct computer advisors capable of independent performance (Woods and Hollnagel 1987; Roth et al. 1987).

To combat several biases related to diagnosis and decision making, support can be provided to human operators in the following ways:

- Bring together all information required to form a mental representation of the situation.
- Present information in appropriate visual forms.
- Provide memory aids.
- Design cognitive aids for overcoming biases.
- Make systems transparent to facilitate perception of different system states.
- Incorporate intelligent facilities for hypothesis testing and evaluation of options.

Ecological interfaces (Vicente and Rasmussen 1992), following the arguments presented earlier, provide a good example of artifacts that meet some of these requirements. Other cognitive aids are presented in Section 5.

Real-world situations requiring diagnosis and decision making can vary, each one presenting its own specific characteristics. As a result, artifacts and cognitive aids require an exhaustive analysis of the demands of the situation, the user requirements, and the user strategies in achieving satisfactory performance. This type of analysis, usually referred to as cognitive analysis, is valuable in putting human performance models into actual practice.

4. COGNITIVE TASK ANALYSIS (CTA)

Ergonomics interventions in terms of man–machine interfaces, cognitive aids, or training programs require a thorough understanding of the work constraints and user strategies. Work constraints can range from system constraints (e.g., time pressure and conflicting goals) to cognitive constraints or

limitations and use constraints imposed by the tool itself (e.g., an interface or a computer program). On the other hand, user strategies can range from informal heuristics, retrieved from similar situations experienced in the past, to optimization strategies for unfamiliar events. The analysis of work constraints and use strategies is the main objective of cognitive task analysis (CTA).

Cognitive task analysis involves a consideration of user goals, means, and work constraints in order to identify the *what, how,* and *why* of operator's work (Rasmussen et al. 1994; Marmaras and Pavard 1999). Specifically, CTA can be used to identify:

- The problem-solving and self-regulation strategies* adopted by operators
- The problem-solving processes followed (heuristics)
- The specific goals and subgoals of operators at each stage in these processes
- The signs available in the work environment (both formal and informal signs), the information carried by them, and the significance attached to them by humans
- The regulation loops used
- The resources of the work environment that could help manage workload
- The causes of erroneous actions or suboptimal performance

CTA differs from traditional task analysis, which describes the performance demands imposed upon the human operator in a neutral fashion (Drury et al. 1987; Kirwan and Ainsworth 1992) regardless of how operators perceive the problem and how they choose their strategies. Furthermore, CTA differs from methods of job analysis that look at occupational roles and positions of specific personnel categories (Davis and Wacker 1987; Drury et al. 1987).

4.1. A Framework for Cognitive Task Analysis

Cognitive task analysis deals with how operators respond to tasks delegated to them either by the system or by their supervisors. *Tasks* is used here to designate the operations undertaken to achieve certain goals under a set of conditions created by the work system** (Leplat 1990). CTA looks at several mental activities or processes that operators rely upon in order to assess the current situation, make decisions, and formulate plans of actions. CTA can include several stages:

1. Systematic observation and recording of operator's actions in relation to the components of the work system. The observed activities may include body movements and postures, eye movements, verbal and gestural communications, etc.
2. Interviewing the operators with the aim of identifying the why and when of the observed actions.
3. Inference of operator's cognitive activities and processes.
4. Formulation of hypotheses about operator's competencies,*** by interpreting their cognitive activities with reference to work demands, cognitive constraints and possible resources to manage workload.
5. Validation of hypotheses by repeating stages 1 and 2 as required.

Techniques such as video and tape recording, equipment mock-ups, and eye tracking can be used to collect data regarding observable aspects of human performance. To explore what internal or cognitive processes underlie observable actions, however, we need to consider other techniques, such as thinking aloud while doing the job (i.e., verbal protocols) and retrospective verbalizations. For high-risk industries, event scenarios and simulation methods may be used when on-site observations are difficult or impossible.

CTA should cover a range of work situations representing both normal and degraded conditions. As the analysts develop a better image of the investigated scenario, they may become increasingly aware of the need to explore other unfamiliar situations. Cognitive analysis should also be expanded into how different operating crews respond to the same work situation. Presumably, crews may differ in their performance because of varying levels of expertise, different decision-making styles, and different coordination patterns (see, e.g., Marmaras et al. 1997).

* Self-regulation strategies are strategies for deciding how to adapt to different circumstances, monitor complete or interrupted tasks, and detect errors.

** The work system consists of the technological system, the workplace, the physical environment, the organizational and management system, and the socioeconomic policies.

*** *Competencies* is used here to designate the specific cognitive strategies and heuristics the operators develop and use to respond to the task's demands within the constraints imposed by a specific work environment.

The inference of cognitive activities and formulation of hypotheses concerning user competencies requires familiarity with models of human cognition offered by cognitive psychology, ethnology, psycholinguistics, and organizational psychology. Several theoretical models, such as those cited earlier, have already found practical applications in eliciting cognitive processes of expert users. Newell and Simon's (1972) human problem-solving paradigm, for instance, can be used as a background framework for inferring operator's cognitive processes when they solve problems. Hutchins's (1990; 1992) theory of distributed cognition can support analysts in identifying operator resources in managing workload. Rasmussen's (1986) ladder model of decision making can be used to examine how people diagnose problems and evaluate goals. Norman's (1988) action-cycle model can be used to infer the cognitive activities in control tasks. Finally, Reason's (1990) model of human errors can be used to classify, explain, and predict potential errors as well as underlying error-shaping factors. Human performance models, however, have a hypothetical rather than a normative value for the analyst. They constitute his or her background knowledge and may support interpretation of observable activities and inference of cognitive activities. Cognitive analysis may confirm these models (totally or partially), enrich them, indicate their limits, or reject them. Consequently, although the main scope of cognitive analysis is the design of artifacts and cognitive advisory systems for complex tasks, it can also provide valuable insights at a theoretical level.

Models of human cognition and behavior can provide practical input to ergonomics interventions when cast in the form of cognitive probes or questions regarding how operators search their environment, assess the situation, make decisions, plan their actions, and monitor their own performance. Table 1 shows a list of cognitive probes to help analysts infer these cognitive processes that underlie observable actions and errors.

TABLE 1 Examples of Cognitive Probes

Cognitive Activities	Probes
Recognition	• What features were you looking at when you recognized that a problem existed? • What was the most important piece of information that you used in recognizing the situation? • Were you reminded of previous experiences in which a similar situation was encountered?
Interpretation	• At any stage, were you uncertain about either the reliability or the relevance of the information that you had available? • Did you use all the information available to you when assessing the situation? • Was there any additional information that you might have used to assist in assessing the situation?
Decision making	• What were your specific goals at the various decision points? • Were there any other alternatives available to you other than the decision you made? • Why were these alternatives considered inappropriate? • At any stage, were you uncertain about the appropriateness of the decision? • How did you know when to make the decision?
Planning	• Are there any situations in which your plan of action would have turned out differently? • When you do this task, are there ways of working smart (e.g., combine procedures) that you have found especially useful? • Can you think of an example when you improvised in this task or noticed an opportunity to do something better? • Have you thought of any side effects of your plan and possible steps to prevent them or minimize their consequences?
Feedback and self-monitoring	• What would this result tell you in terms of your assessment of the situation or efficiency of your actions? • At this point, do you think you need to change the way you were performing to get the job done?

This need to observe, interview, test, and probe operators in the course of cognitive analysis implies that the role of operators in the conduct of analysis is crucial. Inference of cognitive activities and elicitation of their competencies cannot be realized without their active participation. Consequently, explicit presentation of the scope of analysis and commitment of their willingness to provide information are prerequisites in the conduct of CTA. Furthermore, retrospective verbalizations and online verbal protocols are central to the proposed methodology (Ericsson and Simon 1984; Sanderson et al. 1989).

CTA permits the development of a functional model of the work situation. The functional model should:

1. Describe the cognitive constraints and demands imposed on operators, including multiple goals and competing criteria for the good completion of the task; unreliable, uncertain, or excessive information to make a decision; and time restrictions.
2. Identify situations where human performance may become ineffective as well as their potential causes—e.g., cognitive demands exceeding operator capacities and strategies that are effective under normal situations but may seem inappropriate for the new one.
3. Identify error-prone situations and causes of errors or cognitive biases—e.g., irrelevant or superfluous information, inadequate work organization, poor workplace design, and insufficient knowledge.
4. Describe the main elements of operator's competencies and determine their strengths and weaknesses.
5. Describe how resources of the environment can be used to support the cognitive processes.

The functional model of the work situation can provide valuable input into the specification of user requirements, prototyping, and evaluation of cognitive aids. Specifically, based on elements 1, 2, and 3 of the functional model, situations and tasks for which cognitive aid would be desirable and the ways such aid must be provided can be determined and specified. This investigation can be made responding to questions such as:

- What other information would be useful to the operators?
- Is there a more appropriate form in which to present the information already used as well as the additional new information?
- Is it possible to increase the reliability of information?
- Could the search for information be facilitated, and how?
- Could the treatment of information be facilitated, and how?
- Could we provide memory supports, and how?
- Could we facilitate the complex cognitive activities carried out, and how?
- Could we promote and facilitate the use of the most effective diagnosis and decision-making strategies, and how?
- Could we provide supports that would decrease mental workload and mitigate degraded performance, and how?
- Could we provide supports that would decrease human errors occurrence, and how?

Cognitive aids can take several forms, including memory aids, computational tools, decision aids to avoid cognitive biases, visualization of equipment that is difficult to inspect, and situation-assessment aids. The functional model is also useful in designing man–machine interfaces to support retrieval of solutions and generation of new methods. By representing system constraints on the interface, operators may be supported in predicting side effects stemming from specific actions. On the other hand, the functional model can also be useful in specifying the competencies and strategies required in complex tasks and hence providing the content of skill training.

Furthermore, based on the information provided by elements 4 and 5 of the functional model, the main features of the human–machine interface can also be specified, ensuring compatibility with operators' competencies. The way task's objects should be represented by the system, the type of man–machine dialogues to be used, the procedures to be proposed, and generic or customizable elements of the system are examples of human–computer interface features that can be specified using the acquired data.

Close cooperation among ergonomics specialists, information technology specialists, and stakeholders in the design project is required in order to examine what system functions should be supported by available information technology, what features of the human-computer interface should be realized, and what functions should be given priority.

4.2. Techniques for Cognitive Task Analysis

CTA can be carried out using a variety of techniques, which, according to Redding and Seamster (1994), can include cognitive interviewing, analysis of verbal protocols, multi-dimensional scaling, computer simulations of human performance, and human error analysis. For instance, Rasmussen (1986) has conducted cognitive interviews to examine the troubleshooting strategies used by electronics technicians. Roth et al. (1992) have used cognitive environment simulation to investigate cognitive activities in fault management in nuclear power plants. Seamster et al. (1993) have carried out extensive cognitive task analyses to specify instructional programs for air traffic controllers. These CTA techniques have been used both to predict how users perform cognitive tasks on prototype systems and to analyze the difficulties and errors in already functioning systems. The former use is associated with the design and development of user interfaces in new systems, while the latter use is associated with the development of decision support systems or cognitive aids and training programs.

The results of CTA are usually cast in the form of graphical representations that incorporate the work demands and user strategies. For cognitive tasks that have been encountered in the past, operators may have developed well-established responses that may need some modifications but nevertheless provide a starting framework. For unfamiliar tasks that have not been encountered in the past or are beyond the design-basis of the system, operators are required to develop new methods or combine old methods in new ways. To illustrate how the results of CTA can be merged in a graphical form, two techniques are presented: hierarchical task analysis and the critical decision method.

4.2.1. Hierarchical Task Analysis

The human factors literature is rich in task analysis techniques for situations and jobs requiring rule-based behavior (e.g., Kirwan and Ainsworth 1992). Some of these techniques can also be used for the analysis of cognitive tasks where well-practiced work methods must be adapted to task variations and new circumstances. This can be achieved provided that task analysis goes beyond the recommended work methods and explores task variations that can cause failures of human performance. Hierarchical task analysis (Shepherd 1989), for instance, can be used to describe how operators set goals and plan their activities in terms of work methods, antecedent conditions, and expected feedback. When the analysis is expanded to cover not only normal situations but also task variations or changes in circumstances, it would be possible to record possible ways in which humans may fail and how they could recover from errors. Table 2 shows an analysis of a process control task where operators start up an oil refinery furnace. This is a safety-critical task because many safety systems are on manual mode, radio communications between control room and on-site personnel are intensive, side effects are not visible (e.g., accumulation of fuel in the fire box), and errors can lead to furnace explosions.

A variant of hierarchical task analysis has been used to examine several cognitive activities, such as goal setting and planning, and failures due to slips and mistakes. Variations in human performance were examined in terms of how teams in different shifts would perform the same task and how the same team would respond to changes in circumstances. A study by Kontogiannis and Embrey (1997) has used this technique to summarize findings from online observations of performance, interviews with process operators about their work methods, near-miss reviews, and critical incident analysis. The task analysis in Table 2 has provided valuable input in revising the operating procedures for start-up: the sequence of operations was reorganized, contingency steps were included for variations in circumstances, check boxes were inserted for tracking executed steps, and warnings and cautions were added to prevent human errors or help in their detection and recovery. In addition, the task analysis in Table 2 has been used to redesign the computer-based process displays so that all information required for the same task could be grouped and presented in the same screen. For instance, the oxygen content in flue gases is an indicator of the efficiency of combustion (see last row in Table 2) and should be related to the flow rates of air and fuel; this implies that these parameters are functionally related in achieving the required furnace temperature and thus should be presented on the same computer screen. The analysis of cognitive tasks, therefore, may provide input into several forms of human factors interventions, including control panel design, revision of operating procedures, and development of job aids and training.

4.2.2. Critical Decision Method

The Critical Decision Method (CDM) (Klein et al. 1989) is a retrospective cognitive task analysis based on cognitive interviews for eliciting expert knowledge, decision strategies and cues attended to, and potential errors. Applications of the CDM technique can be found in fireground command, tactical decision making in naval systems, ambulance emergency planning, and incident control in offshore oil industries. The technique relies on subject matter experts (SMEs) recalling a particularly memorable incident they have experienced in the course of their work. The sequence of events and actions are organized on a timeline that can be rearranged as SMEs remember other details of the

TABLE 2. Extract from the Analysis of Starting an Oil Refinery Furnace (a variant of hierarchical task analysis)

Goal Setting	Work Method (planning)	Antecedent Conditions (planning)	Feedback	Common Errors and Problem Detection
2. Establish flames on all burners.	Light first burner (2.1) and take safety precautions (2.2) if flame is not "healthy." Proceed with other burners.	Furnace has been purged with air and free of residual fuel	"Healthy" flames on all burners	√ Selects wrong equipment to test furnace atmosphere. √ Repeated failures to ignite burners may require shutting down the furnace.
2.1. Light selected burner.	Remove slip plate, open burner valve, and ignite burner.	Flame has not been extinguished more than twice before.	"Healthy" flame on selected burner	√ Forgets to light and insert torch before removing slip plate from fuel pipe; explosive mixture could be created in the event of a leaking block valve. √ Tries to light burner by flashing off from adjacent burners. √ Does not check and reset safety trips, which gives rise to burner failing to ignite.
2.2. Take safety precautions.	Close burner valve and inject steam.	Burner flame has been extinguished.	Steam injection for 2–3 minutes	√ Forgets to put air/fuel ratio control and furnace temperature control on manual; it can cause sub-stoichiometric firing √ Forgets to investigate problem if a burner does not light after two attempts.
3. Gradually increase furnace load to target temperature.	Adjust fuel flow (3.1) and air flow (3.2) in cycles until thermal load is achieved.	All burners remain lighted throughout operation.	Temperature of crude oil on target	√ In the event of a burner failure (e.g., flame put out), compensates by increasing fuel to other burners.
3.1. Adjust flow of fuel supply.	Monitor fuel supply indicator and adjust fuel valve.	Burners are fitted with suitable fuel diffusion plugs.	Temperature of crude oil on target	√ Does not consult criterion table for changing plugs at different fuel supplies
3.2. Adjust supply of combustion air.	Monitor oxygen in flue gases and adjust air damper to keep oxygen above limit.		Oxygen content above limit	√ Risk of explosion if oxygen below limit (may indicate unburned fuel).

incident. The next stage is to probe SMEs to elicit more information concerning each major decision point. Cognitive probes address the cues attended to, the knowledge needed to make a decision, the way in which the information was presented, the assessment made of the situation, the options considered, and finally the basis for the final choice. The third stage of the CDM technique involves comparisons between experts and novices. The participants or SMEs are asked to comment on the expected performance of a less-experienced person when faced with the same situation. This is usually done in order to identify possible errors made by less experienced personnel and potential recovery routes through better training, operating procedures, and interface design. The results of the cognitive task analysis can be represented in a single format by means of a decision analysis table.

One of the most important aspects of applying the CDM technique is selecting appropriate incidents for further analysis. The incidents should refer to complex events that challenged ordinary operating practices, regardless of the severity of the incident caused by these practices. It is also important that a "no-blame" culture exist in the organization so that participants are not constrained in their description of events and unsuccessful actions. To illustrate the use of the CDM technique, the response of the operating crew during the first half hour of the Ginna nuclear power incident is examined below, as reported in Woods (1982) and INPO (1982).

The operating crew at the Ginna nuclear plant encountered a major emergency in January 1982 due to a tube rupture in a steam generator; as a result, radioactive coolant leaked into the steam generator and subsequently into the atmosphere. In a pressurized water reactor such as Ginna, water coolant is used to carry heat from the reactor to the steam generator (i.e., the primary loop); a secondary water loop passes through the steam generator and the produced steam drives the turbine that generates electricity. A water leak from the primary to the secondary loop can be a potential risk when not isolated in time. In fact, the delayed isolation of the faulted or leaking steam generator was one of the contributory factors in the evolution of the incident. Woods (1982) uses a variant of the CDM technique to analyze the major decisions of the operating crew at the Ginna incident.

Figure 7 shows a timeline of events and human actions plotted against a simplified version of the SRK model of Rasmussen. *Detection* refers to the collection of data from control room instruments and the recognition of a familiar pattern; for instance, the initial plant symptoms leads to an initial recognition of the problem as a steam generator tube rupture (i.e., a SGTR event). However, alternative events may be equally plausible, and further processing of information at the next stage is required. Interpretation then involves identifying other plausible explanations of the problem, predicting the criticality of the situation, and exploring options for intervention. The formulation of

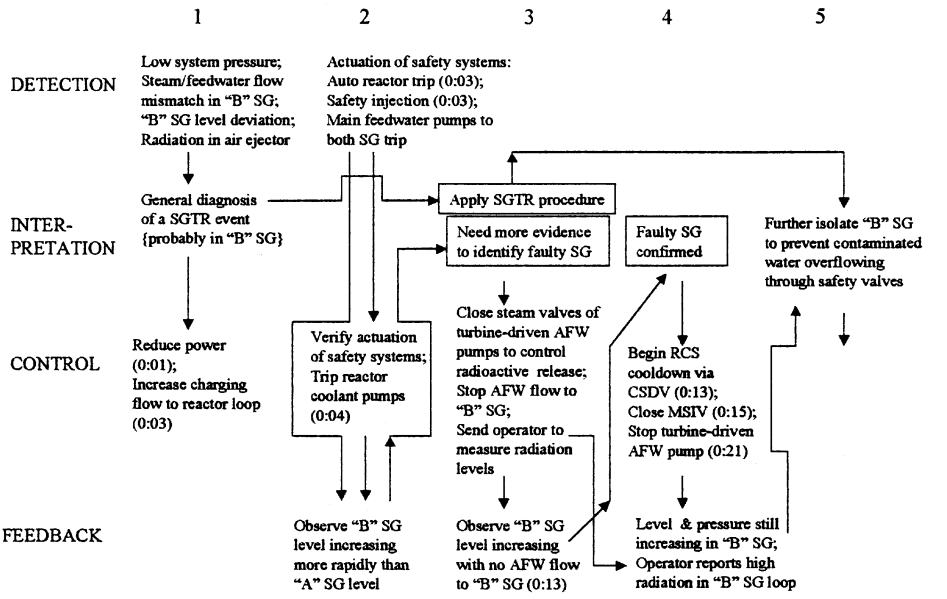

Figure 7 Analysis of the Response of the Crew During the First Half Hour at the Ginna Incident (an example of the critical decision method).

specific actions for implementing a plan and executing actions are carried out at the following stage of control. The large number of actions at the control stage provides a context for the work conditions that may affect overall performance; for instance, high workload at this stage could prevent the crew from detecting emerging events. The feedback stage is similar to the detection stage because both are based on the collection of data; however, in the detection stage, observation follows an alarm, while in the feedback stage, observation is a follow-up to an action. The decision flowchart in Figure 7 has been developed on the basis of cognitive interviews with the operators involved and investigations of the operating procedures in use.

To understand the cognitive processes involved at critical decision points, analysts should employ several cognitive probes similar to those shown in Table 1. It is worth investigating, for instance, the decision of the crew to seek further evidence to identify the tube rupture in one of the two steam generators (Figure 7, column 3). At this point in time, the crew was aware that the level in the B steam generator was increasing more rapidly than the level of the A steam generator (i.e., due to tube rupture) with auxiliary feedwater flows established to both steam generators. However, the crew needed additional evidence to conclude their fault diagnosis. Was this delay in interpretation caused by insufficient plant knowledge? Did the crew interpret the consequences of the problem correctly? Were the instructions in the procedures clear? And in general, what factors influenced this behavior of the crew?

These are some cognitive probes necessary to help analysts explore the way that the crew interpreted the problem. As it appeared, the crew stopped the auxiliary feedwater flow to the B steam generator and came to a conclusion when they observed that its level was still increasing with no input; in addition, an auxiliary operator was sent to measure radioactivity in the suspect steam generator (Figure 7, column 3). Nevertheless, the crew isolated the B steam generator before feedback was given by the operator with regard to the levels of radioactivity. The cognitive interviews established that a plausible explanation for the delayed diagnosis was the high cost of misinterpretation. Isolation of the wrong steam generator (i.e., by closing the main steam isolation valve [MSIV]) would require a delay to reopen it in order to repressurize and establish this steam generator as functional. The crew also thought of a worse scenario in which the MSIV would stick in the closed position, depriving the crew of an efficient mode of cooldown (i.e., by dumping steam directly to the condensers); in the worst-case scenario, the crew would have to operate the atmospheric steam dump valves (ASDVs), which had a smaller cooling function and an increased risk of radiological release.

Other contextual factors that should be investigated include the presentation of instructions in the procedures and the goal priorities established in training regimes. Notes for prompt isolation of the faulty steam generator were buried in a series of notes placed in a separate location from the instructions on how to identify the faulty steam generator. In addition, the high cost of making an incorrect action (an error of commission) as compared to an error of omission may have contributed to this delay. In other words, experience with bad treatment of mistaken actions on the part of the organization may have prompted the crew to wait for redundant evidence. Nevertheless, the eight-minute delay in diagnosis was somewhat excessive and reduced the available time window to control the rising water level in the B steam generator. As a result, the B steam generator overflowed and contaminated water passed through the safety valves; subsequent actions (e.g., block ASDV, column 5) due to inappropriate wording of procedural instructions also contributed to this release.

Cognitive analysis of the diagnostic activity can provide valuable insight into the strategies employed by experienced personnel and the contextual factors that led to delays and errors. It should be emphasized that the crew performed well under the stressful conditions of the emergency (i.e., safety-critical event, inadequate procedures, distractions by the arrival of extra staff, etc.) given that they had been on duty for only an hour and a half. The analysis also revealed some important aspects of how people make decisions under stress. When events have high consequences, experienced personnel take into account the cost of misinterpretation and think ahead to possible contingencies (e.g., equipment stuck in closed position depriving a cooling function). Intermingling fault interpretation and contingency planning could be an efficient strategy under stress, provided that people know how to switch between them. In fact, cognitive analysis of incidents has been used as a basis for developing training programs for the nuclear power industry (Kontogiannis 1996).

The critical decision method has also been used in eliciting cognitive activities and problem-solving strategies required in ambulance emergency planning (O'Hara et al. 1998) and fire-fighting command (Klein et al. 1986). Taxonomies of operator strategies in performing cognitive tasks in emergencies have emerged, including maintaining situation assessment, matching resources to situation demands, planning ahead, balancing workload among crew members, keeping track of unsuccessful or interrupted tasks, and revising plans in the light of new evidence. More important, these strategies can be related to specific cognitive tasks and criteria can be derived for how to switch between alternative strategies when the context of the situation changes. It is conceivable that these problem-solving strategies can become the basis for developing cognitive aids as well as training courses for maintaining them under psychological stress.

5. DESIGNING COGNITIVE AIDS FOR COMPLEX COGNITIVE TASKS

Recent developments in information technology and system automation have provided challenging occasions for developing computerized artifacts aiming to support cognitive processes such as diagnosis, decision making, and planning. This enthusiasm with the capabilities of new technology has resulted in an overreliance on the merits of technology and the development of stand-alone systems capable of undertaking fault diagnosis, decision making, and planning. Recent reviews of such independent computer consultants (e.g., Roth et al. 1997), however, have found them to be difficult to use and brittle in the face of novel circumstances. Woods et al. (1990) argue that many of these systems cannot anticipate operator responses, provide unsatisfactory accounts of their own goals, and cannot redirect their line of reasoning in cases of misperception of the nature of the problem. To make cognitive aids more intelligent and cooperative, it is necessary to examine the nature of human cognition in complex worlds and its coupling with the wider context of work (Marmaras and Pavard 2000). Because of the increasing interest in developing cognitive aids for complex tasks, this section presents two case studies that address this issue in an applied context.

5.1. The Case of a Cognitive Aid for CNC Lathe Programming

The scope of this study was to design a cognitive aid for CNC lathe programming (Marmaras et al. 1997) by adopting a problem-driven approach. This approach combines an analysis of the task in terms of constraints and cognitive demands with an analysis of user strategies to cope with the problem (Marmaras et al. 1992; Woods and Hollnagel 1987). A cognitive task analysis was undertaken in the first place in order to identify the cognitive demands of the task and investigate likely problem-solving strategies leading to optimal and suboptimal solutions. On the basis of the cognitive task analysis and the results of a follow-up experiment, an information technology cognitive aid was developed for CNC lathe programming. A prototype of the cognitive aid was evaluated in a second experiment.

5.1.1. Cognitive Task Analysis

Programming a CNC lathe requires the development of a program that will guide the lathe to transform a simple cylindrical part into a complex shape. This cognitive task requires planning and codification, and it is very demanding due to several interdependent constraints, competing criteria for task efficiency, delayed feedback, and lack of memory aids for maintaining a mental image of the manufacturing process.

A cognitive analysis of the activities and strategies was conducted on the basis of real-time observations of experienced operators programming their CNC lathes and off-the-job interviews. The analysis identified three main cognitive tasks:

1. Planning the whole process of manufacturing, which entails deciding upon:
   - The order of cutting several elements of the complex shape
   - The cutting tool to be used at each stage of the cutting process
   - The movement of the tool at each stage of the cutting process (e.g., starting and ending points, type of the movement, and speed)
   - The number of iterative movements of the tool at each stage
   - The speed of rotation of the part
2. Codification of the manufacturing process to the programming language of the CNC machine. The operator has to consider the vocabulary of this language to designate the different objects and functions of the manufacturing process, as well as the grammar and syntax of the language.
3. Introduction of the program to the machine by using various editing facilities and by starting the execution of the program. It is worth noting that at this stage certain omission and syntax errors can be recognized by the computer logic and the operator may be called upon to correct them.

Table 3 summarizes the results of the cognitive analysis for the planning task. Experienced operators must take a number of constraints into account when deciding upon the most suitable strategy to manufacture the part. These include:

- The shape of the part and the constraints imposed by its material.
- The constraints of the machine tool, e.g., the rotating movement of the part, the area and movement possibilities of the cutting tool, its dimensions, and its cutting capabilities.
- The product quality constraints derived from the specification; these are affected by the speeds of the part and tools, the type of tools, and the designation of their movements.

TABLE 3 Decision Table for the Task of Planning How to Cut a Part in a CNC Lathe

Tasks	Decision Choices	Constraints	Sources of Difficulty	Strategies
Planning the manufacturing process	• Order of cutting • Cutting tools at each phase • Movement of tools • Iterative tool movements • Rotation speed of the part	• Part shape and material • Tool constraints • Product quality • Manufacturing time	• Interdependent constraints • Competing criteria for task efficiency • Lack of real-time feedback • Lack of aids for mental imagery of manufacturing process	• Serial strategy • Optimization strategy

- The manufacturing time, which is affected by the number of tool changes, the movements the tools make without cutting (idle time of the tool) and the speeds of the part and cutting tools.
- The safety considerations, such as avoiding breaking or destroying the part or the tools; safety rules concerning the area of tool movement and the speeds of the part and cutting tools.

An analysis of how experienced operators decide to use the CNC lathe in cutting parts into complex shapes revealed a variety of problem strategies ranging from serial to optimized strategies. The simplest strategy, at one end of the spectrum, involved cutting each component of the part having a different shape separately and in a serial order (e.g., from right to left). A number of heuristics have been introduced in the problem-solving process resulting in such a serial strategy, including:

- Decomposition of the part to its components (problem decomposition)
- Specification and prioritization of several criteria affecting task efficiency (criteria prioritization)
- Simplification of mental imagery of the manufacturing process (mental representation)
- Use of a unique frame of reference regarding the part to be manufactured (frames of reference minimization)

At the other end of the spectrum, a more complex strategy was adopted that relied on optimizing a number of criteria for task efficiency, such as product quality, manufacturing time, and safety considerations. A case in point is a cutting strategy that integrates more than one different shape into one tool movement, which alters the serial order of cutting the different shapes of the part. This strategy would decrease the time-consuming changes of tools and the idle time, thus minimizing the manufacturing time. Optimized cutting strategies require complex problem-solving processes, which may include:

- Adopting a holistic view of the part to be manufactured
- Considering continuously all the criteria of task efficiency
- Using dynamic mental imagery of the cutting process that includes all intermediate phases of the whole part
- Adopting two frames of reference regarding the part to be manufactured and the cutting tools in order to optimize their use

Two hypotheses have been formulated with respect to the observed differences in the performance of CNC lathe programmers: (1) very good programmers will spend more time on problem formulation before proceeding to the specification of the program than good programmers, and (2) very good programmers will adopt an optimized cutting strategy while good programmers would settle for a serial strategy. Consequently, very good programmers will adopt a more complex problem-solving process than good programmers. To test these hypotheses, an experiment was designed that would also provide valuable input into the cognitive task analysis utilized in this study. Details on the design of the experiment and the results obtained can be found in Marmaras et al. (1997).

5.1.2. User Requirements for a Cognitive Aid Supporting CNC Lathe Programming

The cognitive task analysis of programming the CNC lathe provided useful insights into the design of an information technology system that supports CNC programmers. The scope of this cognitive aid was twofold. On the one hand, the aid should guide programmers in using efficient cutting strategies, and on the other hand, it should alleviate the cognitive demands that are often associated with optimized problem-solving strategies. Specifically, the cognitive aid could have the following features:

- Support users in deciding upon a cutting strategy at the front-end stages of the programming process
- Generate several suggestions about efficient strategies, e.g., ''try to integrate as many different shapes as possible into one movement of the cutting tool'' and ''avoid many changes of the cutting tool''
- Support human memory throughout the whole programming process
- Provide real-time feedback by showing programmers the effects of their intermediate decisions through real-time simulation
- Facilitate the standard actions of the whole programming process

A description of the prototype cognitive aid that was developed in accordance with the user requirements can be found in Marmaras et al. (1997). Another experiment showed that the quality of the CNC lathe programs was improved and the time required to program the lathe was decreased by approximately 28% when operators used the proposed cognitive aid. Not only did the performance of good CNC lathe programmers improve, but so did the performance of the very good programmers.

5.2. The Case of a Cognitive Aid for Managerial Planning

This section presents a study of user requirements in the design of an information technology system that supports high-level managerial planning tasks in small to medium-sized enterprises (Laios et al. 1992; Marmaras et al. 1992). High-level managerial planning tasks, usually referred to as strategic or corporate planning, involve a series of cognitive processes preceding or leading to crucial decisions about the future course of a company. Managerial planning entails:

1. *Strategies* or high-level decisions that have a long-lasting influence on the enterprise
2. *Tactics* or lower-level strategies regarding policies and actions
3. *Action plans* that specify detailed courses of action for the future

In large companies, strategic planning is an iterative, lengthy, and highly formalized process involving many managers at several levels in the organization. In contrast, in small companies, the manager-owner is the sole, most important actor and source of information on planning issues; in this case, planning is an individual cognitive process without the formalism required in larger organizations.

Elements that affect planning decisions are past, present, and expected future states of the external environment of the firm, which have a complex relationship with the internal environment. Managers may perceive these elements as threats or opportunities in the marketplace (external environment) and strengths or weaknesses of the enterprise (internal environment). Effective planning decisions should neutralize threats from the external environment and exploit its opportunities, taking into account the strengths and weaknesses of the company. At the same time, effective planning decisions should increase the strengths of the company and decrease its weaknesses.

A literature review and three case studies were undertaken in order to identify the main elements of the external and internal environments that may constrain managerial planning. The main constraints identified were:

- *Complexity/multiplicity of factors:* The external and internal environments of an enterprise include a large number of interacting factors. Market demand, intensity of competition, socio-economic situation, labor market, and technology are examples of the external environment factors. Product quality, process technology, distribution channels, and financial position are examples of the internal environment factors.
- *Change/unpredictability:* The world in which firms operate is constantly changing. Very often these changes are difficult to predict with regard to their timing, impact, and size effects. Managers therefore face a great degree of uncertainty.
- *Limited knowledge* with respect to the final impact of planning decisions and actions. For example, what will be the sales increase resulting from an advertising campaign costing X, and what from a product design improvement costing Y?

- *Interrelation between goals and decisions:* Planning decisions made in order to achieve a concrete goal may refute—if only temporarily—some other goals. For example, renewal of production equipment aiming at increasing product quality may refute the goal of increased profits for some years.
- *Risk related to planning decisions:* The potential outcomes of planning decisions are crucial to the future of the enterprise. Inaccurate decisions may put the enterprise in jeopardy, often leading to important financial losses.

Providing valuable input to cognitive analysis was a series of structured interviews with managers from 60 small- to medium-sized enterprises in order to collect taxonomic data about typical planning tasks in various enterprises, environmental and internal factors, and personality characteristics. In other words, the aim of these interviews was to identify the different situations in which managerial planning takes place.

The scenario method was used to conduct a cognitive analysis of managerial planning because of the difficulties involved in direct observations of real-life situations. The scenario presented a hypothetical firm, its position in the market, and a set of predictions regarding two external factors: an increase in competition for two of the three types of products and a small general increase in market demand. The description of the firm and its external environment was quite general, but realistic so that managers could create associations with their own work environment and therefore rely on their own experience and competencies. For example, the scenario did not specify the products manufactured by the hypothetical firm, the production methods and information systems used, or the tactics followed by the firm. The knowledge elicited from the three case studies and the structured interviews was used to construct realistic problem scenarios.

Scenario sessions with 21 practicing managers were organized in the following way. After a brief explanation about the scope of the experiment, managers were asked to read a two-page description of the scenario. Managers were then asked to suggest what actions they would take had they owned the hypothetical firm and to specify their sequence of performance. Additional information about the scenario (e.g., financial data, analysis of profits and losses, production and operating costs) were provided in tables in case managers would like to use them. Managers were asked to think aloud and were allowed to take notes and make as many calculations as needed. The tape recordings of the scenario sessions were transcribed and verbal protocols were analyzed using a 10-category codification scheme (see Table 4). The coded protocols indicated the succession of decision-making stages and the semantic content of each stage—for example, the sort of information acquired, the specific goals to be attained, or the specific tactic chosen. Details of the verbal protocol analysis can be found in Marmaras et al. (1992). A brief presentation of the main conclusions drawn from the cognitive analysis follow, with particular emphasis on the managers' cognitive strategies and heuristics used in managerial planning.

- *Limited generation of alternative tactics:* Most managers did not generate at the outset an extensive set of alternative tactics to select the most appropriate for the situation. Instead, as

TABLE 4 Ten-Category Scheme for Interpreting the Verbal Protocols of Managers

Code	Description
C1	*Information acquisition* from the data sheets of the scenario or by the experimenter
C2	Statement about the *tactic* followed by the manager (e.g., "I will reduce the production of product C and I will focus on product A . . .")
C3	Reference to *threats or opportunities, strengths and weaknesses* of the firm (e.g., ". . . with these tactics, I will neutralize competitors penetration in the market . . .")
C4	Reference to *conditions* necessary for implementing a tactic (e.g., "I will apply tactic X only if tactic Y does not bring about the expected results . . .")
C5	Reference to the *time* a tactic would be put into effect and the duration of its implementation (e.g., "I will reduce the product price immediately . . .")
C6	Reference to *goals* (e.g., ". . . with this tactic I expect sales to grow . . .")
C7	Reference to data and *calculations* in order to form a better picture of the present planning situation
C8	Explicit reference to a *generic strategy* (e.g., "I would never reduce the prices of the product . . .")
C9	*Justification* of the selected strategy
C10	Calculations for *quantitative evaluation* of selected tactics

soon as they acquired some information and formed a representation of the situation, they defined a rather limited set of tactics that they would apply immediately (e.g., C1→C2, C1→C7→C3→C2, C1→C3→C2, C1→C3→C1→C2). This finding could be attributed to the fact that experienced managers possess an extensive repertoire of experiences accessed through recognition rather than conscious search. Optimization strategies are time consuming and difficult to sustain under the constraints of the work environment and the limited knowledge regarding the impact of decisions. In addition, the high risks associated with different decisions would probably push managers to adopt already tested tactics. Limited generation of alternative tactics, however, may lead to ineffective practices. For instance, a past solution may be inappropriate if the current situation has some subtle differences from others experienced in the past. In the case of managerial planning, new innovative solutions and radical departures may be of great importance.

- *Acting/thinking cycles:* After deciding upon a first set of actions, managers would wait for immediate feedback before proceeding to corrective actions or applying other tactics. This behavior compensates to some extent for the potential negative consequences of the previous strategy. That is, early decisions may be based on past experiences, but their suitability can be evaluated later on when feedback becomes available; thus, managers may undertake other corrective actions. However, these cycles of acting/thinking behavior may lead to delays in acting, increased costs, or money loss.
- *Limited use of information and analysis:* Most managers avoided speculating on the available predictive quantitative account data and did not make any projections in their evaluation of selected tactics. Instead, they quickly came up with ideas about what to do and stated that they would base their evaluation and future actions on specific outcomes of their initial actions. Decisions were justified by making references to environmental factors (C2→C3, C3→C2), other superordinate goals (C2→C6, C6→C2, C8→C2, C2→C8), and feedback from previous actions. This behavior may be attributed to the constraints of the environment, the uncertainty in making predictions, and the interleaving goals that may render a quantitative evaluation of tactics rather difficult or even impossible. The possible negative consequences of this behavior are that data important for planning decisions may be neglected during the planning process.
- *Lack of quantitative goals and evaluation:* The results of the analysis suggested that, in general, managers do not set themselves quantitative goals that will influence the selection and evaluation of their actions. Instead, their planning decisions seem to be based mainly on assessments of external and internal environment factors and certain generic goals related to past experiences. This observation provides evidence supporting the criticism of several authors (e.g., Lindblom 1980) with respect to the relevance of goal-led models; it also suggests that cognitive aids should not be based on optimization models of managerial planning.

Drawing on the results of the cognitive analysis, an information technology system that supports managerial planning in small- to medium-sized enterprises was specified and designed. The system took the form of an active framework that supports cognitive processes in the assessment of environmental factors and generation, selection, and evaluation of strategies and tactics. At the same time, the support system would limit some negative consequences of the managers' cognitive strategies and heuristics. With the use of appropriate screens and functions, the proposed cognitive aid should provide support in the following ways:

- Assisting managers in considering additional data in the planning process and identifying similarities to and differences from other experiences in the past. This could be done by presenting menus of external and internal factors in the planning environment and inviting managers to determine future states or evolutions of system states.
- Enriching the repertoire of planning decisions by presenting menus of candidate options and tactics relevant to the current situation.
- Supporting the acting/thinking process by providing crucial information concerning the state of external and internal environment factors at the successive action/thinking cycles and the different planning decisions made during these cycles.

The planning process proposed by the cognitive aid could be achieved through a series of steps. First, an assessment should be made of the past, present, and future states of environmental factors; this is in contrast to the setting of quantitative goals, as proposed by formal models of strategic planning. The next step involves the specification of alternative tactics and evaluation using qualitative and, optionally, quantitative criteria. Additional steps with regard to the setting of generic strategies and goals have been included in between. However, some degrees of freedom should be allowed in

the choice and sequence of these steps. Although this procedure imposes a certain formalism in managerial planning (this is inevitable when using an information technology system), sufficient compatibility has been achieved with the cognitive processes entailed in managerial planning. A prototype of the proposed cognitive aid was evaluated by a number of managers of small- to medium-sized enterprises, and its functionality and usability were perceived to be of high quality.

6. CONCLUDING REMARKS

Advances in information technology and automation have changed the nature of many jobs by placing particular emphasis on cognitive tasks and, on the other hand, by increasing their demands, such as coping with more complex systems, higher volume of work, and operating close to safety limits. As a result, successful ergonomic interventions should consider the interactions in the triad of ''users, tools or artifacts, work environment.'' These interactions are affected by the user strategies, the constraints of the work environment, and the affordances and limitations of the work tools. In this respect, techniques of cognitive task analysis are valuable because they explore how users' cognitive strategies are shaped by their experience and interaction with the work environment and the tools. This explains why a large part of this chapter has been devoted to illustrating how cognitive task analysis can be used in the context of applied work situations.

Cognitive analysis provides a framework for considering many types of ergonomic interventions in modern jobs, including the design of man–machine interfaces, cognitive tools, and training programs. However, cognitive analysis requires a good grasp of human cognition models in order to understand the mechanisms of cognition and develop techniques for eliciting them in work scenarios or real-life situations. The cognitive probes and the critical decision method, in particular, demonstrate how models of human cognition can provide direct input into cognitive task analysis. Further advances in cognitive psychology, cognitive science, organizational psychology, and ethnography should provide more insights into how experienced personnel adapt their strategies when work demands change and how they detect and correct errors before critical consequences are ensued.

The chapter has also emphasized the application of cognitive analysis in the design of information technology cognitive aids for complex tasks. The last two case studies have shown that cognitive aids should not be seen as independent entities capable of their own reasoning but as agents interacting with human users and work environments. Because unforeseen situations beyond the capabilities of cognitive aids are bound to arise, human operators should be able to take over. This requires that humans be kept in the loop and develop an overall mental picture of the situation before taking over. In other words, user-aid interactions should be at the heart of system design. Recent advantages of technology may increase the conceptual power of computers so that both users and cognitive aids can learn from each other's strategies.

CHAPTER 40

Physical Tasks: Analysis, Design, and Operation

WALDEMAR KARWOWSKI
DAVID RODRICK
University of Louisville

Handbook of Industrial Engineering: Technology and Operations Management, Third Edition.
Edited by Gavriel Salvendy

1. INTRODUCTION

According to the Board of Certification in Professional Ergonomics (BCPE 21000), ergonomics is a body of knowledge about human abilities, human limitations, and other human characteristics that are relevant to design. Ergonomic design is the application of this body of knowledge to the design of tools, machines, systems, tasks, jobs, and environments for safe, comfortable, and effective human use. The underlying philosophy of ergonomics is to design work systems where job demands are within the capacities of the workforce. Ergonomic job design focuses on fitting the job to capabilities of workers by, for example, eliminating occurrence of nonnatural postures at work, reduction of excessive strength requirements, improvements in work layout, design of hand tools, or optimizing work/rest requirements (Karwowski 1992; Karwowski and Salvendy 1998; Karwowski and Marras 1999).

Ergonomics is seen today as a vital component of the value-adding activities of the company, with well-documented cost–benefit aspects of the ergonomics management programs (GAO 1997). A company must be prepared to accept a participative culture and utilize participative techniques in implementation of work design principles. The job design-related problems and consequent interven-

tion should go beyond engineering solutions and include all aspects of business processes, including product design, engineering and manufacturing, quality management, and work organizational issues, along the side of task design or worker education and training (Karwowski and Salvendy 1999; Karwowski and Marras 1999; Genaidy et al. 1999).

This chapter deals primarily with work analysis and design, as well as related human performance on physical tasks. The information about cognitive and other human performance aspects can be found in other chapters of this Handbook.

2. ENGINEERING ANTHROPOMETRY

Anthropometry is an empirical science branching from physical anthropology that deals with physical dimensions of human body and its segments, such as body size and form, including location and distribution of center of mass; segment lengths and weights; range of joint movements; and strength characteristics. Anthropometric data are fundamental to work analysis and design. Engineering anthropometry focuses on physical measurements and applies appropriate methods to human subjects in order to develop engineering design requirements (Roebuck et al. 1975). Anthropometry is closely related to biomechanics because occupational biomechanics provides the criteria for the application of anthropometric data to the problems of workplace design (Pheasant 1989).

Anthropometry can be divided into two types: physical anthropometry, which deals with basic dimensions of the human body in standing and sitting positions (see, e.g., Tables 1 and 2), and functional anthropometry, which is task oriented. Both physical and functional anthropometry can be considered in either a static or dynamic sense. Static analysis implies that only the body segment lengths in fixed position will be considered in workplace design. Dynamic analysis requires that acceptability of design be evaluated with respect to the need to move the body from one position to another, as well as the reach and clearance considerations.

An example of the important dynamic data for workplace design is range of joint mobility (Table 3) which corresponds to postures illustrated in Figure 1. Very useful anthropometric data, both static and dynamic, are provided by the Humanscale (Henry Dreyfuss Associates 1981). When anthropometric requirements for the workplace are not met, biomechanical stresses, which may manifest themselves in postural discomfort, low back pain, and overexertion injury, are likely to occur (Grieve and Pheasant 1982). Inadequate anthropometric design can lead to machine safety hazards, loss of motion economy, and poor visibility. In other words, the consequences of anthropometric misfits may of be a biomechanical and perceptual nature, directly impacting worker safety, health, and plant productivity.

2.1. Description of Human Body Position

The anatomical body position depicts a person standing upright, with feet together, arms by the sides, and with palms forward. As a reference posture, this position is symmetrical with respect to so-called *mid-sagittal plane*. All planes parallel to it are also called *sagittal*. The vertical plane perpendicular to the sagittal is called the *coronal* plane. The horizontal (or *transverse*) plane is perpendicular to both the sagittal and coronal planes. Definition of planes of reference are especially important when the body is in other than the anatomical position.

According to Grieve and Pheasant (1982), terms of *relative* body position can be defined as follows. The *medial* and *lateral* positions refer to nearer to or farther from the mid-sagittal plane. The *superior* or *inferior* positions refer to nearer to or further from the top of the body. The *anterior* (*ventral*) and *posterior* (*dorsal*) positions refer to in front of or behind another structure. The *superficial* and *deep* positions refer to nearer to and farther from the body surface, respectively. Nearer to or farther from the trunk positions are called *proximal* and *distal*. Terms of body movements are defined in Table 4.

2.2. The Statistical Description of Anthropometric Data

The concept of normal distribution can used to describe random errors in the measurement of physical phenomena (Pheasant 1989). If the variable is normally distributed, the population may be completely described in terms of its mean ($\bar{x}$) and its standard deviation (s), and specific percentile (X_p) values can be calculated, where: $X_p = \bar{x} + sz$, where z (the standard normal deviate) is a factor for the percentile concerned. Values of z for some commonly used percentiles (X_p) are given in Table 5. Figure 2 depicts data from Humanscale calculated for different percentiles of U.S. females. A word of caution: anthropometric data are not necessarily normally distributed in any given population (Kroemer 1989).

2.3. The Method of Design Limits

The recommendations for workplace design with respect to anthropometric criteria can be established by the principle of *design for the extreme,* also known as the *method of limits* (Pheasant 1989). The basic idea behind this concept is to establish specific boundary conditions (percentile value of the

TABLE 4 Terms of Movements

Body Part	Movement	Plane of Reference		
		Sagittal	Coronal	Transverse
Trunk[1]	Bend forward	Flexion		
	Bend backwards	Extension		
	Bend sideways		Lateral flexion	
	Rotate about the Long axis			Axial rotation
Shoulder[2] girdle	Raise shoulders	Elevation		
	Lower shoulders	Depression		
	Draw forward	Protraction		
	Draw backward	Retraction		
Shoulder and hip joints	Raise arm or thigh forward	Flexion (extension[a])		
	Raise arm or thigh to side		Abduction (adduction[a])	
	Rotate arm or leg along its long axis			Lateral or outward rotation (medial or inward rotation[a])
Elbow and knee joints	Bend from the fully straightened position	Flexion (extension[a])		
Wrist joint (combined with carpal joints)	Bend palm upwards	Flexion (extension[a])		
	Move hand away from trunk to the side of radius		Adduction or radial deviation (adduction or ulnar deviation[a])	
Forearm rotation	Towards:			
	palm up position	Supination		
	palm down position	Pronation

X_p	z	X_p	z
1	−2.33	99	2.33
2.5	−1.96	97.5	1.96
5	−1.64	95	1.64
10	−1.28	90	1.28
15	−1.04	85	1.04
20	−0.84	80	0.84
25	−0.67	75	0.67
30	−0.52	70	0.52
40	−0.25	60	0.25
50	−0.00	50	0.00

relevant human characteristic) that, if satisfied, will also accommodate the rest of the expected user population. The NIOSH's (1991) recommended weight limit concept is an example of application of the method of limits or design for the extreme principles to the design of manual lifting tasks. Such design is based on the expected human characteristics, where the limiting users are the weakest of the worker population.

2.4. Anthropometric Design Criteria

The basic anthropometric criteria for workplace design are clearance, reach, and posture (Pheasant 1986). Typically, clearance problems refer to design of space needed for the knees, availability of space for wrist support, or safe passageways around and between equipment. If the clearance problems are disregarded, they may lead to poor working postures and hazardous work layouts. Consideration of clearance requires designing for the largest user, typically by adapting the 95th percentile values of the relevant characteristics for male workers. Typical reach problems in industry include consid-

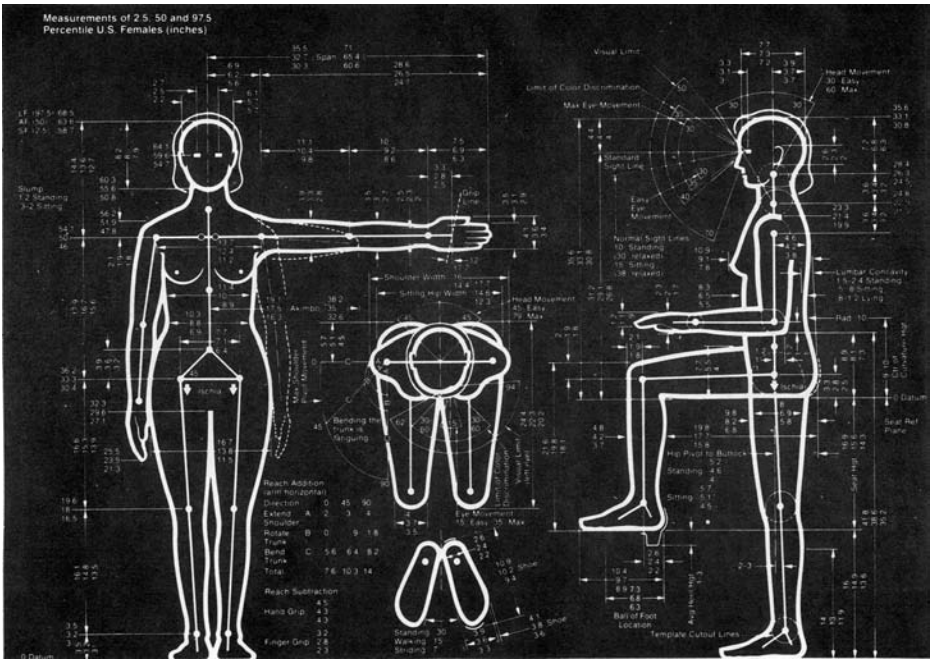

Figure 2 Illustration of Design Data Presented in Humanscale. (Reproduced with permission from Henry Dreyfuss Associates 1984)

eration of the location of controls and accessibility of control panels in the workplace. The procedure for solving the reach problems is similar to the one used for solving the clearance problems. This time, however, the limiting user will be a smaller member of the population and the design will be usually based upon the 5th percentile value of the relevant characteristic for female workers.

Both the clearance and the reach criteria are *one-tailed constraints,* that is, they impose the limits in one direction only (Pheasant 1989). The clearance criterion points out when an object is too small. It does not, however, indicate when an object is too large. In some design problems, such as safeguarding of industrial machinery, the conventional criteria of clearance and reach are often reversed.

2.5. Alternative Design Procedures

An alternative to single-percentile anthropometric design models has been presented by Robinette and McConville (1981). They point out that single-percentile models are inappropriate for both theoretical and practical reasons. As discussed by Kroemer (1989), there are two other methods that can be used to develop the analogues of the human body for the design purposes. One method is to create models that represent the extreme ends of the body size range called the subgroup method. The other method is the regression-based procedure. which generates design values that are additive. The estimated U.S. civilian body dimensions published by Kroemer (1981) are given in Table 1. A useful and correct general procedure for anthropometric design was recently proposed by Kroemer et al. (1986). This procedure consists of the following steps:

- *Step 1:* Select those anthropometric measures that directly relate to defined design dimensions. Example: hand length related to handle size.
- *Step 2:* For each of these pairings, determine independently whether the design must fit either only one given percentile of the body dimension, or if a range along that body dimension must be fitted. The height of a seat should be adjustable to fit persons with short and with long lower legs.
- *Step 3:* Combine all selected dimensions in a careful drawing, mock-up, or computer model to ascertain that all selected design values are compatible with each other. For example: the required leg room clearance height needed for sitting persons with long lower legs may be very close to the height of the working surface, determined from elbow height.
- *Step 4:* Determine whether one design will fit all users. If not, several sizes or adjustment must be provided to fit all users.

2.6. Computer-Aided Models of Man

In order to facilitate the application of anthropometric data and biomechanical analysis in workplace design, several computer-based models of man have been developed. These computer-aided tools

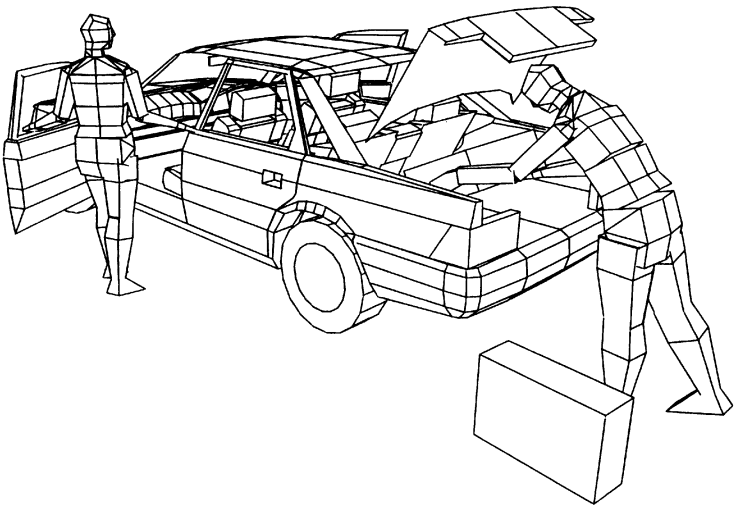

Figure 3 Illustration of Workplace Design Using SAMMIE System. (Reproduced with permission from SAMMIE CAD, Ltd.)

should make the analysis and application of biomechanical principles at work less complicated and more useful. For a review of the state of the art in ergonomic models of anthropometry, human biomechanics and operator–equipment interfaces, see Kroemer et al. (1988). Other developments in computer-aided ergonomics, specifically computer models of man and computer-assisted workplace design, are discussed by Karwowski et al. (1990). According to Schaub and Rohmert (1990), man model development originated with SAMMIE (System for Aiding Man–Machine Interaction Evaluation) in England (see Figure 3) (Porter et al. 1995). Examples of computer models developed in the United States include BOEMAN (Ryan 1971) for aircraft design, COMBIMAN and CREW CHIEF (McDaniel 1990) (see Figure 4), Deneb/ERGO (Nayar 1995) and JACK (Badler et al. 1995)

Other computer-aided man models developed in Europe include ERGOMAN (France), OSCAR (Hungary), ADAPTS (Netherlands), APOLINEX (Poland), and WERNER, FRANKY, and ANYBODY (Germany). A comprehensive 3D man model for workplace design, HEINER, was developed by Schaub and Rohmert (1990). Advances in applied artificial intelligence made it possible to develop knowledge-based expert systems for ergonomic design and analysis (Karwowski et al. 1987; Jung and Freivalds 1990). Examples of such models include SAFEWORK (Fortin et al. 1990), ERGONEXPERT (Rombach and Laurig1990), and ERGOSPEC (Brennan et al. 1990). Other models, such as CAD-video somotograph (Bullinger and Lorenz 1990) and AutoCAD-based anthropometric design systems (Grobelny 1990), or ergonomic databases (Landau et al. 1990), were also developed.

The computer-aided systems discussed above serve the purpose of biomechanical analysis in workplace design. For example, COMBIMAN, developed in the Human Engineering Division of Armstrong Laboratory since 1975, is both illustrative and analytic software. It allows the analysis of physical accessibility (reach and fit capabilities), strength for operating controls, and visibility accessibility. CREW CHIEF, a derivative of COMBIMAN, also allows the user with similar analyses. Another important development is Deneb's ERGO, a system capable of rapid prototyping of human motion, analyzing human joint range of motion, reach, and visual accessibility. In a recent study by Schaub et al. (1997), the authors revised the models and methods of ERGOMAN and reported added capabilities to predict maximum forces/moments of relevant posture, evaluate stress of human body joints, and carry out a general risk assessment. Probably the most advanced and comprehensive computer-aided digital human model and design/evaluation system today is JACK, from Transform Technologies (2000).

3. DESIGN FOR HUMAN STRENGTH

Knowledge of human strength capabilities and limitations can be used for ergonomic design of jobs, workplaces, equipment, tools, and controls. Strength measurements can also be used for worker preemployment screening procedures (Chaffin et al. 1978; Ayoub 1983). Human strengths can be assessed under static (isometric) or dynamic conditions (Kroemer 1970; Chaffin et al. 1977). Dynamic strengths can be measured isotonically, isokinetically, and isoinertially. Isometric muscle strengths are the capacity of muscles to produce force or moment force by a single maximal voluntary exertion; the body segment involved remains stationary and the length of the muscle does not change. In

TABLE 6 Static Strengths Demonstrated by Workers when Lifting, Pushing, and Pulling with Both Hands on a Handle Placed at Different Locations Relative to the Midpoint between the Ankles on Floor

	Location of Handle (cm)[a]		Male Strengths (N)			Female Strengths (N)		
Test Description	Vertical	Horizontal	Sample Size	Mean	SD	Sample Size	Mean	SD
Lift—leg partial squat	38	0	673	903	325	165	427	187
Lift—torso stooped over	38	38	1141	480	205	246	271	125
Lift—arms flexed	114	38	1276	383	125	234	214	93

[a]The location of the handle is measured in midsagittal plane, vertical from the floor and horizontal from the midpoint between the ankles.

dynamic muscular exertions, body segments move and the muscle length changes (Ayoub and Mital 1989). The static strengths demonstrated by industrial workers on selected manual handling tasks are shown in Table 6. Maximum voluntary joint strengths are depicted in Table 7.

3.1. Occupational Strength Testing

The main goal of worker selection is to screen the potential employee on the basis of his or her physical capability and match it with job demands. In order to evaluate an employee's capability, the following criteria should be applied when selecting between alternative screening methods (NIOSH 1981):

1. Safety in administering
2. Capability of giving reliable, quantitative values
3. Relation to specific job requirements
4. Practicality
5. Ability to predict the risk of future injury or illness

Isometric strength testing has been advocated as a means to predict the risk of future injuries resulting from jobs that require a high amount of force. Chaffin et al. (1977) reported that both frequency and severity rates of musculoskeletal problems were about three times greater for workers placed in jobs requiring physical exertion above that demonstrated by them in isometric strength tests when compared with workers placed in jobs having exertion requirements well below their demonstrated capabilities. The literature on worker selection has been reviewed by NIOSH (1981), Ayoub (1983), Chaffin et al. (1999), and Ayoub and Mital (1989). Typical values for the static strengths are shown in Figure 5.

3.2. Static vs. Dynamic Strengths

The application of static strength exertion data has limited value in assessing workers' capability to perform dynamic tasks that require application of force through a range of motions (Ayoub and Mital 1989). Mital et al. (1986) found that the correlation coefficients between simulated job dynamic strengths and maximum acceptable weight of lift in horizontal and vertical planes were substantially higher than those between isometric strengths and weights lifted. Two new studies offer design data based on dynamic strengths (Mital and Genaidy 1989; Mital and Faard 1990).

TABLE 7 Maximum Voluntary Joint Strengths (Nm)

	Range of Moments (Nm) of Subjects from Several Studies			
Joint strength	Joint Angle (degrees)	Men	Women	Variation with Joint Angle +
Elbow flexor	90	50–120	15–85	Peak at about 90°
Elbow extensor	90	25–100	15–60	Peak between 50° and 100°
Shoulder flexor	90	60–100	25–65	Weaker at flexed angles
Shoulder extensor	90	40–150	10–60	Decreases rapidly at angles less than 30°
Shoulder adductor	60	104	47	As angle decreases, strength increases then levels at 30° to −30°
Trunk flexor	0	145–515	85–320	Pattern differ among authors
Trunk extensor	0	143	78	Increases with trunk flexion
Trunk lateral flexor	0	150–290	80–170	Decreases with joint flexion
Hip extensor	0	110–505	60–130	Increases with joint flexion
Hip abductor	0	65–230	40–170	Increases as angle decreases
Knee flexor	90	50–130	35–115	In general, decreases some disagreement with this, depending on hip angle
Knee extensor	90	100–260	70–150	Minima at full flexion and extension
Ankle plantarflexor	0	75–230	35–130	Increases with dorsiflexion
Ankle dorsiflexor	0	35–70	25–45	Decreases from maximum plantar flexion to maximum dorsiflexion

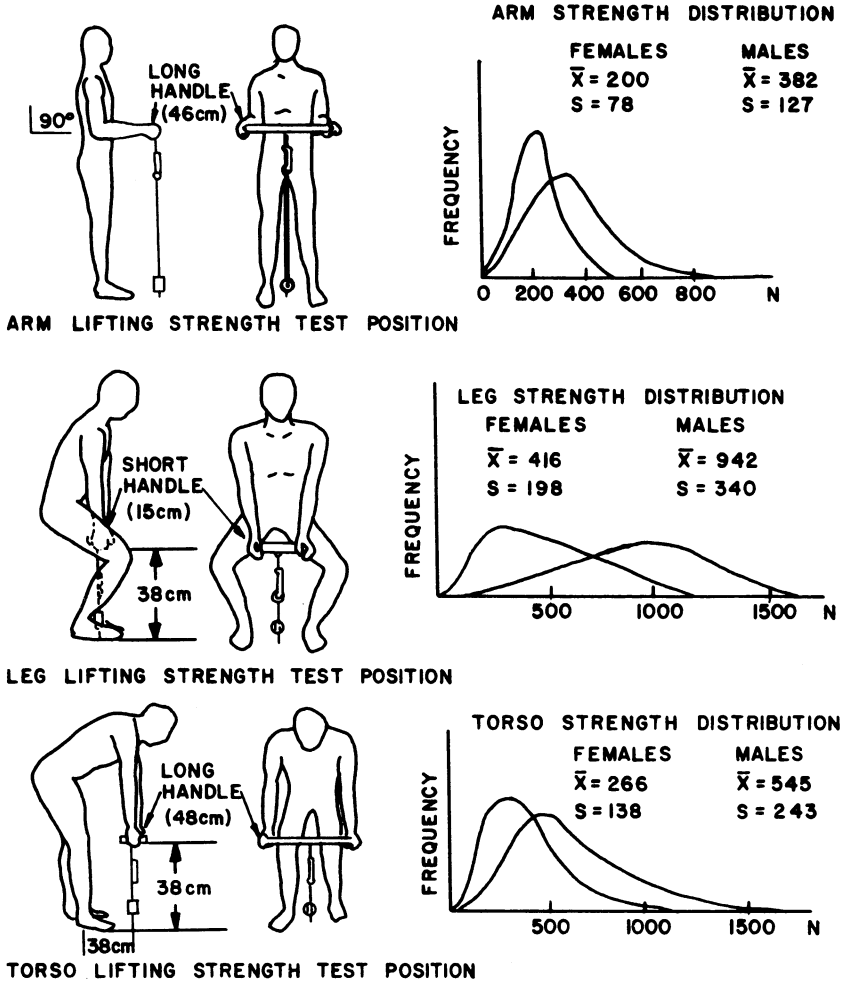

Figure 5 Results of Static Strength Measurement. (Adapted from Chaffin et al., *Occupational Biomechanics,* 3rd Ed. Copyright © 1999. Reprinted by permission of John Wiley & Sons, Inc., New York.)

The study by Mital and Genaidy (1989) provides isokinetic strengths of males and females for infrequent vertical exertions in 15 different working postures. This study showed that dynamic strength exertions of females are approximately half those of the male exertions, not about 67%, as in the case of isometric strength exertions. Mital and Faard (1990) investigated the effects of reach distance, preferred arm orientation, and sitting and standing posture on isokinetic force exertion capability of males in the horizontal plane. The results indicated that peak isokinetic strengths increased with the reach distance and were strongly influenced by the arm orientation. Also, peak isokinetic exertions were substantially greater than static strength when subjects were allowed to exert at freely chosen speed.

Karwowski and Mital (1986) and Karwowski and Pongpatanasuegsa (1988) tested the additivity assumption of isokinetic lifting and back extension strengths (the additivity assumption states that strength of a team is equal to the sum of individual members' strengths). They found that, on average, the strength of two-person teams is about 68% of the sum of the strengths of its members. For three-member teams, male and female teams generate only 58% and 68.4% of the sum of the strengths of its members, respectively. For both genders, the isokinetic team strengths were much lower than static team strengths.

3.3. Computer Simulation of Human Strength Capability

The worker strength exertion capability in heavy manual tasks can be simulated with the help of a microcomputer. Perhaps the best-known microcomputer system developed for work design and analysis concerning human strength is the Three Dimensional Static Strength Program (3D SSPP), developed by the Center for Ergonomics at the University of Michigan and distributed through the Intellectual Properties Office (University of Michigan, 1989). The program can aid in the evaluation of the physical demands of a prescribed job, and is useful as a job design/redesign and evaluation tool. Due to its static nature, the 3D SSPP model assumes negligible effects of accelerations and momentums and is applicable only to slow movements used in manual handling tasks. It is claimed that the 3D SSPP results correlate with average population static strengths at $r = 0.8$, and that the program should not be used as the sole determinant of worker strength performance (University of Michigan, 1989). In their last validation study, Chaffin and Erig (1991) reported that if considerable care is taken to ensure exactness between simulated and actual postures, the prediction error standard deviation would be less than 6% of the mean predicted value. However, 3D SSPP does not allow simulation of dynamic exertions.

The body posture, in 3D SSPP, is defined through five different angles about the joints describing body link locations. The input parameters, in addition to posture data, include percentile of body height and weight for both male and female populations, definition of force parameters (magnitude and direction of load handled in the sagittal plane), and the number of hands used. The output from the model provides the estimation of the percentage values of the population capable of exerting the required muscle forces at the elbow, shoulder, lumbosacral (L5/S1), hip, knee and ankle joints, and calculated back compression force on L5/S1 in relation to NIOSH action limit and maximum permissible limit. The body balance and foot/hip potential is also considered. An illustration of the model output is given in Figure 6.

3.4. Push–Pull Force Limits

Safe push–pull force exertion limits may be interpreted as the maximum force magnitudes that people can exert without injuries (for static exertions) or CTD (for repeated exertions) of the upper extremities under a set of conditions.

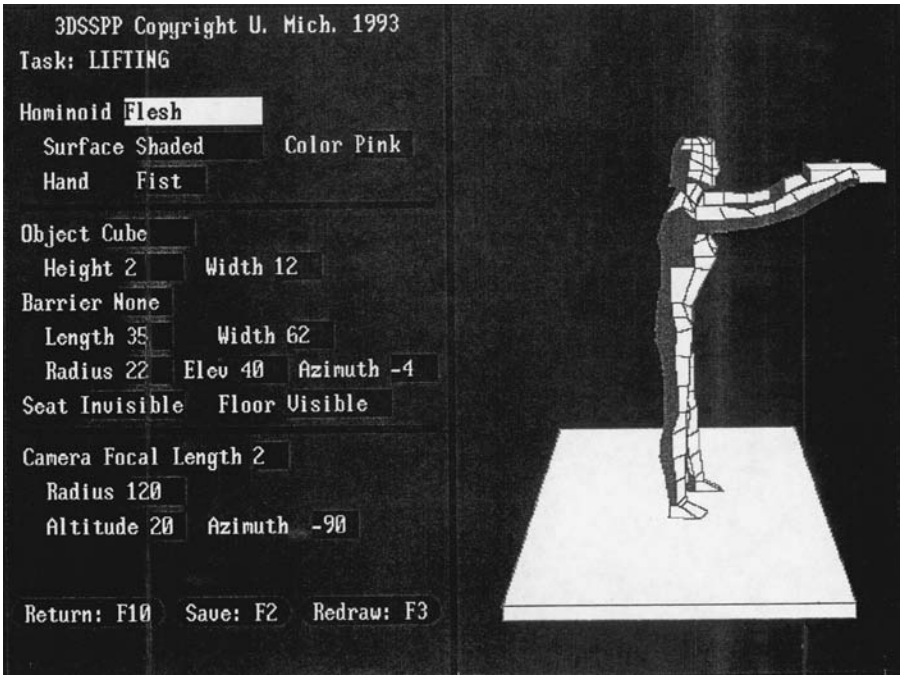

Figure 6 Illustration of Results from the 3D Static Strength Prediction Program of the University of Michigan.

3.4.1. Static Standing Forces

Because many factors influence the magnitude of a static MVC force, it would be wise not to recommend a single value for either push or pull force limits. After reviewing several studies Imrhan (1999), has concluded that average static two-handed MVC push forces have ranged from about 400–620 N in males and 180–335 N in females without bracing of the body, and pull forces from about 310–370 N in males and 180–270 N in females.

3.4.2. Dynamic Standing Forces

Dynamic push forces have ranged from 170 to 430 N in males and 200 to 290 N in females, and pull forces from 225 to 500 N in males and 160 to 180 N in females. As a result of series of researches by Snook and his colleagues (Snook et al. 1970; Snook and Ciriello 1974a; Snook 1978; Ciriello and Snook 1978, 1983; Ciriello et al. 1990), by utilizing psychophysical methodology, Snook and Ciriello (1991) have published the most useful guidelines on maximum initial or sustained push–pull force limits. Partial reproductions of the final four tables are given in Tables 8–11. The forces in are stated as a function of other work-related independent variables for both males and females. These are as follows:

1. Distance of push/pull: 2.1, 7.6, 15.2, 30.5, 45.7, and 61.0 m.
2. Frequency of push/pull: each distance has force limits for one exertion per 8 hr., 30 min, 5 min, and 2 min.
3. Height (vertical distance from floor to hands: 144, 95, 64 cm for males and 135, 89, and 57 for females.
4. The percentage of workers: (10, 25, 50, 75, and 90%) who are capable of sustaining the particular force during a typical 8-hr job.

3.4.3. One-Handed Force Magnitudes

One-handed forces vary considerably among studies with similar variables and within individual studies depending on test conditions or variables. Generalizations about recommended forces, therefore, are not easy to make. Average static standing-pull forces have ranged from 70 to 134 N and sitting forces from 350 to 540 N. Dynamic pull forces, in almost all studies, have ranged from 170 to 380 N in females and from 335 to 673 N in males when sitting. Average pull forces in males while lying down prone have ranged from 270 to 383 N and push forces from 285 to 330 N (Hunsicker and Greey 1957).

3.4.4. Pinch–Pull Force Magnitudes

Pinching and pulling with one hand while stabilizing the object with the other hand has been observed in male adults to yield forces of 100, 68, and 50 N when using the lateral, chuck, and pulp pinches, respectively (Imrhan and Sundararajan 1992; Imrhan and Alhaery 1994).

4. STATIC EFFORTS AND FATIGUE

4.1. Design Limits for Static Work

Static efforts at work are often fatiguing and cannot be sustained over a long period of time (Rohmert 1960; Monod and Scherrer 1965; Pottier et al. 1969 and Monod 1972). Figure 7 illustrates the relationship between a percentage of the maximum voluntary contraction used and the time duration. This relationship has been determined for arm, leg, and trunk muscles by Rohmert (1960), for an upperlimb pulling action by Caldwell and Smith (1963), and for biceps brachii, triceps brachii, the middle finger flexor, and quadriceps femoris by Monod and Scherrer (1965). The results of these

three studies indicate that the limit time approaches infinity at a force of 8–10% maximum voluntary contraction and converges to zero at 100% of the maximum strength.

As discussed by Kahn and Monod (1989), the maximum duration of static effort or the maximum maintenance time (limit time) varies inversely with the applied force and may be sustained for a long time if the force does not exceed 15–20% of the maximum voluntary contraction (MVC) of the muscle considered. The relation between force and limit time has been defined by Monod (1965) as:

$$t = \frac{k}{(F - f)^n}$$

where t is the limit time (min), F the relative force used (%), f the force (%) for which t tends to infinity (called the critical force), and k and n are constants. Rohmert (1960) subsequently proposed a more elaborate equation:

$$t = -1.5 + \left(\frac{2.1}{F}\right) - \left(\frac{0.6}{F^2}\right) + \left(\frac{0.1}{F^3}\right)$$

In both cases the maximum maintenance time is linked to the force developed by a hyperbolic relation, which applies to all muscles.

4.2. Intermittent Static Work

In the case of intermittent static efforts during which the contraction phases are separated by rest periods of variable absolute and relative duration, the maximum work time, given the relative force used and the relative duration of contraction, can be predicted as follows (Rohmert 1973):

TABLE 11 Maximum Acceptable Forces of Pull for Males (kg)

From Snook and Ciriello (1991). Used with permission by Taylor & Francis Ltd., London, http://www.tandf.co.uk.
Height = vertical distance from floor to hand–object (handle) contact
Percent = percentage of industrial workers capable of exerting the stated forces in work situations.

$$t = \frac{k}{(F - f)^{np}}$$

where p is the static contraction time as a percentage of the total time. Rohmert (1962) had devised another method for estimating the minimum duration of rest periods required to avoid fatigue during intermittent static work:

$$t_r = 18\left(\frac{t}{t_{\max}}\right)^{1.4} \times \left(\frac{F}{F_{\max}} - 0.15\right) \times 100\%$$

where t_r is the rest time as a percentage of t, which is the duration of contraction (min). Kahn and Monod (1989) concluded that the main causal factor in the onset of fatigue due to static efforts (isometrically contracting muscles) is local muscle ischemia. Furthermore, the onset of local muscle fatigue can be delayed if changes in recovery time are sufficient to allow restoration of normal blood flow through the muscle.

4.3. Static Efforts of the Arm

As of this writing, only limited guidelines regarding the placement of objects that must be manipulated by the arm have been proposed (Chaffin et al. 1999). Figure 8 depicts the effect of horizontal reach on shoulder muscle fatigue endurance times. This figure illustrates that the workplace must be designed to allow for the upper arm to be held close to the torso. In general, any load-holding tasks should be minimized by the use of fixtures and tool supports. Strasser et al. (1989) showed experimentally that the local muscular strain of the hand–arm–shoulder system is dependent upon the direction of horizontal arm movements. Such strain, dependent on the direction of repetitive manual movements, is of great importance for workplace layout. The authors based their study on the premise

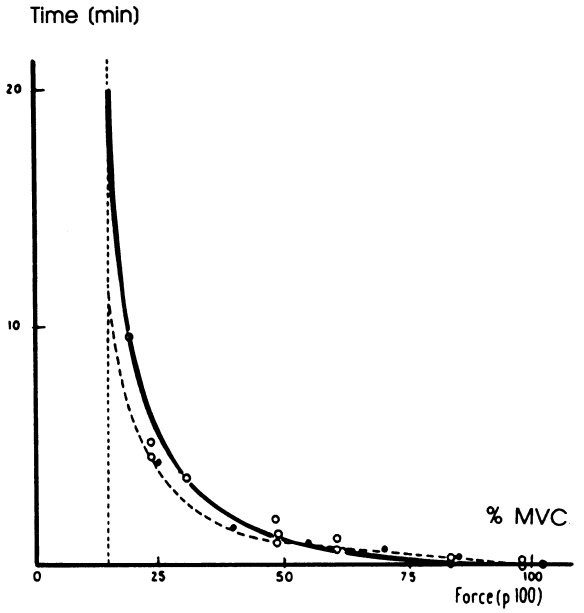

Figure 7 Isometric Muscle Endurance Time as a Function of Percentage of Muscle Strength. (Reproduced with permission from Kahn and Monod, copyright © by Taylor & Francis, http://www.tandf.co.uk 1989.)

that in order to avoid unnecessary strain imposed by unfavorable postures and working directions in repetitive material-handling tasks, patterns of static and dynamic musculoskeletal loads need to be determined. Figure 9 shows the results of this normalization procedure applied to the experimental data. The static components of the EA values within an angle range between 110° and 200° are also

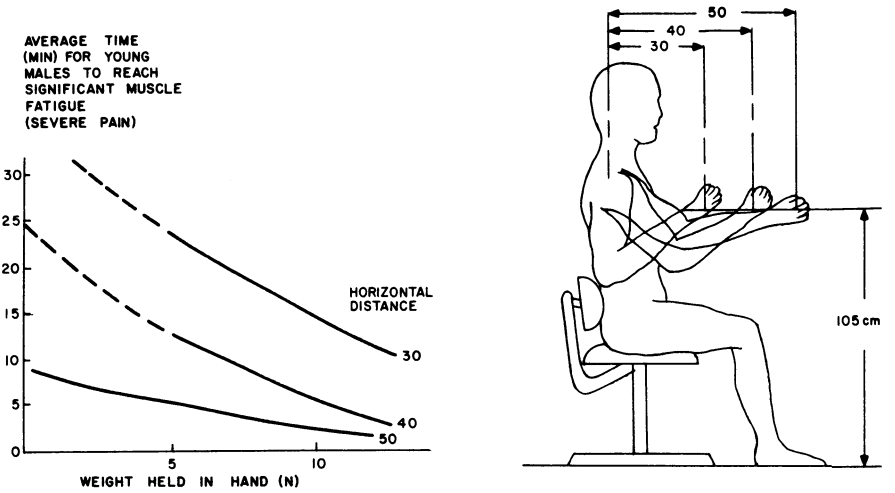

Figure 8 Endurance Time of Shoulder Muscles at Different Arm Reach Postures. (Adapted from Chaffin et al., *Occupational Biomechanics,* 3rd Ed. Copyright © 1999. Reprinted by permission of John Wiley & Sons, Inc., New York.)

significantly higher than those of 20°, 30°, 40°, 60°, and 230°. With regard to the musculature of the shoulder region represented by two recordings of the trapezius (right part of Figure 9), an essentially lower dependence of the muscular strain on the direction of the repetitive horizontal arm movements was observed.

5. WORKPLACE ANALYSIS AND DESIGN

5.1. Evaluation of Working Postures

The posture of the human body at work is influenced by several factors, including workstation layout (heights of the workplace, orientation of tools and work objects), hand tool design, work methods and work habits, visual control and force exertion requirements, and anthropometric characteristics of the workers (Chaffin et al. 1999; Grandjean 1980; Habes and Putz-Anderson, 1985; Corlett et al. 1986; Kilbom et al. 1986; Keyserling 1986; Wallace and Buckle 1987). Poor and unnatural (i.e., not-neutral) working postures have been associated with the onset of fatigue, bodily discomforts and pains, and musculoskeletal disorders (Tichauer 1978; Karhu et al. 1977; and Keyserling et al. 1988). Keyserling (1990) discusses the scientific evidence of such associations. For example, it was shown that trunk flexion, lateral bending, or twisting increases muscle stress and intervetrabral disc pressure, while prolonged sitting or forward bending leads to increased risk of low back pain and muscle fatigue (Chaffin 1973; Schultz et al. 1982; Kelsey and Hochberg 1988). Prolonged elevation of the arms may cause tendonitis (Hagberg 1984), while shoulder extension and elevation may lead to thoracic outlet syndrome (Armstrong 1986). Also, strong association was found between poor neck posture and cervicobrachial disorders (Jonsson et al. 1988).

5.2. Computer-Aided Analysis of Working Postures

Ergonomics provides useful guidelines for evaluation of working postures, especially with respect to identification and quantification of postural stresses and their relation to posture-related work injury. The ultimate goal of such analysis is to improve the workplace design by reducing postural stresses imposed upon the body to the acceptable (safe) levels. Some of the methods used in the past to systematically evaluate work postures by using computerized or semicomputerized techniques are reported by Karhu et al. (1977); Corlett et al. (1979); Holzmann (1982); Keyserling (1986); Pearcy et al. (1987); and Wangenheim and Samuelson (1987). Snijders et al. (1987) introduced devices for measurement of forward bending, lateral bending, and torsion continuously. Ferguson et al. (1992) used a lumbar motion monitor to measure the back motion during asymmetric lifting tasks. The Ovako Working Posture Analysis System (OWAS), which uses predefined standard postures, was first reported by Karhu et al. (1977). The posture targeting technique (1988) and RULA (1996), developed by Corlett et al. (1979), are based on the recording of the positions of the head, trunk, and upper and lower arms.

5.3. Postural Analysis Systems

5.3.1. OWAS

OWAS (the Ovako Working Posture Analyzing System), first reported by Karhu et al. (1977), identifies the most common work postures for the back, arms, and legs and estimates the weight of the loads handled or the extent of the strength (effort). A rating system categorizes 72 different postures in terms of discomfort caused and the effect on health. Back postures are defined as either straight, bent, straight and twisted, or bent and twisted. No specificity (in terms of number of degrees) is provided. This categorization results in the specification of four action categories. The observed posture combinations are classified according to the OWAS method into ordinal scale action categories. The four action categories described here are based on experts' estimates on the health hazards of each work posture or posture combination in the OWAS method on the musculoskeletal system:

1. Work postures are considered usually with no particular harmful effect on the musculoskeletal system. No actions are needed to change work postures.
2. Work postures have some harmful effect on the musculoskeletal system. Light stress, no immediate action is necessary, but changes should be considered in future planning.
3. Work postures have a distinctly harmful effect on the musculoskeletal system. The working methods involved should be changed as soon as possible.
4. Work postures have an extremely harmful effect on the musculoskeletal system. Immediate solutions should be found to reduce these postures.

OWASCA, a computer-aided visualizing and training software for work posture analysis, was developed using OWAS. OWASCA is intended as OWAS training software (Vayrynen et al. 1990).

The system is also suitable for visualizing the work postures and for the basic analysis of the postures and their loads. The posture is presented with parametric vector using 2D graphics, OWAS codes, and texts. The posture of the back, arms and legs, posture combination, force or effort used, additional postures, and action categories can be studied interactively step by step. The required OWAS skills can be tested by OWASCA. The program shows a random work posture, and the user is asked to identify it. OWASCA describes the errors and gives the numbers of test postures and correct answers (Mattila et al. 1993).

5.3.2. Standard Posture Model

A standard system for analyzing and describing postures of the trunk, neck, shoulders, and lower extremities during dynamic work was developed at the University of Michigan (Keyserling 1990) (see Figure 10). Neutral joint postures and their deviations were also defined (Table 12). The postural

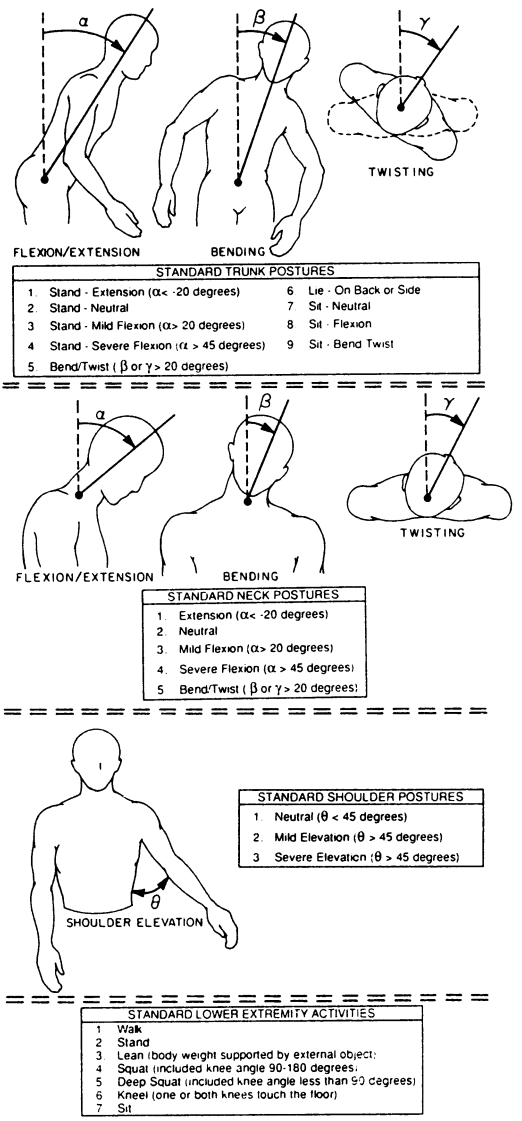

Figure 10 Illustration of Standard Posture Categories. (Reproduced with permission from Keyserling, copyright © by Taylor & Francis, 1990.)

TABLE 12 Classification of Working Postures That Deviate from Neutral

Body Segment	Neutral Posture	Deviated Posture Description
Trunk	Vertical with no axial twisting	Extended (bent backward more than 20°)
		Mildly flexed (bent forward between 20 and 40°)
		Severely flexed (bent forward more than 45°)
		Bent sideways or twisted more than 20° from the neutral position
Neck		Extended (bent backward more than 20°)
		Mildly flexed (bent forward between 20 and 45°)
		Severely flexed (bent forward more than 90°)
		Bent sideways or twisted more than 20°
Shoulder		Neutral (included angle less than 45°)
		Mild elevation (included angle between 45 and 90°)
		Severe elevation (included angle more than 45°)
Lower extremities	(standard postures)	Walk (locomotion while maintaining an upright posture)
		Stand (free standing with no support other than the feet)
		Lean (weight partially supported by an external object such as a wall or railing)
		Squat (knees bent with the included angle between thigh and calf 90–180°)
		Deep squat (included angle between thigh and calf less than 90°)
		Kneel (one or both knees contact the floor and support part of the body weight)
		Sit (body weight primarily supported by the ischial tuberosities)

Adapted from Keyserling 1990.

analysis involves three steps. First, a continuous video recording of the job is obtained. Second, a sequential description of the major tasks required to perform the job is done in a laboratory, with the job being broken into fundamental work elements and their times measured. The third and final step involves collection of the postural data using the common time scale developed from the fundamental work elements. Postural changes are keyed into the system through the preassigned keys corresponding to specific postures. The value of each posture and the time of postural change for a given joint are recorded and stored in a computer. Based on the above data, the system generates a posture profile for each joint, consisting of the total time spent on each standard posture during the work cycle, the range of times spent in each standard posture, the frequency of posture use, and so on. The system can also provide a graph showing postural changes over time for any of the body joints (segments) of interest.

5.4. Acceptability of Working Postures

Analysis of posture must take into consideration not only the spatial elements of the posture, that is, how much is the person flexed, laterally bent, or rotated (twisted), but how long these postures are maintained. Milner et al. (1986) pointed out where an individual is working to the limits of endurance capacity, it has been found that full recovery is not possible within a rest period 12 times the maximum holding time. Full recovery is possible as long as the holding time is a small percentage of maximum handling time.

Bonney et al. (1990) studied tolerability of certain postures and showed that complex postures requiring movement in more than one direction are more uncomfortable than simple postures. Lateral bending produced more discomfort than either flexed or rotated postures and appears to be the least well-tolerated posture. Rotation by itself does not cause significant discomfort. This finding is consistent with epidemiological results of Kelsey and Golden (1988), who hypothesized that twisting along may not produce enough stress to bring about a detectable increase in risk.

Corlett and Manenica (1980) derived estimates for maximum handling times for various postures when performing a no-load task. These recommendations are as follows:

1. Slightly bent forward postures (approx. 15–20°) = 8 min
2. Moderately bent forward posture (approx. 20–60 °) = 3–4 min
3. Severely bent forward postures (greater than about 60°) = approx. 2 min

Colombini et al. (1985) presented criteria on which posture assessments should be based. Postures considered tolerable include (1) those that do not involve feelings of short-term discomfort and (2) those that do not cause long-term morpho-functional complaints. Short-term discomfort is basically the presence of a feeling of fatigue and/or pain affecting any section of the asteo-arthromuscular and ligamentous apparatus appearing in periods lasting minutes, hours, or days.

Miedema et al. (1997) derived the maximum holding times (MHT) of 19 standing postures in terms of percent of shoulder height and percent of arm reach. They also classified such working postures into three categories, depending on the mean value of the MHT: (1) comfortable; (2) moderate; and (3) uncomfortable postures (see Table 13).

Recently, Kee and Karwowski (2001) presented data for the joint angles of isocomfort (JAI) for the whole body in sitting and standing postures, based on perceived joint comfort measures. The JAI value was defined as a boundary indicating joint deviation from neutral (0°), within which the perceived comfort for different body joints is expected to be the same. The JAI values were derived for nine verbal categories of joint comfort using the regression equations representing the relationships between different levels of joint deviation and corresponding comfort scores for each joint motion. The joint angles with marginal comfort levels for most motions around the wrist, elbow, neck, and ankle were similar to the maximum range-of-motion (ROM) values for these joints. However, the isocomfort joint angles with the marginal comfort category for the back and hip motions were much smaller than the maximum ROM values for these joints.

There were no significant differences in percentage of JAI in terms of the corresponding maximum ROM values between standing and sitting postures. The relative marginal comfort index, defined as the ratio between joint angles for marginal comfort and the corresponding maximum ROM values, for hip was the smallest among all joints. This was followed in increasing order of the index for lower back and for shoulder, while the index values for elbow were the largest. This means that hip motions are less comfortable than any other joint motion, while elbow motions are the most comfortable. The relative good comfort index exhibited much smaller values of joint deviation, with most

TABLE 13 MHT and Postural Load Index for the 18 Postures[a]

Posture Categories	MHT (min)	Postural Load Index
Comfortable postures (MHT > 10 min)		
SH/AR = 75/50	37.0	3
75/25	18.0	3
100/50	17.0	3
50/25	14.0	0
125/50	12.0	8
50/50	12.0	0
Moderate postures (5 min ≤ MHT ≤ 10 min)		
100/25	10.0	7
100/100	9.0	5
75/100	9.0	4
125/100	8.0	8
75/75	6.0	12
50/100	6.0	10
100/75	5.5	8
50/75	5.3	5
Uncomfortable postures (MHT < 5 min)		
25/25	5.0	10
25/50	4.0	10
150/50	3.5	13
25/75	3.3	10
25/100	3.0	13

[a]Posture was defined after Miedema et al. 1997 in terms of % of shoulder height (SH)/% of arm reach (AR).

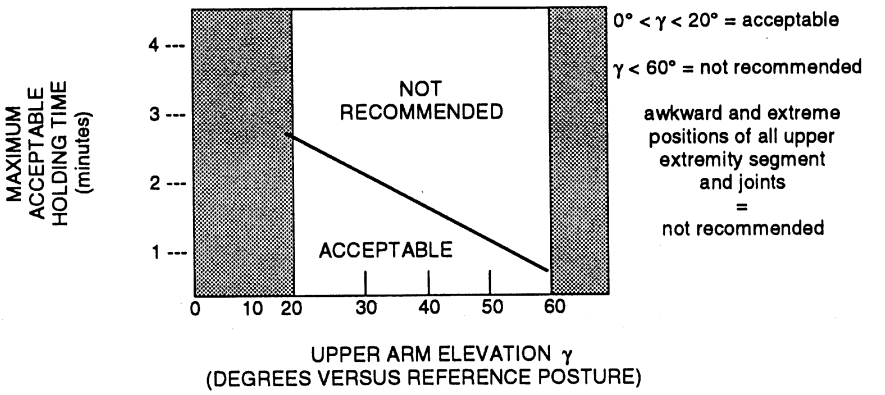
The holding time for upper arm elevation can beevaluated as follows.

HOLDING TIME	ACCEPTABLE	NOT RECOMMENDED
> maximum acceptable holding time* ≤ maximum acceptable holding time*	X	X

- Refer to diagram shown below.

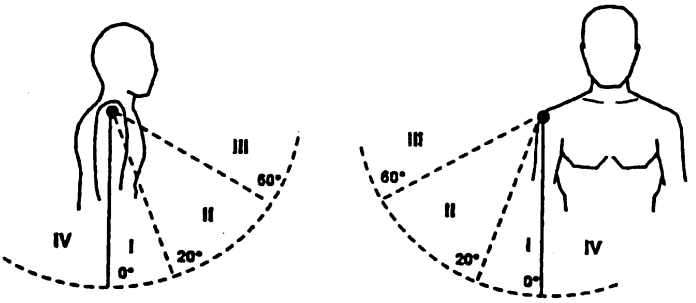


Note: An adequate recovery time should be provided following the holding time for a certain upper arm elevation.

Figure 11 Evaluation of Working Postures (ISO/DIS 11226, 1998).

UPPER ARM ELEVATION

STEP 1 – refer to figure and table below



Upper arm elevation

Evaluation of upper arm elevation

	Static posture	Movement	
		low frequency (<2/minute)	high frequency (≥2/minute)
I*	acceptable	ACCEPTABLE	acceptable
II	conditonally acceptable (step 2A)	acceptable	conditionally acceptable (step 2C)
III	not acceptable	conditionally acceptable (step 2B)	not acceptable
IV	not acceptable	conditionally acceptable (step 2B)	not acceptable

Static posture and high frequency movements (≥ 2 / minute), awkward and extreme positions of all upper extremity segments and joints
=
not acceptable

* It is recommended to strive for working postures with the upper arms hanging down.

STEP 2:
a) acceptable if there is full arm support; if there in so full arm support, acceptability depends on duration of the posture and period of recovery;
b) not acceptable if the machine may be used for long durations;
c) not acceptable if frequency ≥10 / minute and/or if the machine may be used for long durations.

Figure 12 Evaluation of Working Postures in Relation to Machinery (CEN prEN 1005—4, 1997): Upper arm elevation.

index values of less than 40.0. The presented data about joint angles of isocomfort can be used as design guidelines for postural comfort in a variety of human–machine systems.

5.5. International Standards

A list of international standards in the area of anthropometry and biomechanics being developed by ISO is shown in Table 14.

5.5.1. Exposure Assessment of Upper-Limb Repetitive Movements

Recently, Colombini et al. (1999) reported the findings of an international expert group working under auspices of the Technical Committee on Musculoskeletal Disorders of the International Ergonomics Association (IEA) and endorsed by the International Commission on Occupational Health (ICOH). This report provides a set of definitions, criteria, and procedures for assessment of working

conditions with respect to exposure of the upper extremities. The document includes two important international standards: Evaluation of Working Postures (ISO/DIS 11226 1998), presented in Figure 11, and Evaluation of Working Postures in Relation to Machinery (CEN prEN 1005—4, 1997): Upper arm elevation, shown in Figure 12.

5.5.2. European Standards for Working Postures During Machinery Operation

The draft proposal of the European (CEN/TC122, WG4/SG5) and the international (ISO TC159/SC3/WG2) standardization document (1993) ''Safety of machinery—human physical performance, Part 4: Working postures during machinery operation,'' specifies criteria of acceptability of working postures vs. exposure times. These criteria are discussed below.

5.5.2.1. General Design Principles Work task and operation should be designed with sufficient physical and mental variation so that the physical load is distributed over various postures and patterns of movements. Designs should accommodate the full range of possible users. To evaluate whether working postures during machinery operation are acceptable, designers should perform a risk assessment, that is, an evaluation of the actual low-varying (static) postures of body segments. The lowest maximum acceptable holding time for the various body segment postures should be determined.

5.5.2.2. Assessment of Trunk Posture An asymmetric trunk posture should be avoided (no trunk axial rotation or trunk lateral flexion). Absence of normal lumbar spine lordosis should be avoided. If the trunk is inclined backward, full support of the lower and upper back should be provided. The forward trunk inclination should be less than 60°, on the condition that the holding time be less than the maximum acceptable holding time for the actual forward trunk inclination, as well as that adequate rest is provided after action (muscle fitness should not be below 80%).

5.5.2.3. Assessment of Head Posture An asymmetric head posture should be avoided (no axial rotation or lateral flexion of the head with respect to the trunk). The head inclination should not be less than trunk inclination (no neck extension). The head inclination should not be larger than the trunk inclination for more than 25° (no extreme neck flexion). If the head is inclined backward, full head support should be provided. The forward head inclination should be less than 25° (if full trunk support is provided), forward inclination should be between less than 85°, on the condition that the holding time should be less than the maximum acceptable holding time for the actual forward head inclination as well as that adequate rest is provided.

5.5.2.4. Assessment of Upper Extremity Posture *Shoulder and upper arm posture.* Upper arm retroflexion and upper-arm adduction should be avoided. Raising the shoulder should be avoided. The upper-arm elevation should be less than 60°, on the condition that the holding time be less than the maximum acceptable holding time for the actual upper-arm elevation as well as that adequate rest be provided after action (muscle fitness should not be below 80%).

Forearm and hand posture. Extreme elbow flexion or extension, extreme forearm pronation or supination, and extreme wrist flexion or extension should be avoided. The hand should be in line with the forearm (no ulnar/radial deviation of the wrist).

6. OCCUPATIONAL BIOMECHANICS

6.1. Definitions

As reviewed by Karwowski (1992), occupational biomechanics is a ''study of the physical interaction of workers with their tools, machines and materials so as to enhance the worker's performance while minimizing the risk of future musculoskeletal disorders'' (Chaffin et al. 1999). There are six methodological areas, or contributing disciplines, important to the development of current knowledge in biomechanics:

1. Kinesiology, or study of human movement, which includes kinematics and kinetics
2. Biomechanical modeling methods, which refer to the forces acting on the human body while a worker is performing well-defined and rather common manual task
3. Mechanical work-capacity evaluation methods in relation to physical capacity of the worker and job demands
4. Bioinstrumentation methods (performance data acquisition and analysis)
5. Classification and time-prediction methods that allow for detailed time analysis of the human work activities and implementation of biomechanics principles to fit the workplace to the worker

6.2. Principles of Mechanics

Biomechanics considers safety and health implications of mechanics, or the study of the action of forces, for the human body (its anatomical and physiological properties) in motion (at work) and at rest. Mechanics, which is based on Newtonian physics, consists of two main areas: statics or the study of the human body at rest or in equilibrium, and dynamics or the study of the human body in motion. Dynamics is further subdivided into two main parts, kinematics and kinetics. Kinematics is concerned with the geometry of motion, including the relationships among displacements, velocities, and accelerations in both translational and rotational movements, without regard to the forces involved. Kinetics, on the other hand, is concerned with forces that act to produce the movements.

The types of forces acting on the human body at any given time are gravitational forces, external forces and ground reaction forces, and muscle forces (Winter 1979). Gravitational forces act downward, through the center of mass of body segments. The external forces are due to the body segment weights and external workload. The forces generated by the muscles are usually expressed as net muscle moments acting upon given joints. It should be noted that body (segment) weight is a (gravitational) force, while body mass is a measure of inertia.

6.3. Biomechanical Analysis

6.3.1. Static Analysis

Static analysis requires consideration of forces and moments of force acting on the body at rest (static equilibrium). A magnitude of the moment of force at the point of rotation is equal to the product of force and the perpendicular distance from the force action line to that point. The moment **(M)** equals force **(F)** times moment arm **(d)**, with unit of measurement (N·m). The static analysis ignores the effects of accelerations, momentum, and friction and is adequate only for analysis of static postures.

The body will be in a static equilibrium state when at rest or dynamic equilibrium when in motion with constant velocity. The translational equilibrium (first condition) of the body (segment) is present when the vector sum of all the forces acting on a body simultaneously is zero ($\Sigma F = 0$). The rotational equilibrium (second condition) of the body is present when the sum of moments about joint is zero ($\Sigma M = 0$). In other words, for the body to be at rest (zero velocity), the sum of all clockwise moments must be equal to the sum of all counterclockwise moments.

6.3.2. Lever Systems

Skeletal muscles of the human body produce movements of the bones about the joints by pulling at their anatomical attachments on the bones across the joints in order to counteract the external forces. This is possible due to three types of lever systems, composed of bones that serve as levers and joints that serve as points of pivot or fulcrums. The lever system consists of an effort force and the resistance force acting at different locations and distances with respect to the fulcrum. The force arm

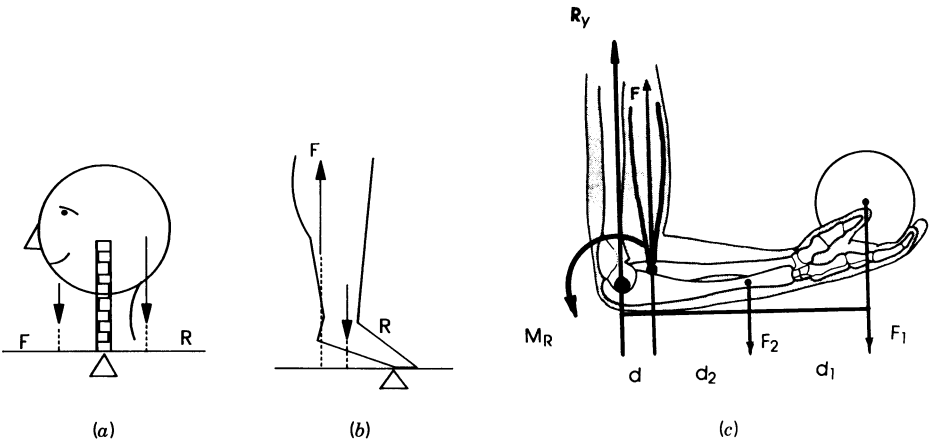


Figure 13 (a) Example of the first-class lever system. (b) Example of the second-class lever system. (c) Example of the third-class lever system and single-segment static analysis. (Adapted from Troup and Edwards, reproduced with permission of the Controller of Her Majesty's Stationery Office)

and the resistance arm are defined as the distance from the fulcrum to the effort force or resistance force, respectively. Mechanical advantage (MA) of the lever system is defined as the ratio between the force arm distance (df) and the resistance arm distance (dr) where MA = df/dr.

In the first class of lever systems, the fulcrum is located between the effort and resistance. Examples include the triceps muscle action of the ulna when the arm is abducted and held over the head, and the splenium muscles, acting to extend the head across the atlanto-occipital joints (Williams and Lissner 1977). The second class of lever systems is one where resistance is located between the fulcrum and the effort, providing for mechanical advantage greater than one. An example of such a lever system is the distribution of forces in the lower leg when raising one's heel off the ground (see Figure 13). In the third class of lever systems, the effort is located between the fulcrum and the resistance, and consequently the mechanical advantage is always less than one, that is, to balance the resistance, the magnitude of effort must be greater than the magnitude of resistance. Many bone lever systems in the human body, for example, the system involved in forearm flexion as illustrated in Figure 13(c), are third-class systems.

7. DESIGN OF MANUAL MATERIALS HANDLING TASKS

7.1. Epidemiology of Low-Back Disorders

As reviewed by Ayoub et al. (1997), manual materials-handling (MMH) tasks, which include unaided lifting, lowering, carrying, pushing, pulling, and holding activities, are the principal source of compensable work injuries affecting primarily the low back in the United States (NIOSH 1981; National Academy of Sciences 1985; *Federal Register* 1986; Bigos et al. 1986; Battié et al. 1990). These include a large number of low-back disorders (LBDs) that are due to either cumulative exposure to manual handling of loads over a long period of time or to isolated incidents of overexertion when handling heavy objects (BNA 1988; National Safety Council 1989; Videman et al. 1990). Overexertion injuries in 1985 for the United States accounted for 32.7% of all accidents: lifting objects (15.1%), carrying, holding, etc. (7.8%), and pulling or pushing objects (3.9%). For the period of 1985–1987, back injuries accounted for 22% of all cases and 32% of the compensation costs.

In the United States, about 28.2% of all work injuries involving disability are caused by overexertion, lifting, throwing, folding, carrying, pushing, or pulling loads that weigh less than 50 lb (National Safety Council 1989). The analysis by industry division showed that the highest percent of such injuries occurred in service industries (31.9%), followed by manufacturing (29.4%), transportation and public utility (28.8%), and trade (28.4%). The total time lost due to disabling work injuries was 75 million workdays, while 35 million days were lost due to other accidents. The total work accident cost was $47.1 billion; the average cost per disabling injury was $16,800. Spengler et al. (1986) reported that while low-back injuries comprised only 19% of all injuries incurred by the workers in one of the largest U.S. aircraft companies, they were responsible for 41% of the total injury costs. It is estimated that the economic impact of back injuries in the United States may be as high as 20 billion annually, with compensation costs exceeding $6 billion per year (BNA 1988).

Major components of the MMH system, related risk factors for low-back pain (LBP), and LBDs include worker characteristics, material/container characteristics, task/workplace characteristics, and work practice characteristics (Karwowski et al. 1997). A wide spectrum of work- and individual-related risk factors have been associated with the LBP and LBDs (Riihimäki 1991). However, the precise knowledge about the extent to which these factors are etiologic and the extent to which they are symptom precipitating or symptom aggravating is still limited. Kelsey and Golden (1988) reported that the risk of lumbar disk prolapse for workers who lift more than 11.3 kg (25 lb) more than 25 times a day is over three times greater than for workers who lift lower weights. The OSHA (1982) study also revealed very important information regarding workers perception of the weights lifted at the time of injury. Among the items perceived by the workers as factors contributing to their injuries were lifting too-heavy objects (reported by 36% of the workers) and underestimation of weight of objects before lifting (reported by 14% of the workers).

An important review of epidemiological studies on risk factors of LBP using five comprehensive publications on LBP was made by Hildebrant (1987). A total of 24 work-related factors were found that were regarded by at least one of the reviewed sources as risk indicators of LBP. These risk factors include the following categories:

1. *General:* heavy physical work, work postures in general
2. *Static workload:* static work postures in general, prolonged sitting, standing or stooping, reaching, no variation in work posture
3. *Dynamic workload:* heavy manual handling, lifting (heavy or frequent, unexpected heavy, infrequent, torque), carrying, forward flexion of trunk, rotation of trunk, pushing/pulling
4. *Work environment:* vibration, jolt, slipping/falling
5. *Work content:* monotony, repetitive work, work dissatisfaction

Many of the cross-sectional studies have shown that LBP is related to heavy manual work (Riihimäki 1991). MMH activities, including those that involve sudden body motions, have been associated with LBP (Svensson and Andersson 1983; Frymoyer et al. 1983, Hansson 1989; Bigos et al. 1991). Among the office workers, LBP was most commonly attributed to lifting tasks (Lloyd et al. 1986). An increased risk of herniated disc was also reported in jobs involving heavy lifting combined with body twisting and forward bending (Kelsey et al. 1984). Manual lifting tasks are often associated with adopting nonneutral trunk postures, which also have been related to LBP (Frymoyer et al. 1980; Maeda et al. 1980; Keyserling et al. 1988; Riihimäki et al 1989).

In addition to physical factors, several studies identified a variety of psychological and psychosocial risk factors of LBP that are related to work environment (Damkot et al. 1984; Magora 1973; Svensson and Andersson 1983, 1989; Bigos et al. 1991). However, as pointed out by Riihimäki (1991), since most of the studies have been retrospective in nature, it is difficult to determine whether these factors are antecedents or consequences of back pain (Kelsey et al. 1988), and whether these factors play a role in the etiology of LBDs or only affect the perception of symptoms and sickness behavior.

7.2. MMH Capacity Design Criteria

Workers who perform heavy physical work are subjected not only to forces and stresses from the immediate physical environment but also to mechanical forces generated from within the body. As a result of these forces and stresses, a strain is produced on the worker's musculoskeletal system as well as on other systems such as the cardiopulmonary system. One of the most important issues in the application of ergonomics to work design is to reduce the stresses imposed on the musculoskeletal and cardiopulmonary systems (Ayoub and Mital 1989). Several approaches have been used by different investigators to establish safe handling limits, including the psychophysical approach, the physiological approach, and the biomechanical approach.

7.3. The Psychophysical Approach

The psychophysical approach relies on the worker's perceived exertion to quantify his or her tolerance level, thereby establishing the maximum acceptable weights or forces (MAW/F) for different MMH activities (e.g., maximum acceptable weight of lift [MAWL]). Psychophysics deals with the relationship between human sensation and their physical stimuli. Borg (1962) and Eisler (1962) found that the perception of both muscular effort and force obey the psychophysical function, where sensation magnitude (S) grows as a power function of the stimulus (I). Stevens (1975) reported the relationship between the strength of the sensation (S) and the intensity of its physical stimulus (I) by the power function:

$$S = k \times I^n$$

where: S = strength of sensation
I = intensity of physical stimulus
k = constant
n = slope of the line, which represents the power function when plotted on log–log coordinates

The use of psychophysics in the study of MMH tasks requires the worker to adjust the weight, force, or frequency in a handling situation until they feel it represents their MAW/F (Asfour et al. 1984; Gamberale and Kilböm 1988; Garg and Banagg 1988; Legg and Myles 1985; Mital et al. 1989; Snook and Ciriello 1991). Psychophysical limits usually refer to weights or forces (MAW/F), although maximum acceptable frequencies have also been established (e.g., Nicholson and Legg 1986; Snook and Ciriello 1991). Despite the relative simplicity of the psychophysical method to determine acceptable limits for manual lifting, which makes this approach quite popular (Karwowski et al 1999), caution should be exercised with respect to interpretation and usability of the currently available design limits and databases.

7.4. MMH Design Databases

One can use already available databases such as the one reported by Snook and Ciriello (1991). Another database was reported by Mital (1992) for symmetrical and asymmetrical lifting, and other databases include work by Ayoub et al. (1978) and Mital (1984). Using such available data replaces conducting a study for every work task and group of workers. Tables provided by the various investigators can be used to estimate the MAW/F for a range of job conditions and work populations. The databases provided in tabular format often make allowances for certain task, workplace, and/or worker characteristics. The use of databases begins with the determination of the various characteristics with which the database is stratified.

7.5. Psychophysical Models

Another method to estimate MAW/F is regression models based on the psychophysical data. Most of these models predict MAWL. The design data presented here are based upon the database of Snook and Ciriello (1991). Table 15 provides Snook and Ciriello's (1991) two-handed lifting data for males and females, as modified by Mital et al. (1993). Those values that were modified have been identified. The data in these tables were modified so that a job severity index value of 1.5 is not exceeded, which corresponds to 27.24 kg. Likewise, a spinal compression value that, on average, provides a margin of safety for the back of 30% was used for the biomechanical criterion, yielding a maximum load of 27.24 for males and 20 kg for females. Finally, the physiological criterion of energy expenditure was used. The limits selected were 4 kcal/min for males and 3 kcal/min for females for an 8-hr working day (Mital et al. 1993). The design data for maximal acceptable weights for two-handed pushing/pulling tasks, maximal acceptable weights for carrying tasks, and maximal acceptable holding times can be found in Snook and Ciriello (1991) and Mital et al. (1993). The maximal acceptable weights for manual handling in unusual postures are presented by Smith et al. (1992).

7.6. The Physiological Approach

The physiological approach is concerned with the physiological response of the body to MMH tasks. During the performance of work, physiological changes take place within the body. Changes in work methods, performance level, or certain environmental factors are usually reflected in the stress levels of the worker and may be evaluated by physiological methods. The basis of the physiological approach to risk assessment is the comparison of the physiological responses of the body to the stress of performing a task with levels of permissible physiological limits. Many physiological studies of MMH tended to concentrate on whole body indicators of fatigue such as heart rate, energy expenditure, blood lactate, or oxygen consumption as a result of the workload. Mital et al. (1993) arrived at the same conclusion as Petrofsky and Lind, that is, that the physiological criteria for lifting activities for males should be approximately 4 kcal/min and 3 kcal/min for females.

The energy cost of manual handling activities can be estimated based on the physiological response of the body to the load, that is, by modeling the physiological cost using work and worker characteristics. The estimates obtained from such models are then compared to the literature recommendations of permissible limits. Garg et al. (1978) report metabolic cost models. Although currently in need of update, they still provide a more comprehensive and flexible set of physiological cost models as a function of the task variables. The basic form of the Garg et al. model is:

$$E_{\text{job}} = \left(\sum_{i=1}^{N_p} (\text{E}_{\text{post-}i} \times T_i) + \sum_{i=1}^{N_t} \text{E}_{\text{task-}i} \right) \div T$$

where: E_{job} = average energy expenditure rate of the job (kcal/min)
$E_{\text{post-}i}$ = metabolic energy expenditure rate due to maintenance of ith posture (kcal/min)
T_i = time duration of ith posture (min)
N_p = total number of body postures employed in the job
$E_{\text{task-}i}$ = net metabolic energy expenditure of the ith task in steady state (kcal)
N_t = total number of tasks in the given job
T = time duration of the job (min)

Different models require different input data, but typically most of these models involve input information regarding task type, load weight/force, load size, height, frequency, and worker characteristics, which include body weight and gender.

7.7. The Biomechanical Approach

The biomechanical approach focuses on the establishment of tissue tolerance limits of the body, especially the spine (e.g., compressive and shear force limits tolerated by the lumbar spine). The levels of stresses imposed on the body are compared to permissible levels of biomechanical stresses, measured by, for example, peak joint moments, peak compressive force on the lumbar spine, and peak shear forces on the lumbar spine. Other measures include mechanical energy, average and integrated moments or forces over the lifting, and MMH activity times (Andersson 1985; Gagnon and Smyth 1990; Kumar 1990). Methods used to estimate the permissible level of stress in biomechanics for MMH include strength testing, lumbar tissue failure, and the epidemiological relationship between biomechanical stress and injury.

Tissue failure studies are based on cadaver tissue strength. Generally, the research has focused on the ultimate compressive strength of the lumbar spine. Studies and literature reviews by Brinckmann et al. (1989) and Jäger and Luttmann (1991) indicate that the ultimate compressive strength of

Adapted from Mital et al. 1993b.
*Weight limited by biomechanical design criterion (3930 N spinal compression for males, 2689 N for females).
Weight limited by physiological design criterion (4 kcal/min for males, 3 kcal/min for females).
()—Values in parentheses are for females
hr = hours; min. = minute(s)

cadaver lumbar segments varies from approximately 800 N to approximately 13,000 N. Jäger and Luttman (1991) report a mean failure for compression at 5,700 N for males with a standard deviation of 2600 N. For females, this failure limit was found to be 3900 N with a standard deviation of approximately 1500 N. In addition, several factors influence the compressive strength of the spinal column, including age, gender, specimen cross-section, lumbar level, and structure of the disc or vertebral body. The ultimate compressive strength of various components of the spine can be estimated with following regression model (Jäger and Luttman 1991):

$$\text{Compressive strength (kN)} = (7.65 + 1.18\,G) - (0.502 + 0.382\,G)\,A + (0.035 + 0.127\,G)\,C - 0.167\,L - 0.89\,S$$

where: G = gender (0 for female; 1 for male)
A = decades (e.g., 30 years = 3, 60 = 6)
L = lumbar level (0 for L5/S1; incremental values for each lumbar disc or vertebra)
C = cross-section (cm^2)
S = structure (0 for disc; 1 for vertebra)

It should be noted that statically determined tolerances may overestimate compressive tolerances (Jäger and Luttman 1992b). Modeling studies by Potvin et al. (1991) suggest that erector spinae oblique elements could contribute about 500 N sagittal shear to leave only 200 N sagittal shear for discs and facets to counter. According to Farfan (1983), the facet joints are capable of absorbing 3,100 N to 3,600 N while the discs support less than 900 N.

Due to the complexity of dynamic biomechanical models, assessment of the effects of lifting on the musculoskeletal system has most frequently been done with the aid of static models. Many lifting motions, which are dynamic in nature, appear to have substantial inertia components. McGill and Norman (1985) also compared the low-back moments during lifting when determined dynamically and statically. They found that the dynamic model resulted in peak L4/L5 moments 19% higher on the average, with a maximum difference of 52%, than those determined from the static model. Given the complexity of the human body and the simplicity of the biomechanical models, values from these models can only be estimates and are best used for comparison purposes rather than suggesting absolute values (Delleman et al. 1992).

7.8. Revised NIOSH (1991) Lifting Equation

The 1991 revised lifting equation has been expanded beyond the previous guideline and can be applied to a larger percentage of lifting tasks (Waters et al. 1993). The recommended weight limit (RWL) was designed to protect 90% of the mixed (male/female) industrial working population against LBP. The 1991 equation is based on three main components: standard lifting location, load constant, and risk factor multipliers. The standard lifting location (SLL) serves as the 3D reference point for evaluating the parameters defining the worker's lifting posture. The SLL for the 1981 Guide was defined as a vertical height of 75 cm and a horizontal distance of 15 cm with respect to the midpoint between the ankles. The horizontal factor for the SLL was increased from 15 cm to 25 cm displacement for the 1991 equation. This was done in view of recent findings that showed 25 cm as the minimum horizontal distance in lifting that did not interfere with the front of the body. This distance was also found to be used most often by workers (Garg and Badger 1986; Garg 1989).

The load constant (LC) refers to a maximum weight value for the SLL. For the revised equation, the load constant was reduced from 40 kg to 23 kg. The reduction in the load constant was driven in part by the need to increase the 1981 horizontal displacement value from a 15-cm to a 25-cm displacement for the 1991 equation (noted above in item 1). Table 16 shows definitions of the relevant terms utilized by the 1991 equation. The RWL is the product of the load constant and six multipliers:

$$\text{RWL (kg)} = LC \times HM \times VM \times DM \times AM \times FM \times CM$$

The multipliers (M) are defined in terms of the related risk factors, including the horizontal location (HM), vertical location (VM), vertical travel distance (DM), coupling (CM), frequency of lift (FM), and asymmetry angle (AM). The multipliers for frequency and coupling are defined using relevant tables. In addition to lifting frequency, the work duration and vertical distance factors are used to compute the frequency multiplier (see Table 17). Table 18 shows the coupling multiplier (CM), while Table 19 provides information about the coupling classification.

The horizontal location (H) is measured from the midpoint of the line joining the inner ankle bones to a point projected on the floor directly below the midpoint of the hand grasps (i.e., load center). If significant control is required at the destination (i.e., precision placement), then H should be measured at both the origin and destination of the lift. This procedure is required if there is a need to: (1) regrasp the load near the destination of the lift, (2) momentarily hold the object at the

TABLE 16 Terms of the 1991 NIOSH Equation

Multiplier	Formula (cm)
Load constant	LC = 23 kg
Horizontal	HM = 25/H
Vertical	VM = 1 − (0.003 | V −75 |)
Distance	DM = 0.82 + 4.5/D
Asymmetry	AM = 1 − 0.0032 A
Frequency	FM (see Table 147)
Coupling	CM (see Table 148)

H = the horizontal distance of the hands from the midpoint of the ankles, measured at the origin & destination of the lift (cm).
V = the vertical distance of the hands from the floor, measured at the origin and destination of the lift (cm).
D = the vertical travel distance between the origin and destination of the lift (cm).
A = the angle of asymmetry—angular displacement of the load from the sagittal plane, measured at the origin and destination of the lift (degrees).
F = average frequency of lift (lifts/minute).
C = load coupling, the degree to which appropriate handles, devices, or lifting surfaces are present to assist lifting and reduce the possibility of dropping the load.
From Waters et al. 1993. Reprinted with permission by Taylor & Francis Ltd., London, http://www.tandf.co.uk.

destination, or (3) position or guide the load at the destination. If the distance is less than 10 in (25 cm), then *H* should be set to 10 in (25 cm).

The vertical location (*V*) is defined as the vertical height of the hands above the floor and is measured vertically from the floor to the midpoint between the hand grasps, as defined by the large middle knuckle. The vertical location is limited by the floor surface and the upper limit of vertical reach for lifting (i.e., 70 in or 175 cm).

The vertical travel distance variable (*D*) is defined as the vertical travel distance of the hands between the origin and destination of the lift. For lifting tasks, *D* can be computed by subtracting the vertical location (*V*) at the origin of the lift from the corresponding *V* at the destination of the

lift. For lowering tasks, D is equal to V at the origin minus V at the destination. The variable (D) is assumed to be at least 10 in (25 cm) and no greater than 70 in (175 cm). If the vertical travel distance is less than 10 in (25 cm), then D should be set to 10 in (25 cm).

The asymmetry angle A is limited to the range of 0° to 135°. If $A > 135°$, then AM is set equal to zero, which results in a RWL of 0. The asymmetry multiplier (AM) is $1 - (0.0032A)$. The AM has a maximum value of 1.0 when the load is lifted directly in front of the body and a minimum value of 0.57 at 135° of asymmetry.

The frequency multiplier (FM) is defined by (1) the number of lifts per minute (frequency), (2) the amount of time engaged in the lifting activity (duration), and (3) the vertical height of the lift from the floor. Lifting frequency (F) refers to the average number of lifts made per minute, as measured over a 15-min period. Lifting duration is classified into three categories: short duration,

TABLE 19 Coupling Classification

Good coupling

1. For containers of optimal design, such as some boxes, crates, etc., a ''Good'' hand-to-object coupling would be defined as handles or hand-hold cutouts of optimal design
2. For loose parts or irregular objects that are not usually containerized, such as castings, stock, and supply materials, a ''Good'' hand-to-object coupling would be defined as a comfortable grip in which the hand can be easily wrapped around the object.

Fair coupling

1. For containers of optimal design, a ''Fair'' hand-to-object coupling would be defined as handles or hand-hold cut-outs of less than optimal design.
2. For containers of optimal design with no handles or hand-hold cutouts or for loose parts or irregular objects, a ''Fair'' hand-to-object coupling is defined as a grip in which the hand can be flexed about 90°.

Poor coupling

1. Containers of less than optimal design or loose parts or irregular objects that are bulky, hard to handle, or have sharp edges.
2. Lifting nonrigid bags (i.e., bags that sag in the middle).

Notes:

1. An optimal handle design has 0.75–1.5 in (1.9–3.8 cm) diameter, $\geq$ 4.5 in (11.5 cm) length, 2 in (5 cm) clearance, cylindrical shape, and a smooth, nonslip surface.
2. An optimal hand-hold cutout has the following approximate characteristics: $\geq$ 1.5 in (3.8 cm) height, 4.5 in (11.5 cm) length, semioval shape, $\geq$ 2 in (5 cm) clearance, smooth nonslip surface, and $\geq$ 0.25 in (0.60 cm) container thickness (e.g., double-thickness cardboard).
3. An optimal container design has $\leq$ 16 in (40 cm) frontal length, $\geq$ 12 in (30 cm) height, and a smooth nonslip surface.
4. A worker should be capable of clamping the fingers at nearly 90° under the container, such as required when lifting a cardboard box from the floor.
5. A container is considered less than optimal if it has a frontal length $>$ 16 in (40 cm), height $>$ 12 in (30 cm), rough or slippery surfaces, sharp edges, asymmetric center of mass, unstable contents, or requires the use of gloves. A loose object is considered bulky if the load cannot easily be balanced between the hand grasps.
6. A worker should be able to wrap the hand comfortably around the object without causing excessive wrist deviations or awkward postures, and the grip should not require excessive force.

After Waters et al. 1994. Courtesy of the U.S. Department of Health and Human Services.

moderate duration, and long duration. These categories are based on the pattern of continuous work-time and recovery-time (i.e., light work) periods.

A continuous work-time period is defined as a period of uninterrupted work. Recovery time is defined as the duration of light work activity following a period of continuous lifting. Short duration defines lifting tasks that have a work duration of one hour or less, followed by a recovery time equal to 1.2 times the work time. Moderate duration defines lifting tasks that have a duration of more than one hour, but not more than two hours, followed by a recovery period of at least 0.3 times the work time. Long duration defines lifting tasks that have a duration of between two and eight hours, with standard industrial rest allowances (e.g., morning, lunch, and afternoon rest breaks).

The lifting index (LI) provides a relative estimate of the physical stress associated with a manual lifting job and is equal to the load weight divided by the RWL. According to Waters et al. (1994), the RWL and LI can be used to guide ergonomic design in several ways:

1. The individual multipliers can be used to identify specific job-related problems. The general redesign guidelines related to specific multipliers are shown in Table 20.
2. The RWL can be used to guide the redesign of existing manual lifting jobs or to design new manual lifting jobs.
3. The LI can be used to estimate the relative magnitude of physical stress for a task or job. The greater the LI, the smaller the fraction of workers capable of safely sustaining the level of activity.
4. The LI can be used to prioritize ergonomic redesign. A series of suspected hazardous jobs could be rank ordered according to the LI and a control strategy could be developed according to the rank ordering (i.e., jobs with lifting indices about 1.0 or higher would benefit the most from redesign).

The 1991 equation should not be used if any of the following conditions occur: lifting/lowering with one hand; lifting/lowering for over eight hours, lifting/lowering while seated or kneeling; lifting/lowering in a restricted workspace, lifting/lowering unstable objects; lifting/lowering while carrying, pushing, or pulling; lifting/lowering with wheelbarrows or shovels; lifting/lowering with high-speed motion (faster than about 30 in/sec); lifting/lowering with unreasonable foot/floor coupling (<0.4 coefficient of friction between the sole and the floor); lifting/lowering in an unfavorable environment (i.e., temperature significantly outside 66–79°F (19–26°C) range; relative humidity outside 35–50% range).

7.9. Computer Simulation of the Revised NIOSH Lifting Equation (1991)

One way to investigate the practical implications of the 1991 lifting equation for industry is to determine the likely results of the equation when applying a realistic and practical range of values

TABLE 20 General Design/Redesign Suggestions for Manual Lifting Tasks

If HM is less than 1.0	Bring the load closer to the worker by removing any horizontal barriers or reducing the size of the object. Lifts near the floor should be avoided; if unavoidable, the object should fit easily between the legs.
If VM is less than 1.0	Raise/lower the origin/destination of the lift. Avoid lifting near the floor or above the shoulders.
If DM is less than 1.0	Reduce the vertical distance between the origin and the destination of the lift.
If AM is less than 1.0	Move the origin and destination of the lift closer together to reduce the angle of twist, or move the origin and destination further apart to force the worker to turn the feet and step, rather than twist the body.
If FM is less than 1.0	Reduce the lifting frequency rate, reduce the lifting duration, or provide longer recovery periods (i.e., light work period).
If CM is less than 1.0	Improve the hand-to-object coupling by providing optimal containers with handles or hand-hold cutouts, or improve the hand-holds for irregular objects.
If the RWL at the destination is less than at the origin	Eliminate the need for significant control of the object at the destination by redesigning the job or modifying the container/object characteristics.

As recommended by Waters et al. 1994. Courtesy of the U.S. Department of Health and Human Services.

for the risk factors (Karwowski 1992). This can be done using modern computer simulation techniques in order to examine the behavior of the 1991 NIOSH equation under a broad range of conditions. Karwowski and Gaddie (1995) simulated the 1991 equation using SLAM II (Pritsker 1986), a simulation language for alternative modeling, as the product of the six independent factor multipliers represented as attributes of an entity flowing through the network. For this purpose, probability distributions for all the relevant risk factors were defined and a digital simulation of the revised equation was performed.

As much as possible, the probability distributions for these factors were chosen to be representative of the real industrial workplace (Ciriello et al. 1990; Brokaw 1992; Karwowski and Brokaw 1992; Marras et al. 1993). Except for the vertical travel distance factor, coupling, and asymmetry multipliers, all factors were defined using either normal or lognormal distributions. For all the factors defined as having lognormal distributions, the procedure was developed to adjust for the required range of real values whenever necessary. The SLAM II computer simulation was run for a total of 100,000 trials, that is, randomly selected scenarios that realistically define the industrial tasks in terms of the 1991 equation. Descriptive statistical data were collected for all the input (lifting) factors, the respective multipliers, and the resulting recommended weight limits. The input factor distributions were examined in order to verify the intended distributions.

The results showed that for all lifting conditions examined, the distribution of recommended weight limit values had a mean of 7.22 kg and a standard deviation of 2.09 kg. In 95% of all cases, the RWL was at or below the value of 10.5 kg (about 23.1 lb). In 99.5% of all cases, the RWL value was at or below 12.5 kg (27.5 lb). That implies that when the LI is set to 1.0 for task design or evaluation purposes, only 0.5% of the (simulated) industrial lifting tasks would have the RWLs greater than 12.5 kg. Taking into account the lifting task duration, in the 99.5% of the simulated cases, the RWL values were equal to or were lower than 13.0 kg (28.6 lb) for up to one hour of lifting task exposure, 12.5 kg (or 27.5 lb) for less than two hours of exposure, and 10.5 kg (23.1 lb) for lifting over an eight-hour shift.

From a practical point of view, these values define simple and straightforward lifting limits, that is, the threshold RWL values (TRWL) that can be used by practitioners for the purpose of immediate and easy-to-perform risk assessment of manual lifting tasks performed in industry. Because the 1991 equation is designed to ensure that the RWL will not exceed the acceptable lifting capability of 99% of male workers and 75% of female workers, this amounts to protecting about 90% of the industrial workers if there is a 50/50 split between males and females. The TRWL value of 27.5 lb can then be used for immediate risk assessment of manual lifting tasks performed in industry. If this value is exceeded, then a more thorough examination of the identified tasks, as well as evaluation of physical capacity of the exposed workers, should be performed.

7.10. Prevention of LBDs in Industry

The application of ergonomic principles to the design of MMH tasks is one of the most effective approaches to controlling the incidence and severity of LBDs (Ayoub et al. 1997). The goal of ergonomic job design is to reduce the ratio of task demands to worker capability to an acceptable level (see Figure 14). The application of ergonomic principles to task and workplace design permanently reduces stresses. Such changes are preferable to altering other aspects of the MMH system, such as work practices. For example, worker training may be ineffective if practices trained are not reinforced and refreshed (Kroemer 1992), whereas altering the workplace is a lasting physical intervention

7.10.1. Job Severity Index

The job severity index (JSI) is a time- and frequency-weighted ratio of worker capacity to job demands. Worker capacity is predicted with the models developed by Ayoub et al. (1978), which use isometric strength and anthropometric data to predict psychophysical lifting capacity. JSI and each of the components are defined below.

$$\text{JSI} = \sum_{i=1}^{n} \frac{\text{hours}_i \times \text{days}_i}{\text{hours}_t \times \text{days}_t} \sum_{j=1}^{m_i} \left[\frac{F_j}{F_i} \times \frac{\text{WT}_j}{\text{CAP}_j} \right]$$

where: n =number of task groups

hours_i = exposure hours/day for group i
days_i = exposure days/week for group i
hours_t = total hours/day for job
days_t = total days/week for job
m_i = number of tasks in group i
WT_j = maximum required weight of lift for task j

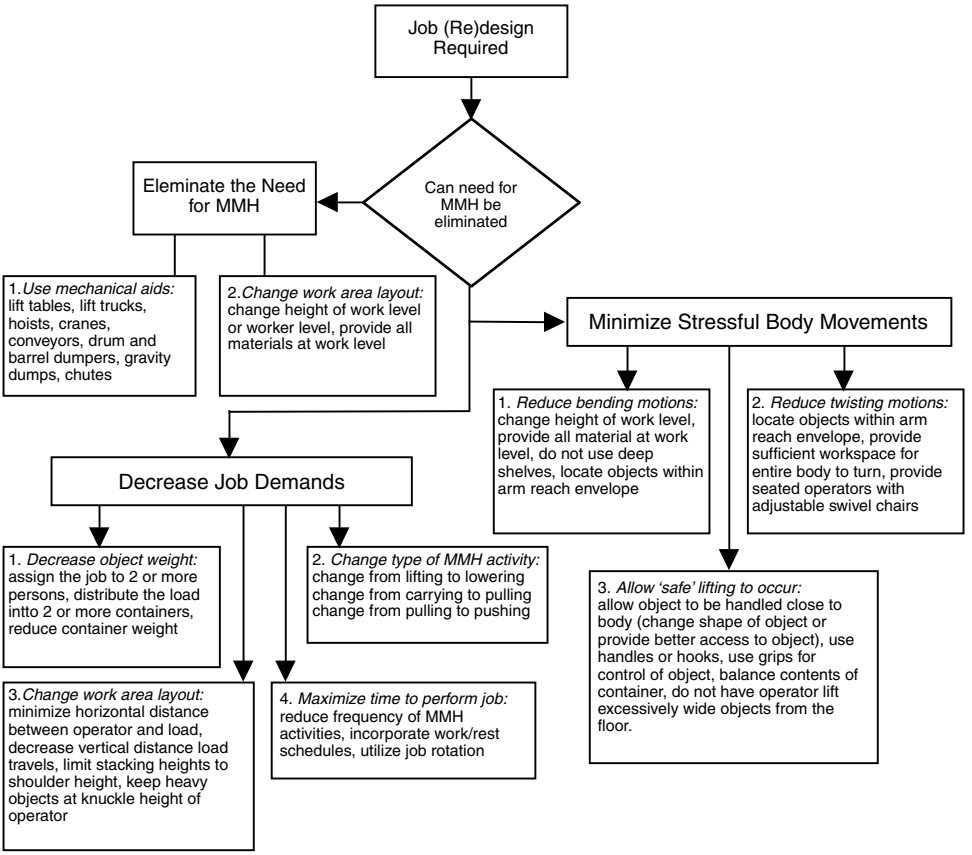

Figure 14 Summary of Ergonomic Approaches to MMH Task (re)design. (Adapted from Ayoub 1982 and Ayoub et al. 1983)

CAP_j = the adjusted capacity of the person working at task j
F_j = lifting frequency for task j
F_i = total lifting frequency for group i

$$= \sum_{j=1}^{m_i} F_j$$

Liles et al. (1984) performed a field study to determine the relationship between JSI and the incidence and severity of LBDs. A total of 453 subjects was included in the study. The results of the field study indicated that both incidence and severity of recordable back injuries rose rapidly at values of JSI greater than 1.5. The denominator for the incidence and severity rates is 100 full-time employees, that is, 200,000 exposure hours. JSI can be reduced to a desirable level by increasing worker capacity (e.g., selecting a worker with higher capacity) or altering task and job parameters to reduce JSI to an acceptable level.

7.10.2. Dynamic Model for Prediction of LBDs in Industry

Marras et al. (1993) performed a retrospective study to determine the relationships between workplace factors and trunk motion factors and LBD occurrence. A logistic regression analysis was performed to provide a model used to estimate the probability of high-risk LBD membership. High-risk jobs were defined as jobs having incidence rates of 12 or more injuries per 200,000 hours of exposure. The regressors included in the model were lift rate (lifts/hr), average twisting velocity (deg/sec),

maximum moment (Nm), maximum sagittal flexion (degrees), and maximum lateral velocity (deg/sec). The above model can be used to guide workplace design changes because the probability of high-risk LBD membership can be computed before and after design changes. For example, maximum moment could be reduced by decreasing the load weight or the maximum horizontal distance between the load and the lumbar spine, and the associated decrease in high-risk membership probability can be estimated. The model is considerably different from the models discussed above in that LBD risk is not assumed to be related to individual capacity.

8. WORK-RELATED MUSCULOSKELETAL DISORDERS OF THE UPPER EXTREMITY

8.1. Characteristics of Musculoskeletal Disorders

The National Institute of Occupational Safety and Health (NIOSH 1997) states that musculoskeletal disorders, which include disorders of the back, trunk, upper extremity, neck, and lower extremity are one of the 10 leading work-related illnesses and injuries in the United States. Praemer et al, (1992) report that work-related upper-extremity disorders (WUEDs), which are formally defined by the Bureau of Labor Statistics (BLS) as cumulative trauma illnesses, account for 11.0 % of all work-related musculoskeletal disorders (illnesses). For comparison, occupational low-back disorders account for more than 51.0% of all WRMDs. According to BLS (1995), the cumulative trauma illnesses of upper extremity accounted for more than 60% of the occupational illnesses reported in 1993. These work-related illnesses, which include hearing impairments due to occupational noise exposure, represent 6.0% of all reportable work-related injuries and illnesses (Marras 1996).

As reviewed by Karwowski and Marras (1997), work-related musculoskeletal disorders currently account for one-third of all occupational injuries and illnesses reported to the Bureau of Labor Statistics (BLS) by employers every year. These disorders thus constitute the largest job-related injury and illness problem in the United States today. According to OSHA (1999), in 1997 employers reported a total of 626,000 lost workday disorders to the BLS, and these disorders accounted for $1 of every $3 spent for workers' compensation in that year. Employers pay more than $15–20 billion in workers' compensation costs for these disorders every year, and other expenses associated with MSDs may increase this total to $45–54 billion a year.

Such statistics can be linked to several occupational risk factors, including the increased production rates leading to thousands of repetitive movements every day, widespread use of computer keyboards, higher percentage of women and older workers in the workforce, better record keeping of reportable illnesses and injuries on the job by employers, greater employee awareness of WUEDs and their relation to the working conditions, and a marked shift in social policy regarding recognition and compensation of the occupational injuries and ilnesses.

8.2. Definitions

Work-related musculoskeletal disorders (WRMDs) are those disorders and diseases of the musculoskeletal system which have a proven or hypothetical work related causal component (Kuorinka and Forcier 1995). Musculoskeletal disorders are pathological entities in which the functions of the musculoskeletal system are disturbed or abnormal, while diseases are pathological entities with observable impairments in body configuration and function. Although WUEDs are a heterogeneous group of disorders, and the current state of knowledge does not allow for a general description of the course of these disorders, it is possible nevertheless to identify a group of so-called generic risk factors, including biomechanical factors, such as static and dynamic loading on the body and posture, cognitive demands, and organizational and psychosocial factors, for which there is an ample evidence of work-relatedness and higher risk of developing the WUEDs.

Generic risk factors, which typically interact and cumulate to form cascading cycles, are assumed to be directly responsible for the pathophysiological phenonmena that depend on location, intensity, temporal variation, duration, and repetitivness of the generic risk factors (Kuorinka and Forcier 1995). It is also proposed that both insufficient and exccessive loading on the musculoskeletal system have deleterious effects and that the pathophysiological process is dependent upon individual characteristics with respect to body responses, coping mechanisms, and adaptation to risk factors.

Musculoskeletal disorders can be defined by combining the separate meanings for each word (Putz-Anderson 1993). *Cumulative* indicates that these disorders develop gradually over periods of time as a result of repeated stresses. The cumulative concept is based on the assumption that each repetition of an activity produces some trauma or wear and tear on the tissues and joints of the particular body part. The term *trauma* indicates bodily injury from mechanical stresses, while *disorders* refer to physical ailments. The above definition also stipulates a simple cause-and-effect model for CTD development. According to such a model, because the human body needs sufficient intervals of rest time between episodes of repeated strains to repair itself, if the recovery time is insufficient, combined with high repetition of forceful and awkward postures, the worker is at higher risk of developing a CTD. In the context of the generic model for prevention shown in Figure 15, the above

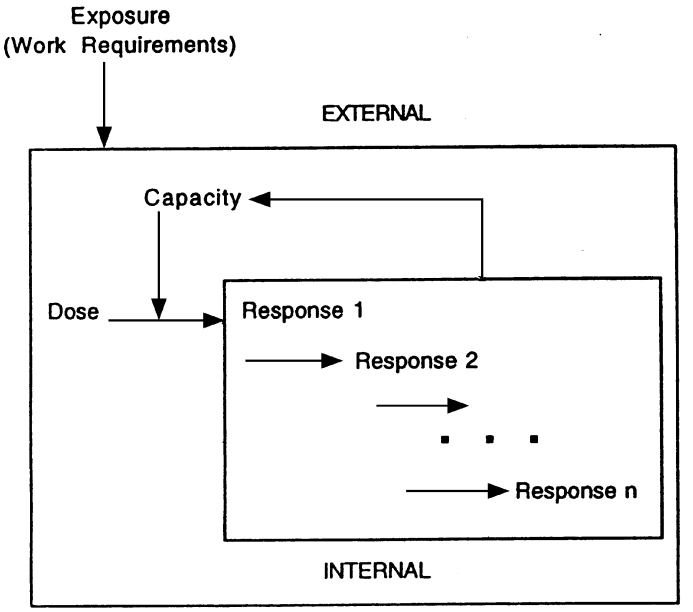

Figure 15 A Conceptual Model for Development of WMSDs proposed by Armstrong et al. (1993). Reproduced with permission from Finnish Institute of Occupational Health.

definition is primarily oriented towards biomechanical risk factors for WUEDs and is, therefore, incomplete. Table 21 presents a summary of the potential risk factors for work-related musculoskeletal disorders.

8.3. Conceptual Models for Development of WRMDs

According to the World Health Organization (WHO 1985), an occupational disease is a disease for which there is a direct cause-and-effect relationship between hazard and disease (e.g., asbestos–

TABLE 21 Potential Risk Factors for Development of Work-Related Musculoskeletal Disorders

1. Physical strength requirements
2. Biomechanical stressors (dynamic and static)
3. Endurance requirement and physiological costs of work
4. Motion factors:
   a. repetitive movement rates
   b. reach distances (functional, extended, and repetitive)
   c. motion times and efficiency
5. Postural factors:
   a. characteristics and range of motion
   b. joint deviations
   c. static loading
   d. awkward postures
6. Work duration factors:
   a. rate/work/rest ratios
   b. stressful task assignments
7. Work organization demands:
   a. work pace/time pressures
   b. machine/team pacing
   c. overtime demands
   d. monotony of work

asbestosis). Work-related diseases are defined as multifactorial when the work environment and the performance of work contribute significantly to the causation of disease (WHO 1985). Work-related diseases can be partially caused by adverse work conditions. However, personal characteristics, environmental, and sociocultural factors are also recognized as risk factors for these diseases.

The scientific evidence of work-relatedness of musculoskeletal disorders has been firmly established by numerous epidemiologic studies conducted over the last 25 years of research in the field (NIOSH 1997). It has also been noted that the incidence and prevalence of musculoskeletal disorders in the reference populations were low, but not zero, most likely indicating the nonwork-related causes of these disorders. It was also documented that such variables as cultural differences, psychosocial and economic factors, which may influence one's perception and tolerance of pain and consequently affect the willingness to report musculoskeletal problems, may have significant impact on the progressions from disorder to work disability (WHO 1985; Leino 1989).

Armstrong et al. (1993) developed a conceptual model for the pathogenesis of work-related musculoskeletal disorders. The model is based on the set of four cascading and interacting state variables of exposure, dose, capacity, and response, which are measures of the system state at any given time. The response at one level can act as dose at the next level (see Figure 15). Furthermore, it is assumed that a response to one or more doses can diminish or increase the capacity for responding to successive doses. This conceptual model for development of WRMDs reflects the multifactorial nature of work-related upper-extremity disorders and the complex nature of the interactions between exposure, dose, capacity, and response variables. The proposed model also reflects the complexity of interactions among the physiological, mechanical, individual, and psychosocial risk factors.

In the proposed model, exposure refers to the external factors (i.e., work requirements) that produce the internal dose (i.e., tissue loads and metabolic demands and factors). Workplace organization and hand tool design characteristics are examples of such external factors that can determine work postures and define loads on the affected tissues or velocity of muscular contractions. Dose is defined by a set of mechanical, physiological, or psychological factors that in some way disturb an internal state of the affected worker. Mechanical disturbance factors may include tissue forces and deformations produced as a result of exertion or movement of the body.

Physiological disturbances are such factors as consumption of metabolic substrates or tissue damage, while the psychological disturbance factors are those related to, for example, anxiety about work or inadequate social support. Changes in the state variables of the worker are defined by the model as responses. A response is an effect of the dose caused by exposure. For example, hand exertion can cause elastic deformation of tendons and changes in tissue composition and/or shape, which in turn may result in hand discomfort. The dose–response time relationship implies that the effect of a dose can be immediate or the response may be delayed for a long periods of time.

The proposed model stipulates that system changes (responses) can also result in either increased dose tolerance (adaptation) or reduced dose tolerance lowering the system capacity. Capacity is defined as the worker's ability (physical or psychological) to resist system destabilization due to various doses. While capacity can be reduced or enhanced by previous doses and responses, it is assumed that most individuals are able to adapt to certain types and levels of physical activity.

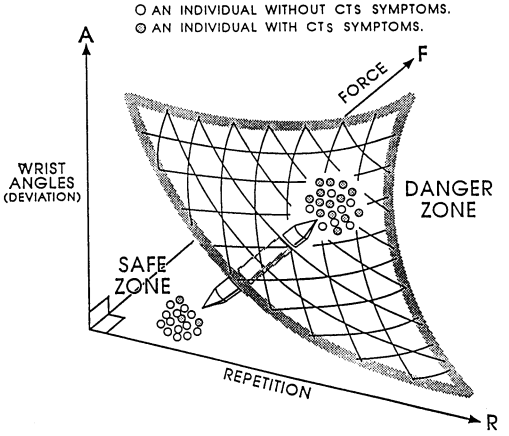

Figure 16 Conceptual CTS Model. (Adapted from Tanaka and McGlothlin 1999, reprinted with permission from Elsevier Science.)

Muscles, for example, can develop increased aerobic or anaerobic metabolic capacity. Furthermore, muscular responses are characterized in the model as a series of cascading mechanical and physiological events. The local changes (system responses), such as deformation and the yielding of connective tissues within the muscle, are conveyed to the central nervous system by sensory afferent nerves and cause corresponding sensations to effort and discomfort, often referred to as perceived fatigue.

The main purpose of the dose-response model is to account for the factors and processes that result in WRMDs in order to specify acceptable limits with respect to work design parameters for a given individual. The proposed model should be useful in the design of studies on the etiology and pathomechanisms of work-related musculoskeletal disorders, as well as in the planning and evaluation of preventive programs. The model should complement the epidemiologic studies, which focus on associations between the top and bottom of the cascade with physical workload, psychological demands, and environmental risk factors of work at one end and the manifestations of symptoms, diseases, or disabilities at the other.

Recently, Tanaka and McGlothlin (1999) updated their 3D heuristic dose–response model for repetitive manual work risk factors using the epidemiologic finding. Their earlier model for the postulated relationships between the risk factors for carpal tunnel syndrome (CTS) (for description see Karwowski and Marras 1997) was modified by including the time exposure factor. This was based on examination of prevalence of CTS data for 1988 from the National Health Review Survey (NHIS) and the Occupational Health Supplement (OHS). The authors found that compared to the nonexposed population, the prevalence (P) of CTS among the people exposed to bending/twisting of the hands/wrists many times an hour increased by several times regardless of the length of daily hours exposed. The prevalence of CTS was then defined as follows:

$$P = k \times I \times T = k \{aF \times bR \times e^{cA}\} T$$

where: P = prevalence of CTS
I = intensity
K = constant
a, b, c = coefficients
F = force
R = repetition
A = joint angles
T = time duration

The proposed model indicates that high-intensity work (involving high force, high repetition, and/or high joint deviation) should not be performed for a long period of time, but low-intensity work may be performed for a longer period. The 3D representation of the relationships between the risk factors for CTS is illustrated in Figures 16 and 17.

8.4. Causal Mechanism for Development of WUEDs

As reviewed by Armstrong et al. (1993), work-related muscle disorders are likely to occur when a muscle is fatigued repeatedly without sufficient allowance for recovery. An important factor in development of such disorders is motor control of the working muscle. Hägg (1991) postulates that the recruitment pattern of the motor neurons can occur according to the size principle, where the small units are activated at low forces. Given that the same units can be recruited continuously during a given work task, even if the relative load on the muscle is low, the active low-threshold motor units can work close to their maximal capacity and consequently maybe at a high risk of being damaged. It has also been shown that muscle tension due to excessive mental load can cause an overload on some specific muscle fibers (Westgaard and Bjørkland 1987). Karwowski et al. (1994) showed that cognitive aspects of computer-related task design affect the postural dynamics of the operators and the related levels of perceived postural discomfort. Finally, Edwards (1988) hypothesizes that occupational mucle pain might be a consequence of a conflict between motor control of the postural activity and control needed for rhythmic movement or skilled manipulations. In other words, the primary cause of work-related muscular pain and injury may be altered motor control, resulting in imbalance between harmonious motor unit recruitment relaxation of mucles not directly involved in the activity.

As discussed by Armstrong et al. (1993), poor ergonomic design of tools with respect to weight, shape, and size can impose extreme wrist positions and high forces on the worker's musculoskeletal system. Holding heavier objects requires an increased power grip and high tension in the finger flexor tendons, causing increased pressure in the carpal tunnel. Furthermore, the tasks that induce hand and arm vibration cause an involuntary increase in power grip through a reflex of the strength receptors. Vibration can also cause protein leakage from the blood vessels in the nerve trunks and result in

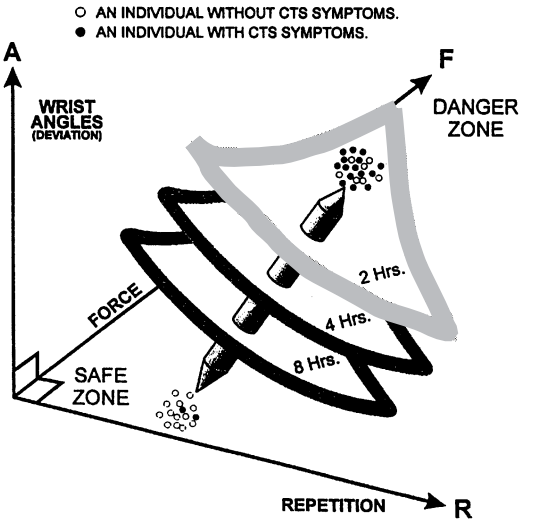

Figure 17 Three-Dimensional Illustration of the conceptual CTS Model with Time Exposure Factor. (Adapted from Tanaka and McGlothlin 1999, reprinted with permission from Elsevier Science.)

TABLE 22 Relationship between Physical Stresses and WRMD Risk Factors (ANSI Z-365)

Physical Stress	Magnitude	Repetition rate	Duration
Force	Forceful exertions and motions	Repetitive exertions	Sustained exertions
Joint angle	Extreme postures and motions	Repetitive motions	Sustained postures
Recovery	Insufficient resting level	Insufficient pauses or breaks	Insufficient rest time
Vibration	High vibration level	Repeated vibration exposure	Long vibration exposure
Temperature	Cold temperature	Repeated cold exposure	Long cold exposure

edema and increased pressure in the nerve trunks and therefore also result in edema and increased pressure in the nerve (Lundborg et al. 1987).

8.5. Musculoskeletal Disorders: Occupational Risk Factors

A risk factor is defined as an attribute or exposure that increases the probability of a disease or disorder (Putz-Anderson, 1988). Biomechanical risk factors for musculoskeletal disorders include repetitive and sustained exertions, awkward postures, and application of high mechanical forces. Vibration and cold environments may also accelerate the development of musculoskeletal disorders. Typical tools that can be used to identify the potential for development of musculoskeletal disorders include conducting work-methods analyses and checklists designed to itemize undesirable work site conditions or worker activities that contribute to injury. Since most of manual work requires the active use of the arms and hands, the structures of the upper extremities are particularly vulnerable to soft tissue injury. WUEDs are typically associated with repetitive manual tasks with forceful exertions, such as those performed at assembly lines, or when using hand tools, computer keyboards and other devices, or operating machinery. These tasks impose repeated stresses to the upper body, that is, the muscles, tendons, ligaments, nerve tissues, and neurovascular structures. There are three basic types of WRDs to the upper extremity: tendon disorder (such as tendonitis), nerve disorder (such as carpal tunnel syndrome), and neurovascular disorder (such as thoracic outlet syndrome or vibration–Raynaud's syndrome). The main biomechanical risk factors of musculoskeletal disorders are presented in Table 22.

9. ERGONOMICS DESIGN TO REDUCE WUEDs

In order to reduce the extent of work-related musculoskeletal injuries, progress in four methodologic areas is expected (NIOSH 1986):

1. Identifying accurately the biomechanical hazards
2. Developing effective health-promotion and hazard-control interventions
3. Changing management concepts and operational policies with respect to expected work performance
4. Devising strategies for disseminating knowledge on control technology and promoting their application through incentives

From the occupational safety and health perspective, the current state of ergonomics knowledge allows for management of musculoskeletal disorders in order to minimize human suffering, potential for disability, and the related workers' compensation costs. Ergonomics can help to:

1. Identify working conditions under which musculoskeletal disorders might occur
2. Develop engineering design measures aimed at elimination or reduction of the known job risk factors
3. Identify the affected worker population and target it for early medical and work intervention efforts

The musculoskeletal disorders-related job risk factors, which often overlap, typically involve a combination of poorly designed work methods, workstations, and hand tools and high production demands. Furthermore, while perfect solutions are rarely available, the job redesign decisions may often require some design trade-offs (Putz-Anderson 1992). In view of the above, the ergonomic intervention should allow:

1. Performing a thorough job analysis to determine the nature of specific problems
2. Evaluating and selecting the most appropriate intervention(s)
3. Developing and applying conservative treatment (implementing the intervention), on a limited scale if possible
4. Monitoring progress
5. Adjust or refining the intervention as needed

9.1. Quantitative Models for Development of WUEDs

It is generally recognized that force, repetition, posture, recovery time, duration of exposure, static muscular work, use of the hand as a tool, and type of grasp are important factors in the causation of WUEDs (Armstrong et al. 1987; Keyserling et al. 1993). Additional job factors that may increase the risk of WUEDs, in combination with the other factors, include cold temperature, use of gloves, and use of vibrating tools. Given the above knowledge, even if limited and in need of more comprehensive validation, it is currently possible to develop quantitative methodologies for ergonomics practitioners in order to discriminate between safe and hazardous jobs in terms of workers being at increased risk of developing the WUEDs. Such models are described below.

9.2. Semiquantitative Job-Analysis Methodology for Wrist/Hand Disorders

Moore and Garg (1995) developed a semiquantitative job analysis methodology (SJAM) for identifying industrial jobs associated with distal upper-extremity (wrist/hand) disorders. An existing body of knowledge and theory of the physiology, biomechanics, and epidemiology of distal upper-extremity disorders was used for that purpose. The proposed methodology involves the measurement or estimation of six task variables:

1. Intensity of exertion
2. Duration of exertion per cycle
3. Efforts per minute
4. Wrist posture
5. Speed of exertion
6. Duration of task per day

An ordinal rating is assigned for each of the variables according to the exposure data. The proposed strain index is the product of these six multipliers assigned to each of the variables.

The strain index methodology aims to discriminate between jobs that expose workers to risk factors (task variables) that cause WUEDs and jobs that do not. However, the strain index is not designed to identify jobs associated with an increased risk of any single specific disorder. It is anticipated that jobs identified as in the high-risk category by the strain index will exhibit higher levels of WUEDs among workers who currently perform or historically performed those jobs that are believed to be hazardous. Large-scale studies are needed to validate and update the proposed methodology. The strain index has the following limitations in terms of its application:

1. There are some disorders of the distal upper extremity that should not be predicted by the strain index, such as hand–arm vibration syndrome (HAVS) and hypothenar hammer syndrome.
2. The strain index has not been developed to predict increased risk for distal upper-extremity disorders to uncertain etiology or relationship to work. Examples include ganglion cysts, osteoarthritis, avascular necrosis of carpal bones, and ulnar nerve entrapment at the elbow.
3. The strain index has not been developed to predict disorders outside of the distal upper extremity, such as disorders of the shoulder, shoulder girdle, neck, or back.

The following major principles have been derived from the physiological model of localized muscle fatigue:

1. The primary task variables are intensity of exertion, duration of exertion, and duration of recovery.
2. Intensity of exertion refers to the force required to perform a task one time. It is characterized as a percentage of maximal strength.
3. Duration of exertion describes how long an exertion is applied. The sum of duration of exertion and duration of recovery is the cycle time of one exertional cycle.
4. Wrist posture, type of grasp, and speed of work are considered via their effects of maximal strength.
5. The relationship between strain on the body (endurance time) and intensity of exertion is nonlinear.

The following are the major principles derived from the epidemiological literature:

1. The primary task variable associated with an increased prevalence or incidence of distal upper-extremity disorders are intensity of exertion (force), repetition rate, and percentage of recovery time per cycle.
2. Intensity of exertion was the most important task variable in two of the three studies explicitly mentioned. The majority (or all) of the morbidity was related to disorders of the muscle–tendon unit. The third study, which considered only CTS, found that repetition was more important than forcefulness (Silverstein et al. 1987).
3. Wrist posture may not be an independent risk factor. It may contribute to an increased incidence of distal upper-extremity disorders when combined with intensity of exertion.
4. The roles of other task variables have not been clearly established epidemiologically; therefore, one has to rely on biomechanical and physiological principles to explain their relationship to upper-extremity disorders, if any.

Moore and Garg (1994) compared exposure factors for jobs associated with WUEDs to jobs without prevalence of such disorders. They found that the intensity of exertion, estimated as a percentage of maximal strength and adjusted for wrist posture and speed of work, was the major discriminating factor. The relationship between the incidence rate for distal upper-extremity disorder and the job risk factors was defined as follows:

$$\mathrm{IE} = \frac{30 \times F^2}{\mathrm{RT}^{0.6}}$$

where: IR = incidence rate (per 100 workers per year)
F = intensity of exertion (%MS)
RT = recovery time (percentage of cycle time)

The proposed concept of the strain index is a semiquantitative job analysis methodology that results in a numerical score that is believed to correlate with the risk of developing distal upper-extremity disorders. The SI score represents the product of six multipliers that correspond to six task variables. These variables:

TABLE 23 Rating Criteria for Strain Index

Rating	Intensity of Exertion	Duration of Exertion (% of Cycle)	Efforts/Minute	Hand–Wrist Posture	Speed of Work	Duration per Day (h)
1	Light	<10	<4	Very good	Very slow	≥1
2	Somewhat hard	10–29	4–8	Good	Slow	1–2
3	Hard	30–49	9–14	Fair	Fair	2–4
4	Very hard	50–79	15–19	Bad	Fast	2–8
5	Near maximal	≤80	≤20	Very bad	Very fast	≤8

Adapted from Moore and Garg 1995.

1. Intensity of exertion
2. Duration of exertion
3. Exertions per minute
4. Hand–wrist posture
5. Speed of work
6. Duration of task per day

These ratings, applied to model variables, are presented in Table 23. The multipliers for each task variable related to these ratings are shown in Table 24. The strain index score as the product of all six multipliers is defined as follows:

$$\begin{aligned}\text{Strain index (SI)} = {} & (\text{intensity of exertion multiplier}) \\ & \times (\text{duration of exertion multiplier}) \\ & \times (\text{exertions per minute multiplier}) \\ & \times (\text{posture multiplier}) \times (\text{speed of work multiplier}) \\ & \times (\text{duration per day multiplier})\end{aligned}$$

Intensity of exertion, the most critical variable of SI, is an estimate of the force requirements of a task and is defined as the percentage of maximum strength required to perform the task once. As such, the intensity of exertion is related to physiological stress (percentage of maximal strength) and biomechanical stresses (tensile load) on the muscle–tendon units of the distal upper extremity. The intensity of exertion is estimated by an observer using verbal descriptors and assigned corresponding rating values (1, 2, 3, 4, or 5). The multiplier values are defined based on the rating score raised to a power of 1.6 in order to reflect the nonlinear nature of the relationship between intensity of exertion and manifestations of strain according to the psychophysical theory. The multipliers for other task variables are modifiers to the intensity of exertion multiplier.

Duration of exertion is defined as the percentage of time an exertion is applied per cycle. The terms cycle and cycle time refer to the exertional cycle and average exertional cycle time, respectively. Duration of recovery per cycle is equal to the exertional cycle time minus the duration of exertion per cycle. The duration of exertion is the average duration of exertion per exertional cycle (calculated by dividing all durations of a series of exertions by the number of observed exertions). The percentage

TABLE 24 Multiplier Table for Strain Index

Rating	Intensity of Exertion	Duration of Exertion (% of Cycle)	Efforts/Minute	Hand–Wrist Posture	Speed of Work	Duration per Day (h)
1	1	0.5	0.5	1.0	1.0	0.25
2	3	1.0	1.0	1.0	1.0	0.50
3	6	1.5	1.5	1.5	1.0	0.75
4	9	2.0	2.0	2.0	1.5	1.00
5	13	3.0[a]	3.0	3.0	2.0	1.50

Adapted from Moore and Garg 1995.
[a]If duration of exertion is 100%, then the efforts/minute multiplier should be set to 3.0.

TABLE 25 An Example to Demonstrate the Procedure for Calculating SI Score

	Intensity of Exertion	Duration of Exertion (% of Cycle)	Efforts/Minute	Posture	Speed of Work	Duration per Day (h)
Exposure dose	Somewhat hard	60%	12	Fair	Fair	4–8
Ratings	2	4	3	3	3	4
Multiplier	3.0	2.0	1.5	1.5	1.0	1.0
SI Score = 3.0 × 2.0 × 1.5 × 1.5 × 1.0 × 1.0 = 13.5						

Adapted from Moore and Garg 1995.

duration of exertion is calculated by dividing the average duration of exertion per cycle by the average exertional cycle time, then multiplying the result by 100. (See equation below.) The calculated percentage duration of exertion is compared to the ranges and assigned the appropriate rating. The corresponding multipliers are identified using Table 23.

$$\%\text{duration of exertion} = \frac{(\text{average duration of exertion per cycle})}{(\text{average exertional cycle time})}$$

Efforts per minute is the number of exertions per minute (i.e., repetitiveness) and is synonymous with frequency. Efforts per minute are measured by counting the number of exertions that occur during a representative observation period (as described for determining the average exertional cycle time). The measured results are compared to the ranges shown in Table 23 and given the corresponding ratings. The multipliers are defined in Table 24.

Posture refers to the anatomical position of the wrist or hand relative to neutral position and is rated qualitatively using verbal anchors. As shown in Table 23, posture has four relevant ratings. Postures that are ''very good'' or ''good'' are essentially neutral and have multipliers of 1.0. Hand or wrist postures progressively deviate beyond the neutral range to extremes, graded as ''fair,'' ''bad,'' and ''very bad.''

Speed of work estimates perceived pace of the task or job and is subjectively estimated by a job analyst or ergonomics team. Once a verbal anchor is selected, a rating is assigned.

Duration of task per day is defined as a total time that a task is performed per day. As such, this variable reflects the beneficial effects of task diversity such as job rotation and the adverse effects of prolonged activity such as overtime. Duration of task per day is measured in hours and assigned a rating according to Table 23.

Application of the strain index involves five steps:

1. Collecting data
2. Assigning rating values
3. Determining multipliers
4. Calculating the SI score
5. Interpreting the results

TABLE 26 Maximum Acceptable Forces for Female Wrist Flexion (Power Grip) (N)

The values of intensity of exertion, hand–wrist posture, and speed of work are estimated using the verbal descriptors in Table 23. The values of percentage duration of exertion per cycle, efforts per minute, and duration per day are based on measurements and counts. Theses values are then compared to the appropriate column in Table 24 and assigned a rating. The calculations of SI are shown in Table 25.

9.3. Psychophysical Models: The Maximum Acceptable Wrist Torque

Snook et al. (1995) used the psychophysical approach to determine the maximum acceptable forces for various types and frequencies for repetitive wrist motion, grips, and repetition rates that would not result in significant changes in wrist strength, tactile sensitivity, or number of symptoms reported by the female subjects. Three levels of wrist motion were used:

1. Flexion motion with a power grip
2. Flexion motion with a pinch grip
3. Extension motion with a power grip

The dependent variables were maximum acceptable wrist torque, maximum isometric wrist strength, tactile sensitivity, and symptoms. The maximum acceptable wrist torque (MAWT) was defined as the number of Newton meters of resistance set in the brake by the participants (averaged and recorded every minute). The data for maximum acceptable wrist torques for the two-days-per-week exposure were used to estimate the maximum acceptable torques for different repetitions of wrist flexion (power grip) and different percentages of the population. This was done by using the adjusted means and coefficients of variation from the two-days-per-week exposure. The original torque values were converted into forces by dividing each torque by the average length of the handle lever (0.081 m).

The estimated values for the maximum acceptable forces for female wrist flexion (power grip) are shown in Table 26. Similarily, the estimated maximum acceptable forces were developed for wrist flexion (pinch grip, see Table 27) and wrist extension (power grip, see Table 28). The torques were converted into forces by dividing by 0.081 m for the power grip and 0.123m for the pinch grip. Snook et al. (1995) note that the estimated values of the maximum acceptable wrist torque do not apply to any other tasks and wrist positions than those that were used in the study.

TABLE 28 Maximum Acceptable Forces for Female Wrist Extension (Power Grip) (N)

Percentage of Population	Repetition Rate				
	2/min	5/min	10/min	15/min	20/min
90	8.8	8.8	7.8	6.9	5.4
75	13.6	13.6	12.1	10.9	8.5
50	18.9	18.9	16.8	15.1	11.9

10. MANAGEMENT OF MUSCULOSKELETAL DISORDERS

10.1. Ergonomic Guidelines

Most of the current guidelines for control of musculoskeletal disorders at work aim to reduce the extent of movements at the joints, reduce excessive force levels, and reduce the exposure to highly repetitive and stereotyped movements. For example, some of the common methods to control for wrist posture, which is believed one of the risk factors for carpal tunnel syndrome, are altering the geometry of tool or controls (e.g., bending the tool or handle), changing the location/positioning of the part, and changing the position of the worker in relation to the work object. In order to control for the extent of force required to perform a task, one can reduce the force required through tool and fixture redesign, distribute the application of force, or increase the mechanical advantage of the (muscle) lever system.

It has been shown that in the dynamic tasks involving upper extremities, the posture of the hand itself has very little predictive power for the risk of musculoskeletal disorders. Rather, it is the velocity and acceleration of the joint that significantly differentiate the musculoskeletal disorders risk levels (Schoenmarklin and Marras 1990). This is because the tendon force, which is a risk factor of musculoskeletal disorders, is affected by wrist acceleration. The acceleration of the wrist in a dynamic task requires transmission of the forearm forces to the tendons. Some of this force is lost to friction against the ligaments and bones in the carpal tunnel. This frictional force can irritate the tendons' synovial membranes and cause tenosynovitis or carpal tunnel syndrom (CTS). These new research results clearly demonstrate the importance of dynamic components in assessing CTD risk of highly repetitive jobs.

With respect to task repetitivness, it is believed today that jobs with a cycle time of less than 30 seconds and a fundamental cycle that exceeds 50% of the total cycle (exposure) time lead to increased risk of musculoskeletal disorders. Because of neurophysiological needs of the working muscles, adequate rest pauses (determined based on scientific knowledge on the physiology of muscular fatigue and recovery) should be scheduled to provide relief for the most active muscles used on the job. Furthermore, reduction in task repetition can be achieved by, for example, by task enlargement (increasing variety of tasks to perform), increase in the job cycle time, and work mechanization and automation.

The expected benefits of reduced musculoskeletal disorders problems in industry are improved productivity and quality of work products, enhanced safety and health of employees, higher employee morale, and accommodation of people with alternative physical abilities. Strategies for managing musculoskeletal disorders at work should focus on prevention efforts and should include, at the plant level, employee education, ergonomic job redesign, and other early intervention efforts, including engineering design technologies such as workplace reengineering, active and passive surveillance. At the macro-level, management of musculoskeletal disorders should aim to provide adequate occupational health care provisions, legislation, and industry-wide standardization.

10.2. Administrative and Engineering Controls

The recommendations for prevention of musculoskeletal disorders can be classified as either primarily administrative, that is, focusing on personnel solutions, or engineering, that is, focusing on redesigning tools, workstations, and jobs (Putz-Anderson 1988). In general, administrative controls are those actions to be taken by the management that limit the potentially harmful effects of a physically stressful job on individual workers. Administrative controls, which are focused on workers, refer to modification of existing personnel functions such as worker training, job rotation, and matching employees to job assignments.

Workplace design to prevent repetitive strain injury should be directed toward fulfilling the following recommendations:

1. Permit several different working postures.
2. Place controls, tools, and materials between waist and shoulder height for ease of reach and operation.
3. Use jigs and fixtures for holding purposes.
4. Resequence jobs to reduce the repetition.
5. Automate highly repetitive operations.
6. Allow self-pacing of work whenever feasible.
7. Allow frequent (voluntary and mandatory) rest breaks.

The following guidelines should be followed (for details see Putz-Anderson 1988):

1. Make sure the center of gravity of the tool is located close to the body and the tool is balanced.
2. Use power tools to reduce the force and repetition required.
3. Redesign the straight tool handle; bend it as necessary to preserve the neutral posture of the wrist.
4. Use tools with pistol grips and straight grips, respectively, where the tool axis in use is horizontal and vertical (or when the direction of force is perpendicular to the workplace).
5. Avoid tools that require working with the flexed wrist and extended arm at the same time or call for the flexion of distal phalanges (last joints) of the fingers.
6. Minimize the tool weight; suspend all tools heavier than 20 N (or 2 kg of force) by a counterbalancing harness.
7. Align the tool's center of gravity with the center of the grasping hand.
8. Use special-purpose tools that facilitate fitting the task to the worker (avoid standard off the-shelf tools for specific repetitive operations).
9. Design tools so that workers can use them with either hand.
10. Use power grip where power is needed and precision grip for precise tasks.
11. The handles and grips should be cylindrical or oval with a diameter of 3.0–4.5 cm (for precise operations the recommended diameter is 0.5–1.2 cm).
12. The minimum handle diameter should be 10.0 cm, and 11.5–12.0 cm is preferable.
13. A handle span of 5.0–6.7 cm can be used by male and female workers.
14. Triggers on power tools should be at least 5.1 cm wide, allowing their activation by two or three fingers.
15. Avoid form-fitting handles that cannot be easily adjusted.
16. Provide handles that are nonporous, nonslip and nonconductive (thermally and electrically).

11. JOB ANALYSIS AND DESIGN

According to ANSI Z-365 (1995), job analysis and design serve two common purposes:

1. To identify potential work-related risk factors associated with musculoskeletal disorders after they are reported
2. To assist in identifying work-related factors associated with musculoskeletal disorders before they occur

Detailed job analysis consists of analyzing the job at the element or micro-level. These analyses involve breaking down the job into component actions, measuring and quantifying risk factors, and identifying the problems and conditions contributing to each risk factor. Job surveys, on the other hand, are used for establishing work relatedness, prioritizing jobs for further analysis, or proactive risk factors surveillance. Such survey methods may include facility walk-throughs, worker interviews, risk-factor checklists, and team problem-solving approaches.

11.1. Risk Factors and Definitions

The risk factors are job attributes or exposures that increase probability of the occurrence of work-related musculoskeletal disorders. The WRMD risk factors are present at varying levels for different jobs and tasks. It should be noted that these risk factors are not necessarily causation factors of WRMDs. Also, the mere presence of a risk factor does not necessarily mean that a worker performing a job is at excessive risk of injury. (The relationship between physical stresses and WRMD risk factors is shown in Table 22.) Generally, the greater the exposure to a single risk factor or combination of factors, the greater the risk of a WRMD. Furthermore, the more risk factors that are present, the higher the risk of injury. According to ANSI Z-365 (1995), this interaction between risk factors may have a multiplicative rather than an additive effect. However, these risk factors may pose minimal risk of injury if sufficient exposure is not present or if sufficient recovery time is provided. It is known that changes in the levels of risk factors will result in changes in the risk of WRMDs. Therefore, a reduction in WRMD risk factors should reduce the risk for WRMDs. Figure 18 shows the flow chart for the ergonomics rule for control of MSDs at the workplace proposed by OSHA (2000).

11.2. Work Organization Risk Factors

The mechanisms by which poor work organization could increase the risk for WUEDs include modifying the extent of exposure to other risk factors (physical and environmental) and modifying the

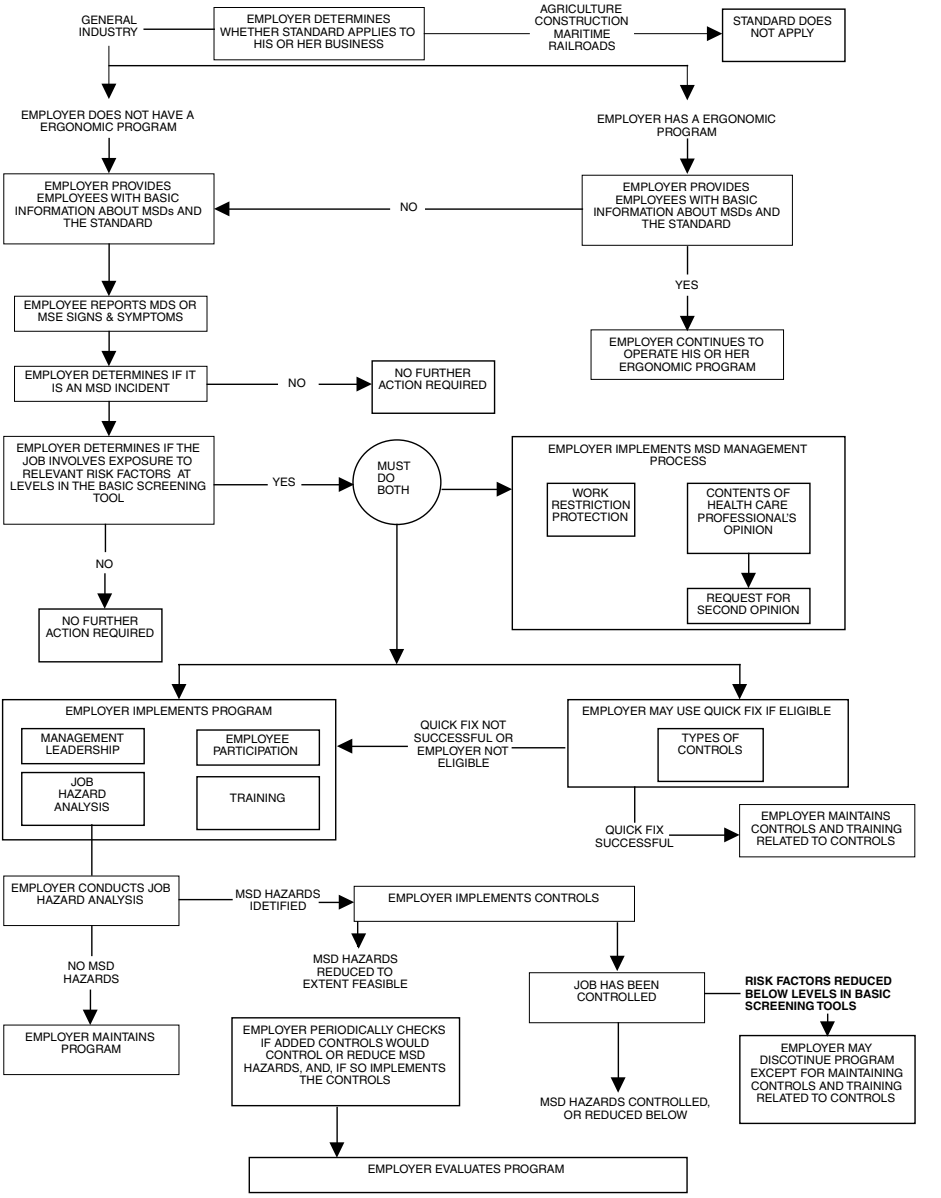

Figure 18 The Proposed OSHA Ergonomics Rule Flow Chart for Control of MSDs at the Workplace. (Modified after OSHA 2000)

stress response of the individual, thereby increasing the risk associated with a given level of exposure (ANSI 1995). Specific work organization factors that have been shown to fall into at least one of these categories include (but are not limited to):

1. Wage incentives
2. Machine-paced work
3. Workplace conflicts of many types

4. Absence of worker decision latitude
5. Time pressures and work overload
6. Unaccustomed work during training periods or after return from long-term leave

11.3. Procedures for Job Analysis and Design

Job analysis should be performed at a sufficient level of detail to identify potential work-related risk factors associated with WRMDs and include the following steps:

1. Collection of the pertinent information for all jobs and associated work methods
2. Interview of the representative sample of the affected workers
3. Breakdown of the jobs into tasks or elements
4. Description of the component actions of each task or element
5. Measurement and quantification of WRMD risk factors
6. Identification of the risk factors for each task or element
7. Identification of the problems contributing to risk factors
8. Summary of the problem areas and needs for intervention for all jobs and associated new work methods

12. SURVEILLANCE FOR JOB ANALYSIS AND DESIGN

12.1. Provisions of the ANSI Z-365 (1999) Draft Standard

Working Draft ANSI Z-365 includes sections on:

1. *Surveillance* of musculoskeletal disorders, including:
   (a) Worker reports
   (b) Analysis of existing records and surveys
   (c) Job surveys/proactive entry into the process
2. *Job analysis and design,* including:
   (a) Description of work
   (b) Definitions of risk factors
   (c) Risk-factor measurement, quantification, and interaction

12.2. Musculoskeletal Disorder Surveillance

As discussed in ANSI Z-365 (1999), surveillance is defined as the ongoing systematic collection, analysis, and interpretation of health and exposure data in the process of describing and monitoring work-related cumulative trauma disorders. Surveillance is used to determine when and where job analysis is needed and where ergonomic interventions may be warranted.

A surveillance system can be used in any workplace to evaluate cumulative trauma disorders (musculoskeletal disorders) in the working population. Surveillance is defined as ''the ongoing systematic collection, analysis and interpretation of health and exposure data in the process of describing and monitoring a health event. Surveillance data are used to determine the need for occupational safety and health action and to plan, implement and evaluate ergonomic interventions and programs'' (Klaucke 1988). Health and job risk-factor surveillance provide employers and employees with a means of systematically evaluating musculoskeletal disorders and workplace ergonomic risk factors by monitoring trends over time. This information can be used for planning, implementing, and continually evaluating ergonomic interventions. Therefore, incidence (rate of new cases), prevalence (rate of existing cases), and parameters that may be used in estimating severity must be defined.

12.3. Worker Reports (Case-Initiated Entry into the Process)

Follow-up to medical/first aid reports or worker symptoms consists of collecting and following employee medical reports through the medical management process.

12.4. Analysis of Existing Records and Survey (Past Case(s)-Initiated Entry into the Process)

Analysis of existing records and surveys consists of reviewing existing databases, principally collected for other purposes, to identify incidents and patterns of work-related cumulative trauma disorders. It can help determine and prioritize the jobs to be further analyzed using job analysis. There are three types of existing records and survey analyses:

1. Initial analysis of upper-limb WRMDs reported over the last 24–36 months
2. Ongoing trend analysis of past cases
3. Health surveys

12.5. Job Surveys (Proactive Entry into the Process)

The aim of proactive job surveys is to identify specific jobs and processes that may put employees at risk of developing WRMDs. Job surveys are typically performed after the jobs identified by the previous two surveillance components have been rectified. Job surveys of all jobs or a sample of representatives should be performed. Analysis of existing records will be used to estimate the potential magnitude of the problem in the workplace. The number of employees in each job, department, or similar population will be determined first. Then the incidence rates will be calculated on the basis of hours worked, as follows:

$$\text{Incidence (new case) rate (IR)} = \frac{\text{\# of new cases during time} \times 200{,}000}{\text{Total hours worked during time}}$$

This is equivalent to the number of new cases per 100 worker years. Workplace-wide incidence rates (IRs) will be calculated for all cumulative trauma disorders and by body location for each department, process, or type of job. (If specific work hours are not readily available, the number of full-time equivalent employees in each area multiplied by 2000 hours will be used to obtain the denominator.) Severity rates (SRs) traditionally use the number of lost workdays rather than the number of cases in the numerator. Prevalence rates (PRs) are the number of existing cases per 200,000 hours or the percentage of workers with the condition (new cases plus old cases that are still active).

12.6. ANSI Z-365 Evaluation Tools for Control of WRMDs

Some of the research evaluation tools defined by the ANSI Z-365 Draft Standard for the purpose of surveillance and job analysis include the following:

1. Proactive job survey (checklist #1)
2. Quick check risk factor checklist (checklist #2)
3. Symptom survey (questionnaire)
4. Posture discomfort survey
5. History of present illness recording form

12.7. Analysis and Interpretation of Surveillance Data

Surveillance data can be analyzed and interpreted to study possible associations between the WRMD surveillance data and the risk-factor surveillance data. The two principal goals of the analysis are to help identify patterns in the data that reflect large and stable differences between jobs or departments and to target and evaluate intervention strategies. This analysis can be done on the number of existing WRMD cases (cross-sectional analysis) or on the number of new WRMD cases in a retrospective and prospective fashion (retrospective and prospective analysis).

The simplest way to assess the association between risk factors and WRMDs is to calculate odds ratios (Table 29). To do this, the prevalence data obtained in health surveillance are linked with the data obtained in risk-factor surveillance. The data used can be those obtained with symptom ques-

TABLE 29 Examples of Odds Ratio Calculations for a Firm of 140 Employees

		WRMDs		
		Present	Not Present	Total
Risk factor				
	Present	15	25	40
		(A)	(B)	($A + B$)
	Not present	15	85	100
		(C)	(D)	($C + D$)
	Total	30	110	140
		($A + C$)	($B + D$)	(N)

Number in each cell indicates the count of employees with or without WRMD and the risk factor.
Odds ratio (OR) = $(A \times D)/(B \times C) = (15 \times 85)/(25 \times 15) = 3.4$

tionnaires (active level 1 health surveillance) and risk-factor checklists (level 1 active risk-factor surveillance). Each risk factor could be examined in turn to see whether it has an association with the development of WRMDs. In the example shown here, one risk factor at a time is selected (overhead work for more than four hours).

Using the data obtained in surveillance the following numbers of employees are counted:

- Employees with WRMDs and exposed to more than four hours of overhead work (15 workers)
- Employees with WRMDs and not exposed to more than four hours of overhead work (15 workers)
- Employees without WRMDs and exposed to more than four hours of overhead work (25 workers)
- Employees without WRMDs and not exposed to more than four hours of overhead work (85 workers)

The overall prevalence rate (PR), that is, rate of existing cases, for the firm is 30/140, or 21.4%. The prevalence rate for those exposed to the risk factor is 37.5% (15/40) compared to 15.0% (15/100) for those not exposed. The risk of having a WRMD depending on exposures to the risk factor, the odds ratio, can be calculated using the number of existing cases of WRMD (prevalence). In the above example, those exposed to the risk factor have 3.4 times the odds of having the WRMD than those not exposed to the risk factor. An odds ratio of greater than 1 indicates higher risk. Such ratios can be monitored over time to assess the effectiveness of the ergonomics program in reducing the risk of WRMDs, and a variety of statistical tests can be used to assess the patterns seen in the data.

13. ERGONOMICS PROGRAMS IN INDUSTRY

An important component of musculoskeletal disorders management efforts is development of a well-structured and comprehensive ergonomic program. According to Alexander and Orr (1992), the basic components of such a program should include:

1. Health and risk-factor surveillance
2. Job analysis and improvement
3. Medical management
4. Training
5. Program evaluation

An excellent program must include participation of all levels of management, medical, safety and health personnel, labor unions, engineering, facility planners, and workers and contain the following elements:

1. Routine (monthly or quarterly) reviews of the OSHA log for patterns of injury and illness and using of special computer programs to identify problem areas.
2. Workplace audits for ergonomic problems are a routine part of the organization's culture (more than one audit annually for each operating area). Problems identified in this manner are dealt with quickly.
3. List maintained of most critical problems—jobs with job title clearly identified. Knowledge of these problem jobs is widespread, including knowledge by management and the workers.
4. Use of both engineering solutions and administrative controls and seeking to use engineering solutions for long-term solutions.
5. Design engineering is aware of ergonomic considerations and actively builds them into new or reengineered designs. People are an important design consideration.
6. Frequent refresher training for the site-appointed ergonomists in ergonomics and access to short courses and seminars.

14. PROPOSED OSHA ERGONOMICS REGULATIONS

The National Research Council/National Academy of Sciences of the United States recently concluded that there is a clear relationship between musculoskeletal disorders and work and between ergonomic interventions and a decrease in such disorders. According to the Academy, research demonstrates that specific interventions can reduce the reported rate of musculoskeletal disorders for workers who perform high-risk tasks (National Research Council 1998). The effective and universal standard for dealing with the work-related hazards should significantly reduce the risk to WRMDS to employees.

The high prevalence of work-related musculoskeletal disorders, has motivated the Occupational Safety and Health Administration (OSHA) to focus on standardization efforts. Recently, OSHA announced the initiation of rulemaking under Section 6(b) of the Occupational Safety and Health Act of 1970, 29 U.S.C. 655, to amend Part 1910 of Title 29 of the Code of Federal Regulations and requested information relevant to preventing, eliminating, and reducing occupational exposure to ergonomic hazards.

According to OSHA (2000), the proposed standard is needed to bring this protection to the remaining employees in general industry workplaces that are at significant risk of incurring a work-related musculoskeletal disorder but are currently without ergonomics programs. A substantial body of scientific evidence supports OSHA's effort to provide workers with ergonomic protection. This evidence strongly supports two basic conclusions: (1) there is a positive relationship between work-related musculoskeletal disorders and workplace risk factors, and (2) ergonomics programs and specific ergonomic interventions can reduce these injuries.

14.1. Main Provisions of the Draft Ergonomics Standard

The standard applies to employers in general industry whose employees work in manufacturing jobs or manual handling jobs or report musculoskeletal disorders (MSDs) that meet the criteria of the standard (see Figure 18). The standard applies to the following jobs:

1. Manufacturing jobs. Manufacturing jobs are production jobs in which employees perform the physical work activities of producing a product and in which these activities make up a significant amount of their work time;
2. Manual handling jobs. Manual handling jobs are jobs in which employees perform forceful lifting/lowering, pushing/pulling, or carrying. Manual handling jobs include only those jobs in which forceful manual handling is a core element of the employee's job; and
3. Jobs with a musculoskeletal disorder. Jobs with an MSD are those jobs in which an employee reports an MSD that meets all of these criteria:
   (a) The MSD is reported after the effective date;
   (b) The MSD is an ''OSHA recordable MSD,'' or one that would be recordable if the employer was required to keep OSHA injury and illness records; and
   (c) The MSD also meets the screening criteria.

The proposed standard covers only those OSHA-recordable MSDs that also meet these screening criteria:

1. The physical work activities and conditions in the job are reasonably likely to cause or contribute to the type of MSD reported; and
2. These activities and conditions are a core element of the job and/or make up a significant amount of the employee's work time.

The standard applies only to the jobs specified in Section 1910.901, not to the entire workplace or to other workplaces in the company. The standard does not apply to agriculture, construction, or maritime operations. In the proposed standard, a full ergonomics program consists of these six program elements:

1. Management leadership and employee participation
2. Hazard information and reporting
3. Job hazard analysis and control
4. Training
5. MSD management
6. Program evaluation

According to the standard, the employer must:

1. Implement the first two elements of the ergonomics program (management leadership and employee participation, and hazard information and reporting) even if no MSD has occurred in those jobs.
2. Implement the other program elements when either of the following occurs in those jobs (unless one eliminates MSD hazards using the quick fix option

(a) A covered MSD is reported; or

(b) Persistent MSD symptoms are reported plus:

(i) The employer has knowledge that an MSD hazard exists in the job;

(ii) Physical work activities and conditions in the job are reasonably likely to cause or contribute to the type of MSD symptoms reported; and

(iii) These activities and conditions are a core element of the job and/or make up a significant amount of the employee's work time.

In other jobs in general industry, the employer should comply with all of the program elements in the standard when a covered MSD is reported (unless the MSD hazards are eliminated using the quick fix option). The employer should do the following to quick fix a problem job:

1. Promptly make available the MSD management
2. Consult with employee(s) in the problem job about the physical work activities or conditions of the job they associate with the difficulties, observe the employee(s) performing the job to identify whether any risk factors are present, and ask employee(s) for recommendations for eliminating the MSD hazard
3. Put in quick fix controls within 90 days after the covered MSD is identified and check the job within the next 30 days to determine whether the controls have eliminated the hazard
4. Keep a record of the quick fix controls
5. Provide the hazard information the standard requires to employee(s) in the problem job within the 90-day period

The employer should set up the complete ergonomics program if either the quick fix controls do not eliminate the MSD hazards within the quick fix deadline (120 days) or another covered MSD is reported in that job within 36 months.

The employer should demonstrate management leadership of your ergonomics program. Employees (and their designated representatives) must have ways to report MSD signs and MSD symptoms, get responses to reports; and be involved in developing, implementing, and evaluating each element of your program. The employer should not have policies or practices that discourage employees from participating in the program or from reporting MSDs signs or symptoms. The employer also should:

1. Assign and communicate responsibilities for setting up and managing the ergonomics program so managers, supervisors, and employees know what you expect of them and how you will hold them accountable for meeting those responsibilities
2. Provide those persons with the authority, resources, information, and training necessary to meet their responsibilities
3. Examine your existing policies and practices to ensure that they encourage and do not discourage reporting and participation in the ergonomics program
4. Communicate periodically with employees about the program and their concerns about MSDs

According to the proposed standard, the employees (and their designated representatives) must have a way to report MSD signs and symptoms; prompt responses to their reports; access to the standard and to information about the ergonomics program; and ways to be involved in developing, implementing, and evaluating each element of the ergonomics program.

The employer should set up a way for employees to report MSD signs and symptoms and get prompt responses. The employer should evaluate employee reports of MSD signs and symptoms to determine whether a covered MSD has occurred. The employer should periodically provide information to employees that explains how to identify and report MSD signs and symptoms. The employer should also provide this information to current and new employees about common MSD hazards, the signs and symptoms of MSDs and the importance of reporting them early, how to report the signs and symptoms, and a summary of the requirements of the standard.

14.2. Job Hazard Analysis and Control

According to the Draft Standard, the employer should analyze the problem job to identify the ergonomic risk factors that result in MSD hazards. The employer should eliminate the MSD hazards, reduce them to the extent feasible, or materially reduce them using the incremental abatement process in the standard. If the MSD hazards only pose a risk to the employee with the covered MSD, the job hazard analysis and control can be limited to that individual employee's job. In such a case, the employer should:

1. Include in the job-hazard analysis all of the employees in the problem job or those who represent the range of physical capabilities of employees in the job.
2. Ask the employees whether performing the job poses physical difficulties and, if so, which physical work activities or conditions of the job they associate with the difficulties.
3. Observe the employees performing the job to identify which of the physical work activities, workplace conditions, and ergonomic risk factors are present.
4. Evaluate the ergonomic risk factors in the job to determine the MSD hazards associated with the covered MSD. As necessary, evaluate the duration, frequency, and magnitude of employee exposure to the risk factors.

The proposed engineering controls include physical changes to a job that eliminate or materially reduce the presence of MSD hazards. Examples of engineering controls for MSD hazards include changing, modifying, or redesigning workstations, tools, facilities, equipment, materials, and processes. Administrative controls are changes in the way that work in a job is assigned or scheduled that reduce the magnitude, frequency, or duration of exposure to ergonomic risk factors. Examples of administrative controls for MSD hazards include employee rotation, job task enlargement, alternative tasks, and employer-authorized changes in work pace.

Finally, it should be noted that the OSHA's Final Ergonomic Program Standard took effect on January 16, 2001.
