Whilst the advice and information in this book are believed to be true and accurate at the date of going to press, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. In particular (but without limiting the generality of the preceding disclaimer) every effort has been made to check drug dosages; however, it is still possible that errors have been missed. Furthermore, dosage schedules are constantly being revised and new side effects recognized. For these reasons the reader is strongly urged to consult the drug companies' printed instructions before administering any of the drugs recommended in this book.

List of contributors	xi
Foreword <i>Edmond Chiu</i>	xix
Preface to the Third Edition	xx
Preface to the Second Edition	xxi
Preface to the First Edition	xxiii
Acknowledgements	xxv
Abbreviations	xxvii
PART 1 Dementia: general aspects	1
Introduction	
1 Dementia: historical overview <i>German Berrios</i>	3
2 Epidemiology <i>Daniel W O'Connor</i>	16
Diagnosis and assessment	
3 Criteria for the diagnosis of dementia <i>Clive Ballard and Carol Bannister</i>	24
4 Assessment of dementia <i>Rebecca Eastley and Gordon K Wilcock</i>	38
5 Neuropsychological assessment of dementia <i>Andrew D Blackwell, Barnaby D Dunn, Adrian M Owen and Barbara J Sahakian</i>	45
6 Neuropsychiatric aspects of dementia <i>Iracema Leroi and Constantine G Lyketsos</i>	55
7 Rating scales in dementia	65
7a Screening instruments for the detection of cognitive impairment <i>Leon Flicker</i>	66
7b Measurement of behavioural disturbance, non-cognitive symptoms and quality of life <i>Ajit Shah, Stephen Foli and Ian O Nnatu</i>	72
Investigations	
8 Structural brain imaging <i>Robert Barber and John O'Brien</i>	81
9 Functional imaging <i>Klaus P Ebmeier, Jane K Sutherland and Nadine J Dougall</i>	94
10 The neurophysiology of dementia <i>Michael Philpot</i>	104

	Management	
11	Caring for people with dementia	117
	11a Family carers for people with dementia	118
	<i>Henry Brodaty, Alisa Green and Lee-Fay Low</i>	
	11b One caregiver's view	132
	<i>Emerson Moran</i>	
12	Health economic aspects of dementia	136
	<i>Anders Wimo, Göran Karlsson and Bengt Winblad</i>	
13	Cross-cultural issues in the assessment of cognitive impairment	147
	<i>Ajit Shah, James Lindesay and Ian O Nnatu</i>	
14	Helping staff and patients with dementia through better design	165
	<i>Mary Marshall</i>	
15	The role of primary care in the management of dementia	170
	<i>Bill Pettit</i>	
16	Multidisciplinary approaches in the management of dementia	179
	16a The role of nursing	180
	<i>Peggy A Szwabo</i>	
	16b Social work and care management	186
	<i>David Challis, Jane Hughes and Caroline Sutcliffe</i>	
	16c Occupational therapy	191
	<i>Michael Loh</i>	
	16d Speech and language therapy	195
	<i>Bronwyn Moorhouse</i>	
	16e Physiotherapy	203
	<i>Irene Smith Lassen</i>	
17	Sexuality and dementia	208
	<i>James P Warner</i>	
18	Quality of life in dementia: conceptual and practical issues	215
	<i>Betty S Black and Peter V Rabins</i>	
19	Moral, ethical and legal aspects of dementia	229
	19a Ethical issues	230
	<i>Stephen J Louw and Julian C Hughes</i>	
	19b Legal issues	235
	<i>Bernard M Dickens</i>	
	19c End-of-life decisions	239
	<i>Julian C Hughes and Stephen J Louw</i>	
	19d Driving	244
	<i>Desmond O'Neill</i>	
20	Services to people with dementia: a worldwide view	253
	20a Africa	254
	<i>Olusegun Baiyewu and Adesola O Ogunniyi</i>	
	20b Australia	256
	<i>Dina LoGiudice, Eleanor Flynn and David Ames</i>	
	20c China	261
	<i>Yu Xin</i>	
	20d The Former Soviet Union	265
	<i>Robin Jacoby</i>	
	20e France	267
	<i>Bruno Vellas, B Bos, Benoit Lavallart and L Gregoire</i>	
	20f Germany	269
	<i>Siegfried Weyerer and Martina Schäufele</i>	
	20g Hong Kong	272
	<i>Helen Chiu</i>	
	20h India	274
	<i>Kalyanasundaram S and Mathew Varghese</i>	

20i	Italy	276
	<i>Angelo Bianchetti and Marco Trabucchi</i>	
20j	Japan	281
	<i>Masahiro Shigeta and Akira Homma</i>	
20k	Mexico	283
	<i>David Resnikoff and Alonso Riestra</i>	
20l	Netherlands	288
	<i>Thea J Heeren</i>	
20m	New Zealand	290
	<i>Pamela S Melding</i>	
20n	Nordic countries	294
	<i>Kirsten Abelskov</i>	
20o	Romania	296
	<i>Nicoleta Tătaru</i>	
20p	Latin America and the Caribbean	299
	<i>João Carlos Barbosa Machado</i>	
20q	Spain	303
	<i>Raimundo Mateos, Manuel Martín-Carrasco and Manuel Sánchez-Pérez</i>	
20r	Britain	306
	<i>Martin Brown, Colin Godber and David G Wilkinson</i>	
20s	North America	311
	<i>Robin J Casten and Barry W Rovner</i>	
21	Services for younger people with dementia	316
	<i>Robert C Baldwin and Michelle Murray</i>	
22	Alzheimer (disease and related disorders) Associations and Societies: supporting family carers	323
	<i>Henry Brodaty, Alisa Green, Nori Graham and Lee-Fay Low</i>	
PART 2	Mild cognitive impairment	331
23	A historical perspective	333
	<i>Karen Ritchie and Sylvaine Artero</i>	
24	Clinical characterization	338
	<i>Selam Negash, Yonas Endale Geda and Ronald C Petersen</i>	
25	Treatment	347
	<i>Roger Bullock</i>	
PART 3	Alzheimer's disease	357
	Clinical aspects	
26	What is Alzheimer's disease?	359
	<i>Hans Förstl</i>	
27	Risk factors for Alzheimer's disease	369
	<i>Anthony F Jorm</i>	
28	The natural history of Alzheimer's disease	376
	<i>Jody Corey-Bloom and Adam S Fleisher</i>	
	Neurobiology	
29	Neurochemistry of Alzheimer's disease	387
	<i>Nicholas A Clarke and Paul T Francis</i>	
30	Neuropathology of Alzheimer's disease	393
	<i>Colin L Masters</i>	
31	Role of tau protein in neurodegenerative dementias	408
	<i>Elizabeta B Mukaetova-Ladinska</i>	
32	Role of Aβ amyloid in the pathogenesis of Alzheimer's disease	426
	<i>Craig W Ritchie, Catriona McLean, Konrad Beyreuther and Colin L Masters</i>	

33	Vascular factors in Alzheimer's disease	436
	<i>Robert Stewart</i>	
34	Genetics of Alzheimer's disease	444
	<i>Margie Smith</i>	
35	Transgenic mouse models of Alzheimer's disease	452
	<i>Simon P Brooks and Stephen B Dunnett</i>	
	Therapeutic strategies	
36	How effective are cholinergic therapies in improving cognition in Alzheimer's disease?	465
	<i>David G Wilkinson</i>	
37	Non-cholinergic therapies of dementia	474
	<i>Lon S Schneider</i>	
38	Treatments for behavioural and psychological symptoms in Alzheimer's disease and other dementias	482
	<i>Louis Profenno, Pierre Tariot, Rebekah Loy and Saleem Ismail</i>	
39	A predominantly psychosocial approach to behaviour problems in dementia: treating causality	499
	<i>Michael Bird</i>	
40	Psychological approaches for the management of cognitive impairment in Alzheimer's disease	510
	<i>Anne Unkenstein</i>	
41	Prevention of Alzheimer's disease	515
	<i>Nitin B Purandare, Clive Ballard and Alistair Burns</i>	
42	Trial design	522
	<i>Serge Gauthier</i>	
PART 4	Cerebrovascular disease and cognitive impairment	527
43	Vascular cognitive impairment	529
	<i>Timo Erkinjuntti</i>	
44	Leukoaraiosis and cognitive impairment	546
	<i>Leonardo Pantoni and Domenico Inzitari</i>	
45	Vascular dementia: neuropathological features	565
	<i>Raj N Kalaria</i>	
46	Therapeutic strategies for vascular dementia	574
	<i>Gustavo Román</i>	
PART 5	Dementia with Lewy bodies and Parkinson's disease	601
47	Dementia with Lewy bodies: a clinical overview	603
	<i>Ian G McKeith</i>	
48	Pathology of dementia with Lewy bodies	615
	<i>Paul G Ince and Elaine K Perry</i>	
49	Neuropsychological changes in dementia with Lewy bodies	634
	<i>David P Salmon and Joanne M Hamilton</i>	
50	The treatment of dementia with Lewy bodies	648
	<i>E Jane Byrne</i>	
51	Cognitive impairment and dementia in Parkinson's disease	657
	<i>Dag Aarsland and Carmen Janvin</i>	
PART 6	Focal dementias	665
52	Frontotemporal dementia	667
	<i>David Neary</i>	
53	Pick's disease: its relationship to progressive aphasia, semantic dementia and frontotemporal dementia	678
	<i>Andrew Graham and John Hodges</i>	
54	The genetics and molecular pathology of frontotemporal lobar degeneration	689
	<i>David M A Mann</i>	
55	Semantic dementia	702
	<i>Julie S Snowden</i>	

56	The cerebellum and cognitive impairment <i>Elsdon Storey</i>	713
57	Progressive aphasia and other focal syndromes <i>Jason D Warren, Richard J Harvey and Martin N Rossor</i>	720
PART 7	Dementia and neuropsychiatric disorders	729
58	Depression with cognitive impairment <i>Bindu Shanmugham and George Alexopoulos</i>	731
59	Alcohol-related dementia and the clinical spectrum of Wernicke–Korsakoff syndrome <i>Stephen C Bowden and Alison J Ritter</i>	738
60	Dementia and intellectual disability <i>Jennifer Torr</i>	745
61	Schizophrenia, cognitive impairment and dementia <i>Oswaldo P Almeida and Robert Howard</i>	750
62	Huntington's disease <i>Phyllis Chua and Edmond Chiu</i>	754
63	Creutzfeldt–Jakob disease and other prion diseases <i>John Collinge</i>	763
64	Human immunodeficiency virus type 1-associated dementia: pathology, clinical features and treatment <i>Apsara Kandaneeratchi and Ian Paul Overall</i>	777
65	Uncommon forms of dementia <i>Anoop Varma</i>	795
	Appendix: national Alzheimer's associations	805
	Index	811

List of contributors

Dag Aarsland MD, PhD
Head of Research,
Psychiatry Centre for Clinical Neuroscience Research,
Stavanger University Hospital,
Stavanger, Norway

Kirsten Abelskov MD
Consultant, Psychiatrist,
Psychogeriatric Department,
Aarhus University Hospitals,
Denmark

George Alexopoulos MD
Professor of Psychiatry,
Weill Medical College,
Cornell University,
New York, USA

Oswaldo P Almeida MD, PhD, FRANZCP
Professor of Geriatric Psychiatry,
School of Psychiatry and Clinical Neurosciences,
University of Western Australia,
Australia

David Ames BA, MD, FRCPsych, FRANZCP
Professor of Psychiatry of Old Age,
University of Melbourne,
St George's Hospital, Melbourne,
Victoria, Australia

Sylvaine Artero
Institut National de la Santé et de la Recherche
Médicale (INSERM),
Hôpital La Colombière,
Montpellier, France

Olusegun Baiyewu MBBS, FMC(Psych), FWACP
Professor of Psychiatry,
College of Medicine,
University of Ibadan,
Ibadan, Nigeria

Robert C Baldwin DM, FRCP, FRCPsych
Consultant Old Age Psychiatrist and
Honorary Professor of Psychiatry,
Institute for the Health of the Elderly,
Wolfson Research Centre,
Newcastle City Health NHS Trust,
Newcastle upon Tyne, UK

Clive Ballard MD, MB ChB, M MedSci, MRCPsych
Professor and Research Director of the Alzheimer's Society,
Wolfson Research Centre for Age-Related Diseases,
King's College London,
London, UK

Carol Bannister MB ChB, MRCPsych
Consultant in Old Age Psychiatry,
The Fiennes Centre,
Banbury, UK

Robert Barber MRCPsych, MD
Consultant Old Age Psychiatrist,
Institute for the Health of the Elderly,
Wolfson Research Centre,
Newcastle General Hospital,
Newcastle upon Tyne, UK

German Berrios BA (OXFORD), MD, DM H.C. HEIDELBERG, FRCPsych, FBPSS
Professor,
University of Cambridge Department of Psychiatry,
Cambridge, UK

Konrad Beyreuther Dr rer nat, Dr med hc
Professor of Molecular Biology and
Head of the Laboratory of Molecular Neuropathology,
Centre for Molecular Biology,
University of Heidelberg,
Heidelberg, Germany

Angelo Bianchetti MD
Head of Department of Internal Medicine and
Alzheimer Evaluation Unit,
Istituto Clinico S. Anna
Brescia, Italy

Michael Bird BA, MPsych, PhD
Senior Clinical Psychologist for the Aged and
Co-ordinator of Aged Mental Health,
Southern Area Health Service,
Queanbeyan, Australia

Betty S Black PhD
Assistant Professor,
Department of Psychiatry and Behavioral Sciences,
John Hopkins School of Medicine,
Baltimore, Maryland, USA

Andrew D Blackwell MA (hons), PhD
Research Associate,
University of Cambridge Department of Psychiatry,
Addenbrooke's Hospital,
Cambridge, UK

B Bos
ARH, Agence Regionale d'Hospitalisation,
Toulouse, France

Stephen C Bowden PhD
Head of Neuropsychology,
St Vincent's Hospital, Melbourne, and
Department of Psychology, University of Melbourne,
Australia

Henry Brodaty AO, MBBS, MD, FRACP, FRANZCP
Professor,
School of Psychiatry,
University of New South Wales,
Australia

Simon P Brooks PhD
Senior Post Doctoral Researcher,
Brain Repair Group,
Cardiff University,
Cardiff, UK

Martin Brown DM, MRCPsych
Consultant in Old Age Psychiatry,
St James Hospital,
Portsmouth, UK

Roger Bullock MA MRCPsych
Consultant in Old Age Psychiatry,
Kingshill Research Centre,
Victoria Hospital,
Swindon, UK

Alistair Burns MPhil, MD, FRCP, FRCPsych
Professor of Old Age Psychiatry,
Wythenshawe Hospital,
Manchester, UK

E Jane Byrne MB ChB, FRCPsych
Senior Lecturer and Honorary Consultant Psychiatrist,
School of Psychiatry and Behavioural Sciences,
Wythenshawe Hospital,
Manchester, UK

Robin Casten PhD
Assistant Professor,
Department of Psychiatry and Human Behavior,
Jefferson Medical College,
Philadelphia, USA

David Challis
Professor of Community Care Research and
Director, PSSRU,
University of Manchester, Manchester, UK

Edmond Chiu AM, MBBS, DPM, FRANZCP
Professor and Director,
Huntington's Disease Clinic,
University of Melbourne, Australia

Helen Chiu FRCPsych
Chair and Professor of Psychiatry,
Department of Psychiatry,
The Chinese University of Hong Kong,
Tai Po, Hong Kong

Phyllis Chua MB BS, MMed, FRANZCP
Senior Lecturer,
University of Melbourne and
Consultant Psychiatrist,
Department of Neuropsychiatry,
The Royal Melbourne Hospital, Australia

Nicholas A Clarke MD, MRCPsych
Consultant in Old Age Psychiatry,
West Kent NHS and Social Care Trust,
and King's Hill Kent and Honorary Research Associate,
Wolfson Centre for Age-Related Diseases,
King's College London,
London, UK

John Collinge MD, FRCP, FRCPATH, FMedSci
Professor,
MRC Prion Unit and
Department of Neurodegenerative Disease,
Institute of Neurology,
National Hospital for Neurology and Neurosurgery,
London, UK

Jody Corey-Bloom MD, PhD
Professor of Neurosciences,
Department of Neurosciences,
University of California, La Jolla,
San Diego, USA

Bernard M Dickens PhD, LL.D, FRS(C)
Professor Emeritus of Health Law and Policy,
University of Toronto,
Canada

Nadine J Dougall BSc, MSc Grad. Stat.

Research Fellow,
Division of Psychiatry,
School of Molecular and Clinical Medicine,
University of Edinburgh,
Edinburgh, UK

Barnaby D Dunn MA, PhD, DClinPsy

Post-doctoral Scientist at the MRC Cognition and
Brain Sciences Unit
Cambridge, UK

Stephen B Dunnett DSc

Professor and Head,
Brain Repair Group,
Cardiff University,
Cardiff, UK

Rebecca Eastley MRCPsych

Consultant in Psychiatry of Old Age,
Avon and Western Wiltshire Mental Health Care NHS Trust,
Avonmead, Southmead Hospital,
Bristol, UK

Klaus P Ebmeier MD

Professor,
Gordon Small Centre for Research in Old Age Psychiatry,
University of Edinburgh,
Edinburgh, UK

Timo Erkinjuntti MD, PhD

Chief, Memory Research Unit,
Department of Neurology,
Helsinki University Central Hospital,
Helsinki, Finland

Ian Paul Everall PhD, MRCPsych, FRCPath

Professor of Psychiatry,
University of California,
San Diego, USA

Adam S Fleisher MD

Medical Director of Alzheimer's Disease
Co-operative Study,
University of California,
San Diego, USA

Leon Flicker MBBS, GDipEpid, PhD, FRACP

Professor,
School of Medicine and Pharmacology,
University of Western Australia,
Australia

Eleanor Flynn MBBS, BEd, BTheol, Dip Ger Med, FRACGP, FRACMA, AFACHSE

Senior Lecturer in Medical Education,
Faculty of Medicine, Dentistry and Health Science,
University of Melbourne, Australia

Stephen Foli MB ChB, MRCPsych

Consultant Psychiatrist,
West London Mental Health NHS Trust,
London, UK

Hans Förstl FRANZCP

Professor and Director,
Department of Psychiatry and Psychotherapy,
Technical University of Munich,
Munich, Germany

Paul T Francis PhD

Senior Lecturer in Biochemistry,
Wolfson Centre for Age-Related Diseases,
King's College London,
London, UK

Serge Gauthier MD, FRCPC

Director,
Alzheimer Disease Research Unit,
McGill Centre for Studies in Aging,
Verdun, QC, Canada

Yonas Endale Geda MD

Neuropsychiatrist,
Assistant Professor of Psychiatry,
Alzheimer's Disease Research Center,
Mayo Clinic College of Medicine,
Rochester, USA

Colin Godber FRCPSych, FRCP, MPhil, OBE

Consultant in Old Age Psychiatry,
Moorgreen Hospital,
Southampton, UK

Andrew Graham MRCP

Wellcome Research Training Fellow and
Honorary Senior Clinical Fellow in Neurology,
MRC Cognition and Brain Sciences Unit,
Cambridge, UK

Nori Graham BM BCh, FRCPSych, D Univ

Chairman of Alzheimer's Disease International,
Consultant in Old Age Psychiatry,
Department of Psychiatry,
Royal Free Hospital,
London, UK

Alisa Green BSc(Psych)(Hons)

Research Psychologist,
Academic Department of Old Age Psychiatry,
Prince of Wales Hospital,
New South Wales, Australia

L Gregoire

DHOS, Ministry of Health,
Paris, France

Joanne M Hamilton PhD

Assistant Project Neuroscientist,
Department of Neurosciences,
University of California,
San Diego, USA

Richard J Harvey MD, MRCPsych, FRANZCP

Associate Professor and
Consultant Psychiatrist for Older People,
Aged Psychiatry Service,
The Geelong Hospital,
Victoria, Australia

Thea J Heeren MD

Professor of Old Age Psychiatry,
Medical Director of the Department of Old Age Psychiatry,
Altrecht Mental Health Care,
The Netherlands

John Hodges FMedSci

Professor of Behavioural Neurology,
MRC Cognition and Brain Sciences Unit and
University of Cambridge Department of Neurology,
Cambridge, UK

Akira Homma MD

Senior Research Scientist,
Tokyo Metropolitan Institute of Gerontology,
Tokyo, Japan

Robert Howard MD, MRCPsych

Professor of Old Age Psychiatry,
Section of Old Age Psychiatry,
Institute of Psychiatry,
University of London, UK

Jane Hughes MSc, BA(Econ), DSW, CQSW

Lecturer in Community Care Research,
PSSRU,
University of Manchester, UK

Julian C Hughes MA, MB ChD, PhD, MRCPsych

Consultant in Old Age Psychiatry and
Honorary Clinical Senior Lecturer,
University of Newcastle upon Tyne,
Newcastle upon Tyne, UK

Paul G Ince MD, FRCPath

Professor of Neuropathology,
University of Sheffield,
Sheffield, UK

Domenico Inzitari MD

Staff Neurologist,
Department of Neurological and Psychiatric Sciences,
University of Florence,
Florence, Italy

Saleem Ismail MD

Department of Neurology,
University of Rochester Medical Center,
Rochester, New York, USA

Robin Jacoby DM, FRCP, FRCPsych

Professor of Old Age Psychiatry,
University of Oxford,
Oxford, UK

Carmen Janvin MPsych

Psychologist,
Section for Geriatric Psychiatry,
Stavanger University Hospital,
Stavanger, Norway

Anthony F Jorm PhD, DSc

Director and Professor,
Centre for Mental Health Research,
Australian National University,
Canberra, Australia

Raj N Kalaria FRCPath

Professor of Cerebrovascular Pathology,
Wolfson Research Centre, CBV Group,
Institute for the Health of the Elderly,
Newcastle General Hospital,
Newcastle upon Tyne, UK

Kalyanasundaram S MD

Principal and Professor of Psychiatry,
The Richmond Fellowship Society (India),
Jayangar, Bangalore, India

Apsara Kandaneeratchi PhD

Postdoctoral Research Worker,
Section of Experimental Neuropathology and Psychiatry,
Institute of Psychiatry,
King's College London,
London, UK

Göran Karlsson PhD

Health Economist,
AstraZeneca,
Stockholm, Sweden

Benoit Lavallart MD

Direction Generale de la Santé,
Ministry of Health,
Paris, France

Iracema Leroi MD, FRCP, MRCPsych

Consultant/Honorary Lecturer in Old Age Psychiatry,
University of Manchester,
Manchester, UK

James Lindsay DM, MRCPsych
Professor of Psychiatry for the Elderly,
University of Leicester,
Leicester General Hospital,
Leicester, UK

Dina LoGiudice MB BS, PhD, FRACP
Geriatrician,
Melbourne Extended Care and Rehabilitation Service,
Victoria, Australia

Michael Loh BAppSc (Occupational Therapy), BSc, Grad Dip Gerontology
Clinical Manager,
Mobile Aged Psychiatry Services,
Caulfield General Medical Centre,
Caulfield, Victoria, Australia

Stephen J Louw MB ChB, MD, FCP(SA), FRCP(Lond), FRCP(Edin)
Consultant Physician and
Clinical Director of Internal Medicine and
Geriatric Medicine,
Freeman Hospital,
Newcastle upon Tyne, UK

Lee-Fay Low BSc
Centre for Mental Health Research,
The Australian National University,
Canberra, Australia

Rebekah Loy PhD
Department of Neurology,
University of Rochester Medical Center,
Rochester, New York, USA

Constantine G Lyketsos MD, MHS
Professor of Psychiatry and Behavioral Sciences,
Co-Director, Division of Geriatric Psychiatry and
Neuropsychiatry,
The Johns Hopkins Hospital,
Baltimore, Maryland, USA

Ian G McKeith MD, BS, FRCPsych, FMedSci
Professor, Department of Old Age Psychiatry,
Wolfson Research Centre,
Newcastle upon Tyne, UK

Catriona McLean BSc, MBBS, FRCPA, MD
Associate Professor and Consultant Pathologist,
The Alfred Hospital,
Pahran, Australia

João Carlos Barbosa Machado
Director,
Aurus IEPE,
Institute of Research and Education on Ageing,
Belo Horizonte, Brazil

David M A Mann BSc, PhD, FRCPath
Professor of Neuropathology,
University of Manchester,
Hope Hospital,
Salford, UK

Mary Marshall MA, DSA, DASS
Professor and Director,
Dementia Services Development Centre,
University of Stirling,
Stirling, UK

Colin L Masters BMedSci, MBBS, MD, FRACP
Professor and Head,
Department of Pathology,
University of Melbourne, Parkville,
Victoria, Australia

Manuel Martín-Carrasco MD, PhD
Clinical Director,
Clínica Psiquiàtrica Padre Menni, and
Associate Professor,
Universidad de Navarra School of Medicine,
Pamplona, Spain

Raimundo Mateos MD, PhD
Professor of Psychiatry,
Department of Psychiatry,
Universidad de Santiago de Compostela (USC),
Coordinator of the Psychogeriatric Unit,
Conxo Psychiatric Hospital,
Complejo Hospitalario Universitario de Santiago de
Compostela,
Santiago, Spain

Pamela S Melding MB ChB, FFARCS, FRANZCP, Dip.HSM
Clinical Senior Lecturer,
Department of Psychological Medicine,
University of Auckland,
New Zealand

Bronwyn Moorhouse BAppSci (Speech Path), MPhil, PhD
Speech Pathologist,
Acquired Brain Injury Unit,
Royal Talbot Rehabilitation Centre,
Victoria, Australia

Emerson Moran
Writer,
Florida, USA

Elizabeta B Mukaetova-Ladinska MD, MMedSci, PhD, MRCPsych
Senior Lecturer/Honorary Consultant in Old Age Psychiatry,
Department of Old Age Psychiatry,
University of Newcastle,
Newcastle upon Tyne, UK

Michelle Murray RMN

Specialist Development Nurse,
Young Onset Dementia Service,
Manchester Royal Infirmary,
Manchester, UK

David Neary MD, FRCP

Professor, Department of Neurology,
Greater Manchester Neuroscience Centre,
Hope Hospital,
Salford, UK

Selam Negash PhD

Cognitive Neuroscience Fellow,
Alzheimer's Disease Research Center,
Mayo Clinic College of Medicine,
Rochester, New York, USA

Ian O Nnatu MB ChB, MRCPsych

Specialist Registrar in Old Age Psychiatry and
General Adult Psychiatry,
West London Mental Health NHS Trust,
Middlesex, UK

John O'Brien MA, DM, FRCPsych

Professor of Old Age Psychiatry,
Institute for Ageing and Health,
University of Newcastle upon Tyne,
Newcastle upon Tyne, UK

Daniel W O'Connor MD, FRANZCP

Professor of Psychiatry of Old Age,
Department of Psychological Medicine,
Monash University,
Victoria, Australia

Adesola O Oggunniyi MB ChB, FMCP, FWACP

Professor of Medicine,
College of Medicine,
University of Ibadan,
Ibadan, Nigeria

Desmond O'Neill

Senior Lecturer in Geriatrics,
Trinity College,
Dublin, Ireland

Adrian M Owen PhD

MRC Senior Scientist,
MRC Cognition and Brain Sciences Unit,
Cambridge, UK

Leonardo Pantoni MD, PhD

Staff Neurologist,
Department of Neurological and Psychiatric Sciences,
University of Florence,
Florence, Italy

Elaine K Perry BSc, PhD, DSc

Professor of Neurochemical Pathology,
MRC Neurochemical Pathology Unit,
Newcastle General Hospital,
Newcastle upon Tyne, UK

Ronald C Petersen PhD, MD

Professor of Neurology and Director,
Alzheimer's Disease Research Center,
Mayo Clinic College of Medicine,
Rochester, New York, USA

Bill Pettit MB ChB, FRCGP

General Practitioner,
Wythenshawe,
Manchester, UK

Michael Philpot BSc, MB BS, FRCPsych

Consultant in Old Age Psychiatry,
Mental Health of Older Adults,
South London and Maudsley NHS Trust,
London, UK

Louis Profenno MD, PhD

Department of Psychiatry and Neurology,
University of Rochester Medical Center,
Rochester, New York, USA

Nitin B Purandare MBBS, DPM MD, DGM MRCPsych

Senior Lecturer and
Honorary Consultant in Old Age Psychiatry,
Wythenshawe Hospital,
Manchester, UK

Peter V Rabins MD, MPH

Professor,
Department of Psychiatry and Behavioral Sciences,
John Hopkins Medical Institutions,
Baltimore, Maryland, USA

David Resnikoff MD

Psychogeriatrician,
Instituto Mexicano De Neurociencias,
Estado de Mexico, Mexico

Foreword

When Raymond Levy and Alistair Burns conceptualized and delivered the first edition of *Dementia* it was a very significant event in the worldwide dissemination of knowledge about dementia. At that time dementia research was already in full flight and workers in the field were finding it increasingly difficult to keep up to date with the rapid advances achieved by dedicated and creative researchers. It was not too long before a second edition was required to add to the knowledge base. No sooner was this edition published, than a further edition was required, such was the speed of knowledge acquisition in fundamental science, clinical practice and service delivery around the world.

This, the third edition, under the charge of Alistair Burns, John O'Brien and David Ames, has set a benchmark that is nigh impossible to surpass. Its content of 65 chapters characterized by breadth, depth, comprehensiveness, thoroughness and relevance has been a Herculean labour of commitment to the essential and necessary education of all who are involved in caring for the elderly.

In addition to the 'usual suspects' of epidemiology, biology, fundamental science and therapeutics underpinning the text, it has comprehensive service reports from a global perspective ranging from Australia, China, many parts of Asia, Africa, East and Western Europe to Latin America, the Caribbean and North America. These chapters remind us that service to the people with dementia is central to all our endeavours and the core of our commitment to this field. The chapter on services to younger people with dementia is very welcome and reminds us that not all people with dementia are elderly and that younger people also require us to attend to their plight.

Chapters on topics such as sexuality, quality of life, moral and legal issues alert and challenge all readers to look at the

personhood and humanity of all people with dementia in a deep and searching analysis of our own attitude towards them. A chapter on trial designs fills a gap in most workers' knowledge and instructs on the backdrop to the development of therapeutics, thus enabling readers to understand how efficacy and safety are established and how the published data may be interpreted. Psychosocial approaches continue to be explored and updated as well as the advances in vascular contributions to dementia, which have gained more relevance between the second and third editions. Other dementias continue to be included to inform the readers that Alzheimer's disease is not the only dementia confronting us all.

No text on dementia is satisfactory without reference to the roles of carers, without whom all systems including fundamental scientific research will not thrive. The moving chapter by Emerson Moran serves to give a very touching practical, human and humorous face to this book. 'And we laugh. Always' – the final four words of this chapter should keep us all warmed and humbled.

Any medical school, hospital and health service to the elderly, which does not have a copy of this book, should not be considered to have any level of quality in their educational and training programme. Indeed, Key Performance Indicators in these clinical environments should include the possession of, or ready access to, this third edition of *Dementia*.

Alistair, John and David, thank you for your continuing contribution to the dissemination of knowledge to the world.

Edmond Chiu
Melbourne, March 2005

Preface to the Third Edition

It is a pleasure to present the Third Edition of our textbook *Dementia*. We have found the success of the first and second edition very gratifying but were conscious of the need to justify the publication of a textbook of this size and scope in a field that is developing very rapidly. It is easy to imagine that such a potential dinosaur may quickly become outdated, will sit on shelves, be thought of affectionately but not be of much practical use to anyone.

However, we became convinced by a number of people, fuelled by our own determination, that we could not let a brand name die, and that a third edition was not only possible but might actually be appreciated by some people.

It is trite to say that the field has moved on since the last edition – of course it has. This is not just in the usual areas where one would expect it, i.e. basic science and treatment,

but also, reassuringly in areas such as service development and carer research.

We have kept the format as it was because it seems to work, but have introduced briefer overviews of services in areas throughout the world.

We owe a great thanks to the contributors who, in the main, have kept to time – we know and they know who they are! The publishers at Hodder Arnold, particularly Layla Vandenberg, have been helpful and we are grateful to Ed Chiu for such a generous foreword. Most of all, our secretaries, Norma Welsh in Newcastle, Marilyn Kemp in Melbourne and particularly Barbara Dignan in Manchester, deserve the biggest thanks. Without their dedication the project would not have been completed.

Preface to the Second Edition

In the 6 years since the first edition of *Dementia* was published in 1994, advances in our knowledge and understanding of the disorder and its subtypes have proceeded at a truly breathtaking pace. Clearly we have a greater appreciation of the importance of genetic factors in dementia, whilst molecular biology has provided novel insights into possible pathogenic mechanisms. However, great advances have also been made in several other areas that, unfortunately, often receive less prominence than they deserve. For example, major progress has been made in the nosology, classification and diagnosis of the many subtypes of dementia and there are now several important sets of clinical and neuropathological diagnostic criteria published, many of which have already been the subject of prospective validation studies. Several subtypes of dementia that were of arguable significance when the first edition was published, such as dementia with Lewy bodies and frontotemporal dementia, have been recognized as important conditions with great clinical relevance. Concepts of vascular dementia have changed and the notion of multi-infarct dementia has now been replaced by more sophisticated models that recognize the fact that several different types of vascular pathology, not just cortical infarction, can cause dementia. In parallel with better understanding of the many conditions that cause dementia, there is also increasing recognition of the importance of heterogeneity and overlap at clinical, neurochemical and neuropathological levels between different disorders. This particularly applies to the overlap between vascular dementia and Alzheimer's disease. The advent in the last few years of cholinesterase inhibitors has for the first time allowed rational and, at least in some patients, moderately effective treatment of cognitive as well as non-cognitive features of Alzheimer's disease. These drugs may also prove helpful in treating some other subtypes of dementia. Services have improved considerably in many countries, allowing research advances to be directly applied to what must be the main goal, that of improving patient care.

However, we cannot at any level be complacent and clearly there is still a long way to go. Statistics regarding demographic changes abound, though it is a sobering thought that in Western society life expectancy has increased from 45 years in 1901 to 80 years in 2001. Such longevity, combined with the well-recognized increase in prevalence and incidence of

dementia with age, will continue to lead to a huge increase in dementia cases over the next 30 years, especially in the developing world. Many problems remain. We still lack sufficiently accurate *in vivo* diagnostic markers to replace the 'gold standard' of neuropathology. We still need to learn more about aetiological factors and the definitive neurobiological mechanisms that ultimately cause neuronal loss remain elusive. Current therapeutic approaches remain limited and effective disease-modifying and preventive strategies still have to be determined. Despite progress, services in many countries remain underdeveloped and too fragmented to cope with the increase in cases which lies ahead. The socioeconomic burden of dementia remains enormous and will continue to increase. Dementia is one of the major challenges facing all societies in the new millennium and will remain so for the foreseeable future.

This combination of exciting recent progress combined with continued challenges ahead was the major driving force for producing this second edition of *Dementia*, which has been radically restructured and updated. Several changes will be immediately apparent. First, the layout of the book reflects the richness and diversity of the different subtypes of dementia and, instead of a simple division between Alzheimer's disease and other dementias, there are now separate sections on each of the main causes of dementia. Second, a number of new chapters are included to provide comprehensive coverage of topics such as new diagnostic criteria, rating scales, investigations, neurobiological mechanisms, as well as all aspects of management including psychosocial and psychological approaches. There are too many new chapters to mention them all, but other important topics, such as moral, ethical and legal aspects of dementia, sexuality and current and new therapeutic options, are included. The section on services has been expanded to include more contributions from Europe as well as from China, South and Central America, the former Soviet Union and services for younger people with dementia. The inclusion of a chapter on Alzheimer's Disease Societies and Associations is a measure of the influence that these have had world wide in supporting patients, carers and researchers. Dementia with Lewy bodies, increasingly recognized as the second main cause of degenerative dementia, is given prominent coverage with four new chapters. The section on focal

dementias includes frontotemporal dementia, Pick's disease, semantic dementia and progressive aphasia and allows readers to observe the different approaches that can be used to define and understand such disorders. Over all, 17 new chapters are included whilst other chapters have been updated and, in most cases, entirely rewritten.

In choosing our authors, we have deliberately sought to try to achieve a balance between retaining sufficient authors from the first edition to provide some continuity whilst including some new contributors. We have also deliberately sought an authorship to reflect a mixture of those who are already internationally renowned experts and those whom we consider to be the rising stars of the future.

This second edition was commissioned by Chapman and Hall, who published the first edition, and has subsequently been published by Arnold, a member of the Hodder Headline Group. We are indebted to all who have been involved in the production of this book, including Peter Altman of Chapman

and Hall, who was responsible for the first edition, Georgina Bentliff, Catherine Barnes and Sarah De Souza of Arnold and to our secretaries (Norma Welsh, Yvonne Liddicoat, Barbara Dignan) for their great efforts and help. We are also deeply grateful to Edmond Chiu for his generous Foreword and to Professor Elaine Murphy for providing the Epilogue. Most of all, we thank all our authors who found the time to produce such excellent chapters and upon whose efforts the success of this book will ultimately rely. Our aim was to produce fully comprehensive and up-to-date coverage of all aspects of dementia within a single text, which would prove accessible to clinicians, researchers and allied professional groups. As before, we leave you, our readers and reviewers, to judge the extent to which this aim has been achieved.

John O'Brien, David Ames, Alistair Burns
Newcastle upon Tyne, Melbourne,
Manchester, April 2000

Preface to the First Edition

It was with some trepidation that we decided to edit a large textbook on dementia. There are, and will continue to be, many texts on dementia and one has to consider critically the need for another. Dementia is one of the major challenges to face society in the twentieth century, numerically dwarfing other disorders which have caught the public's imagination. The attraction of being involved in this venture is that it attempts to encompass, in a single volume, all aspects of all types of dementia. However hard we have tried we could obviously not succeed in this and someone somewhere will complain we have omitted something important. In addition, this is a field which is expanding rapidly and we have tried therefore to concentrate on a solid core of information, which although requiring some updating in the future is likely to remain part of the mainstream view of the field.

We have divided the book into two parts, the first dealing with Alzheimer's disease and the second with other dementias. We recognize that this will be considered by many to be a false dichotomy and we accept that criticism. However, from an organizational point of view some form of order was necessary and we hope this makes sense. Overlap between chapters is a difficult issue and while we have exercised the editorial Tippex to the best of our ability, some duplication

remains. However, much of this is intentional and some chapters would have been denuded unnecessarily and could not have stood alone. Areas where we have unashamedly fostered such overlap include Chapters 7 and 8, Chapters 12 and 13 and Chapters 46 and 51. We feel this is a way of encouraging debate about contentious subjects as well as avoiding undue artistic tantrums.

We have been lucky in our choice of authors, the vast majority of whom have delivered their manuscripts on time and without much persuasion. To them, we give thanks, and to our recalcitrant contributors we heave a sigh of relief that we received their submissions at all. We are indebted to Annelisa Page and Peter Altman of Chapman & Hall for their tireless support and to our secretaries for their help. We also thank Professor Alwyn Lishman for his generous foreword.

We hope that our efforts have not been wasted and will leave you, the readers and reviewers, to judge.

CHAPTER 5

ADB is funded by a Wellcome Trust Programme Grant (RN 019407). Portions of the work described in this chapter were supported by an MRC LINK grant and carried out within the MRC Centre for Behavioural and Clinical Neuroscience. BJS is a consultant for Cambridge Cognition Ltd.

CHAPTER 23

The authors gratefully acknowledge the thoughts and comments of Jacques Touchon that helped form the basis for this chapter.

CHAPTER 24

We should like to thank Ms Donna Asleson for her superb secretarial assistance. Preparation of this chapter was supported by UO1 AG06786, P50 AG16574, U01 AG10483 and KO1 MH68351.

CHAPTER 31

I am most grateful to Dr Charles R Harrington for his, as always, knowledgeable comments and suggestions and thorough reading of the text. His red pen changed its colour to blue on this occasion, and found out hidden 'gran chasing bears'. I would also like to thank Mrs Caroline Kirk for editing the text and secretarial support, Mr Stephen Lloyd for IT support and Dr Vladimir B Ladinski for help with graphic presentation and constructive discussions during various stages of writing the manuscript. The text is based on a review of the published literature up to and including 31 January 2004.

CHAPTER 39

The author gratefully acknowledges, first, the support of the Australian Government Department of Health and Ageing, Office for Older Australians, who funded some of the research reported in this chapter. Second, profound thanks are due to all the people with dementia, their families, and residential aged care nursing staff, who participated in the clinical interventions described and so generously assisted in providing research data. Finally, thanks to Tanya Caldwell, who assisted in preparation of this paper.

CHAPTER 45

Our work has been supported by grants from the Medical Research Council (UK), Alzheimer's Association (Chicago, USA) and the Alzheimer's Research Trust (UK).

CHAPTER 49

Preparation of this chapter was supported by funds from NIA grants AG-05131 and AG-12963 to the University of California, San Diego.

CHAPTER 53

AG is supported by the Wellcome Trust.

CHAPTER 57

The authors thank Professor Elizabeth Warrington for helpful discussion and Dr Nick Fox for permission to reproduce the brain images.

Since the second edition of this textbook, no ground-breaking scholarly work has been published that may challenge the historical hypotheses propounded therein on the development of the concept of dementia (Berrios, 2000a); indeed, the ‘constructionist’ view has gained support from the way in which the nosological surface of ‘dementia’ has been redrawn during the last 10 years.

All clinical categories, including those pertaining to the dementias, are the result of the coming together in the work of an author of selected behavioural markers, explanatory concepts and terms to refer to them. Complex social and economic variables will determine whether or not the ensuing ‘convergence’ will last. For reason that have to do with the rhetoric of science, these social acts are sold to the throng as pure ‘scientific acts’. For example, it would be naïve to believe that the decision to consider a symptom-cluster such as, for example, ‘Lewy body dementia’ as a ‘new disease’ is solely based on the ‘discovery’ of powerful, ineluctable and replicable correlations (Perry *et al.*, 1996). Given that not all correlations are privileged in this way, and that there is no clear theory linking all the symptoms to each other and to the Lewy bodies themselves, it is not difficult to surmise that such consideration is also driven by social variables. The current model of science as a pure pursuit of truth, however, leaves no space for broader explanations and hence all manner of social variables remain understudied.

This is not a new phenomenon, for the same complex mechanisms operated at the time when Kraepelin constructed the concept of Alzheimer’s disease (AD) (Berrios, 1990b). The crucial issue here is that there is nothing wrong with the fact that social forces shape ‘scientific facts’ and hence contribute to the construction of psychiatric diseases. Indeed, understanding such mechanisms would render psychiatry more complete,

the psychiatrist wiser and doctoring more useful to patients. Hopefully, the time will come when denying social processes may be considered as unethical and offensive to patients.

Knowledge of the history of dementia as a word, a concept and a behavioural syndrome is a precondition for scientific research. Successive historical convergences have shaped the current notion of dementia. A full study should map the changes in the history of ‘dementia’ at least since Roman times. For the purposes of this chapter, however, it should suffice to study a shorter period, say, the one stretching from the work of Boissier de Sauvages (1771), who still offered a static view of disease to Marie (1906) whose great treatise would read as very modern to anachronistic eyes. The former defined ‘dementia’ as a generic term; the latter saw in dementia a ‘syndrome’, which could be enacted by a variety of ‘diseases’ each with its recognizable phenomenology and putative neuropathology.

1.1 TERMS

Up to the 1700s, states of cognitive and behavioural deterioration of whatever origin ending up in psychosocial incompetence were called amentia, dementia, imbecility, morosis, *fatuitas*, anoea, foolishness, stupidity, simplicity, carus, idiocy, dotage and senility. In Roman times, the word ‘dementia’ was also used to mean ‘being out of one’s mind, insanity, madness, folly’ (Lewis and Short, 1969). For example, in the first century BC, Cicero (1969) (*Tusculanan disputations*, Book 3, para 10) and Lucretius (1975) (*De Rerum Natura*, Book 1, line 704) used ‘dementia’ as a synonym of madness.

The term dementia first appears in the European vernaculars after the seventeenth century. In Blancard’s English

dictionary (1726) it is used as an equivalent of *anoea* or ‘extinction of the imagination and judgment’ (p. 21). By 1644, according to the *Oxford English Dictionary*, an adjectival form (‘demented’) entered the English language. In his Spanish–French dictionary Sobrino (1791) wrote: ‘demencia = démence, folie, extravagance, égarement, alienation d’esprit’ (p. 300). Rey (1995), in turn, states that *démence* appeared in French in 1381 to refer to ‘madness, extravagancy’ but that the adjective *dément* came into currency only from 1700. It would seem, therefore, that between the seventeenth and eighteenth centuries the Latin stem *demens* (without mind) had found a home in most European vernaculars. As we shall see presently the full medicalization of ‘dementia’ started after the 1750s.

1.2 MEDICAL USAGE

Evidence for an early medical usage of the term dementia is found in the French Encyclopaedia (Diderot and d’Alembert, 1765):

Dementia is a disease consisting in a paralysis of the spirit characterized by abolition of the reasoning faculty. It differs from *fatuitas*, *morosis*, *stultitia* and *stoliditas* in that in the latter there is a weakening of understanding and memory; and from delirium which is a temporary impairment in the exercise of the said functions. Some modern writers confuse dementia with mania, which is a delusional state accompanied by disturbed behaviour (*audace*); these symptoms are not present in subject[s] with dementia who exhibit foolish behaviour and cannot understand what they are told, cannot remember anything, have no judgment, are sluggish, and retarded ... Physiology teaches that the vividness of our understanding depends on the intensity of external stimuli ... in pathological states these may be excessive, distorted or abolished; dementia results from abolition of stimuli which may follow: 1. damage to the brain caused by excessive usage, congenital causes or old age, 2. failure of the spirit, 3. small volume of the brain, 4. violent blows to the head causing brain damage, 5. incurable diseases such as epilepsy, or exposure to venoms (Charles Bonnet reports of a girl who developed dementia after being bitten by a bat) or other substances such as opiates and mandragora.

Dementia is difficult to cure as it is related to damage of brain fibres and nervous fluids; it becomes incurable in cases of congenital defect or old age ... [otherwise] treatment must follow the cause ...

[The legal definition of dementia reads]: Those in a state of dementia are incapable of informed consent, cannot enter into contracts, sign wills, or be members of a jury. This is why they are declared incapable of managing their own affairs. Actions carried out before the declaration of incapacity are valid unless it is demonstrated that dementia predated the action.

Ascertainment of dementia is based on examination of handwriting, interviews by magistrates and doctors, and testimony

from informants. Declarations made by notaries that the individual was of sane mind whilst signing a will are not always valid as they may be deceived by appearances, or the subject might have been in a lucid period. In regards to matrimonial rights, *démence* is not a sufficient cause for separation, unless it is accompanied by aggression (*furour*). It is, however, sufficient for a separation of property, so that the wife is no longer under the guardianship of her husband. Those suffering from dementia cannot be appointed to public positions or receive privileges. If they became demented after any has been granted, a coadjutor should be appointed ...

Although modern-sounding, the above definition must be read with caution: its clinical description depends on contrasts and differences with delirium and a list of disorders which are no more; its legal meaning is based on the old Roman accounts, and its mechanisms make use of the camera obscura metaphor and assume the passive definition of the mind that Condillac (who inspired the author of the article) had borrowed from John Locke.

1.3 BEHAVIOURS REDOLENT OF CURRENT DEMENTIA DURING THIS PERIOD

In the literature of the seventeenth and eighteenth centuries (and indeed of earlier periods), it is possible to recognize behaviours that nowadays we may wish to refer as dementia being reported under different rubrics. For example, in relation to ‘Stupidity or Foolishness,’ Thomas Willis (1684) wrote:

although it chiefly belongs to the rational soul, and signifies a defect of the intellect and judgement, yet it is not improperly reckoned among the diseases of the head or brain; for as much as this eclipse of the superior soul proceeds from the imagination and the memory being hurt, and the failing of these depends upon the faults of the animal spirits, and the brain itself (p. 209).

Willis suggested that stupidity might be genetic (‘original,’ as when ‘fools beget fools’) or caused by ageing (‘Some at first crafty and ingenious, become by degrees dull, and at length foolish, by the mere declining of age, without any great errors in living’) (p. 211), or other causes such as ‘strokes or bruising upon the head,’ ‘drunkenness and surfeiting,’ ‘violent and sudden passions’ and ‘cruel diseases of the head’ such as epilepsy.

The same is the case with Boissier de Sauvages (1771), one of the great classifiers of the eighteenth century. Order 3rd (8th class) of his *Nosographie Methodique* encompasses delirium, paraphrosyne, imbecility, melancholia, demonomania and mania. Synonyms of ‘Imbecility are *Bêtise* (stupidity, foolishness), *Niaiserie* (silliness), and *Démence*; in Greek *paranoia*, and in Latin *Dementia*, *Fatuitas*, *Vecordia*. The term is used to refer to patients who are fools, (*fous*), imbeciles (*imbécilles*), mentally weak (*foibles d’esprit*), mad (*insensés*)’ (p. 723). Boissier lists 12 subtypes of imbecility of which the first one is the imbecility of the elderly (*L’imbécillite de vieillard*), also known as puerile state, drivelling or senile madness, and

which he explains thus: 'Because of the stiffness of their nervous fibres, old people are less sensitive to external impressions ...' (p. 724).

In the *Nosographie* (1818; first published 1798), Pinel dealt with cognitive impairment under amentia and morosis, which he explains as a failure in the association of ideas leading to disordered activity, extravagant behaviour, superficial emotions, memory loss, difficulty in the perception of objects, obliteration of judgement, aimless activity, automatic existence, and forgetting of words or signs to convey ideas. He also referred to *démence senile* (para 116). Pinel did not emphasize the difference between congenital and acquired dementia (Pinel 1806).

The above entries summarize well views on dementia before the nineteenth century. There was, first of all, a 'legal' meaning according to which dementia was a state of non-imputability. In France, this was enshrined in Article 10 of the Napoleonic Code: 'There is no crime when the accused is in a state of dementia at the time of the alleged act' (Code Napoléon, 1808). Second, there was a clinical meaning. This could be very general (i.e. a synonym of madness) or specific, i.e. a clinical condition that was differentiable from mania (which, at the time, described any state of acute excitement, be it schizophrenic, hypomanic, or organic) and delirium (which referred, more or less, to what goes on nowadays under the same name). Although chronic, dementia could still be reversible, affect individuals of any age, and be a final common pathway, i.e. the end deficit for many other mental disorders. This created a template for the alienists of the nineteenth century.

1.4 DEMENTIA DURING THE NINETEENTH CENTURY

There is a major difference between eighteenth-century views on dementia and what the historian finds a century later when dementia starts to refer more or less specifically to states of cognitive impairment mostly affecting the elderly, and almost always irreversible. The word 'amentia' was no longer used in this context and started to name a 'psychosis, with sudden onset following severe, often acute physical illness or trauma' (Meynert, 1890). The syndromatic view of the dementias was still in use but mainly in regards to the 'vesanic dementias', i.e. terminal states for all manner of mental disorders. This section will explore such momentous changes.

In his doctoral thesis, Esquirol (1805) used the word dementia to refer to loss of reason, as in *démence accidentale*, *démence mélancolique*; then, he distinguished between acute, chronic and senile dementia. Acute dementia was short-lived, reversible, and followed fever, haemorrhage and metastasis; chronic dementia was irreversible and caused by masturbation, melancholia, mania, hypochondria, epilepsy, paralysis and apoplexy; lastly, senile dementia resulted from ageing, and consisted in a loss of the faculties of the understanding (Esquirol, 1814). Esquirol's final thoughts on dementia were

influenced by his controversy with Bayle (1822) who via his concept of *chronic arachnoiditis* propounded an anatomical ('organic') view of all the insanities and scorned Pinel's views that some vesanias might develop in a psychological space (Bayle, 1826).

Together with his student Georget, Esquirol supported a 'descriptivist' approach, at least in relation to some forms of mental disorder. He reported 15 cases of dementia (seven males and eight females) with a mean age of 34 years ($SD = 10.9$), seven being, in fact, cases of general paralysis of the insane, showing grandiosity, disinhibition, motor symptoms, dysarthria and terminal cognitive failure. There also was included a 20-year-old girl who, in modern terms, suffered from a catatonic syndrome; and a 40-year-old woman with pica, cognitive impairment, and space-occupying lesions in her left hemisphere and cerebellum (Esquirol, 1838). Although the mean age of these samples and the absence of cases of senile dementia may simply reflect a short life expectancy in Esquirol's day, or that at the Charenton Hospital some selection bias was in operation, it is more likely to reflect the view that age was not an important variable. Together with irreversibility, age became a defining criterion only by the second half of the nineteenth century.

Like his teacher Esquirol, aware of the importance of clinical description, Calmeil wrote: 'It is not easy to describe dementia, its varieties, and nuances; because its complications are numerous ... it is difficult to choose its distinctive symptoms' (p. 71). Dementia followed chronic insanity and brain disease, and was partial or general. Calmeil was less convinced than his co-student Georget that all dementias were associated with alterations in the brain.

In regards to senile dementia, Calmeil remarked: 'there is a constant involvement of the senses, elderly people can be deaf, and show disorders of taste, smell and touch; external stimuli are therefore less clear to them, they have little memory of recent events, live in the past, and repeat the same tale; their affect gradually wanes away ...' (p. 77). Although a keen neuropathologist, Calmeil concluded that there was no sufficient information on the nature and range of anomalies found in the skull or brain to decide on the cause of dementia (pp. 82–83) (Calmeil, 1835).

A Ghent alienist, thinking in Flemish and writing in French, Guislain believed that in dementia:

All intellectual functions show a reduction in energy, external stimuli cause only minor impression on the intellect, imagination is weak and uncreative, memory absent, and reasoning pathological. There are two varieties of dementia ... one affecting the elderly (senile dementia of Cullen) the other younger people. Although confused with dementia, idiocy must be considered as a separate group (p. 10). [In dementia.] 'the patient has no memory, or at least is unable to retain anything ... impressions evaporate from his mind. He may remember names of people but cannot say whether he has seen them before. He does not know what time or day of the week it is, cannot tell morning from evening, or say what 2 and 2 add to ... he has lost the

instinct of preservation, cannot avoid fire or water, and is unable to recognize dangers; has also lost spontaneity, is incontinent of urine and faeces, and does not ask for anything, he cannot even recognize his wife or children ... (p. 311) (Guislain, 1852).

Because in the past the mentally ill: 'had been categorized only in terms of a [putative] impairment of their mental faculties ...' (p. 2), Morel (1860) endeavoured to develop a taxonomy that distinguished between occasional and determinant causes of mental disorder (p. 251) and suggested six clinical groups: hereditary, toxic, associated with the neuroses, idiopathic, sympathetic and dementia. In regards to the latter, Morel (1860) believed that:

... if we examine dementia (amentia, progressive weakening of the faculties) we must accept that it constitutes a terminal state. There will, of course, be exceptional insane individuals who, until the end, preserve their intellectual faculties; the majority, however, are subject to the law of decline. This results from a loss of vitality in the brain ... Comparison of brain weights in the various forms of insanity shows that the heavier weights are found in cases of recent onset. Chronic cases show more often a general impairment of intelligence (dementia). Loss in brain weight – a constant feature of dementia – is also present in ageing, and is an expression of decadence in the human species. [There are] natural dementia and that dementia resulting from a pathological state of the brain ... some forms of insanity are more prone to end up in dementia (idiopathic) than others ... it could be argued that because dementia is a terminal state it should not be classified as a sixth form of mental illness ... I must confess I sympathize with this view, and it is one of the reasons why I have not described the dementias in any detail ... on the other hand from the legal and pathological viewpoints, dementia warrants separate treatment ... (pp. 837–838).

Morel's view is in keeping with his 'degenerationist' hypothesis, which he himself had developed three years earlier (Morel, 1857; Pick, 1989). One consequence of this view was that there were no specific brain alterations in dementia.

In spite of his early death, L. F. Marcé published a series of important articles on the neuropathology of senile dementia which challenged Morel's non-specificity hypothesis.

There is no space in this chapter to analyse with the same level of detail the evolution of the concept of dementia in other European countries, although it can be said that it followed similar lines. Views in England, for example, were mainly derivative from French ones. In a popular textbook, and following Pinel, Esquirol and Calmeil, Prichard included a category which he called 'incoherence or dementia':

[it] is a very peculiar and well-marked form of mental disorder. The mind in this state is occupied, without ceasing, by unconnected thoughts and evanescent emotions; it is incapable of continued attention and reflection, and at length loses the faculty of distinct perception or apprehension. Numerous examples of this disease, or decay of the mental powers are to be met within every receptacle containing a considerable assemblage

of deranged persons ... incoherence is either a primary disease, arising immediately from the agency of exciting causes on a constitution previously health, or it is a secondary affection, the result of other disorders of the brain and nervous system which, by their long duration or severity, give rise to disease in the structure of those organs ... secondary incoherence or dementia follows long-protracted mania, attacks of apoplexy, epilepsy or paralysis, or fevers attended with severe delirium. This decay of the faculties has been termed fatuity or imbecility, and it has been confounded with idiotism, which in all its degrees and modifications is a very different state ... (pp. 83–85) (Prichard, 1835).

The same can be said of the views expressed by Bucknill and Tuke in their popular textbook:

Dementia may be either primary or consecutive; acute or chronic. It may also be simple or complicated; it is occasionally remittent but rarely intermittent. It is primary when it is the first stage of the mental disease of the patient; and when this occurs, it is, perhaps, one of the most painful forms of insanity; the patient often being acutely sensible of a gradual loss of memory, power of attention, and executive ability. At this period, the distinction is often well marked between the strictly intellectual and affective disorder ... dementia is much more frequently consecutive, that is the consequence of other diseases of the mind. Thus during 44 years, while 277 cases of mania and 215 of melancholia were admitted at the Retreat, only 48 of dementia were admitted during the same period; yet, at the end of that term, there were remaining in the institution, 20 patients in a state of dementia out of 91 inmates. Mania very often degenerates into dementia; as also do melancholia and monomania ... it should be observed, that the term dementia may be, and sometimes is, too indiscriminately employed. All writers of authority agree in representing impairment of the memory as one of the earliest symptoms of dementia; but we believe cases are occasionally classed under incipient dementia, in which close observation would show that the memory is unimpaired ... It is often rather a torpid condition of the mind, falling under the division 'apathetic insanity, which ought not to be confounded with dementia ...' (pp. 117–119) (Bucknill and Tuke, 1858).

The same concepts are found in German-speaking nations and the views of Heinroth, Feuchtersleben, Griesinger and Kahlbaum were influential until the beginning of the second half of the nineteenth century. Heinroth (1818/1975) used the term dementia in a very broad sense to refer to a state of mind that might accompany or follow other mental disorders, i.e. 'vesanic dementia', a term that late in the century was to become very popular, particularly in France. This concept, which is not related to age, is redolent of the later notion of secondary dementia, i.e. the state of psychosocial and cognitive incompetence that might follow a functional psychosis. Feuchtersleben's usage (1845/1847) is even more general. In his work he uses dementia as a synonym of madness and may refer to forms of acute madness with and without accompanying

idiocy. There is only one form of dementia, which he refers to as *moria* and considered as more or less chronic and more or less cognitive. Although possibly ending up in a state of idiocy, the patient can also show lucid intervals. Once again, age is of no relevance to *moria* and hence one must conclude that Feuchtersleben is referring to a form of vesanic dementia.

Griesinger's nosology is not altogether clear and has often been interpreted as being based on the belief that there is only one form of madness (*unitary psychoses concept*), which may go through at least three stages: depression (as in melancholia), exaltation (as in mania) and weakness (as in chronic madness and dementia). In the second edition of his great work, Griesinger (1861/1867) insists that the states of mental weakness 'do not constitute primary but consecutive forms of insanity' (p. 319). This suggests that he is also referring to a form of vesanic dementia, although he includes under this large class all the forms of mental handicap where no preliminary 'primary' forms of madness can be recognized. Under the heading 'dementia', Griesinger includes mental disorders fundamentally caused by a 'general weakness of the mental faculties' including loss of emotions. Age is not a factor in the development of dementia or apathetic dementia and hence it must also be concluded that Griesinger is referring to vesanic dementia.

The work of Kahlbaum, particularly his important book of 1863 on the definition and classification of mental disorders, mark the beginning of a new era in psychiatry. His incorporation of time as a variable in the analysis of madness (longitudinal definition) and his view that period of life is relevant to the form of the disease remain the pillars of psychiatric nosology to this day. The concept of 'Dementia' is dealt with in the third section of Kahlbaum's book (1863) under the name of *aphrenia*. This clinical category refers to states of mental impotence (*Zustand geistiger Impotenz*) (p. 153), which Kahlbaum equates to the old German notion of *Blödsinn*. After complaining that neither the Greeks nor Latin writers managed to specify a term for this condition, he insists that a word is needed to refer to states of cognitive and behavioural incompetence such as those seen in *dementia terminalis* (Berrios, 1996).

1.5 THE FRAGMENTATION OF DEMENTIA

During the second half of the nineteenth century, and based on the clinical observations and reconceptualization carried out by the French, German and English writers mentioned above, dementia starts to be considered as a syndrome and hence could be attached to a variety of disorders. The primary classification was to be between primary and secondary, the latter including all the vesanic dementias, i.e. states of defect that could follow any severe form of insanity. An increased use of light microscopy during the second half of the century led to the view that primary forms of dementia could be caused by degenerations of cerebral parenchyma or

by arteriosclerosis. By 1900, senile, arteriosclerotic, infectious and traumatic forms of dementia had been reported (Berrios and Freeman, 1991). 'Mixed forms', such as 'dementia praecox' were also suggested reflecting Kahlbaum's view that mental disorders appeared during specific biological transitions. The list of parenchymal forms became longer after the inclusion of states of degeneration from alcoholism, epilepsy, myxoedema and lead poisoning. The history of some of these forms will be discussed presently.

1.5.1 General paralysis of the insane

Bayle (1822) described under the name *arachnitis chronique* cases of what later was to be called 'general paralysis of the insane'. Whether this 'new phenomenon' resulted from 'a mutation in the syphilitic virus towards the end of the eighteenth century' is unclear (p. 623) (Hare, 1959). Equally dubious is the claim that its discovery reinforced the belief of alienists in the anatomoclinical view of mental disease (Zilboorg, 1941). In fact, it took more than 30 years for general paralysis to gain acceptance as a 'separate' disease. Bayle's 'discovery' was more important in another way, namely that it challenged the 'cross-sectional' view of disease; in the words of Bercherie (1980): 'for the first time in the history of psychiatry there was a morbid entity which presented itself as a sequential process unfolding itself into successive clinical syndromes' (p. 75).

By the 1850s, no agreement had yet been reached as to how symptoms were caused by the *periencephalite chronique diffuse* (as general paralysis was known at the time). Three clinical types were recognized: manic-ambitious, melancholic-hypochondriac, and dementia; according to the 'unitary view', all three constituted stages of a single disease, the order of their appearance depending on the progress of the cerebral lesions. Baillarger (1883), however, sponsored a 'dualist' view: 'paralytic insanity and paralytic dementia are different conditions'. It is clear that the debate had less to do with the nature of the brain lesions than with how mental symptoms and their contents were produced in general: how could the 'typical' content of paralytic delusions (grandiosity) be explained? Since the same mental symptoms could be seen in all manner of conditions, Baillarger believed that chronic periencephalitis could account only for the motor signs – mental symptoms 'therefore, having a different origin' (p. 389). The absence of a link between lesion and symptom also explained why some patients recovered.

The view that general paralysis might be related to syphilis (put forward by Fournier, 1875) was resisted. Indeed, the term 'pseudogeneral paralysis' was coined to refer to cases of infections causing psychotic symptoms (Baillarger, 1889). In general, there is little evidence that alienists considered general paralysis as a 'paradigm-disease', i.e. a model for all other mental diseases. It can even be said that the new 'disease' created more problems than it solved (for a discussion of this issue see Berrios, 1985a).

1.5.2 The vesanic dementias

The term ‘vesanic dementia’ began to be used after the 1840s to refer to the clinical states of cognitive disorganization following insanity (Berrios, 1987); its meaning has changed with equal speed alongside psychiatric theory. According to the unitary insanity notion, vesanic dementia was a terminal stage (after mania and melancholia); according to degeneration theory, it was the final expression of a corrupted pedigree; and according to post-1880s’ nosology, a final common pathway to some insanities. Vesanic dementias were reversible, and could occur at any age; risk factors such as old age, lack of education, low social class, bad nutrition etc., accelerated the progression of the dementia or impeded recovery (p. 597) (Ball and Chambard, 1881).

The vesanic dementias included cases suffering from cognitive impairment associated with melancholia. Under the term *démence mélancolique* Mairét (1883) reported a series of cases of depressed patients with cognitive impairment who on post mortem showed changes in the temporal lobe; this led Mairét to hypothesize that the affected sites were related to feelings, and to suggest that nihilistic delusions appeared when the lesion spread to the cortex (Berrios, 1985a). Mairét’s cases (some of which would now be called ‘Cotard’s syndrome’) showed psychomotor retardation, refused food and died in stupor (Cotard, 1882; Berrios and Luque, 1995). Others, however, got better and these cases are redolent of what nowadays might be called ‘depressive pseudodementia’.

Another contributor to the understanding of cognitive impairment in the affective disorders was George Dumas (1894) who suggested that it was ‘mental fatigue that explained the psychological poverty and monotony of melancholic depressions’ and that the problem was not ‘an absence but a stagnation of ideas’; he was, therefore, the first to explain the disorder as a failure in performance.

The word ‘pseudodementia’, however, originated in a different clinical tradition. It was first used by Carl Wernicke to refer to ‘a chronic hysterical state mimicking mental weakness’ (Bulbena and Berrios, 1986). Not used until the 1950s, it was given a lease of life by writers such as Madden *et al.* (1952), Anderson *et al.* (1959) and Kiloh (1961). Current usage is ambiguous in that it relates to three clinical situations: a real (albeit reversible) cognitive impairment accompanying some psychoses, a parody of such impairment, and the cognitive deficit of delirium (Bulbena and Berrios, 1986).

1.5.3 Brain changes and ageing

Since the beginning of the nineteenth century, cases had been described of brain ‘softening’ followed by cognitive failure. Rostan (1823) reported 98 subjects thus affected, thought to be scorbutic in origin, and divided them into simple, abnormal and complicated (the latter two groups being accompanied by psychiatric changes). Mental symptoms might occur before, during and after the softening itself; thus, senile dementia

and insanity might precede the brain changes. When it accompanied stroke, Rostan described cognitive failure and attacks of insanity suggesting that these symptoms were ‘a general feature ... not a positive sign of localisation’ (pp. 214–215). Durand-Fardel (1843) provided an account of the relationship between softening and insanity, warning that softening was used to refer both to a disease (stroke) and to a state of the brain. Psychiatric complications were acute and long term, the former including confusion, depression, irritability, acute insanity and loss of mental faculties (p. 139); the latter had gradual onset, and exhibited an impairment of memory, poverty of thinking, and a regression to infantile forms of behaviour, features which led to ‘true dementia’ (pp. 327–328).

Years later, Jackson (1875) reviewed the problem: ‘softening ... as a category for a rude clinical grouping was to be deprecated’ (p. 335); he nonetheless, followed Durand-Fardel’s classification, and suggested that, after stroke, mental symptoms might be immediate or occurring after a few hours or months; he recognized that major cognitive failure may ensue, and saw this as an instance of ‘dissolution’: emotional symptoms being release phenomena (for an analysis of this concept see Berrios, 1991). He believed that anxiety, stress and irritability might be harbingers of stroke.

1.5.4 The concept of arteriosclerotic dementia

Old age was considered an important factor in the development of arteriosclerosis (Berrios, 1994) and a risk factor in diseases such as melancholia (Berrios, 1991). By 1910, there was a trend to include all dementias under ‘mental disorders of cerebral arteriosclerosis’ (Barrett, 1913). Arteriosclerosis, might be generalized or cerebral, inherited or acquired, and caused by syphilis, alcohol, nicotine, high blood pressure or ageing. In those genetically predisposed, cerebral arteries were considered as thinner and less elastic. Arteriosclerosis caused mental changes by narrowing of arteries and/or reactive inflammation. The view that arteriosclerotic dementia resulted from a gradual strangulation of blood supply to the brain was also formed during this period; consequently, emphasis was given to prodromal symptoms, and strokes were but the culmination of a process started years before.

Some opposed this view from the beginning. For example, Marie (1906) claimed that such explanation was a vicious circle, as alienists claimed that: ‘ageing was caused by arteriosclerosis and the latter by ageing’ (p. 358), and Walton (1912) expressed serious doubts from the histopathological point of view. The frequent presence in post mortem of such changes also concerned pathologists who worried that they could not ‘safely exclude cerebral arteriosclerosis of greater or lesser degree in any single case’ of senile dementia (p. 677) (Southard, 1910). Based on a review of these arguments, Olah (1910) concluded that there was no such thing as ‘arteriosclerotic psychoses’. However, the ‘chronic global ischaemia’ hypothesis won the day, and it was to continue well into the second half of the twentieth century. For some it became a

general explanation; for example, North and Bostock (1925) reported a series of 568 general psychiatric cases in which around 40 per cent suffered from ‘arterial disease’, which – according to the authors – was even responsible for schizophrenia. The old idea of an apoplectic form of dementia, however, never disappeared.

1.5.5 Apoplectic dementia

‘Apoplectic dementia’ achieved its clearest enunciation in the work of Benjamin Ball (Ball and Chambard, 1881). ‘Organic apoplexy’ resulted from bleeding, softening or tumour and might be ‘followed by a notable decline in cognition, and by a state of dementia which was progressive and incurable ... of the three, localized softening (*ramollissement en foyer*) caused the more severe states of cognitive impairment’ (p. 581). Ball believed that prodromal lapses of cognition (e.g. episodes of somnolence and confusion with automatic behaviour, for which there was no memory after the event) and sensory symptoms were caused by atheromatous lesions. Visual hallucinations, occasionally of a pleasant nature, were also common. After the stroke, persistent cognitive impairment was frequent. Post-mortem studies showed in these cases softening of ‘ideational’ areas of cortex and white matter. Ball also suggested a laterality effect (p. 582) in that right hemisphere strokes led more often to dementia whereas left hemisphere ones caused perplexity, apathy, unresponsiveness, and a tendency to talk to oneself (p. 583). Following Luys, he believed that some of these symptoms resulted from damage to corpus striatum, insular sulci and temporal lobe. During Ball’s time, attention also shifted from white to red softening. Charcot (1881) wrote on cerebral haemorrhage (the new name for red softening): ‘having eliminated all these cases, we find ourselves in the presence of a homogeneous group corresponding to the commonest form of cerebral haemorrhage. This is, par excellence, sanguineous apoplexy ... as it attacks a great number of old people, I might call it senile haemorrhage’ (p. 267).

1.5.6 Presbyophrenia and confabulation

The word ‘presbyophrenia’ was coined by Kahlbaum (1863) to name a subtype of the paraphrenias (insanities occurring during periods of biological change). Presbyophrenia was a form of paraphrenia senilis characterized by amnesia, disorientation, delusional misidentification and confabulation. Ignored for more than 30 years, the term reappeared in the work of Wernicke, Fischer and Kraepelin. Wernicke’s classification of mental disorders was based on his theory of the tripartite relational structure consciousness (outside world, body and self) (Lanczik, 1988). Impairment of the link between consciousness and outside world led to presbyophrenia, delirium tremens, Korsakoff’s psychosis, and hallucinosis. Amongst the features of presbyophrenia, Wernicke included confabulations, disorientation, hyperactivity, euphoria, and a fluctuating

course; acute forms resolved without trace, chronic ones merged with senile dementia (Berrios, 1986).

In France, Rouby (1911) conceived of presbyophrenia as a final common pathway for cases suffering from Korsakoff’s psychosis, senile dementia or acute confusion. Truelle and Bessière (1911) suggested, in turn, that it might result from a toxic state caused by liver or kidney failure. Kraepelin (1910) lumped presbyophrenia together with the senile and pre-senile insanities, and (as compared with Korsakoff’s patients) believed presbyophrenic patients to be older, free from polyneuritis and history of alcoholism, and showing hyperactivity and elevated mood. Ziehen (1911) wrote that ‘their marked memory impairment contrasts with the relative sparing of thinking’. Fischer (1912) suggested that disseminated cerebral lesions were the essential anatomical substratum of presbyophrenia.

During the 1930s, two new hypotheses emerged. Bostroem (1933) concluded on phenomenological grounds that presbyophrenia could be identified with mania, suggesting an interplay between two factors: cerebral arteriosclerosis and cyclothymic premorbid personality. Lafora (1935) emphasized the role of cerebrovascular pathology, and claimed that disinhibition and presbyophrenic behaviour were caused by a combination of senile and atherosclerotic changes. Burger-Prinz and Jacob (1938), however, questioned the view that cyclothymic features were a necessary precondition. Bessière (1948) claimed that presbyophrenia was a syndrome found in conditions such as senile dementia, brain tumours, traumatic psychoses and confusional states. More recently, it has been suggested that presbyophrenia may be a subform of AD characterized by a severe atrophy of locus caeruleus (Berrios, 1985b).

One of the features of presbyophrenia was confabulation. This complex symptom has not quite found a place in psychopathology (Berrios, 2000b). Two phenomena are included under the name ‘confabulation’. The *first type* concerns ‘untrue’ utterances of subjects with memory impairment; often provoked or elicited by the interviewer, these confabulations are accompanied by little conviction and are believed by most clinicians to be caused by the (conscious or unconscious) need to ‘cover up’ for some memory deficit. Researchers wanting to escape the ‘intentionality’ dilemma have made use of additional factors such as presence of frontal lobe pathology, dysexecutive syndrome, difficulty with the temporal dating of memories leading to an inability temporally to string out memory data, etc.

The *second type* concerns confabulations with fantastic content and great conviction as seen in subjects with functional psychoses and little or no memory deficit. Less is said in the neuropsychological literature about this group, although (at least in the case of schizophrenics) it has been correlated with a bad performance on frontal lobe tests. It is our belief that this group remains of crucial importance to psychiatrists. Little is known about the epidemiology of either type of confabulation.

In clinical practice, these two ‘types’ can be found in combination. It remains unclear why so many patients with

Korsakoff's psychosis or frontal lobe disorder, in spite of the fact that they do meet the putative conditions for confabulation (amnesia, frontal lobe damage, difficulty with the dating of memories, etc.) do not confabulate. Furthermore, confabulations have also been reported in subjects with lesions in the non-dominant hemisphere and in the thalamus.

Under different disguises, the 'covering up' or 'gap filling' hypothesis is still going strong. Although superficially plausible, it poses a serious conceptual problem in regard to the issue of 'awareness of purpose': if full awareness is presumed, then it is difficult to differentiate confabulations from lying; if no awareness is presumed, then the semantics of the concept of 'purpose' is severely stretched and confabulations cannot be differentiated from delusions.

The received view of confabulations also neglects the clinical observation that confabulations (particularly provoked ones!) do occur in dialogical situations: for example, the way in which the patient is asked questions may increase the probability of producing a confabulation. This suggests that the view that confabulations are a disorder of a putative narrative function found in normal human subjects must be taken seriously. It is hypothesized here that this trait is normally distributed in the population. In the absence of adequate epidemiological information, research efforts should be directed at mapping the distribution of this narrative (or confabulatory) capacity in the community at large. Only then will it be possible to understand the significance of its disorders. In the long term, this approach will prove more heuristic than unwarranted speculation based on a few anecdotal cases.

Reported in relation to clinical conditions other than memory deficit, 'confabulation-like' behaviours can already be found in the clinical literature of the second half of the nineteenth century. Sully (1885) suggested that such behaviours might be related to a psychological function whose role was filling gaps in the flow of our lives and explained why 'our image of the past is essentially one of an unbroken series of conscious experiences'. Sully believed that this function also intervened when memory failed: 'just as the eye sees no gap in its field of vision corresponding to the 'blind' spot of the retina, but carries the impression over this area, so memory sees no lacuna in the past, but carries its image of conscious life over each of the forgotten spaces' (p. 282).

Kraepelin (1886–1887) reported typical cases of confabulation associated with, among other things, general paralysis of the insane, melancholia and dementia; and later on suggested that 'pseudomemories' could be a symptom of paraphrenia (*without* cognitive impairment), and described a clinical variety called *paraphrenia confabulans* (Kraepelin, 1919). Under schizophrenic *akzessorischen Gedächtnisstörungen*, Bleuler (1911) discussed three related phenomena: *Gedächtnisillusionen* (illusions or distortions of memory), *identifizierenden Erinnerungstäuschungen* (memory falsifications based on identification), and *Erinnerungshalluzinationen* (memory hallucinations). Of the former he wrote: 'memory illusions often constitute the main material for the construction of delusions

in paranoids. The entire previous life of the patient may be changed in his memory in terms of this complex' (p. 115). On this definition, it is difficult, on the basis of their *intrinsic* features, to distinguish illusion of memory from confabulation. Indeed, symptom-naming is determined by whether schizophrenia or 'organic disorder' is the associated disease. Unsuccessfully, Bleuler (1911) tried to establish a differentiation on the basis of *mechanism*: 'until now, and in contrast to the views of some authors, I have not observed confabulation as it appears in organic cases; e.g. memory hallucinations which fill in memory gaps which at first appear at a (usually external) given moment and mostly adapt themselves to such an occasion' (p. 117). Kleist (1960) described patients with 'progressive confabulosis' as 'cheerful, expansive, and with little in the way of thought or speech disorder' (p. 211); and Leonhard (1957) redescribed the condition as 'confabulatory euphoria'.

1.5.7 Alzheimer's disease

AD has become the prototypical form of dementia. From this point of view, a study of its origins should throw light on the evolution of the concept of dementia. The writings of Alzheimer, Fischer, Fuller, Lafora, Bonfiglio, Perusini, Ziveri, Kraepelin and other protagonists are deceptively fresh, and this makes anachronistic reading inevitable. However, the psychiatry of the late nineteenth century is a remote country: concepts such as dementia, neurone, neurofibril and plaque were then still in process of construction and meant different things to different people. A discussion of these issues is beyond the scope of this chapter (for this see Berrios, 1990b).

1.5.7.1 THE NEUROPATHOLOGY OF DEMENTIA BEFORE ALZHEIMER

Enquiries into the brain changes accompanying dementia started during the 1830s but consisted in descriptions of external appearance (Wilks, 1865). The first important microscopic study was that of Marcé (1863) who described cortical atrophy, enlarged ventricles and 'softening'. The vascular origin of softening was soon ascertained (Parrot, 1873), but the distinction between vascular and parenchymal factors had to await until the 1880s. From then on, microscopic studies concentrated on cellular death, plaques and neurofibrils.

1.5.7.2 ALZHEIMER AND HIS DISEASE

Alzheimer (1907) reported the case of a 51-year-old woman, with cognitive impairment, delusions, hallucinations, focal symptoms, and whose brain showed plaques, tangles and arteriosclerotic changes. The existence of neurofibrils had been known for some time (DeFelipe and Jones, 1988); for example, that in senile dementia 'the destruction of the neurofibrils appears to be more extensive than in the brain of a paralytic subject' (Bianchi 1906, p. 846). Fuller (1907) had remarked in June 1906 (i.e. five months before Alzheimer's

report) on the presence of neurofibrillar bundles in senile dementia (p. 450). Likewise, the association of plaques with dementia was not a novelty: Beljadow (1889) had reported them in 1887, and so had Redlich and Leri few years later (Simchowicz, 1924); in Prague, Fischer (1907) gave an important paper in June 1907 pointing out that miliary necrosis could be considered as a marker of senile dementia.

Nor was the syndrome described by Alzheimer new: states of persistent cognitive impairment affecting the elderly, accompanied by delusions and hallucinations were well known (Marcé, 1863; Krafft-Ebing, 1873; Crichton-Browne, 1874; Marie, 1906). As a leading neuropathologist Alzheimer was aware of this work. Did he then mean to describe a new disease? The answer is that it is most unlikely he did, his only intention having been to point out that such a syndrome could occur in younger people (Alzheimer, 1911). This is confirmed by commentaries from those who worked for him: Perusini (1911) wrote that for Alzheimer 'these morbid forms do not represent anything but atypical form of senile dementia' (p. 143).

1.5.7.3 THE NAMING OF THE DISEASE

Kraepelin (1910) coined the term in the 8th edition of his *Handbook*: at the end of the section on 'senile dementia' he wrote:

the autopsy reveals, according to Alzheimer's description, changes that represent the most serious form of senile dementia ... the *Drusen* were numerous and almost one third of the cortical cells had died off. In their place instead we found peculiar deeply stained fibrillary bundles that were closely packed to one another, and seemed to be remnants of degenerated cell bodies ... The clinical interpretation of this AD is still confused. Whilst the anatomical findings suggest that we are dealing with a particularly serious form of senile dementia, the fact that this disease sometimes starts already around the age of 40 does not allow this supposition. In such cases we should at least assume a 'senium praecox' if not perhaps a more or less age-independent unique disease process.

1.5.7.4 THE RECEPTION OF THE NEW DISEASE

Alzheimer (1911) showed surprise at Kraepelin's interpretation, and always referred to his 'disease' as *Erkrankungen* (in the medical language of the 1900s a term softer than *Krankheit*, the term used by Kraepelin). Others also expressed doubts. Fuller (1912), whose contribution to this field has been sadly neglected, asked 'why a special clinical designation – Alzheimer's disease – since, after all, they are but part of a general disorder' (p. 26). Hakkébousch and Geier (1913), in Russia, saw it as a variety of the involution psychosis. Simchowicz (1911) considered 'Alzheimer's disease' as only a severe form of senile dementia. Ziehen (1911) does not mention the disease in his major review of senile dementia. In a meeting of the New York Neurological Society, Ramsay Hunt (Lambert, 1916) asked Lambert, the presenter of a case of 'Alzheimer's disease' that 'he would like to understand clearly

whether he made any distinction between the so-called Alzheimer's disease and senile dementia' other than ... in degree and point of age'. Lambert agreed suggesting that, as far as he was concerned, the underlying pathological mechanisms were the same (Lambert, 1916). Lugaro (1916) wrote: 'For a while it was believed that a certain agglutinative disorder of the neurofibril could be considered as the main "marker" (*contrassegno*) of a presenile form [of senile dementia], which was "hurriedly baptized" (*fretta battezzate*) as "Alzheimer's disease"' (p. 378). He went on to say that this state is only a variety of senile dementia. Simchowicz (1924), who had worked with Alzheimer, wrote 'Alzheimer and Perusini did not know at the time that the plaques were typical of senile dementia [in general] and believed that they might have discovered a new disease' (p. 221). These views, from men who lived in Alzheimer's and Kraepelin's time, must be taken seriously (for a detail discussion of these issues see Berrios, 1990a).

Of late there has been an attempt to rewrite the history of AD. After having been lost for years, the case notes of Auguste D., the first patient with AD, were found in the late 1990s (Maurer and Maurer, 1998). As mentioned above the original report by Alzheimer (1907) clearly stated that Auguste suffered from severe confusion, delusions, hallucinations, focal symptoms, and on post mortem her brain showed plaques, tangles and, most importantly, *arteriosclerotic* changes. As if to confirm the ontology of AD, Graeber *et al.* (1998) reported that in tissue sections belonging to this case they confirmed the presence of neurofibrillar tangles and amyloid plaques. Most interestingly, and given that vascular changes are currently not supposed to be a diagnostic criterion, these authors have put Alzheimer right by stating that Auguste's brain showed no arteriosclerotic lesions. Furthermore, they report that the apolipoprotein E (ApoE) genotype of Auguste was $\epsilon 3/\epsilon 3$, 'indicating that mutational screening of the tissue is feasible'.

On the basis of these findings, can one say that back in 1910 Kraepelin was, after all, right in claiming that Alzheimer had 'discovered' a new disease? The answer has to be that one must judge his decision in terms of what Kraepelin knew at the time and of the academic pressure he was under. He knew what Alzheimer's report stated in 1907, what the latter might have verbally added, and upon Kraepelin's perusal of Auguste's case notes, which were requested by him from Frankfurt (indeed this is the reason why they were lost for such a long time). In clinical terms, Auguste was not a 'typical' case. At 51 she had delusions, hallucinations and Alzheimer's reported arteriosclerotic changes. None of these features is mentioned in Kraepelin's original claim. The question is, why?

It is also interesting that the so-called 'second case' of Alzheimer's (Graeber *et al.*, 1997), Johann F., reported in 1911, is now considered to have suffered a 'plaques-only' form of AD. The same authors suggest that knowledge of this case may have encouraged Kraepelin to report the discovery by Alzheimer of a new disease. Unfortunately, there is no evidence that Kraepelin knew of this case when he was writing the relevant section of the 8th edition of his *Lehrbuch*. More to the

point is that he knew of Perusini's review (1909) as he himself had asked the young Italian assistant to collect four cases. In addition to Auguste D. (which includes more information than that provided by Alzheimer in 1907), Perusini reviewed the cases of Mr. R.M., a 45-year-old basket maker who had epileptic seizures, of Mrs. B.A. a 65-year-old who had marked clinical features of myxoedema, and Schl. L, a 63-year-old who had suffered from syphilis since 1870, was Romberg-positive, had a pupillary syndrome and heard voices. Since these are likely to have been the cases on which Kraepelin based his decision to construct the new disease, it would be interesting if the neuropathology and neurogenetics of the other three cases (Auguste's has already been done) were to be investigated.

1.5.8 Pick's disease and the frontal dementias

Dementias believed to be related to frontal lobe pathology have once again become of interest, and authors often invoke the name of Arnold Pick (Niery *et al.*, 1988). However, when the great Prague neuropsychiatrist described the syndrome named after him, all he wanted was to draw attention to a form of localized (as opposed to diffuse) atrophy of the temporal lobe (Pick, 1892). This alteration was to give rise to a dysfunction of language and praxis, and be susceptible to diagnosis during life. Pick believed that lobar atrophies constituted a stage in the evolution of the senile dementias.

The story starts, as it should, before Pick. Louis Pierre Gratiolet (1854) was responsible for renaming the cerebral lobes after their overlying skull: thus 'anterior' became 'frontal' lobe. He made no assumption as to the function of the 'anterior extremity of the cerebral hemisphere'. 'Phrenologists', however, did and related reflective and perceptive functions (qualitatively defined) to the forehead (Anonymous, 1832) (for the science of phrenology see Combe, 1873; Lanteri-Laura, 1970). 'Modular' assumptions (i.e. a one-to-one correlation between mental function and brain site) involving the frontal lobes started only during the 1860s, following reports on dysfunction of language in lesions of the frontal lobes (Broca, 1861; Henderson, 1986). These claims ran parallel to those of Jackson's that the cerebral cortex was the general seat of personality and mind (Jackson, 1894). Meynert (1885) believed that 'the frontal lobes reach a high state of development in man' but still defined mental disorders as diseases of the 'fore-brain' (by which he meant 'prosencephalon' or human brain as a whole).

In his first report (the case of focal senile atrophy and aphasia in a man of 71) Pick (1892) did not inculcate the frontal lobes nor did he in his second case (Pick, 1901) (a woman of 59 with generalized cortical atrophy, particularly of the left hemisphere). The association with the frontal lobes appears only in his fourth case (Pick, 1906) (a 60-year-old man with 'bilateral frontal atrophy'). Which of these cases should, therefore, be considered as the first with Pick's disease? At the time, in fact, no one thought that Pick had described a new

disease; Barrett (1913) considered the two first cases of Pick's as atypical forms of AD, and Ziehen (1911) did not see anything special in them.

During the same period, Liepmann, Stransky, and Spielmeyer had described similar cases with aphasia and circumscribed cerebral atrophy (Mansvelt, 1954); so much so, that Urechia and Mihalescu felt tempted to name the syndrome 'Spielmeyer's disease' (Caron, 1934). This did not catch on, however, and in two classical papers on what he called 'Pick's disease', Carl Schneider (1927, 1929) constructed the new view of the condition by suggesting that it evolved in three stages – the first with a disturbance of judgement and behaviour, the second with localized symptoms (e.g. speech), and the third with generalized dementia. He recognized rapid and slow forms, the former with an akinetic and aphasic subtypes and a malignant course, and the latter with a predominance of plaques (probably indistinguishable from AD).

1.6 THE AFTERMATH

The history of the word 'dementia' must not be confused with that of the concepts or behaviours involved. By the year 1800, two definitions of dementia were recognized and both had psychosocial incompetence as their central concept: in addition to cognitive impairment, the clinical definition included other symptoms such as delusions and hallucinations; irreversibility and old age were not features of the condition, and in general dementia was considered to be a terminal state to all sorts of mental, neurological and physical conditions. The adoption of the anatomoclinical model by nineteenth century alienists changed this. Questions were asked as to the neuropathological basis of dementia and this, in turn, led to readjustments in its clinical description. The history of dementia during the nineteenth century is, therefore, the history of its gradual attrition. Stuporous states (then called acute dementia), vesanic dementias and localized memory impairments, were gradually reclassified, and by 1900 the cognitive paradigm, i.e. the view that the essential feature of dementia was intellectual impairment, was established. From then on, efforts were made to explain other symptoms, such as hallucinations, delusions, and mood and behavioural disorders, as epiphenomena and as unrelated to whatever the central mechanism of dementia was. There has also been a fluctuating acceptance of the parenchymal and vascular hypotheses, the latter leading to the description of arteriosclerotic dementia. The separation of the vesanic dementias and of the amnesic syndromes led to the realization that age and ageing mechanisms were important, and by 1900 senile dementia became the prototype of the dementias; by 1970, AD had become the flagship of the new approach. During the last few years, the cognitive paradigm has become an obstacle, and a gradual re-expansion of the symptomatology of dementia is fortunately taking place (Berrios, 1989, 1990a).

Epidemiology

DANIEL W O'CONNOR

2.1 Scope of epidemiology	16	2.5 Vascular dementia	21
2.2 Methodological issues	17	2.6 Other dementias	22
2.3 Dementia prevalence	19	2.7 Conclusions	22
2.4 Alzheimer's disease	20	References	22

2.1 SCOPE OF EPIDEMIOLOGY

Epidemiology is the study of the distribution and determinants of disease in human populations. It maps the frequency of disease and identifies people at higher or lower risk of contracting particular conditions. Once risk factors are confirmed, their impact can be reduced. Studies linking cigarette smoking with lung cancer and hypertension with stroke have sparked successful campaigns to limit smoking and detect hypertension. These programmes have saved lives and extended life expectancy. Ideally, epidemiological studies will identify triggers to Alzheimer's disease (AD) and other causes of dementia.

Links between life experience and disease are identified by means of *observational*, *analytical* and *experimental* approaches (Jablensky, 2002). Observational studies entail large scale surveys to measure the frequency of dementia and note simple correlations with sociodemographic, biological and medical variables. Surveys, while costly and time-consuming, are essential in conditions like dementia, which go mostly unrecognized by primary and specialist health services, even in developed countries. In one UK study, in a town with well-developed aged psychiatry services, general practitioners recognized only 58 per cent of dementia cases and psychiatrists knew of only 20 per cent (O'Connor *et al.*, 1988, 1990).

Analytical studies contrast the backgrounds of people with dementia (drawn from community surveys or clinical practice) with those of matched controls to identify points of difference that might, on further study, prove to be risk factors. These could include past illnesses or injuries, occupational exposures, diet and lifestyle. Case-control studies are economical, but accurate matching is problematic and correlations

may emerge by chance if questions cover many dozens of items. To complicate matters, people with advanced dementia cannot report accurately on their own social, occupational and medical histories. Information must therefore be sought from relatives whose knowledge is imperfect and subject to bias.

Both types of study, observational and analytical, generate hypotheses to be tested in randomized control trials (RCTs). These are essential as analytical studies are sometimes misleading. The finding in some (but not all) case-control studies that oestrogen replacement therapy conferred protection against dementia (e.g. Yaffe *et al.*, 1998) was not confirmed by RCTs (e.g. Shumaker *et al.*, 2003). Possible explanations for this anomaly include small study size and sample bias (e.g. women in the case-control series who took hormone therapy were often better educated and generally healthier) (Shumaker *et al.*, 2003).

Epidemiology, which is both an applied and theoretical science, also addresses healthcare requirements, carer burden, access to services and the larger-scale effectiveness of medical and social interventions. Practical questions regarding social burden, service use and the like are easily 'tacked on' to community surveys. More penetrating questions regarding the larger-scale effectiveness of medical and social interventions require independent study.

2.1.1 Scope of this chapter

Other chapters in this text address risk factors for AD (Chapter 27) and vascular dementia (Chapter 43); carer burden (Chapter 11); health economics (Chapter 12) and international service perspectives (Chapter 20). This chapter will

focus instead on the prevalence and incidence of dementia, AD and vascular dementia (VaD).

2.2 METHODOLOGICAL ISSUES

The *prevalence* of dementia is the proportion of people within a defined population who meet investigators' diagnostic specifications (usually expressed as a per cent). *Incidence* refers to the proportion of people who develop dementia within a period of time (usually expressed as a rate per 1000 person-years at risk). Prevalence studies are simpler: people are divided into 'cases' of dementia and 'non-cases' at a single point in time. Some will have developed dementia recently: others will have had it for many years. A community might therefore have a higher than usual prevalence because residents with dementia live longer than usual. *Incidence* studies entail two surveys, a year or more apart, to determine annual conversion rates of former 'non-cases' to 'cases'. They are of greater scientific value since risk factors for conversion are not confounded by longevity.

The first surveys of mental disorder date from the 1950s. Lin (1953), who supplemented brief evaluations of the inhabitants of three Taiwanese communities with information from relatives, officials and hospitals, concluded that only 0.5 per cent of people aged 60+ had 'senile dementia'. By contrast, Essen-Möller (1956), who made a similar two-staged sweep of the entire population of adjoining Swedish parishes, diagnosed 19 per cent of people aged 70+ years with 'mild dementia' and another 9 per cent with 'severe dementia'.

This 30-fold discrepancy might reflect genuine differences between European and Asian communities or else discrepancies in contact procedures, refusal rates, assessment procedures

and diagnostic criteria. Methodological factors were most probably to blame. Studies in which a low score on a simple cognitive test triggers a 'diagnosis' will generate more cases than studies that require evidence of cognitive and functional decline (Jorm *et al.*, 1987).

Even the simplest assessment procedures distinguish correctly between healthy old people and those with advanced dementia. Discrepancies arise mostly at the cleavage point between 'mild cognitive impairment' on the one hand and 'early dementia' on the other. Since most early dementias merge imperceptibly with age-related cognitive impairment, the dividing line is arbitrary.

Erkinjuntti *et al.* (1997) used data from a multistage survey of 10 000 older Canadians to illustrate how diagnostic criteria (and also assessment procedures) shape prevalence rates. Within the 19 per cent of respondents selected for further testing, 3.1 per cent met ICD-10 criteria for dementia compared with 29 per cent for DSM-III-R. The more stringent ICD-10 requires impairment of long-term memory, activities of daily living and executive function. Had all respondents in this study been examined in detail, the discrepancy would certainly have been smaller but the point remains that results are influenced by assessment procedures, diagnostic criteria and cut-points.

Despite decades of research, there is no commonly recognized procedure to identify, screen, assess and diagnose dementia in community populations. Table 2.1 summarizes the methods employed in three unusually large, well-documented reports from established researchers in Liverpool, UK (Copeland *et al.*, 1987); Shanghai, China (Zhang *et al.*, 1990) and Cache County, USA (Lyketsos *et al.*, 2000). Their diversity of approach, which makes it difficult to compare one study with another, stems from dementia's insidious onset and lack of distinct biological correlates. Other degenerative conditions

Table 2.1 Comparison of methods in three dementia prevalence studies

	Liverpool, UK (1987)	Shanghai, China (1990)	Cache County, USA (2000)
First author	Copeland	Zhang	Lyketsos
Respondents (N)	1070	5055	5092
Age range	65+	55+	65+
Contact mode	General practice sample	Household sample	Whole aged population
Institutions	Included	Excluded	Included
First screening test	None	MMSE	Modified MMSE or informant interview
Second screening test	None	None	Dementia Questionnaire
Diagnostic assessment	Structured interview	Clinical evaluation	Clinical evaluation
Other investigations	None	Neuropsychology, physical examination	Neuropsychology, physical examination, laboratory tests, brain MRI
Diagnostic criteria	AGECAT	DSM-III	DSM-IV
Dementia severity ratings	AGECAT	DSM-III	CDR scale
Dementia subtypes*	No	AD, VaD	AD, VaD, FTD, DLB, others
Research personnel	Trained interviewers	Trained interviewers, psychiatrist	Trained interviewers, psychiatrist, neurologist, neuropsychologist
Dementia prevalence 65+	5.2%	4.6%	6.6%

* Dementia subtypes: Alzheimer (AD), vascular (VaD), frontotemporal (FTD), dementia with Lewy bodies (DLB)

like arthritis and cataracts can be visualized and graded directly: dementia cannot, with the result that investigators persist in developing their own procedures and instruments. Despite this, prevalence rates in the three selected projects are remarkably similar.

2.2.1 Screening

Surveys are so expensive that most researchers use the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975) or other brief cognitive tests to select respondents for more detailed evaluation (Fratiglioni *et al.*, 1999). The 30-point MMSE, which takes only 10 minutes or so to administer and requires no specialist equipment, is well-suited to this task, at least in developed countries. In a large British community survey, 86 per cent of people with dementia scored 23 points or less (sensitivity) and 92 per cent of 'normals' scored 24 and above (specificity) (O'Connor *et al.*, 1989a). However, only 55 per cent of persons scoring 23 points or less met criteria for an organic mental disorder (true positive ratio) so further investigation is mandatory.

Since the MMSE tests reading, writing and arithmetic, performance is shaped by education. In the same UK study, 11 per cent of 'normal' older people who left school before their fifteenth birthday scored 23 points or less compared with only 3 per cent of those with higher education. Conversely, the same cut-point missed 27 per cent of dementias in better educated people compared with only 12 per cent in those with limited educations (O'Connor *et al.*, 1989b). One strategy in two-phase studies is to evaluate all who fail the screening test and a proportion of 'high scorers' to limit the risk of missing early dementias.

The MMSE is not an appropriate screening tool in developing countries where older people are often illiterate and innumerate. It is better to combine tests less subject to educational bias (e.g. naming, praxis and recall) with reports from family members about cognitive and functional capacity. One such instrument, the Community Screening Instrument for Dementia (CSI-D), has high sensitivity and specificity in Native American, African American and Nigerian communities, particularly when scores are adjusted for years of education (Hall *et al.*, 1993). Further refinements emerged from a multinational study of older people in India, China, Asia, Latin America and the Caribbean (Prince *et al.*, 2003), but these instruments still tap skills acquired in the schoolroom. Computer-administered tests with a game-like interface have been developed for clinical purposes but have much to offer in community research (Sahakian and Owen, 1992; Darby *et al.*, 2002).

With respect to geographic scope, some investigators approach all eligible residents of a suburb or town. Others employ complex strategies to select representative residents of entire cities, states or countries. A narrower focus promotes compliance, reduces costs and makes follow up easier. Larger scale studies ensure that findings can be generalized to the

whole of a region or nation (Jablensky, 2002). The choice of method is driven by study resources and objectives.

2.2.2 Diagnosis

Diagnostic evaluations vary widely. Structured interviews administered by lay interviewers (e.g. the Geriatric Mental State: Copeland *et al.*, 1987) or trained clinicians (e.g. CAMDEX: Roth *et al.*, 1986) have been largely supplanted by combinations of a history, mental state examination, cognitive battery and informant interview. Interviews, which are conducted by a neurologist or psychiatrist with input from a neuropsychologist, are then supplemented by laboratory tests and neuroimaging. Most recent European and North American surveys have adopted the latter, more expensive approach (e.g. Fratiglioni *et al.*, 1999).

Informant interviews are essential. Dementia impairs memory, insight and understanding and so information must be sought from a relative or carer about the subject's personal details, cognitive and functional status, medical and psychiatric history and current medications. These details help to confirm the diagnosis of dementia, especially in its early stages, and to distinguish AD from other disorders. Informants' reports correlate highly with other markers of cognitive and functional capacity: underreporting and overreporting are remarkably uncommon (Jorm and Korten, 1988; O'Connor *et al.*, 1989c). Unfortunately, some respondents forbid contact with informants and a few have no surviving relatives.

If research findings are to carry weight, diagnostic criteria must be interpreted similarly in different centres (i.e. have high interrater reliability) and be accurate. In a study of five research centres in Australia, Germany, the Netherlands, UK and USA, in which clinicians were asked to apply DSM-III-R and Clinical Dementia Rating (CDR) criteria to 100 vignettes of older people identified in clinics and community surveys, between-centre agreement rates were good (Kappa 0.74–0.83 for DSM-III-R, and 0.50–0.69 for CDR). Rates were lower for people in the borderland between 'normal ageing' and 'mild dementia', and for those who were physically frail, deaf, anxious or depressed (O'Connor *et al.*, 1996), but not to a degree that jeopardized comparison of one study with another.

Community diagnoses based on thorough clinical evaluations and informant histories have acceptable validity. In a large British survey, only three of 56 people diagnosed with mild dementia by CAMDEX were passed as normal 2 years later (O'Connor *et al.*, 1991). Factors contributing to mistaken diagnoses included deafness, depression and unstable diabetes mellitus.

Validity is best confirmed by neuropathological examination but collecting post-mortem material in community populations is difficult. Holmes *et al.* (1999) succeeded in collecting brain tissue from 80 aged people with dementia recruited from psychiatric, medical and social services in London, UK. Initial assessments comprising a structured diagnostic and informant interview (CAMDEX), physical

examination and CT brain scan were followed by yearly re-examinations until death. Clinical and neuropathological diagnoses were based on detailed, standardized criteria and protocols. Of the 38 people judged in life to have probable AD, 29 showed only neuritic plaques at autopsy, six had mixed pathologies and three had other conditions. Of the seven judged to have probable vascular dementia (VaD), three showed only infarcts and four had other conditions. Similarly, 41 per cent of people with dementia in a community autopsy series in Cambridge, UK had 'micro-infarcts', 14 per cent had 'macro-infarcts' and 23 per cent had cortical Lewy bodies (Xuereb *et al.*, 2000). Multiple pathologies are the norm in advanced old age and simple attributions to AD or VaD must be interpreted cautiously.

2.3 DEMENTIA PREVALENCE

If dementia is truly commoner in one part of the world, or in people from a particular background, searches using finer-grained observational and analytical techniques will uncover the genetic, sociodemographic or environmental factors responsible. Unfortunately, the discrepancies reported to date most probably stem from the methodological vagaries noted already and there is little point, therefore, in listing every completed study. The following sections will focus instead on

- meta-analyses that pool the results of individual studies, and
- reports comparing prevalence rates in disparate communities using identical techniques.

The latter approach is of greater scientific interest since meta-analyses, which arrive at an average figure, might overlook genuinely novel observations.

In the first of several meta-analyses, Jorm *et al.* (1987) took findings from 22 reports to construct a statistical model

relating dementia prevalence to age and study characteristics (Table 2.2). Rates varied widely but underlying all studies was a consistent trend for prevalence to rise exponentially with age with a doubling in rates with every 5.1 years. This was confirmed by Hofman *et al.* (1991) who reanalysed data from 12 European studies conducted between 1977 and 1989 in which dementia was defined using DSM-III or equivalent criteria. No major differences emerged between countries. Fratiglioni *et al.* (1999) drew similar conclusions with the proviso that rates from a new African study were strikingly low (see below). Broadly speaking, the prevalence of dementia as defined by DSM-III or its equivalent looks to be fairly uniform, at least in developed countries.

This makes it possible to map the likely numbers of people with dementia in coming decades. Since the growth in older age-groups is higher in developing countries than developed ones, half of all people with dementia currently live in Asia (Table 2.3). Wimo *et al.* (2003) anticipate that dementia cases will increase in number in less developed countries from 13 million in the year 2000 to 84 million in 2050 (646 per cent increase). Numbers in developed countries might grow from 12 million to 20 million (167 per cent increase). The implications for health and social services in all world areas are staggering.

Table 2.3 *Estimated numbers of people with dementia in 2000 (Source: Wimo et al., 2003)*

	Number of cases (millions)	% of total
Asia	11.87	46.5
Europe	7.43	29.1
North America	3.08	12.1
Latin America	1.69	6.6
Africa	1.25	4.9
Oceania	0.21	0.8
<i>Total</i>		100.0

Table 2.2 *Prevalence rates (%) for dementia in four meta-analyses*

	Jorm <i>et al.</i> (1987)	Hofman <i>et al.</i> (1991)	Ritchie and Kaldea (1995)	Fratiglioni <i>et al.</i> (1999)	
Number of studies	22	12	9	36	
Places	Europe, USA, Japan, Australia	Europe	Europe, Canada, Japan	Europe, USA, Canada, Asia, Africa	
<i>Results</i>					
Age					Mean
65–69	1.4	1.4	1.5	1.5	1.5
70–74	2.8	4.1	3.5	3	3.5
75–79	5.6	5.7	6.8	6	6.3
80–84	10.5	13.0	13.6	12	13.1
85–89	20.8	21.6	22.3		22.1
90–94	38.6	32.2	31.5		31.7
95–99		34.7	44.5		41.2

If it is true that prevalence increases exponentially with age, varying only in its time of onset, all of us will be affected at some point in our lives. This hypothesis, which has major public health implications, was tested by Ritchie and Kildea (1995), who constructed another statistical model derived from 12 studies with data for subjects over age 80 and with adequate sampling procedures and diagnostic methods. This modified logistic model differed slightly – but critically – from Jorm’s, showing a flattening of growth at age 95 when prevalence is 40 per cent, suggesting that dementia is not inevitable.

2.4 ALZHEIMER'S DISEASE

2.4.1 Prevalence

While mapping the spread of dementia, irrespective of cause, has great practical value, pointers to risk factors are more likely to come from studies of specific dementing conditions. Unfortunately, ‘yes-no’ diagnoses of AD, VaD and the like are artificial constructs and epidemiological reports must be interpreted cautiously. Neuropathology in advanced old age, when most dementias arise, is so complex that many ‘Alzheimer’ cases also have cerebrovascular disease and *vice versa* (see above).

Table 2.4 presents findings from a meta-analysis of AD prevalence using data from 11 European studies conducted in the 1990s (Lobo *et al.*, 2000). Rates were similar to those in an earlier, overlapping analysis by Rocca *et al.* (1991). Differences exist between studies nonetheless. In the 11

Table 2.4 Prevalence rates (%) of Alzheimer's disease in a meta-analysis of 11 European studies (Source: Lobo *et al.*, 2000)

65–69	3.5	3.3	1.2	1.7
70–74	7.4	8.4	3.3	3.5
75–79	15.5	18.2	9.1	7.1
80–84	32.7	33.6	21.8	14.4
85–89	68.7	53.3	35.3	29.2
90–94	144.3	72.9		59.5
95+				121.0

reports considered by Lobo *et al.*, methods varied widely with prevalence at age 85–89 years, for example, ranging from 5 per cent to 25 per cent.

Rates were lower overall in the 17 Chinese reports summarized by Liu *et al.* (2003) but females were at higher risk than men on both continents. In China, for instance, about 5 per cent of men aged 80–84 years have AD compared with 13 per cent of women. In China, rates were also higher in urban areas than rural ones.

Corrada *et al.* (1995) applied logistic regression to identify methodological reasons for differences in 15 published papers from Europe, USA, Japan and China. After age had been adjusted for, higher rates occurred in studies that included mild cases and used laboratory tests to aid in diagnosis. Lower rates emerged from studies that used CT brain scans and cerebral ischaemia scores. This is not surprising. Studies that can afford laboratory tests are likely to be more thorough in other respects too, and studies using brain scans might attribute cases (rightly or wrongly) to vascular pathology.

2.4.2 Incidence

Differences between groups in the prevalence of AD could stem from differences in either its incidence or duration. Incidence studies, which entail a second sweep of a population to identify new cases, are better suited to identifying causative factors, but are expensive and relatively few in number.

Table 2.5 summarizes findings from four meta-analyses. Incidence rose with age in all four, just as expected. Rates were somewhat higher in two and lower in the others. Incidence levelled off in extreme old age in one study (Gao *et al.*, 1998) but not in another (Jorm and Jolley, 1998). (It also decreased in a recent, well-conducted study of 5000 older people in the USA (Miech *et al.*, 2002).) Women were at increased risk in all of the three studies that specified rates by gender. Possible explanations include women’s lower levels of education and the premature onset of dementia in men owing to head trauma, occupational toxicity and smoking (Andersen *et al.*, 1999; Fratiglioni *et al.*, 2000). Rates were a little lower in Asian countries than the USA and Europe,

perhaps because of the lower prevalence of the ApoE ϵ 4 allele in Japan and environmental and lifestyle differences (Jorm and Jolley, 1998).

2.4.3 Comparative studies

Putative socio-environmental risk factors will be identified more confidently if identical case-finding tools are applied to groups with vastly different social, educational, dietary, occupational and medical exposures. Studies of North American Whites, Blacks and Latinos generally show higher dementia rates in socially disadvantaged groups (Hendrie, 1999) but their backgrounds overlap too much to draw straightforward conclusions.

More revealing findings have emerged from a direct comparison of dementia in elderly Nigerian Africans and African Americans. This decade-long study applied identical screening tests and diagnostic evaluations comprising neuropsychology, informant interviews, personal evaluations and CT brain scans to residents of Ibadan, Nigeria and Indianapolis, USA (Hendrie *et al.*, 1995). Contrary to expectation, the age-standardized prevalence rate of AD was lower in Nigerians aged 65+ years than African Americans (1.4 per cent versus 6.2 per cent). Rates for dementia of all causes were lower too (2.3 per cent versus 8.2 per cent). This disparity was not due just to the longer survival of dementia cases in North America. In a 5-year follow up, age-standardized annual incidence rates of AD were still lower in Ibadan than Indianapolis (1.2 per cent versus 2.5 per cent) (Hendrie *et al.*, 2001). Possible reasons include the marginally significant association in Africa between AD and possession of the ApoE ϵ 4 allele (Osuntokun *et al.*, 1995) and also lower cholesterol levels, lower body mass index, less hypertension and less diabetes mellitus (Hendrie *et al.*, 2001). Other methodologically rigorous cross-cultural investigations will prove of great interest.

2.5 VASCULAR DEMENTIA

2.5.1 Prevalence

Estimating the prevalence of VaD is difficult: definitions and assessment methods vary too widely to give confidence in study findings. In a review by Rocca and Kokmen (1999), for example, prevalence rates were higher in studies that lumped 'mixed dementia' with 'vascular dementia' and that based diagnoses on neuroimaging reports rather than clinically evident stroke.

In a meta-analysis by Lobo *et al.* (2000), rates were lower than those for AD (Table 2.6). This fits well with findings from community autopsy series in the USA and UK showing the preponderance of Alzheimer's pathology with high admixtures of vascular abnormalities (Holmes *et al.*, 1999; Lim *et al.*, 1999).

Vascular dementia rates look to be higher, though, in Asian countries. When Fratiglioni *et al.* (1999) summarized findings from 25 European studies and five from Japan, Korea, India and China, the proportions of cases ascribed to VaD were 28 per cent in Europe and 38 per cent in Asia. It occurred twice as often than AD in a series of Japanese studies but exceptions exist: ratios were similar, for example, in two studies conducted in China with US collaborators (Graves *et al.*, 1996).

Caucasian-Asian differences might be real, not artefactual. In one rigorous, 7-year Japanese study in which diagnoses were confirmed whenever possible by post-mortem examination, 61 per cent of dementias in men were attributed to vascular disease, a much higher rate than observed in equivalent studies in Europe and the USA (Yoshitake *et al.*, 1995). Lifestyle is possibly more influential than genes: rates of VaD in elderly Japanese-American men in mainland USA were similar to those of other North Americans (Graves *et al.*, 1996). By contrast, Japanese men in Hawaii, whose lifestyle is more authentically Asian, have VaD rates similar to those in Japan (White *et al.*, 1996).

2.5.2 Incidence

Incidence rates vary widely from study to study for the reasons outlined above but are generally much lower than for AD (Table 2.7). Males are possibly at higher risk than females in 'younger' old age but at lower risk later (Rocca and Kokmen, 1999; Fratiglioni *et al.*, 2000). Rates look to be higher too in Asian populations than North American ones (Fratiglioni *et al.*, 2000), more in older studies perhaps than recent ones (Homma

Table 2.6 Prevalence rates (%) of vascular dementia in a meta-analysis of 11 European studies (Source: Lobo *et al.*, 2000)

Age	Males	Females
65-69	0.5	0.1
70-74	0.8	0.6
75-79	1.9	0.9
80-84	2.4	2.3
85-89	2.4	3.5
90+	3.6	5.8

Age	Males	Females
65-69	1.2	0.3
70-74	1.6	0.8
75-79	3.9	3.2
80-84	8.3	4.5
85-89	6.2	6.1
90+	10.9	7.0

and Hasegawa, 2000). More definitive findings will emerge from the ongoing Ni-Hon-Sea dementia project which applies identical methodologies to longitudinal surveys in Japan, Hawaii and Seattle (Graves *et al.*, 1996).

2.6 OTHER DEMENTIAS

While most attention has been paid to AD and VaD, dementia due to other causes accounted for 11 per cent of cases in the 25 European prevalence surveys summarized by Fratiglioni *et al.* (1999) and 15 per cent of North American and Asian ones. Few studies have applied current diagnostic criteria for dementia with Lewy bodies (DLB) and frontotemporal dementia (FTD) to community populations, but more will do so in the future as study methods become more sophisticated.

The findings to hand are too variable to interpret. In Finland, 3.3 per cent of people aged 75 years and over were judged to have DLB (Rahkonen *et al.*, 2003). By contrast, only 0.1 per cent of Japanese people aged 65 years and over met identical criteria following a detailed personal evaluation (Yamada *et al.*, 2001). Dementias due to genuinely reversible causes (e.g. vitamin deficiency, cerebral tumours and normal pressure hydrocephalus) are rare (Clarfield, 2003).

2.7 CONCLUSIONS

Descriptive epidemiological surveys have failed to identify factors other than age and genetic endowment that cause dementia in community populations. The return for investment to date is very low.

Surveys of dementia prevalence and incidence provide widely varying rates, mostly because of differences in methodology.

Dementia might be commoner in certain places and cultures. It is important, therefore, to compare incidence (not prevalence) rates of AD, VaD, etc. in aged people from widely different genetic, social, occupational and medical backgrounds.

Future studies will rely greatly on culture-free cognitive tests and interviews with informants. Computerized tests with game-like interfaces offer great promise.

Criteria for the diagnosis of dementia

CLIVE BALLARD AND CAROL BANNISTER

3.1 Diagnosis of dementia	24	3.3 Conclusion	34
3.2 Differential diagnosis of dementia subtypes	27	References	34

There are two main diagnostic challenges within the dementia field, distinguishing patients with dementia from those without and the accurate differential diagnosis of dementia subtypes (Kaye, 1998). The diagnosis of dementia has always had enormous prognostic implications, however, with the availability of licensed treatments for dementia (O'Brien and Ballard, 2001) and with the likelihood of more effective treatments becoming available over the next decade, issues of differential diagnosis will become progressively more important. This chapter will initially review criteria and standardized approaches for the diagnosis of dementia, and then tackle the diagnosis of common specific subtypes of dementia.

3.1 DIAGNOSIS OF DEMENTIA

The concept of dementia has evolved from the rather non-specific notion of organic brain syndrome to a more specific operationalized concept. For example the ICD 10 criteria (World Health Organization, 1992) described dementia as:

a syndrome due to disease of the brain, usually of a chronic or progressive nature in which there is disturbance of multiple higher cortical function including memory, thinking, orientation, comprehension, calculation, learning capacity, language and judgement. Consciousness is not clouded. The impairments of cognitive function are commonly accompanied, and occasionally preceded by deterioration in emotional controls, social behaviour or motivation.

The DSM-IV (American Psychiatric Association, 1994) definition incorporates similar elements, emphasizing the necessity for a detrimental influence upon activities of daily living. A number of key elements exist across all diagnostic criteria, mainly that dementia is a brain disease, tends to be progressive, and globally affects higher cognitive functions as

well as emotional and social functioning. The DSM-III-R criteria (American Psychiatric Association, 1987) (Box 3.1), attempted to operationalize these concepts and have been widely used as the basis for the diagnosis of dementia in research studies, with interrater reliability keeping scores of up to +0.7 (Baldereschi *et al.*, 1994). Although the key elements within these definitions are based upon sound, commonsense principles, with much that most clinicians would agree upon, there are a number of subtle difficulties. For example, the majority of definitions suggest that disturbances of consciousness or delirium should be absent. We all, however, recognize that disturbances of consciousness are common in both vascular dementia (Hachinski *et al.*, 1975) and dementia with Lewy bodies (Ballard *et al.*, 1993) and occur in a minority of patients with Alzheimer's disease (AD) (Robertson *et al.*, 1998). There are also well documented cases of patients suffering from a variety of different dementia syndromes where the early manifestations were relatively focal (e.g. Coen *et al.*, 1994). In addition not all cases of dementia are progressive.

Despite these minor caveats, the majority of diagnostic criteria have good face validity, and are probably useful in clinical practice when applied flexibly. There are, however, greater difficulties when applying these criteria within research studies. Much research work published within the dementia domain has focused upon specific dementia subtypes, and has therefore avoided this issue. Within a research setting the operationalized format of the DSM-III-R criteria have advantages of established interrater reliability. Validity is not, however, a straightforward issue. Unlike specific disease processes such as AD, dementia is ultimately a clinical diagnosis describing a syndrome, and neuropathology cannot be used as a gold standard.

Semistructured psychiatric interviews have been used as an alternative. The Cambridge Examinations for Mental Disorders in the Elderly (CAMDEX; Roth *et al.*, 1986), for example,

Box 3.1 *DSM-III-R criteria for dementia*

1. Demonstrable evidence of impairment in short- and long-term memory. Impairment in short-term memory (inability to learn new information) may be indicated by inability to remember three objects after 5 minutes. Long-term memory impairment (inability to remember information that was known in the past) may be indicated by inability to remember past personal information (e.g. what happened yesterday, birthplace, occupation) or facts of common knowledge (e.g. past presidents, well-known dates).
2. At least one of the following:
 - (a) impairment in abstract thinking, as indicated by inability to find similarities and differences between related words, difficulty in defining words and concepts, and other similar tasks;
 - (b) impaired judgement, as indicated by inability to make reasonable plans to deal with interpersonal, family, and job-related problems and issues;
 - (c) other disturbances of higher cortical function, such as aphasia (disorder of language), apraxia (inability to carry out motor activities despite intact comprehension and motor function), agnosia (failure to recognize or identify objects despite intact sensory function), and 'constructional difficulty' (e.g. inability to copy three-dimensional figures, assemble blocks, or arrange sticks in specific designs);
 - (d) personality change, i.e. alteration or accentuation of premorbid traits.
3. The disturbance in 1 and 2 significantly interferes with work or usual social activities or relationships with others.
4. Not occurring exclusively during the course of delirium.
5. Either (a) or (b):
 - (a) There is evidence from the history, physical examination, or laboratory tests of a specific organic factor (or factors) judged to be aetiologically related to the disturbance.
 - (b) In the absence of such evidence, an aetiological organic factor can be presumed if the disturbance cannot be accounted for by any non-organic mental disorder, e.g. major depression accounting for cognitive impairment.

includes an informant history, physical examination and standardized cognitive assessment, to which operationalized check spelling criteria can be applied. The technique provides a standardized information base that can discriminate controls from patients with dementia with adequate reliability and validity, and is hence useful in either a clinical or research setting. The Geriatric Mental State Schedule (GMSS;

Copeland *et al.*, 1976) is a further semistructured psychiatric interview, which covers a range of psychiatric conditions and includes a brief cognitive screening section. It is applied directly as a patient interview and can be completed by medical or allied professionals with appropriate training. Diagnosis is based upon a diagnostic algorithm (Copeland *et al.*, 1986), which specifies the degree of certainty. The requirement for the computerized diagnostic system probably limits its value in clinical settings, although it has again been demonstrated to have adequate reliability and validity in discriminating controls from dementia patients.

A technique, used by many epidemiological studies, has been to use a standardized cognitive screening instrument, such as the Mini-Mental State Examination (Folstein *et al.*, 1975) or a brief semistructured interview, usually using a two stage design with a more detailed evaluation of patients scoring below a set cut-off score (Boothby *et al.*, 1994). Outside the context of a dual design, the cut-off score on a cognitive screening instrument is an unsatisfactory way of diagnosing dementia, given the great variability between individuals and the high level of impact that previous education, current psychiatric morbidity and motivation have upon test results.

The Clinical Dementia Rating Scale (Hughes *et al.*, 1982, updated by Morris, 1987) provides a mechanism for grading dementia severity in a relatively user-friendly manner. A description of typical performance for dementia patients with different severities of illness, in a number of different domains are provided, with the rater required to make a judgement as to which category of severity most appropriately matches the impairments of an individual patient. Whilst this is not intended as a method to diagnose dementia *per se*, it provides an excellent method in tandem with a standardized definition to characterize the severity of impairments either in a clinical or research setting. Although the method was designed predominantly to improve the sensitivity of clinical staging in people with more severe dementia, the Functional Assessment Staging tool of Auer and Reisberg (1997) could be used in the same way.

Any of the standardized clinical definitions, particularly when used in conjunction with a severity rating, are likely to be very successful in the diagnosis of patients with moderate or severe dementia. The study populations used to investigate the reliability and validity of instruments such as the CAMDEX and GMSS, have been rather polarized. This has avoided the much more difficult issue of whether these criteria can distinguish between patients with no dementia and those with minimal or questionable dementia. Various terms have been used to describe older patients with a mild degree of cognitive impairment, who are clearly functioning below their premorbid level, but who do not have dementia. Historically, labels such as benign senescent forgetfulness (Kral, 1978) and age-associated memory impairment (Crook *et al.*, 1986) have been employed. Currently, the most widely used concept for early cognitive deficits is Mild Cognitive Impairment (MCI; Petersen *et al.*, 1999, 2001), which focuses upon memory deficits to identify 'pre-AD'. To meet the criteria,

people have to perform at a level of 1.5 standard deviations below the mean of an age-matched group on a standardized memory task. The criteria therefore achieve a form of 'thresholding', which identifies a cluster of people at increased risk of AD, together with a heterogeneous mix of individuals with mild memory deficits for a range of reasons. Other frequently used concepts include Aging-Associated Cognitive Decline (AACD; Ritchie *et al.*, 2001), which again relies upon thresholding but can be applied to impairments in any cognitive domain; and Cognitive Impairment No Dementia (CIND; Tuokko *et al.*, 2003), which relates to global cognitive performance in addition to operationalized clinical criteria. A detailed review of MCI or the related concepts is beyond the remit of the current chapter, although it would appear from numerous follow-up studies that between 4 and 12 per cent of people per year will develop dementia depending upon the population sampled (higher in clinic settings, lower in the community, e.g. O'Connor *et al.*, 1990; O'Brien *et al.*, 1992; Petersen *et al.*, 1999, 2001; Ritchie *et al.*, 2001; Tuokko *et al.*, 2003). As there are no satisfactory methods for distinguishing patients with progressive decline from those who continue to exhibit a static degree of mild impairment or improve, it is difficult to see how any clinical diagnostic criteria could distinguish these patients accurately from those in the early stages of a dementia process, and in many ways this is an arbitrary distinction, as 'early cognitive impairment' is not a disease entity. Although some characteristics, such as the presence of hippocampal atrophy, may increase the risk of developing dementia (Jack *et al.*, 2000), the only reliable diagnostic method at present is clinical follow up and re-evaluation. Combining clinical, neuropsychological and neuroimaging indices over time is probably the best method. Whilst this approach is prudent clinically, it is extremely difficult to employ in research studies without considerable resources for large scale prospective longitudinal studies, which probably explains the paucity of such studies in the literature.

A number of exciting recent studies highlight the potential utility of various biological markers such as phosphorylated tau in the cerebrospinal fluid (CSF) (Buerger *et al.*, 2002), characteristic patterns of hypometabolism identified on positron emission tomography (PET) scanning (de Leon *et al.*, 2001) and the identification of amyloid with specific PET ligands (Agdeppa *et al.*, 2001). We hope that further understanding of these markers will enable us to progress to a point where we can make more meaningful diagnoses such as 'very early AD' rather than relying upon thresholding from coarse neuropsychological evaluations.

Concurrent psychiatric morbidity is a further major confounding factor in the diagnosis of dementia. Probably the most extreme example is so called 'depressive pseudodementia' (Kiloh, 1961; Caine, 1981), where a typical patient will experience an apparently rapid onset of cognitive impairment, in the context of a past history or family history of affective disorder, and will probably exhibit concurrent depressive symptoms (Caine, 1981). The overlap between depression and

cognitive impairment is, however, more complex (Feinberg and Goodman, 1984). It is well established that depression affects both motivation and attention, therefore detrimentally influencing performance on activities of daily living and cognitive assessments. In addition, however, there is growing evidence of subtle neuropsychological deficits which may be specific to patients with late onset depression, and which persist after treatment (Abas and Sahakian, 1990). This issue is further confounded by the fact the many psychotropic drugs detrimentally influence cognitive function, whilst some organic factors, such as diffuse microvascular pathology, may predispose to both cognitive impairment and depression (O'Brien *et al.*, 1996). Other psychiatric conditions such as anxiety may also affect attention and performance on activities of daily living and formal cognitive assessments, while both depression and anxiety disorders are common in people with dementia, especially in the early stages of the illness. It is well known that a proportion of patients with late onset psychosis have a degree of cortical atrophy (Pearlson and Rabins, 1988), whilst a substantial minority of patients with early onset of psychotic disorders experience cognitive decline (Carpenter and Strauss, 1991). Again, except in patients with marked depressive pseudodementia who should be clinically diagnosed, it is unlikely that these factors will substantially affect misdiagnosis of patients with moderate or severe dementia, but they could have a substantial impact upon the diagnosis of minimal or mild dementia. Although well recognized by clinicians and described in a number of review articles, this is, however, an issue that has not received a great deal of research attention. In clinical practice a certain degree of pragmatism can be employed, while treating any concurrent psychiatric morbidity and evaluating the progress of any cognitive deficits over time. For research studies, however, these diagnostic issues could be a major confounding factor, which is why, for example, patients with concurrent psychiatric symptoms are often excluded from pharmacological trials pertaining to dementia.

The inclusion of statements pertaining to disturbances of consciousness in the standardized diagnostic definitions of dementia is clearly designed to distinguish dementia from delirium. Some of the difficulties with this approach have already been described, but in addition, although delirium is classically thought of as an acute condition, related to a treatable physical condition, a proportion of patients experience a subacute delirium, which can persist for some months (Lipowski, 1989) and those most vulnerable to delirium are patients with pre-existing dementia. As a consequence, in practice it is not always straightforward to make the diagnosis, particularly in patients with chronic physical conditions predisposing to repeated delirium. Certainly within the CAMDEX and GMSS validation studies, patients with delirium and dementia were distinguished with a good degree of interrater reliability and validity against expert clinical diagnosis and it is unlikely to apply to a large enough group of patients to make it a relevant issue in research studies. Within clinical services, however, this issue will occasionally arise

and is probably best dealt with by clinical judgement rather than standardized diagnostic criteria.

In summary, standardized clinical definitions of dementia have good face validity and are probably useful in both clinical practice and research studies, particularly combined with a standardized rating of severity. There are, however, specific groups of patients where diagnostic difficulties might exist, particularly patients with concurrent psychiatric morbidity, those with very mild degrees of cognitive impairment and patients with persistent delirium. For these groups longitudinal follow up and clinical judgement are better methods of diagnosis than the standardized diagnostic criteria.

3.2 DIFFERENTIAL DIAGNOSIS OF DEMENTIA SUBTYPES

3.2.1 Alzheimer's disease

More than 50 per cent of dementia patients have AD (Cummings and Benson, 1992). It is most the common dementia condition and is therefore the most important to diagnose accurately, particularly as licensed pharmacological treatments are now available.

As with all types of dementia, a wide array of diagnostic criteria have been published, including various renditions of the DSM and ICD classifications. However, it was the introduction of the NINCDS ADRDA criteria in 1984 (McKhann *et al.*, 1984) that represented a major landmark in dementia research, with the availability of reliable and valid operationalized criteria for AD. These criteria have been used far more widely than any other in research studies, and are also straightforward to use in a clinical setting. This section will therefore review the evidence pertaining to these criteria. The criteria themselves are shown in Box 3.2. Two degrees of certainty are described: probable AD and possible AD. Section 1 is the most important and contains the operationalized element of the diagnosis. First it is necessary to establish that the person has dementia. Although the same caveats exist as in the previous section where this problem was discussed, the criteria make sensible recommendations that standardized assessments of cognitive function and activities of daily living are completed as well as a detailed clinical examination, in order to establish the presence of dementia. It is also specifies that deficits are required in two or more areas of cognition, which should ensure that an individual is not suffering from a focal cognitive deficit. Note of progressive decline of memory and other cognitive functions is required. Disturbances of consciousness render patients unsuitable for a diagnosis of probable AD. Even though recent work does suggest that 20 per cent of AD patients do experience disturbances of consciousness (Robertson *et al.*, 1998), this is probably a sensible exclusion and a diagnosis of possible AD can still be made. An upper age limit of 90 is set, which is sensible in some ways given the difficulties in determining the significance of

cognitive impairment in patients above this age, but renders the criteria inapplicable to an increasingly large section of the population who are at especially high risk of AD. In the final part of section 1, it is stated that the systemic disorders or other brain diseases that could account for the progressive cognitive deficits should be excluded. Although this is an appropriate recommendation, the lack of operationalization does permit variable interpretation.

Whilst application is clear cut when another significant brain disease is present, for example cerebrovascular disease, difficulties can arise in the presence of systemic disorders, such as hypothyroidism, which can result in cognitive deficits but are not necessarily the cause of cognitive impairment in a particular individual. In practice, the presence of a concurrent disorder, which may contribute to the dementia, does not preclude a diagnosis of possible AD, particularly if treatment has not resulted in an improvement of the dementia syndrome. Other typical clinical features and the results of investigations such as electroencephalogram (EEG) and CT scans, can be used in support of the diagnosis but are not a fundamental part of the operationalized criteria.

There are several advantages to applying these criteria in clinical practice. First, they require a standardized blood screen, detailed clinical evaluation and standardized cognitive assessment, but do not depend upon novel or expensive investigative techniques, which are unlikely to be available in many clinical centres. Second, they follow a logical diagnostic process similar to that adopted by most clinicians in the diagnosis of AD. Third, the criteria for probable AD would seem to be a suitably rigorous method for selecting patients with a clear-cut diagnosis in pharmacological interventions.

The NINCDS ADRDA criteria have been widely evaluated in a large number of research studies, with excellent inter-rater reliability (Kukull *et al.*, 1990; Baldereschi *et al.*, 1994; Farrer *et al.*, 1994). In addition a number of clinicopathological correlative studies have been completed, demonstrating good agreement between clinical and neuropathological diagnosis (Morris *et al.*, 1987; Martin *et al.*, 1987; Tierney *et al.*, 1988; Boller *et al.*, 1989; Jellinger *et al.*, 1989; Burns *et al.*, 1990). Although 100 per cent diagnostic accuracy for probable AD has been reported in some studies, the overall specificity is approximately 80 per cent. Put in to context, this is substantially better than can be achieved by using a CT scan alone (Jacoby and Levy, 1980) and is better than has been achieved for the diagnosis of Parkinson's disease (PD) (Hughes *et al.*, 1992). Despite the excellent overall performance of these criteria, a number of caveats must be considered.

First, the exact accuracy of clinical diagnostic criteria, depends to some degree upon the neuropathological criteria (Nagy *et al.*, 1998) chosen for diagnosis. Second, the majority of studies have compared polarized groups of patients such as controls and those with moderate dementia, omitting many of the difficult-to-diagnose cases. This issue is not relevant if the study is aiming to recruit a group of patients with clear cut AD. However, if the objective is to differentially diagnose a representative epidemiological or clinical sample of patients,

Box 3.2 *Criteria for clinical diagnosis of Alzheimer's disease*

- I The criteria for the clinical diagnosis of PROBABLE Alzheimer's disease include:
- dementia established by clinical examination and documented by the Mini-Mental test, Blessed Dementia Scale, or some similar examination, and confirmed by neuropsychological tests;
 - deficits in two or more areas of cognition;
 - progressive worsening memory and other cognitive functions;
 - no disturbance of consciousness;
 - onset between ages 40 and 90, most often after age 65; and absence of systemic disorders or other brain diseases that in and of themselves could account for the progressive deficits in memory and cognition.
- II The diagnosis of PROBABLE Alzheimer's disease is supported by:
- progressive deterioration of specific cognitive functions such as language (aphasia), motor skills (apraxia) and perception (agnosia);
 - impaired activities of daily living and altered patterns of behaviour;
 - family history of similar disorders, particularly if confirmed neuropathologically; and
 - laboratory results of:
 - normal lumbar puncture as evaluated by standard techniques;
 - normal pattern or non-specific changes in EEG; such as increased slow-wave activity; and
 - evidence of cerebral atrophy on CT with progression documented by serial observation.
- III Other clinical features consistent with the diagnosis of PROBABLE Alzheimer's disease, after exclusion of causes of dementia other than Alzheimer's disease, include:
- plateaus in the course of progression of the illness;
 - associated symptoms of depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic verbal, emotional, or physical outbursts, sexual disorders, and weight loss;
 - other neurological abnormalities in some patients, especially with more advanced disease and including
- motor signs such as increased muscle tone, myoclonus, or gait disorder;
 - seizures in advanced disease; and
 - CT normal for age.
- IV Features that make the diagnosis of PROBABLE Alzheimer's disease uncertain or unlikely include:
- sudden, apoplectic onset;
 - focal neurological findings such as hemiparesis, sensory loss, visual field deficits and incoordination early in the course of the illness; and
 - seizures or gait disturbances at the onset or very early in the course of the illness.
- V Clinical diagnosis of POSSIBLE Alzheimer's disease:
- may be made on the basis of the dementia syndrome, in the absence of other neurological, psychiatric, or systemic disorder sufficient to cause dementia, and in the presence of variation in the onset, in the presentation, or in the clinical course;
 - may be made in the presence of a second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia; and
 - should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable cause.
- VI Criteria for diagnosis of DEFINITE Alzheimer's disease are:
- the clinical criteria for probable Alzheimer's disease and histopathological evidence obtained from a biopsy or autopsy.
- VII Classification of Alzheimer's disease for research purpose should specify features that may differentiate subtypes of the disorder, such as:
- familial occurrence;
 - onset before age 65;
 - presence of trisomy-21; and
 - coexistence of other relevant conditions such as Parkinson's disease.

it does become more important. Third, many of these studies were completed before there was wide clinical awareness of dementia with Lewy bodies (DLB) as a major form of dementia, although most reports focusing on more diverse samples including patients with DLB suggest that the criteria still perform well. For example, McKeith *et al.* (2000) reported a sensitivity and specificity of around 80 per cent for probable AD, whereas Litvan *et al.* (1998), in an even more diverse sample, reported a sensitivity of 95 per cent and specificity of 79 per cent for probable AD; in a further study Lopez *et al.* (1999) reported a sensitivity of 95 per cent and a specificity of 79 per

cent for probable AD. Fourth, many people with dementia have a combination of different disease pathologies, for example a substantial number of patients with Alzheimer-type pathology will have some degree of concurrent cerebrovascular disease and a small number of cortical Lewy bodies, which are often seen in the amygdala in people with otherwise clear cut AD. Again the exact degree of diagnostic accuracy will depend upon whether mixed cases are considered separately or as a subtype of AD, but in general the presence of mixed pathologies reduces the level of diagnostic accuracy (Holmes *et al.*, 1999).

Box 3.3 *The Hachinski ischaemia score*

Focal neurological signs	2

3.2.2 Vascular dementia (VaD)

VaD is probably the second most common dementia illness, accounting for 10–20 per cent of people with late onset dementia (Rocca *et al.*, 1991), either on its own or in combination with neurodegenerative pathologies. There have been far fewer studies examining the diagnostic accuracy of criteria for VaD than for AD. The longest established criteria are based upon the Hachinski ischaemic score (Hachinski *et al.*, 1975; Box 3.3), originally derived on the basis of cerebral blood flow patterns in dementia patients. On the weighted scale, a score of 7 or more is taken to indicate VaD, whilst a score of 4 or less suggests that this is an unlikely diagnosis. Although the scale has been much criticized, either in its pure form, or in the modified form suggested by Rosen *et al.* (1980), sensitivities and specificities of approximately 80 per cent have been achieved for the diagnosis of ‘pure’ VaD cases (Loeb and Gandolfo, 1983; Small, 1985; Katzman *et al.*, 1988). The scale is, however, far less successful in identifying mixed cases (Katzman *et al.*, 1988). Items within the scale, such as abrupt onset, stepwise progression, fluctuation and focal neurological symptoms and signs, are geared much more to the identification of multiple infarctions than to other forms of VaD (Chui, 1989), such as the insidious development of microvascular pathology, hypoxia or haemorrhage. In addition, individual symptoms within the scale are poorly operationalized and are therefore open to variable interpretation. Despite this, rather like the concept of hysteria, this scale has yet to be bettered and is likely to outlive its obituarists.

More recently two sets of operationalized criteria (Boxes 3.4 and 3.5) have been proposed, the California criteria – ADDTC (Chui *et al.*, 1992) and the NINDS AIREN criteria (Roman *et al.*, 1993). Diagnostic criteria for VaD are also included within ICD 10 (World Health Organization, 1992), DSM-IV (American Psychiatric Association, 1994) and the CAMDEX (Roth *et al.*, 1986). A preliminary study examining the ICD 10 research criteria was rather disappointing, suggesting that only 25 per cent of patients with clear vascular lesions on a

CT scan fulfilled ICD 10 criteria for VaD (Wallin, 1994). Baldereschi *et al.* (1994) did, however, demonstrate a good interrater reliability of +0.66 for the diagnosis of VaD using these criteria. Chui *et al.* (1998) compared several different diagnostic criteria for VaD in 25 case vignettes, examining interrater reliability as well as sensitivity and specificity against expert clinical judgement. The highest interrater reliability was achieved for the Hachinski scale, which performed better than the DSM-IV, the California criteria (ADDTC) and the NINDS AIREN criteria. Most of the criteria had poor sensitivity, but specificity was generally adequate. The DSM-IV criteria had the best sensitivity (50 per cent), and the best specificity was achieved by the NINDS AIREN criteria (97 per cent). In a more extensive study, the same group (Chui *et al.*, 2000) examined the interrater reliability for the NINDS AIREN, ADDTC, DSM-IV, modified Hachinski score and ICD 10 criteria, identifying only moderate agreement (κ values of 0.24–0.60) between the criteria; again the DSM-IV and the Hachinski score were the most liberal and the NINDS AIREN were the most conservative.

Gold *et al.* (1997) examined the diagnosis of VaD in a study of 113 autopsy-confirmed dementia cases. For a diagnosis of VaD, the Hachinski scale had the best specificity of 0.88, with the NINDS AIREN criteria achieving a specificity of 0.80. The ADDTC criteria had the best sensitivity (0.63). More recently Gold *et al.* (2002) examined the validity of various operationalized clinical criteria for VaD (NINDS AIREN, DSM-IV, ADDTC, ICD-10) against autopsy criteria. Eighty-nine patients (20 VaD, 23 mixed dementia, 46 AD) were included. Overall the NINDS AIREN criteria for possible VaD (sensitivity 0.55, specificity 0.84) and the possible ADDTC criteria (sensitivity 0.70, specificity 0.78) performed best. Consistent with previous studies the NINDS AIREN criteria were the more conservative of the two. All of the criteria for probable VaD were too restrictive. A fuller breakdown is shown in Table 3.1. Across both of the Gold studies, none of the criteria performed well for mixed cases. There is, however, a slight caveat in interpreting these results as the neuropathological criteria were very weighted towards infarcts, and would not have labelled people with extensive small vessel disease but no infarcts or lacunae as having VaD. In practice this is likely to be a small proportion of individuals.

Given the current state of play, NINDS AIREN and ADDTC criteria for possible VaD appear to be the most useful instruments, although the Hachinski scale probably remains useful, particularly as a clinical instrument to help distinguish between VaD and other types of dementia in clinical practice.

The notoriously unreliable clinical diagnosis of ‘mixed’ Alzheimer and VaD, with no established clinical diagnostic criteria (Bowler, 2000), is, however, a considerable concern, particularly as at least 40 per cent of dementia patients have an overlap of vascular and neurodegenerative pathologies (Kalara and Ballard, 1999). To give an indication of the scope of the problem, the Gold studies indicated that between 30 and 50 per cent of ‘mixed dementia’ cases are misclassified as VaD (Gold *et al.*, 1997, 2002). The potential overlap of

Box 3.4 *Criteria for the diagnosis of ischaemic vascular dementia (IVD)***I Dementia**

Dementia is a deterioration from a known or estimated prior level of intellectual function sufficient to interfere broadly with the conduct of the patient's customary affairs of life, which is not isolated to a single narrow category of intellectual performance, and which is independent of level of consciousness.

This deterioration should be supported by historical evidence and documented either by bedside mental status testing or ideally by more detailed neuropsychological examination, using tests that are quantifiable, reproducible, and for which normative data are available.

II Probable IVD

The criteria for the clinical diagnosis of PROBABLE IVD include ALL of the following:

- dementia;
- evidence of two or more ischaemic strokes by history, neurological signs, and/or neuroimaging studies (CT or T1-weighted MRI); or occurrence of a single stroke with a clearly documented temporal relationship to the onset of dementia;
- evidence of at least one infarct outside the cerebellum by CT or T1-weighted MRI.

The diagnosis of PROBABLE IVD is supported by:

- evidence of multiple infarcts in brain regions known to affect cognition;
- a history of multiple transient ischaemic attacks;
- history of vascular risk factors (e.g. hypertension, heart disease, diabetes mellitus);
- elevated Hachinski ischaemia scale (original or modified version).

Clinical features that are thought to be associated with IVD, but await further research include:

- relatively early appearance of gait disturbance and urinary incontinence;
- periventricular and deep white matter changes on T2-weighted MRI that are excessive for age;
- focal changes in electrophysiological studies (e.g. EEG, evoked potentials) or physiological neuroimaging studies (e.g. SPECT, PET, NMR spectroscopy).

Other clinical features that do not constitute strong evidence either for or against a diagnosis of PROBABLE IVD include:

- periods of slowly progressive symptoms;
- illusions, psychosis, hallucinations, delusions;
- seizures.

Clinical features that cast doubt on a diagnosis of PROBABLE IVD include:

- transcortical sensory aphasia in the absence of corresponding focal lesions on neuroimaging studies;

- absence of central neurological symptoms/signs, other than cognitive disturbance.

III Possible IVD

A clinical diagnosis of POSSIBLE IVD may be made when there is dementia and one or more of the following:

- a history or evidence of a single stroke (but not multiple strokes) without a clearly documented temporal relationship to the onset of dementia; or
- Binswanger's syndrome (without multiple strokes) that includes all of the following:
 - early onset urinary incontinence not explained by urological disease, or gait disturbance (e.g. parkinsonian, magnetic, apraxic, or 'senile' gait) not explained by peripheral cause,
 - vascular risk factors, and
 - extensive white matter changes on neuroimaging.

IV Definite IVD

A diagnosis of DEFINITE IVD requires histopathological examination of the brain, as well as:

- clinical evidence of dementia;
- pathological confirmation of multiple infarcts, some outside of the cerebellum.

(Note: if there is evidence of Alzheimer's disease or some other pathological disorder that is to have contributed to the dementia, a diagnosis of MIXED dementia should be made.)

V Mixed dementia

A diagnosis of MIXED dementia should be made in the presence of one or more other systemic or brain disorders that are thought to be causally related to the dementia.

The degree of confidence in the diagnosis of IVD should be specified as possible, probable, or definite, and the other disorder(s) contributing to the dementia should be listed. For example: mixed dementia due to probable IVD and possible Alzheimer's disease or mixed dementia due to definite IVD and hypothyroidism.

VI Research classification

Classification of IVD for RESEARCH purposes should specify features of the infarcts that may differentiate subtypes of the disorder, such as:

- location – cortical white matter, periventricular, basal ganglia, thalamus;
- size – volume;
- distribution – large, small or microvessel;
- severity – chronic ischaemia versus infarction;
- aetiology – atherosclerosis, embolism, arteriovenous malformation, hypoperfusion.

Box 3.5 *Criteria for clinical diagnosis of vascular dementia (VaD)*

- I The criteria for the clinical diagnosis of probable vascular dementia include all of the following:
- dementia defined by cognitive decline from a previously higher level of functioning and manifested by impairment of memory and of two or more cognitive domains (orientation, attention, language, visuospatial functions, executive functions, motor control, and praxis), preferably established by clinical examination and documented by neuropsychological testing; deficits should be severe enough to interfere with activities of daily living not due to physical effects of stroke alone.
- Exclusion criteria: cases with disturbance of consciousness, delirium, psychosis, severe aphasia, or major sensorimotor impairment precluding neuropsychological testing. Also excluded are systemic disorders or other brain diseases (such as AD) that in and of themselves could account for deficits in memory and cognition.
- cerebrovascular disease (CVD), defined by the presence of focal signs on neurological examination, such as hemiparesis, lower facial weakness, Babinski sign, sensory deficit, hemianopia, and dysarthria consistent with stroke (with or without history of stroke), and evidence of relevant CVD by brain imaging (CT or MRI) including multiple large-vessel infarcts or a single strategically placed infarct (angular gyrus, thalamus, basal forebrain, or PCA or ACA territories), as well as multiple basal ganglia and white matter lacunes or extensive periventricular white matter lesions, or combinations thereof.
 - a relationship between the above two disorders, manifested or inferred by the presence of one or more of the following:
 - (a) onset of dementia within 3 months following a recognized stroke;
 - (b) abrupt deterioration in cognitive functions; or fluctuating, stepwise progression of cognitive deficits.
- II Clinical features consistent with the diagnosis of probable vascular dementia include the following:
- early presence of a gait disturbance (small-step gait or marche à petits pas, or magnetic apraxic-ataxic or parkinsonian gait);
 - history of unsteadiness and frequent, unprovoked falls;
 - early urinary frequency, urgency, and other urinary symptoms not explained by urological disease;
 - pseudobulbar palsy; and
 - personality and mood changes, abulia, depression, emotional incontinence, or other subcortical deficits including psychomotor retardation and abnormal executive function.
- III Features that make the diagnosis of vascular dementia uncertain or unlikely include:
- early onset of memory deficit and progressive worsening of memory and other cognitive functions such as language (transcortical sensory aphasia), motor skills (apraxia), and perception (agnosia), in the absence of corresponding focal lesions on brain imaging;
 - absence of focal neurological signs, other than cognitive disturbance; and
 - absence of cerebrovascular lesions on brain CT or MRI.
- IV Clinical diagnosis of possible vascular dementia may be made:
- in the presence of dementia (Section I) with focal neurological signs in patients in whom brain imaging studies to confirm definite CVD are missing; or
 - in the absence of clear temporal relationship between dementia and stroke; or
 - in patients with subtle onset and variable course (plateau or improvement) of cognitive deficits and evidence of relevant CVD.
- V Criteria for diagnosis of definite vascular dementia are:
- clinical criteria for probable vascular dementia;
 - histopathological evidence of CVD obtained from biopsy or autopsy;
 - absence of neurofibrillary tangles and neuritic plaques exceeding those expected for age; and
 - absence of other clinical or pathological disorder capable of producing dementia.
- VI Classification of vascular dementia for research purposes may be made on the basis of clinical, radiological and neuropathological features, for subcategories or defined conditions such as cortical vascular dementia, subcortical vascular dementia, BD and thalamic dementia.
- The term 'AD with CVD' should be reserved to classify patients fulfilling the clinical criteria for possible AD and who also present clinical or brain imaging evidence of relevant CVD. Traditionally, these patients have been included with VaD in epidemiological studies. The term 'mixed dementia', used hitherto, should be avoided.

pathologies is multifaceted and broadly classifying lesions as vascular or neurodegenerative may be inadequate; meaningful neuropathological classification of different types of vascular and neurodegenerative changes that reflect specific

neurochemical and clinical symptom patterns that have prognostic value are required. Furthermore, these distinctions are arbitrary unless they are clinically useful and guide the clinician with respect to treatment approaches.

Table 3.1 *Clinicopathological validation of the major criteria for vascular dementia (numbers extracted from Gold et al., 2002)*

N = 89 (20 VaD, 23 Mixed, 46 AD)			
Criteria	Sensitivity	Specificity	
DSM-IV	0.5	0.84	
ICD 10	0.2	0.94	
Possible ADDTC	0.7	0.78	
Possible NINDS AIREN	0.55	0.84	
Probable ADDTC	0.2	0.91	
Probable NINDS AIREN	0.2	0.93	

There are three main substrates of dementia in patients with VaD: localized areas of infarction (e.g. Tomlinson *et al.*, 1970), microvascular disease (e.g. Esiri *et al.*, 1997), and concurrent atrophy (e.g. Cordoliani-Mackowiak *et al.*, 2003). Focusing on specific substrates of VaD may help improve the diagnostic accuracy for both 'pure' and 'mixed' VaD cases. The best example of this approach so far has been the development of criteria for subcortical ischaemic vascular dementia (SIVD; Erkinjuntti *et al.*, 2000), which describes VaD related to small-vessel disease, combining the overlapping clinical syndromes of 'Binswanger's disease' and 'lacunar state' (Erkinjuntti *et al.*, 2000; Román *et al.*, 2002). SIVD is hypothesized to be caused by a loss of subcortical neurones or disconnection of cortical neurones from subcortical structures. The neuropsychological profile is described as characteristic of:

- a dysexecutive syndrome (difficulties in goal formulation, initiation, planning, organizing, sequencing, executing, set-shifting and abstracting);
- slowed cognitive and motor processing speed;
- other more general attentional impairments (Erkinjuntti *et al.*, 2000; Román *et al.*, 2002; O'Brien *et al.*, 2003);
- memory deficits with impaired recall but relatively intact recognition.

The concept appears useful, but has not yet been validated in a prospective clinicopathological study.

3.2.3 Dementia with Lewy bodies (DLB)

A number of representative, hospital-based post-mortem series and studies based upon clinical cohorts have suggested that DLB is a common form of dementia, accounting for 10–20 per cent of cases in clinical settings (Lennox *et al.*, 1989; Burns *et al.*, 1990; Hansen *et al.*, 1990; Kosaka, 1990; Perry *et al.*, 1990). Diagnostic criteria were proposed by Byrne *et al.* (1991) and McKeith *et al.* (1992), although they have been superseded by international consensus criteria (McKeith *et al.*, 1996; Box 3.6). A general description of the condition is given, followed by three operationalized criteria, two of which need to be present for diagnosis of probable DLB. A number of validation studies have now been reported (Table 3.2). The data do suggest that probable DLB can be diagnosed with a specificity better than 80 per cent, and Mega *et al.* (1996) suggested that this was

Box 3.6 Consensus criteria for the clinical diagnosis of probable and possible DLB

The central feature required for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention and of frontal-subcortical skills and visuospatial ability may be especially prominent.

Two of the following core features are essential for a diagnosis of probable DLB, and one is essential for possible DLB:

- fluctuating cognition with pronounced variations in attention and alertness;
- recurrent visual hallucinations that are typically well formed and detailed;
- spontaneous motor features of parkinsonism.

Features supportive of the diagnosis are:

- repeated falls;
- syncope;
- transient loss of consciousness;
- neuroleptic sensitivity;
- systematized delusions;
- hallucinations and other modalities.

A diagnosis of DLB is less likely in the presence of:

- stroke disease, evident as focal neurological signs or on brain imaging;
- evidence on physical examination and investigation of any physical illness or other brain disorder sufficient to account for the clinical picture.

improved further if parkinsonism was present. Sensitivity has, however, been very variable across these studies. The McKeith *et al.* (2000) study reported a specificity >90 per cent and a sensitivity >80 per cent. Many of the other studies have, however, reported sensitivities <50 per cent (Table 3.2).

The majority have been retrospective, identifying clinical symptoms from a case-note review, which may well have reduced the accuracy of diagnosis. Fluctuating cognition appears to be particularly difficult to identify, with two inter-rater reliability studies suggesting very poor agreement between different expert raters (Mega *et al.*, 1996; Litvan *et al.*, 1998), problems that are likely to be compounded by a retrospective design. Patients with a combination of cerebrovascular disease and cortical Lewy bodies are also particularly difficult to diagnose accurately (McKeith *et al.*, 2000).

Importantly, diagnostic accuracy may also vary with dementia severity; for example, Lopez *et al.* (2000) compared 180 patients with AD alone to 60 patients with AD and concurrent DLB. In patients with mild dementia, there was no specific clinical syndrome associated with concurrent

Table 3.2 Sensitivity, specificity, positive predictive value and negative predictive value of the consensus criteria for probable DLB: diagnostic validation studies

Lewy bodies. However, as the disease progressed, patients with AD and concurrent DLB developed progressively more extrapyramidal signs. In the progression from mild to severe dementia, sensitivity of the DLB diagnosis rose from 62 per cent to 93 per cent, while specificity declined from 54 per cent to 16 per cent. The authors concluded that the relatively high sensitivity/low specificity of the DLB diagnosis, seen in more severe dementia, suggests that AD patients can also develop symptoms of DLB in the later stages of the dementia process.

In the clinical diagnosis of DLB, considerable attention has been paid to differentiating it from AD, PD and VaD. As the majority of DLB cases exhibit some pathological features of AD, the distinctions are in some ways arbitrary; although are useful as they are associated with different clinical and neurochemical phenotypes. Seventy five per cent of DLB patients have many of the neuropathological features of AD, particularly senile plaques (Hansen *et al.*, 1990). Although typically the density of neocortical plaques is similar to AD (Hansen *et al.*, 1990), the burden of tangles is less than in 'pure' AD (Hansen *et al.*, 1990; Del Ser *et al.*, 2001). For example, when Lewy bodies occur in conjunction with Alzheimer pathology sufficient to meet CERAD criteria for probable or definite AD, neocortical neurofibrillary tangles are usually rare or absent, and tangles in the entorhinal cortex and hippocampus are intermediate between elderly controls and AD patients (Hansen *et al.*, 1990; Del Ser *et al.*, 2001). Fewer than 40 per cent of DLB patients meet criteria for a Braak stage IV or higher, although importantly several recent studies indicate that these patients are less likely to present with a 'typical' DLB profile and are less likely to meet consensus criteria for probable DLB (Ballard *et al.*, 2004).

With regard to the relationship between PD and DLB, however, overlap in symptoms very probably reflects a common underlying molecular pathology. Lewy bodies are a common diagnostic feature for both conditions at autopsy. PD patients have severe loss of nigrostriatal dopaminergic neurones (Kuikka *et al.*, 1993; Ouchi *et al.*, 1999) and neocortical

cholinergic deficits, which are greatest in the context of cognitive impairment (e.g. Piggott and Marshall, 1996), although diffuse cortical Lewy bodies appear to be the main substrate of dementia (Apaydin *et al.*, 2002). Although for clinical diagnosis within the framework of the consensus criteria DLB and PD dementia are distinguished on the basis of whether the parkinsonism is present for more than a year prior to the dementia, this is not an evidence-based distinction.

The majority of people developing dementia in the context of longstanding parkinsonism meet the clinical criteria for a diagnosis of DLB, and the similarities in the neuropsychiatric (Aarsland *et al.*, 2001a), cognitive (Ballard *et al.*, 2002) and motor symptoms (Aarsland *et al.*, 2001b) of the two groups are becoming increasingly apparent. Following a recent consensus meeting, this is likely to change in a new revision of the criteria to stipulate that the differential diagnosis between PD dementia and DLB should be made upon the basis of whether the cognitive or motor symptoms present first. This, however, is clearly still a very arbitrary distinction and future studies need to clarify the similarities and differences in the underlying pathology, clinical syndromes and treatment response of DLB and PD dementia to determine whether there is clinical usefulness in distinguishing the syndromes, and if so where the boundaries lie. One of the diagnostic validation studies (Litvan *et al.*, 1998) did include a number of patients with other parkinsonian syndromes, and suggested that diagnostic discrimination is possible between patients with DLB and other parkinsonian syndromes using the current criteria.

The consensus criteria also describe a typical neuropsychological profile characterized by marked attention deficits, although these have no weighting in the actual diagnostic process. Comparative studies do confirm greater impairment of attention and fluctuating attention in DLB patients compared with people with AD (e.g. Ala *et al.*, 2001; Calderon *et al.*, 2001; Ballard *et al.*, 2002). In addition, visuospatial deficits are more severe in DLB (Walker *et al.*, 1997; Gnanalingham *et al.*, 1997; Ballard *et al.*, 1999a).

Neuropsychology may therefore also contribute to diagnosis in some instances.

Various neuroimaging techniques have been used to compare DLB and AD patients. From a point of view of potential differential diagnosis, studies using SPECT scans with dopaminergic ligands such as FP-CIT and other similar compounds are of particular interest. Clear differences are evident between DLB and AD patients in dopaminergic loss in the basal ganglia and subtle differences in the symmetry and rostrocaudal gradient have been identified between DLB and PD dementia (Walker *et al.*, 2002). The full clinical usefulness of this is not yet evident; for example, is this just a marker of the severity of parkinsonism or does it contribute something additional that is useful in the differential diagnosis?

Overall the consensus criteria for DLB work reasonably well in clinical practice, and certainly people who meet the criteria are very likely to actually have the condition. People with concurrent vascular pathology or marked concurrent neurofibrillary tangle pathology are, however, much more difficult to diagnose clinically. There are some useful clinical commonsense steps that can be adopted to try to improve the accuracy in everyday practice. For example, visual hallucinations are much more indicative of DLB if they initially arise in the relatively early stages of the dementia, and become more frequent in AD patients during the moderate stages of the disease (Ballard *et al.*, 1999b). Similarly parkinsonian symptoms are a less useful discriminator in the more severe stages of the disease where they become more frequent in the context of AD (Lopez *et al.*, 2000). In addition, better methods for evaluating fluctuating cognition may be useful, with three published standardized clinical rating methods (Walker *et al.*, 2000; Doubleday *et al.*, 2002).

The criteria also describe a list of features that are considered to be supportive of the diagnosis of DLB. These include:

- repeated falls
- syncope
- transient loss of consciousness
- neuroleptic sensitivity
- systematized delusions and
- hallucinations in modalities other than visual (auditory, olfactory, and tactile)

and are likely to also include REM sleep behaviour disorder (Boeve *et al.*, 2001) in the next revision of the criteria. Although these have no formal weighting in the operationalized diagnostic method, they may be useful in supporting a diagnosis of possible DLB (where only one of the three core features is present) as a primary clinical diagnosis.

3.2.4 Other dementias

Although much less common than AD, VaD or DLB, criteria for the clinical evaluation of frontal lobe dementias have been published (Lund and Manchester Groups, 1994). This includes a description of typical clinical symptoms, together

with a SPECT profile. Several studies have confirmed the predominance of behavioural problems, language impairments and hypoprontality (Miller *et al.*, 1997; Lindau *et al.*, 1998) in these patients. Litvan *et al.* (1998) included several participants with frontotemporal dementia in their clinicopathological study, reporting a sensitivity and specificity of 97 per cent for clinical diagnosis against autopsy confirmation. A further report has, however, suggested that the interrater agreement for the pathological diagnosis of frontotemporal dementia is poor (Halliday *et al.*, 2002), which makes interpretation of clinicopathological studies difficult. Further validation studies are clearly required.

The ICD-10 criteria (World Health Organization, 1992) include a description of dementia in Pick's disease, dementia in Creutzfeldt–Jakob disease, dementia in Huntington's disease, dementia in human immunodeficiency virus (HIV) disease and dementia in other specified diseases classified elsewhere (which incorporates a list including a variety of conditions such as epilepsy, hypothyroidism, intoxications, multiple sclerosis, neurosyphilis, niacin deficiency, polyarthritis nodosa and vitamin B₁₂ deficiency). For specific systemic diseases, diagnosis can be more difficult than it first appears, as often the severity of cognitive impairments can be exacerbated without the underlying condition being the predominant cause of the dementia. For many of these conditions, where an underlying cause or specific gene can be identified, the validity of clinical criteria is obviously redundant as long as the clinical profile indicates the appropriate investigation.

3.3 CONCLUSION

In the current chapter many of the potential difficulties in differential diagnosis have been highlighted. However, particularly for AD, the success of operationalized diagnostic criteria is considerable and they can be used with a degree of confidence for the diagnosis of most dementia patients. There are clearly a number of areas where further work is required, and for dementias other than AD further validation studies are needed to improve and establish accurate diagnostic methodology. The current chapter has not focused upon more detailed neuropsychological evaluation or biological markers, but it is likely in the future that more comprehensive research diagnostic criteria will include results from additional neuropsychological evaluation and more specialized investigation.

4.4 Physical examination	42		

4.1 CAUSES OF DEMENTIA AND COGNITIVE IMPAIRMENT

There are probably over a hundred different disorders that may cause dementia or chronic cognitive impairment. Box 4.1 lists the commonest causes.

Alzheimer's disease (AD) is the most frequently diagnosed cause of dementia but the majority of people with AD have concomitant cerebrovascular pathology including a third who have cerebral infarction (Kalara, 2000). Although vascular pathology has been found in 29–41 per cent of dementia cases in post-mortem studies, pure vascular pathology was only identified as a cause for dementia in 9–10 per cent of cases (Holmes *et al.*, 1999; Lim *et al.*, 1999). VaD (VaD) is a syndrome that includes a number of heterogeneous subtypes such as dementia caused by 'strategic' infarction, cerebral haemorrhage, and conditions where there is diffuse ischaemic damage (Amar and Wilcock, 1996).

Dementia with Lewy bodies (DLB) accounts for 15–20 per cent cases in hospital post-mortem series (Weiner, 1999) and is the second commonest cause of neurodegenerative dementia after AD. Again, mixed pathological changes are the rule and cases of pure DLB without plaques, tangles or vascular changes are uncommon (Holmes *et al.*, 1999).

Frontotemporal dementia is less common than AD, DLB or VaD overall but the second commonest form of primary neurodegenerative dementia in middle age, accounting for up to 20 per cent of presenile dementia cases (Snowden *et al.*, 2002).

4.1.1 Potentially reversible dementia

In a study of 1000 memory clinic patients a potentially reversible primary underlying cause was found in 19 per cent

cases, and one or more potentially reversible concomitant conditions in 23 per cent (Hejl *et al.*, 2002). Potentially reversible causes were more likely to be found in people who

- had no objective cognitive deficits, or
- had cognitive impairment but not dementia

compared to people with dementia. Potentially reversible causes were also found more frequently in those under the age of 60 years. Only 4 per cent of people who had dementia had a potentially reversible primary cause. Probably only about 1 per cent of potentially reversible cases of dementia actually do reverse with treatment (Walstra *et al.*, 1997), but a higher proportion may show a partial response. The commonest causes of 'reversible or partially reversible dementia' found in Clarfield's (1988) review of 32 studies involving 2889 subjects were as shown in Box 4.2.

Some potential causes of cognitive impairment such as vitamin B₁₂ deficiency appear to be most amenable to treatment before dementia is established (Eastley *et al.*, 2000), and so people presenting with mild cognitive impairment should receive the same degree of assessment as those who present with a dementia syndrome.

4.1.2 Delirium

Delirium is an important differential diagnosis, and a common cause of the misdiagnosis of dementia (Ryan, 1994). Delirium is commonly superimposed on dementia and some causes of delirium may subsequently lead to the development of dementia if not treated. Almost any acute illness may cause delirium in an elderly person, but infections, particularly of the urinary tract or respiratory system, and iatrogenic causes

Box 4.1 *Causes of dementia or chronic cognitive impairment***Neurodegenerative**

- Alzheimer's disease
- Dementia with Lewy bodies
- Frontal or frontotemporal dementias

Vascular

- Infarction
- Haemorrhage
- Cardiovascular disease
- Binswanger's encephalopathy
- Vasculitis

Endocrine disorders

- Diabetes
- Thyroid disease
- Parathyroid disease
- Cushing's disease
- Addison's disease

Vitamin deficiencies

- B₁₂, thiamine and nicotinic acid

Systemic diseases

- Respiratory disease
- Anaemia

Neurological disorders or trauma

- Normal pressure hydrocephalus
- Head injury
- Space-occupying lesions
- Multiple sclerosis

Infection

- Syphilis
- Encephalitis
- HIV
- Creutzfeldt-Jakob disease

Box 4.2 *Commonest causes of 'reversible or partially reversible dementia'*

- Drugs
- Depression
- Metabolic causes
- Thyroid disease
- Vitamin B₁₂ deficiency
- Calcium disturbance
- Liver disease
- Normal pressure hydrocephalus
- Subdural haematoma
- Neoplasm

Box 4.3 *Clinical features that help to distinguish delirium from dementia*

- Rapid onset over hours or days (usually)
- Onset coincides with an identifiable medical or iatrogenic cause
- Fluctuation in consciousness
- Fluctuation in severity of symptoms (but beware DLB)
- Typically worse confusion at night

are frequent culprits. Clinical features that help to distinguish delirium from dementia are given in Box 4.3.

Physical disorders that can cause cognitive impairment do not always present with delirium. An insidious onset and slow progressive deterioration may be observed in hypothyroidism and vitamin B₁₂ deficiency for example.

4.1.3 Depression

The relationship between dementia and depression is complex. In a memory clinic setting depression was found to be the most common potential reversible cause of cognitive symptoms and the most common potentially reversible concomitant condition (Hejl *et al.*, 2002). However, elderly people with depression often show deficits on standard cognitive tests, which do not always resolve with treatment (Abas *et al.*, 1990). Poor performance on cognitive testing is sometimes related to lack of motivation and impaired concentration, and is typically characterized by 'I don't know' answers, or a similar response. In some cases the cognitive impairment does not appear to be directly related to 'lack of effort' but may still resolve with treatment of the depression. However, those patients with 'reversible dementia' presumed to be secondary to depression are at higher risk of subsequently developing dementia on follow up than those with depression alone (Alexopoulos *et al.*, 1993). Depression can also be a comorbid condition with dementia. The prevalence rate of comorbid depressive illness in people with dementia varies with the study population and definition of depression, but the mean is 20 per cent (Ballard *et al.*, 1996).

It may not be possible at the initial assessment to determine whether delirium, depression or other treatable disorder is a primary diagnosis or a comorbid condition. In either case appropriate treatment should be initiated and the patient reassessed. Depressive symptoms in the elderly and cognitive dysfunction may take several months to improve with treatment, so full neuropsychological testing should probably not be repeated until a minimum of 3 months have elapsed.

4.2 THE ASSESSMENT PROCESS

The assessment of the person with dementia or cognitive impairment usually requires a multidisciplinary approach

and should be holistic rather than solely aimed at making a diagnosis. Functional ability, behaviour, the presence of psychiatric symptoms, and the psychosocial consequences of the illness on the person and their carer should also be assessed. Assessment should be a dynamic process. This chapter focuses on the diagnostic aspect of the assessment process. Obviously local service arrangements will determine where the patient is seen and by whom. The initial assessment process will involve history-taking, mental state and physical examination, blood tests and neuroimaging.

4.2.1 History

The history is the cornerstone of any assessment. The quality of information available from the patient will depend on the degree of cognitive impairment and the level of insight. Even when a patient has adequate insight into their difficulties, it is still essential to obtain supplementary information from other sources. Informants should be reliable, know the patient well and be in close contact with them. A review of the medical notes often provides important clues to the present problem.

4.2.2 Presenting complaint

The publicity generated by the launch of drug treatment for AD has done much to raise general awareness of this illness. Clinicians are increasingly likely to see patients who refer themselves with complaints of memory impairment. This requires the same degree of assessment as severe global cognitive impairment. Memory impairment in isolation is insufficient for a diagnosis of dementia but can represent the first symptom of a dementing illness. Potentially treatable causes of dementia are most likely to be amenable to reversal in the early stages of the illness, and initial symptoms of cognitive dysfunction may be quite subtle.

Subjective cognitive impairment is a common symptom of depression. Typically patients complain of thinking difficulties, poor concentration and memory impairment. There may be evidence of concentration and memory impairment on examination, but cortical symptoms such as dysphasia, dyspraxia or agnosia are rare in uncomplicated depression. Affective disorder is an important differential diagnosis for dementia, but also a common comorbid condition.

While patients may admit to mislaying things, or having to rely on written notes as *aides-memoire*, carers usually provide a better assessment of the severity of the impairment. Patients rarely offer information, which raises concern about their ability to function independently. It is invariably concerned friends or relatives who reveal that the patient forgets to lock their door or turn the gas off.

Much can be learnt about other areas of cognitive function from the history. Special attention should be given to symptoms of language impairment, dyspraxia, agnosia and visuospatial impairment. Direct enquiry may provide evidence of

problems with orientation, initiating, planning and carrying through activities, reading, or handling money.

Non-cognitive symptoms, such as a change in personality, behavioural disturbance and psychiatric symptoms, are usually best elicited from a carer. Patients who have impaired insight into their dementia are less likely to admit to depressive symptoms for example (Ott and Fogel, 1992).

The importance of the assessment of non-cognitive symptoms is two-fold. First they provide essential information for the diagnostic process. Loss of drive, disinhibition, and poverty of speech are common symptoms of frontal lobe damage, and may be the first signs of frontal lobe dementia. Visual hallucinations may point to delirium or DLB, or prominent mood symptoms may suggest an affective disorder. Second, non-cognitive symptoms have an enormous impact on the day-to-day life of both patient and carer, and may require intervention in their own right.

4.2.2.1 HISTORY OF PRESENTING COMPLAINT

A sudden, acute onset of cognitive impairment, usually excludes a neurodegenerative condition. However, caution should be exercised when assessing this. Physical or psychiatric illness may exacerbate existing problems, which only become evident on careful enquiry. Social changes such as moving house or illness in the carer may suddenly reveal deficits that hitherto went unnoticed.

The onset of AD is typically insidious, and the decline in function occurs gradually. Memory impairment is followed by the development of dysphasia, dyspraxia and agnosia. The course of dementia after a stroke is usually like that of AD (Kokmen *et al.*, 1996). The sudden onset of cognitive impairment without subsequent deterioration might suggest a cerebrovascular infarct or other acute event. The classic description of a step-wise deterioration in vascular dementia is sometimes seen but not invariably so. The symptom profile in vascular dementia is variable and determined by the site and severity of the damage.

A relatively short history with fluctuations in the level of consciousness could suggest delirium, either as a primary cause or superimposed on a dementia, or subdural haematoma. Marked fluctuation in the degree of cognitive impairment is a hallmark characteristic of DLB.

4.2.3 Past medical history

Treatment decisions may be influenced by the medical history, and past medical conditions may be implicated in the aetiology of the cognitive impairment, or be responsible for an exacerbation of current problems. However, causality should not be inferred without supporting evidence. A close temporal relationship between recent medical problems and the onset of cognitive impairment rightly raises suspicion but could be coincidental. People also measure their lives by events, and not infrequently relate their history to medical landmarks.

A multitude of medical conditions may compromise brain function through a variety of pathological mechanisms, and only the more common can be considered here. Vascular risk factors such as hypertension, diabetes and hyperlipidaemia are risk factors for both VaD and AD (Stewart, 1998). Past myocardial infarction or episodes of dysrhythmias may suggest a vascular component. Any condition that could cause anoxic or hypoxic damage may be relevant, such as severe respiratory problems or anaemia.

Hypothyroidism can lead to cognitive impairment and should always be considered in an elderly person with a past history of thyroid disease. Liver and renal disease may impact on cognitive function but are rare causes of dementia.

Particular attention should be given to any history of head injury. Even minor head trauma can cause a subdural haematoma in elderly people, and this occasionally presents with deteriorating cognitive function. Head injury also increases the risk of normal pressure hydrocephalus and AD.

4.2.4 Systems review

A brief review of the major body systems should not be forgotten. Occasionally important symptoms are only elicited by direct questioning as the patient or carer may not have made any association between them and the cognitive dysfunction.

4.2.5 Psychiatric history

A specific enquiry about any past psychiatric illness is recommended as this information is often not volunteered. A history of depressive illness increases the risk of current affective disorder, whether this is the primary diagnosis or not. Details about the symptom profile of any past episodes of psychiatric disorder often prove extremely helpful. Occasionally a review of the psychiatric notes reveals that cognitive problems were prominent during a previous illness but resolved with treatment. More rarely younger patients with somatoform or dissociative disorders may present with complaints of cognitive impairment.

Alcoholism or alcohol abuse is more likely to be missed in elderly people than younger adults (Caracci and Miller, 1991). Alcohol is neurotoxic and the damage caused by long-term abuse can be irreversible. There is an association between alcoholism and thiamine deficiency although the exact relationship is not fully understood (Kopelman, 1995). Thiamine deficiency can cause Wernicke's encephalopathy and Korsakoff's psychosis. Wernicke's encephalopathy presents acutely with confusion, clouded consciousness, ophthalmoplegia, nystagmus and ataxia, and requires immediate treatment. Korsakoff's psychosis is an amnesic syndrome.

4.2.6 Medication and substance use/abuse

When you are taking the medication history, it is always worthwhile checking the length of time particular drugs have

been prescribed. A new treatment or change in dosage coinciding with the onset or exacerbation of cognitive problems should alert the clinician to the possibility of an iatrogenic cause. However, longstanding prescriptions can sometimes be implicated. The development of a medical illness may change the bioavailability or metabolism of previously well-tolerated drugs. The possibility of non-prescription drug use, such as cough and cold remedies, or the use of relative's medications should not be forgotten.

Older people are particularly vulnerable to adverse effects from psychotropic medication for a variety of reasons. Age-related physiological factors can alter drug pharmacokinetics and dynamics. Additionally, elderly people are more likely to be suffering from physical illness and taking multiple medications. Special consideration should be given to the possible effects of tricyclic antidepressants, long-acting hypnotics, neuroleptics and the older anticonvulsants. Any medication with anticholinergic activity may impact cognitive function, and those individuals with reduced neuronal reserve are especially sensitive.

Sometimes the medication problems arise secondary to cognitive impairment, and exacerbate it further. People with impaired memory function may overdose because they forget they have taken their tablets, or else forget to take them at all. Non-compliance may account for poor diabetic control, or inadequate thyroid treatment, for example.

Illicit substance use is rare in current elderly cohorts but alcohol abuse is much commoner. Present and past alcohol intake should be assessed.

4.2.7 Family history

Family histories can aid the diagnostic process but need to be reliable. Reports of 'confusion' in elderly relatives adds little to the assessment, but a family history of formally diagnosed AD or Huntington's chorea, for example, can be all important. It is also necessary to ascertain the age at which first-degree relatives died as, especially for late-onset AD, relatives may have died before reaching the age of maximum risk.

Affective disorders in first-degree relatives may be relevant if depressive symptoms are prominent. Sometimes enquiries about general health problems in the family yield crucial information about possible aetiological causes, which would not otherwise be considered. Inherited clotting disorders or thrombophilias for example may come to light.

4.2.8 Social history

It is essential to assess the person's social circumstances in order to formulate a care plan. Living arrangements and support networks may be inadequate and this part of the history may reveal unmet needs for assistance with practical tasks such as shopping or food preparation. There may be issues involving the patient's financial situation that need to be addressed, such as their ability to manage their own finances or their

entitlement to benefits. If not already covered at this point a specific enquiry should be made about whether the patient is still driving and, if they are, whether there have been any difficulties. Both patients and informants are often reluctant to admit to any problems with driving because of the potential consequences. If patients are driving, special attention should be given to the findings of the neuropsychological examination.

4.3 MENTAL STATE EXAMINATION

The mental state examination begins with the first contact with the patient whether this is at home or in a clinic setting. Untidiness, inappropriate clothing or poor personal hygiene may indicate dyspraxia or self-neglect from severe depression. A mood disorder may be suggested by a downcast or anxious expression. Disinhibition may be demonstrated by an inappropriate greeting.

Language function is assessed during the interview and by formal testing. Abnormalities in the rate and form of speech may be indicative of an affective disorder or underlying neurological dysfunction. Decreased rate or poverty of speech may be a feature of depression or frontotemporal dementia. Patients who repeat answers, phrases or words from preceding questions are perseverating, a sign of frontal lobe impairment. Dysarthria, the disorder of the articulation of speech, can be caused by lesions of the upper or lower motor neurones, extrapyramidal and cerebellar pathways. Paraphasias, which are slightly incorrect words, can be a feature of temporal lobe problems, but also can occur when the patient is particularly anxious. Expressive dysphasia occurs secondary to frontal lobe involvement, and receptive dysphasia is caused by a lesion in Wernicke's area.

The symptoms of mood disorders in people with mild to moderate cognitive impairment or dementia are the same as for anyone else. People who are more severely impaired may lack the ability to express their distress in cognitive terms, and then the diagnosis relies more on the biological symptoms, informant history and behavioural assessment. Suicide ideation should be assessed if there are any depressive symptoms whether the person has dementia or not. Dementia does not necessarily preclude a completed suicide (Cattell and Jolley, 1995). Lability of mood is classically seen in vascular dementia and cognitive impairment and, when extreme, is termed emotional incontinence.

Psychotic symptoms may arise secondary to functional psychiatric illness, in which case they are usually mood congruent. In delirium, delusions are often paranoid in flavour and not well systematized. Some abnormal beliefs occurring in a person with dementia can often be understood in terms of the person trying to make sense of their experiences. Family members may be accused of stealing things, or neighbours of coming into the house and moving things. Hallucinations can occur in any modality, but are commonly auditory or visual.

Detailed visual hallucinations of people or animals in particular are common symptoms in DLB.

The mental state examination should include basic cognitive testing, although a more detailed neuropsychological assessment by a psychologist may be required. The general interview will give an impression of the patient's attention and concentration. Formal tests of attention include asking them to repeat a series of digits forwards and backwards, giving the months of the year or days of the week backwards, or subtracting serial sevens from 100. Aspects of memory including registration and recall can be briefly assessed by asking the patient to repeat a name and address or a series of words immediately and after a delay. The inability to understand instructions may indicate receptive language problems. The presence of nominal dysphasia may not be apparent in social conversation as patients often compensate by using circumlocution. It is tested by asking the patient to name a series of objects. Visuospatial function can be assessed by a number of tests including drawing a clock face and copying an asymmetric design. Parietal lobe impairment may be evidenced by loss of the ability to distinguish right from left, finger agnosia (cannot name fingers), astereognosis (cannot recognize an item placed in the hand with eyes closed), dressing apraxia (cannot dress), topographical agnosia (cannot find way around) and sensory inattention. Perseveration in frontal lobe impairment can be demonstrated by card-sorting tests and repetition in motor tasks. The FAS word fluency test is a useful screening test for frontal impairment.

The person's degree of insight into their current difficulties can aid the diagnosis and of course has implications for further management.

4.4 PHYSICAL EXAMINATION

Like the mental state examination, the physical examination begins as soon as you meet the patient. Some conditions may be apparent from the patient's appearance alone.

There may be obvious discomfort when they get out of the chair in the waiting room, or unsteadiness on standing. Shaking hands when introduced may reveal the forced grasping seen in frontal lobe lesions. The gait can be observed when the patient is walking to the consulting room or through the house. Is there evidence of ataxia, the broad-based gait of normal pressure hydrocephalus, or the parkinsonian shuffling steps? Does the patient get out of breath with minimal exertion? Abnormal movements such as resting tremors or choreoathetoid movements may be obvious before a neurological examination is performed.

Noting the skin colour takes seconds and may reveal the paleness of anaemia, jaundice, cyanosis, or the plethoric appearance of polycythaemia.

Measure the patient's temperature if toxicity is suspected. The general examination should include a check of the thyroid gland, lymph nodes and breasts (in women).

4.4.1 Cardiorespiratory examination

A vascular cause for the cognitive impairment may be indicated by the rate and rhythm of the pulse, the presence of hypertension, heart murmurs, carotid bruits, or poor peripheral circulation. A slow regular pulse may suggest heart block, overtreatment with some drugs, e.g. β -blockers, or hypothyroidism. Sitting and standing blood pressure should be measured in the case of orthostatic hypotension.

Chest examination may reveal evidence of infection, cardiac failure, or occasionally pleural effusion.

4.4.2 Abdomen

Any abnormal findings may be important but liver disease stigmata, the presence of an aortic aneurysm or discomfort on bladder palpation may be directly relevant to the aetiology. Faecal loading in the large bowel sometimes accounts for new behavioural problems. Constipation can be caused by medications with anticholinergic activity and also opiate derivatives, which themselves may exacerbate cognitive impairment.

4.4.3 Musculoskeletal

Musculoskeletal disorders are only rarely associated with the aetiology of cognitive impairment, but require assessment in their own right. A few conditions such as rheumatoid arthritis can cause cognitive impairment through vascular pathology.

4.4.4 Nervous system

Any abnormalities in posture, gait and movement may already have been noted but should also be formally assessed. Intention and static tremors are found when there is a cerebellar disorder, and the pill-rolling tremor is characteristic of parkinsonism. Action tremors may be exaggerated in thyrotoxicosis, uraemia and liver disease.

Of particular importance in the cranial nerve examination is any sign of facial weakness, abnormal eye movements, nystagmus and visual field defects. Ophthalmoscopy should be performed routinely as it may reveal signs of systemic disease such as diabetic or hypertensive retinopathy as well as papilloedema secondary to raised intracranial pressure.

Abnormalities in the pyramidal and the extrapyramidal motor systems may help to confirm the diagnosis of VaD, DLB, Parkinson's disease, and amyotrophic lateral sclerosis. Myoclonus may be associated with epilepsy, or Creutzfeldt-Jakob disease.

The grasp, sucking and snout reflexes are examples of primitive reflexes which are normal in infants. People with frontal dementias usually acquire primitive reflexes in the early stages of their illness, otherwise their occurrence is usually associated with advanced dementia. The grasp reflex, a flexion of the thumb and fingers, can be elicited by stroking the patient's palm between their thumb and index finger. The

sucking reflex can be provoked by touching the lips with a wooden spatula or other instrument and, as its name implies, involves contraction of the muscles used for sucking. A pout provoked by tapping the centre of closed lips is the snout reflex.

Sensation is particularly difficult to assess in a person with dementia and in addition an impairment of lower limb vibratory sense and proprioception is a common normal finding in many elderly people. However, sensory examination can still be useful and may reveal abnormalities suggestive of cerebrovascular lesions, peripheral neuropathy in diabetes or vitamin B₁₂ deficiency and, more rarely these days, tabes dorsalis and subacute combined degeneration of the cord.

4.5 INVESTIGATIONS

Standard blood screening is a recommended part of the assessment, and serves several purposes. It may reveal potentially treatable causes of cognitive impairment and organic mood disorder, or coexistent medical disorders which were not suspected from the history or physical examination. Additionally impaired renal function or liver function tests for example may influence treatment decisions.

Standard blood investigations should include those in Box 4.4.

There are areas, such as parts of North America, where tertiary syphilis has become so rare that screening for syphilis is no longer recommended as a routine investigation (Knopman *et al.*, 2001). However, if there is a clinical suspicion or the patient resides in a high incidence area, screening should be performed.

Other investigations including an electrocardiogram may be arranged as indicated by the history and examination.

Unfortunately clinical rules for predicting which patients should have standard structural neuroimaging introduce the risk of missing clinically significant structural lesions (Gifford *et al.*, 2000). Where neuroimaging is possible as part of the initial evaluation, this should be with either non-contrast computed tomography (CT) or magnetic resonance imaging (Knopman *et al.*, 2001).

Although it is not widely available, there is evidence that using a dopaminergic presynaptic ligand, ¹²³I-labelled

Box 4.4 Standard blood investigations

2 β -carbomethoxy-3 β -(4-iodophenyl)-N-(3-fluoropropyl) nortropane (FP-CIT) and single photon emission tomography (SPET) can distinguish DLB from AD during life (Walker *et al.*, 2002). Further evaluation is required to determine whether this will be useful as a routine investigation.

Lumbar puncture is only indicated as an investigation if an infective or inflammatory cause is suspected.

There has been a lot of interest in cerebrospinal fluid (CSF) markers but to date only the CSF 14–3–3 protein assay for Creutzfeld–Jakob disease has clinical usefulness, although the ratio of phosphorylated τ to β -amyloid peptide in the CSF looks promising as an aid to diagnosing AD (Galasko, 2003).

4.6 CONCLUSION

The clinical features of the history, mental state, physical examination and the findings of investigations must all be considered when making a diagnosis of dementia. Many causes of dementia or cognitive impairment are potentially reversible, and comorbid conditions may require therapeutic intervention. For those causes that are irreversible, there are treatment options that may offer symptomatic improvement and alter the course of the illness.

Neuropsychological assessment of dementia

ANDREW D BLACKWELL, BARNABY D DUNN, ADRIAN M OWEN AND BARBARA J SAHAKIAN

5.1 Neuropsychological assessment: background and general considerations	45	5.4 Neuropsychological assessment for the purposes of monitoring change in cognitive function	51
5.2 Neuropsychological assessment in the early detection of dementia	47	5.5 Conclusions	52
5.3 Neuropsychological assessment in the differential diagnosis of the dementias	49	References	52

It is estimated that dementia currently affects approximately 37 million people worldwide, with an estimated 775 200 cases in the United Kingdom (World Health Organization, 2001; Alzheimer's Society Demography Policy Position, 2004). As the population ages these prevalence rates can be expected to increase substantially, especially in industrialized nations (Hebert *et al.*, 2003). Dementia can have a devastating personal impact upon the lives of patients and their carers, and may also be associated with substantial financial costs; the total cost of Alzheimer's disease (AD) alone in the US for the year 2000 has been estimated to be US\$1.75 billion (World Health Organization, 2001).

Over the past two decades, the concept of dementia as a 'progressive global cognitive decline in clear consciousness' has been revised. It is increasingly apparent that each form of dementia has a distinct cognitive profile, at least in the mild stages of the disease, and that this reflects the pattern of underlying neuropathological change (Hodges, 1998; Rahman *et al.*, 1999a; Lee *et al.*, 2003). The advent of potentially disease-modifying therapies has reinforced the immediate need for reliable, sensitive and specific *in vivo* markers for each form of dementia. Significant recent advances in our understanding of the cognitive neuropsychology of the dementias (coupled with an absence of accurate biomarkers) have emphasized the importance of neuropsychological assessment in the early and differential diagnosis of the dementias, in objective monitoring of changes in cognitive function across disease course or as a function of treatment, and in estimating functional status.

In this chapter a brief outline of the rationale for neuropsychological assessment will be given, together with a

description of what a detailed neuropsychological assessment can offer a clinician over and above simple rating scales such as the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975) and Alzheimer's Disease Assessment Scale (ADAS-cog) (Rosen *et al.*, 1984). The chapter will focus on Alzheimer's disease (AD), since this is the most prevalent and probably the best understood dementia from a neuropsychological perspective, but will also refer to frontotemporal dementia, dementia with Lewy bodies (DLB) and vascular dementia (VaD) in the section on differential diagnosis. In describing the neurocognitive profile of these conditions, an emphasis will be placed on neuropsychological tests that are of use in the early detection and differential diagnosis of the dementias.

5.1 NEUROPSYCHOLOGICAL ASSESSMENT: BACKGROUND AND GENERAL CONSIDERATIONS

5.1.1 What is neuropsychological assessment and how is it relevant to dementia?

Clinical neuropsychology is an applied science concerned with the behavioural expression of brain dysfunction (Lezak, 1995). In general, the aim of neuropsychological assessment in cases of dementia is to provide a clinician with a profile of the patient's performance demonstrating specific areas of cognitive impairment and cognitive sparing. The acquired information can be used for several purposes. These include aiding diagnosis, informing management, care and planning,

evaluating the efficacy of a treatment, providing information about competency for legal matters, or for research.

5.1.2 How should I choose which tests to use?

The neuropsychological tests used in a particular clinical assessment must be tailored to the individual needs of the patient and the reason for the referral. Nevertheless, it is also important to include 'benchmark' tests in order that the neuropsychologist can compare between patients within the same group, across patient groups and for use in longitudinal follow up. On a very general level, the assessment of a patient should involve an evaluation of their cognitive function in the major domains afflicted by the dementia, an assessment of mood (e.g. Beck Depression Inventory [Beck *et al.*, 1961], Hamilton Depression Rating Scale [Hamilton, 1960]), an estimate of premorbid intelligence level together with years of education to compare results to, and a measure of how much the deficits in cognitive function affect the patient's functioning in everyday life. The test battery chosen should ideally be sensitive to even subtle deficits in patients, be relatively easy and quick to administer and have been validated longitudinally (including equivalent forms and characterization of any practice effects) (Ferris and Kluger, 1997).

The quality of a neuropsychological test is measured by how well its psychometric properties conform to theoretical notions of reliability and validity (Kline, 1986). Good validity means that the test actually measures what it is purported to measure. Good reliability means that the test's measurements are accurate and consistent across different clinicians, locations and times. So that the test can be used reliably for diagnosis at a single case level, the key qualities required are specificity (any deficit found on a test is unique to one patient group and not a range of conditions) and sensitivity (the test should be sensitive to the earliest stages of a neurodegenerative disease and even subtle changes in a patient's condition).

Exactly which test to use depends on the precise hypothesis being tested. For example, different tests are sensitive to different levels of severity of dementia. A test like the CANTAB Paired Associate Learning task (Sahakian *et al.*, 1988) is excellent for early detection of AD (see below), but owing to its sensitivity it may not be ideal for measuring disease progression in more advanced stages of disease progression. Other CANTAB tests, such as the Delayed Matching To Sample Test, the Attentional Shift Test and the Visual Search Test may be more suitable for assessing stage and severity of dementia (see Sahakian *et al.*, 1988, 1990; Sahgal *et al.*, 1992a). Further, a lengthy battery may be useful for the detailed assessment of cognitive function in the mild stages of dementia but may not be appropriate or feasible in more moderately/severely demented patients with major attentional difficulties. It is important to include verbal and non-verbal stimuli, to examine both recognition and recall, and to assess performance at both immediate and delayed memory. The CANTAB non-verbal tests may be combined with tests of verbal function,

together with measures of premorbid or current intelligence level (e.g. National Adult Reading Test [NART], Wechsler Adult Intelligence Scale – Revised [WAIS-R], respectively). For those without access to computerized assessment, an example of a 'pencil and paper' battery may include measures of premorbid and current intellectual function (e.g. NART, WAIS-R, respectively), episodic memory (e.g. Wechsler Logical Memory, Kendrick Object Learning Task, Warrington Recognition Memory for words and faces), working memory (e.g. Corsi block tapping task, forward and backwards digit span), semantic memory (e.g. Graded Naming Test, category fluency, Boston Naming Test, Pyramids and Palm Trees Test), attention (e.g. the Stroop test, symbol digit substitution, Test of Everyday Attention), visuospatial perception and construction (e.g. drawing a clock face, Ray–Oesterreich figure, the Visual Object and Space Perception Battery [VOSP]), language comprehension and expression (e.g. Test for Reception of Grammar [TROG], Token Test) and executive functions (e.g. Wisconsin Card Sorting Test, Behavioural Assessment of the Dysexecutive Syndrome [BADs]). An alternative to combining individual tests is to use an already constructed battery. Some batteries commonly used in memory clinics are described briefly below.

- The Consortium to Establish a Registry for Dementia of the Alzheimer's type (CERAD; Morris, 1997; Welch *et al.*, 1992) battery includes the Boston Naming Test, verbal fluency, the MMSE and two other subtests, covering memory, language, constructional praxis and intellectual status.
- The Wechsler Memory Scale revised (WMS-R; Kaplan *et al.*, 1991) is made up of 13 subtests that take about 45 minutes to administer. The areas tested include orientation, attention, verbal memory, visual memory and delayed recall.
- The Halstead–Reitan battery (Reitan and Wolfson, 1993) consists of 10 tests that tap sensory, perceptual, motor, attention, language and problem solving abilities.
- The Cambridge Neuropsychological Test Automated Battery (CANTAB; Robbins and Sahakian, 1994) is a set of computerized neuropsychological tests that tap visual memory, attention, and working memory and planning. Computerized batteries have number of distinct advantages over more traditional 'paper and pencil' tests and this has been discussed in detail elsewhere (see Robbins *et al.*, 1994b, 1998; Fray *et al.*, 1996).

5.1.3 What is the merit in using a battery of tests versus a short screening tool?

A neuropsychological assessment involving a battery of tests is almost always preferable to short screening measures where resources and time permit. This is because short mental status tests are suitable for some aspects of performance assessment (e.g. some forms of screening, gross staging of severity), but neglect others. For example, the MMSE (Folstein *et al.*, 1975) is one of the most widely used brief measures of global

cognitive function. Its strengths are that it is inexpensive, rapid, highly portable, and can be interpreted and administered with little training. It is standardized and has been successfully applied in cross-national studies. However, the MMSE has poor sensitivity to very mild dementia, is sensitive to age and educational level, and demonstrates ethnicity biases (Tombaugh and McIntyre, 1992; Nadler *et al.*, 1994; Wilder *et al.*, 1995). It is also limited in that it provides only a global index of cognitive performance; a full neuropsychological battery taps more cognitive domains and has greater sensitivity, increasing the usefulness of the assessment in terms of early and differential diagnosis within the dementias. In addition, a comprehensive assessment can provide information from which to measure change in multiple cognitive domains as a result of the progression of the disease or the administration of a new treatment and, in some cases, may aid in the management decisions regarding individual patients.

5.1.4 Feedback of test results

Neuropsychological reports should be informative and useful and should highlight, where possible, the practical implications for improving the patient's quality of life (e.g. use of memory aids, carer support and training). These reports should also include observations of the behaviour of the client during testing (e.g. distractibility, motivation, anxiety), as such observations can usefully complement the results of objective neuropsychological tests (see Lezak, 1995).

In all cases, neuropsychology should be viewed as contributing to a diagnosis along with other forms of assessment (e.g. structured clinical interview, neuroimaging, etc.). The most accurate diagnosis and treatment recommendations will always be made by combining converging forms of clinical, neuropsychological and neuroimaging evidence.

5.2 NEUROPSYCHOLOGICAL ASSESSMENT IN THE EARLY DETECTION OF DEMENTIA

Current criteria for the diagnosis of probable AD stipulates deterioration in two or more areas of cognition including memory and this to be of sufficient magnitude to interfere with work or social function (McKhann *et al.*, 1984; see also Small *et al.*, 1997). Clinically, the presenting problem in probable AD patients is often difficulty in new learning and memory (Sahakian *et al.*, 1988). In particular, AD is characterized by deficits in episodic memory (i.e. memory for specific events or experiences that can be defined in terms of time and space) (Welch *et al.*, 1992). Critically, however, substantial neuropathological change may have occurred before clinically significant symptoms appear (Jack *et al.*, 1999; Killiany *et al.*, 2002; Visser *et al.*, 2002). Thus, commencing treatment of AD at the time of clinical diagnosis may be suboptimal or

even ineffective owing to the advanced stage of neurodegeneration at that time. The identification of cognitive tests that are sensitive to early pathological changes would facilitate the diagnosis of patients in a 'prodromal' state (i.e. those in whom the pathological process is present but whose symptoms are currently subclinical).

Until relatively recently, the early detection of dementia has been neglected, partly due to the absence of effective treatments and also because sufficiently sensitive neuropsychological tests were not available. The emergence of drugs to treat the symptoms of AD (e.g. rivastigmine, donepezil, galantamine) brings an end to the therapeutic nihilism previously seen in the dementias and, excitingly, several drugs are currently in development that are hoped will modify disease progression. However, it is widely believed that if neuroprotective agents that modify the disease process are to be effective (or indeed for their efficacy to be evaluated), then it is vital that clinicians are able to detect a dementia early and accurately, before the emergence of global cognitive impairment and substantial and irreversible atrophic damage (Fox *et al.*, 1999; Blackwell *et al.*, 2004). Early detection of dementias can also offer patients and their families more time to come to terms with the diagnosis of dementia, to make the necessary personal and financial arrangements, and to reduce the anxiety patients may feel when they are unsure of their diagnosis (Morgan and Baade, 1997; see also Holroyd *et al.*, 1996, 2002; Geldmacher *et al.*, 2003). Thus, early detection would serve to maximize the potential therapeutic benefit of treatment, enhance patient quality of life and, in so doing, reduce the burden on residential and nursing care services. Consequently, a very high therapeutic and economic premium is placed on the early detection and diagnosis of AD.

Over the past few years, attempts to identify individuals in the prodrome of AD (and other dementias) have largely focused upon patients who report memory problems but who do not fulfil criteria for clinically probable AD, in that activities of daily living and non-memory cognitive faculties are intact. This condition has been given several labels, including 'questionable dementia' (see e.g. Swainson *et al.*, 2001; Blackwell *et al.*, 2004) and 'mild cognitive impairment' (MCI) (Petersen *et al.*, 1999).

According to Petersen (2003), 'the concept of MCI represents the earliest point in the cognitive decline of an individual who is destined to develop AD' and approximately 7–15 per cent per annum of a sample meeting criteria for MCI will 'convert' to meet criteria for probable AD, several fold the conversion rate expected in a general population (Celsis, 2000; Bennett *et al.*, 2002; Petersen, 2003). There is, however, controversy regarding the prognostic utility of MCI as it has been currently defined (see Box 5.1). In particular, the usefulness of the subjective memory complaint (Jorm *et al.*, 1997; Busse *et al.*, 2003), the stability of MCI diagnosis over time, and the optimal operationalization of the objective memory criteria (e.g. the choice of a particular test and criteria to deem a deficit clinically significant) have all been questioned (Ritchie *et al.*, 2001; Larrieu *et al.*, 2002; see also Collie *et al.*, 2002; Petersen,

Box 5.1 (*Amnesic**) mild cognitive impairment criteria

- Memory complaint, preferably corroborated by a collateral source
- Objective memory impairment for age and education
- Normal general cognition
- Preserved activities of daily living
- Non-demented

*Other clinical subtypes of MCI have recently been proposed. It has been suggested that 'single non-memory cognitive domain MCI' and 'multiple-domain MCI' may have a different aetiology and outcome (Petersen, 2003). Further research is needed to evaluate the validity/utility of these subtypes

2003). Identifying appropriate tests with which to objectively quantify memory impairment is likely to improve the prognostic utility of MCI as a nosological entity and represents a crucial step in identifying patients who may benefit from disease-modifying treatments, while avoiding exposure of those who do not have prodromal AD to potential side effects of these drugs (and unnecessary costs).

In attempting to identify neuropsychological tests that are sensitive to the cognitive markers of prodromal AD (and thus appropriate indices of memory function in MCI), it is crucial to ensure that performance on such tests is not deleteriously affected by other neuropsychiatric complaints that may confuse diagnosis. Furthermore, in order for maximum diagnostic sensitivity to be achieved, it is important to test those cognitive functions that are subserved by brain areas directly implicated in AD neuropathogenesis. The earliest pathological markers of AD, neurofibrillary tangles and neuropil threads, are first seen in the transentorhinal cortex, before neuropathology later spreads to the entorhinal cortex and hippocampus proper (Braak and Braak, 1991). Converging evidence from lesion studies in humans (Smith and Milner, 1981) and experimental animals (McDonald and White, 1993; Miyashita *et al.*, 1998) and functional neuroimaging studies in normal volunteers (Owen *et al.*, 1996; Maguire *et al.*, 1998) suggests that these brain areas are necessarily involved in visuospatial associative learning. Accordingly, it is likely that a decline in visuospatial associative learning ability may be a good candidate marker of early neuropathological abnormality.

A number of longitudinal studies have investigated the relative merits of various neuropsychological tests of memory for announcing AD in its prodromal phase. Fox *et al.* (1998) followed 63 asymptomatic individuals at risk of autosomal dominant AD over a 6-year period. The 10 subjects who developed dementia during this time could be identified at first assessment (when they were ostensibly unaffected) by significantly lower verbal memory and performance IQ on cognitive testing. These subjects were initially no different in terms of age, family history and initial MMSE scores. First assessment was typically 2–3 years before symptoms were manifest and 4–5 years before a diagnosis of probable AD was made, a result which clearly illustrates the potential sensitivity

of cognitive testing. Blinded assessment of serial MRI imaging showed that diffuse cerebral and medial temporal lobe atrophy was found in subjects only after they were clinically affected, suggesting that a patient's neuropsychological profile may be a more sensitive early indicator than structural brain imaging data (see also Laakso *et al.*, 2000). These results support the notion that the earliest cognitive deficits seen in AD include objective episodic memory impairments that may even precede the onset of subjective memory complaints.

Other longitudinal studies in elderly subjects generally concur with these results. In the Framingham study 'preclinical' deficits in verbal recall (as indexed by the per cent retained in the Logical Memory Test and Paired Associate Learning Test) preceded clinical diagnosis of AD in some cases by more than 6 years (Linn *et al.*, 1995; Elias *et al.*, 2000). Similarly, in the Bronx ageing study, two tests of verbal memory, the Fuld Object Memory Evaluation and the Bushke Selective Reminding Test, predicted many subjects who would go on to develop AD (Masur *et al.*, 1995) (see also Albert *et al.*, 2001; Artero *et al.*, 2003).

Fowler *et al.* (1995, 1997, 2002) used the Cambridge Neuropsychological Test Automated Battery (CANTAB) to ascertain whether early AD could be detected in a group of individuals with 'questionable dementia' (QD). As discussed above, these are people who present with subjective memory complaints, may or may not show some degree of impairment on standard neuropsychological tests (this differentiates QD from MCI criteria), but do not fulfil NINCDS-ADRDA criteria for dementia (McKhann *et al.*, 1984). Fowler *et al.* (1997) demonstrated that the CANTAB PAL scores of the QD group fell into two clusters: follow-up longitudinal data revealed that individuals in one cluster (characterized by declining PAL performance) had a poor prognosis and an increased likelihood of a diagnosis of AD, whereas those in the other cluster (characterized by stable PAL performance) had a good prognosis and remained unimpaired. A later study (Swainson *et al.*, 2001; Blackwell *et al.*, 2004) found that PAL performance could be used to accurately predict incident probable AD diagnosis in a QD group based on assessment at a one-time point alone (see below).

The CANTAB PAL requires subjects to learn and remember abstract visual patterns associated with various locations on a touch-sensitive computer screen. Patterns are presented in one of six or eight boxes around the edge of the screen (Figure 5.1). After a brief delay, the same patterns are presented in the middle of the screen and the subject is required to touch the box in which they saw that pattern appear. If this is not completed correctly the subject is reminded where each pattern belonged and tested again. This process continues until the task is satisfactorily completed or 10 trials have been attempted.

Further studies using CANTAB PAL have confirmed it to be useful in early and differential diagnosis in AD on a case-by-case basis. The CANTAB PAL performance of patients with mild AD was impaired relative to both demographically-matched healthy controls (Sahakian *et al.*, 1988) and to

Figure 5.1 (a, b) CANTAB paired associates learning task – 1, 2, 3, 6 or 8 patterns are displayed sequentially in the available boxes (in the 8-pattern stage two more boxes are added). Each pattern is then presented in the centre of the display and the subject is required to touch the box in which the pattern was previously seen. If all the responses are correct the test moves on to the next stage; an incorrect response results in all the patterns being redisplayed in their original locations, followed by another recall phase. The task terminates after 10 presentations and recall phases if all patterns have not been placed correctly. Reproduced by kind permission of CANTAB, Cambridge Cognition Ltd.

individuals with frontal variant frontotemporal dementia (Lee *et al.*, 2003). Of critical importance, CANTAB PAL was also found to be relatively insensitive to major unipolar depression (only 7 per cent of scores of patients with depression and AD fell within an overlapping range) (Swainson *et al.*, 2001) (see Figure 5.2). This result suggests that PAL is of use in the differential diagnosis of early AD and depression (unlike word recall tests – see O’Carroll *et al.*, 1997). Unlike on ADAS-cog, performance on PAL was also found to correlate significantly with subsequent deterioration in global cognitive function. Furthermore, in a group of individuals with QD, baseline PAL results revealed an apparent subgroup of patients who performed like AD patients. In a follow-up study, Blackwell *et al.* (2004) showed that by taking into account age and performance on one other neuropsychological test (the Graded Naming Test [McKenna and Warrington, 1980]), CANTAB PAL gave a 100 per cent distinction between subjects with QD who either did or did not convert to probable AD (NINCDS-ADRDA criteria) 32 months after baseline testing (see also De Jager *et al.*, 2002). These studies also revealed that the sensitivity (in detecting prodromal AD in a QD group) and specificity (in differentiating AD from depression) of CANTAB PAL was considerably better than that of all other frequently used tests included in the study (including ADAS-cog and Wechsler Logical Memory Delayed Passage Recall).

The accumulating evidence demonstrating the sensitivity and specificity of CANTAB PAL for the early and differential diagnosis of AD suggest that this test represents a potential tool for operationalizing the criteria for objective memory impairment in MCI along with other candidate tests (see Petersen, 2003). CANTAB PAL has the additional advantage of existing in a form that can be used in experimental animals (Taffe *et al.*, 2002), facilitating translational medicine phases of treatment development, and may be less sensitive than other tests to the effects of depression (Swainson *et al.*, 2001). Further research into the usefulness and operationalization of each of the MCI criteria will doubtless improve their prognostic use.

Ultimately, however, the results of neuropsychological tests that are found to be sensitive and specific for early AD should be incorporated into AD diagnostic criteria, rather than invoking amnesic MCI as an intermediary state.

5.3 NEUROPSYCHOLOGICAL ASSESSMENT IN THE DIFFERENTIAL DIAGNOSIS OF THE DEMENTIAS

The need for early and accurate detection of AD is paralleled by the need to accurately differentiate the dementias. Accurate differential diagnosis is important because it allows clinicians to make appropriate treatment decisions and to provide appropriate advice to patients and relatives regarding the likely nature and course of decline. Over the last decade our understanding of the neurocognitive profiles of various dementias has advanced significantly; this knowledge can be used to facilitate accurate differential diagnosis.

5.3.1 Frontotemporal dementias and AD

The prevalence of frontotemporal dementia equals that of AD in individuals aged 45–64 (Ratnavalli *et al.*, 2002). The term frontotemporal dementia is used to refer to a group of non-Alzheimer’s conditions most frequently characterized by a predominant pathology of either the frontal lobes (frontal variant frontotemporal dementia: FvFTD) or of the temporal lobes (often referred to as semantic dementia: SD). In SD there is a selective impairment of semantic memory, which causes severe anomia, single word comprehension, reduced exemplar production in category fluency tests, and an impaired general knowledge. Other components of speech production, perceptual and non-verbal problem-solving abilities, and episodic memory are relatively spared (Snowden *et al.*, 1989; Hodges *et al.*, 1992; Breddin *et al.*, 1994; Saffran and Schwartz, 1994).

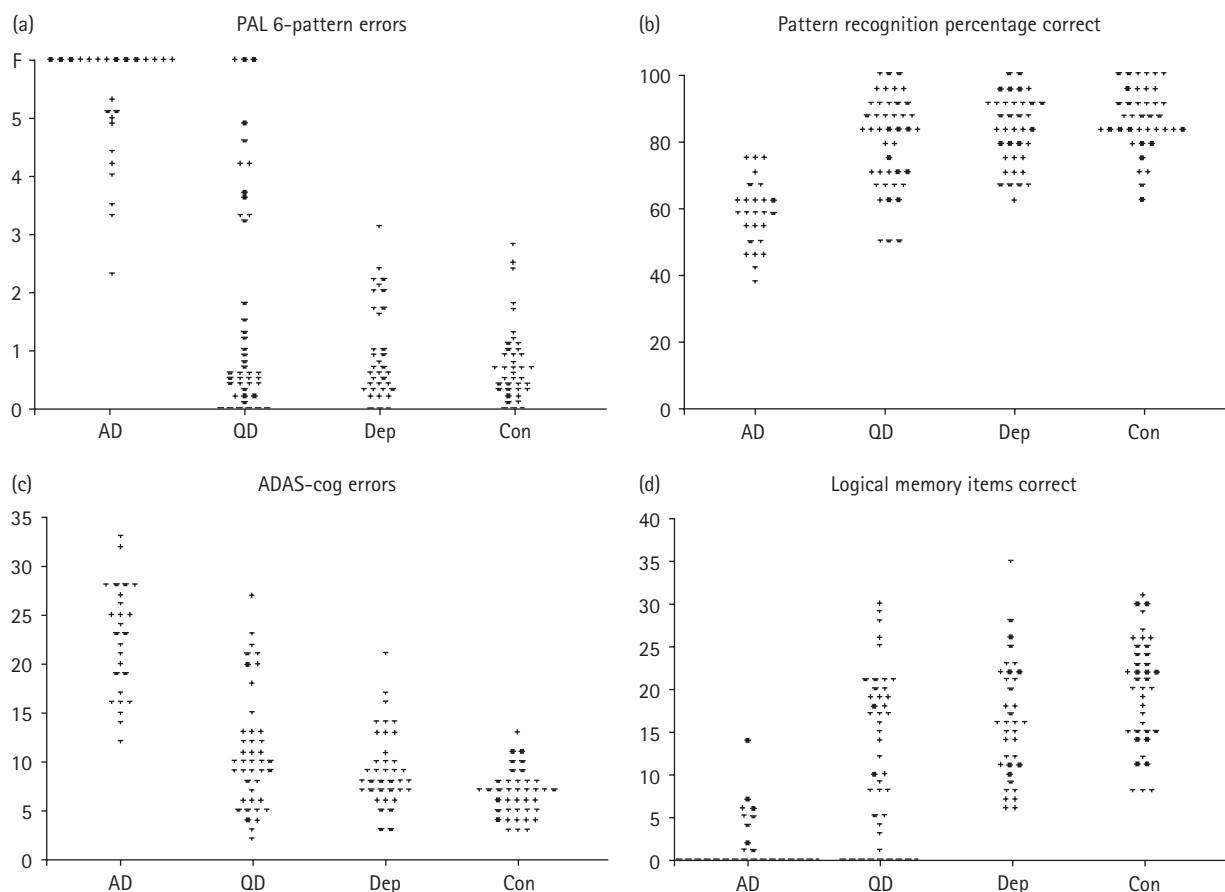

Figure 5.2 (a–d) Scores of individual subjects on PAL, ADAS-cog, pattern recognition and logical memory recall (i.e. the four tests best able to classify Alzheimer's disease (AD) and depressed/control (Dep/Con) subjects). NB. PAL and ADAS-cog are scored in terms of errors so a high score indicates poor performance, whereas pattern recognition and logical memory recall are scored in terms of items correct, so a low score indicates poor performance. 'F' indicates that the subjects failed to reach the 6-pattern stage. In the 'questionable dementia' (QD) group, baseline PAL results revealed an apparent subgroup of patients who performed like AD patients. PAL performance of individuals with depression did not differ significantly from that of matched control subjects (Swainson *et al.*, 2001). Reproduced with permission from Karger, Basel.

FvFTD is usually associated with failure on frontal lobe tests in the absence of severe amnesia, aphasia, perceptual or spatial disorders. However, there are frequently marked behavioural changes including lack of insight, disinhibition, loss of personal and social awareness, mental rigidity and inflexibility, perseverative behaviour, and emotional lability (Gregory and Hodges, 1996). Recent studies by Rahman, Sahakian and colleagues (Rahman *et al.*, 1999a, b) indicate that performance neuropsychological tests of decision-making that are sensitive to orbitofrontal/ventromedial cortex could be used to differentiate mild FvFTD patients from IQ-matched control subjects. By contrast, patients and controls did not show performance differences on tasks thought to be sensitive to dorsolateral prefrontal cortex function.

Hodges *et al.* (1999) directly compared the neuropsychological profiles of FTD (both frontal and temporal variants) and early AD. AD patients showed a substantial deficit in episodic memory (as indexed by the logical memory subtest of Wechsler Memory Scale – Revised [Wechsler, 1987] and 45

minute recall of the Rey complex figure drawing [Rey, 1941]) accompanied by more modest deficits in semantic memory (memory for meaning and facts) and visuospatial skills; SD was associated with major isolated deficits in semantic memory and anomia. The FvFTD group were, overall, the least impaired group, and showed mild deficits in episodic memory and verbal fluency with relatively preserved semantic memory. A follow up with the same diagnostic groups examining attention, executive function and semantic memory has recently complemented these findings. SD patients showed a preservation of attention and executive function with severe deficits in semantic memory; FvFTD patients showed the opposite pattern (Perry and Hodges, 2000). A study by Lee *et al.* (2003) has further reinforced the value of CANTAB PAL in the differentiation of SD, FvFTD and AD. Analysis revealed that relative to patients with AD, the PAL performance (as indexed by stages completed, and errors at the six pattern stage) of patients with FvFTD and SD was generally spared. By contrast, the PAL 'memory score' measure was impaired in both SD and AD but not FvFTD.

5.3.2 VaD versus AD

Vascular dementia (VaD) is the second most common form of dementia comprising approximately 20 per cent of dementia cases in the United Kingdom (Alzheimer's Society Demography Policy Position Report, 2004).

A number of studies have investigated the cognitive profile associated with VaD and its differentiation from AD. Cross-study comparison has been impeded by problems such as differing diagnostic criteria and failure to match adequately for demographic factors and disease severity but some consensus is now forming. In general, when compared with patients with probable AD, VaD patients appear to show relatively preserved episodic memory but impaired executive and attentional function. Both AD and VaD show deficits of a comparable severity in the domains of language, constructional abilities, and working memory (see Looi and Sachdev, 1999).

In contrast to episodic memory and executive function, there is a paucity of data in the literature relating to the semantic memory in VaD. One recent study (Graham *et al.*, 2004) has addressed this issue by examining neurocognitive performance in groups of patients with subcortical vascular dementia and probable AD (groups matched for age, education, global cognitive and everyday function), and included assessment of semantic memory in the testing battery. In accordance with previous literature, AD was associated with more impairment in episodic memory, whereas VaD was associated with more deficient executive/attentional functioning and visuospatial skills. Importantly semantic memory was also found to be generally more impaired in the VaD group. Logistic regression analysis indicated that the most useful discriminator of VaD and AD in this study was a combination of delayed passage recall and performance of a test of naming silhouetted objects at various rotations (a test that can be considered to measure both visuospatial processing and semantic processing).

5.3.3 Dementia with Lewy bodies versus AD

It is estimated that dementia with Lewy bodies (DLB) is the third most prevalent form of dementia, representing approximately 15 per cent of all dementia cases (Alzheimer's Society Demography Policy Position Report, 2004). DLB is characterized by progressive cognitive decline, hallucinations, fluctuating course, spontaneous parkinsonism and heightened sensitivity to neuroleptic drugs (McKeith *et al.*, 1992, 2000). The neurocognitive profile of DLB is less well understood than that of AD and VaD, but some important studies have been conducted.

Sahgal *et al.* (1992b) investigated matching-to-sample visual recognition memory in DLB and AD patients. The results revealed that, although the performance of both DLB and AD patients was impaired relative to controls, the DLB patients performed most poorly, particularly when a delay was introduced between stimulus presentation and recognition. In a

follow-up study of mnemonic processing (Sahgal *et al.*, 1995) AD and DLB patients were compared on a self-ordered test of spatial working memory (CANTAB Spatial Working Memory: SWM). The results revealed that SWM was more impaired in the DLB group than in the AD group, but the authors suggest that, since the two groups did not differ from each other in the performance of a different test of spatial span, the SWM deficit may not reflect a specific impairment *per se*, but rather reflect the failure of a non-mnemonic cognitive process subserved by frontostriatal circuitry (i.e. attention or planning).

Shimomura *et al.* (1998) compared the performance of age-, MMSE-, sex-, and education-matched DLB and AD patients on standard neuropsychological tests from the Alzheimer's Disease Assessment Scale – Cognitive Scale (ADAS-cog), Raven's Progressive Matrices (RPM) (Raven, 1965), and the Wechsler Adult Intelligence Scale – Revised (WAIS-R; Wechsler, 1981). Relative to AD, DLB was associated with a greater degree of impairment on the ADAS construction score, WAIS-R picture arrangement, Block Design, Object Assembly, and Picture Substitution scales. RPM score was also significantly worse in the DLB group. By contrast, ADAS word recall performance was generally spared in the DLB relative to the AD group.

More recently, Calderon *et al.* (2001) found that DLB was associated with deficits in visual object and space perception relative to AD and controls. DLB subjects also showed deficits in tests of attention and executive function greater than those seen in AD at a similar stage of global cognitive decline, but were significantly less impaired on tests of episodic memory. Additionally, DLB, but not AD subjects, showed impaired performance in a test of divided attention.

In summary, although more research is needed, studies to date suggest that DLB is characterized, in neurocognitive terms, by a relative sparing of episodic memory but marked attentional and visuospatial deficits when compared to AD.

5.4 NEUROPSYCHOLOGICAL ASSESSMENT FOR THE PURPOSES OF MONITORING CHANGE IN COGNITIVE FUNCTION

Another role for neuropsychological testing is to measure the rate of progression of disease, achieved by giving an identical assessment (usually in parallel forms) at a number of different time intervals. This is important because it can help the clinician assess the efficacy of any pharmacological intervention. At the moment the ADAS-cog (Rosen *et al.*, 1984; Mohs *et al.*, 1997) is a test commonly used clinical tool for this purpose. However, as discussed above, other objective measures of cognitive function have been shown to be more sensitive and specific in the early stages of AD and therefore may provide more appropriate indices of change at these early stages. Furthermore, other tests (e.g. CANTAB Rapid Visual Information Processing Task, CANTAB Simple and Choice Reaction

Time Task) are also likely to prove to be effective in monitoring change later in the disease course (see Sahakian *et al.*, 1989, 1993; Eagger *et al.*, 1992).

5.5 CONCLUSIONS

Neuropsychological assessment can make an important contribution to the early and differential diagnosis of the dementias, including for the identification of 'enriched samples' for clinical trials, and is also vital for the objective monitoring of changes in cognitive function across disease course or as a function of treatment.

Key challenges for neuropsychologists over the next decade include decomposing the cognitive and neural substrates of task performance in order to more accurately characterize the neuropsychological phenotype of each form of dementia. It will be particularly important to examine the relationship between neuropsychological function and specific neuropathological features using novel *in vivo* neurochemical techniques (Shoghi-Jadid *et al.*, 2002; Klunk *et al.*, 2004). Improved neuropsychological characterization will be translated into more sensitive and specific diagnostic tools, which in turn should lead to earlier intervention with psychological and pharmacological therapies, potentially even prior to the onset of disabling cognitive impairments.

Neuropsychiatric aspects of dementia

IRACEMA LEROI AND CONSTANTINE G LYKETSOS

6.1 Epidemiology and spectrum of neuropsychiatric symptoms of dementia	55	6.4 Pathophysiology of neuropsychiatric symptoms of dementia	60
6.2 Classification of symptoms	57	6.5 Conclusions	61
6.3 Diagnostic criteria for the neuropsychiatric symptoms of dementia	59	References	61

The neuropsychiatric changes in dementia are nearly universal and may result in extremely challenging management problems. This is in spite of the definition of dementia being based on the cognitive and functional changes alone. These symptoms include personality changes, mood deterioration, perceptual abnormalities, psychomotor disturbances (such as agitation, aggression, wandering and purposeless behaviour), and neurovegetative changes (alterations in sleep and appetite). Collectively, these manifestations in dementia syndromes can be regarded under the recently adopted rubric of 'behavioural and psychological symptoms of dementia' (BPSD) (Finkel *et al.*, 1996); however, they have been variously termed as 'neuropsychiatric symptoms', 'behavioural disturbances', 'non-cognitive changes' and 'challenging behaviours'. Here we will refer to them as the neuropsychiatric symptoms of dementia. The importance and ubiquity of these symptoms is highlighted by Alois Alzheimer's first clinical description of Alzheimer's disease (AD) in 1907. In this case study, he stated:

The first noticeable symptom of illness shown by this 51-year-old woman was suspiciousness of her husband. Soon, a rapidly increasing memory impairment became evident; she could no longer orient herself in her own dwelling, dragged objects here and there and hid them, and at times, believing that people were out to murder her, started to scream loudly (Alzheimer, translated by Jarvik and Greenon, 1987).

The impact of these disturbances on both patients with dementia and their families and caregivers has been well documented. The burden on caregivers is significant and is most often the primary reason for admission to long-term care (Sanford, 1975; Rabins *et al.*, 1982; Victoroff *et al.*, 1998).

Furthermore, patients suffering with the disturbances require more medication and physical restraints (Teri *et al.*, 1989; Bianchetti *et al.*, 1997).

6.1 EPIDEMIOLOGY AND SPECTRUM OF NEUROPSYCHIATRIC SYMPTOMS OF DEMENTIA

Neuropsychiatric symptoms are extremely common in the dementias; however, a given symptom or syndrome may not reliably appear in any one dementia diagnosis. Unlike the inexorable decline seen in cognitive and functional abilities of patients with dementia, the neuropsychiatric symptoms may fluctuate in their presence and intensity. It has been suggested that early detection of such symptoms, even in the absence of cognitive impairment, might be a harbinger of dementia. Such a diagnosis of 'mild neuropsychiatric syndrome' later in life might be an early marker of dementia, in much in the same way as the syndrome of 'mild cognitive impairment' predicts later cognitive decline (Assal and Cummings, 2002). Indeed, there is evidence that the first onset of a depressive episode in older age, which is associated with a transient dementia syndrome ('pseudodementia'), may predict the later development of dementia (Alexopoulos and Chester, 1992). The risk for development of later dementia in this group is so great that it appears that the risk for developing AD increases for each depressive symptom suffered by those over the age of 65 (Wilson *et al.*, 2002). These findings underscore the necessity for early detection of neuropsychiatric symptoms in the non-demented elderly population.

In AD, the most common form of dementia, several studies have examined incidence and prevalence rates of neuropsychiatric symptoms. The most robust epidemiological studies are population based. Burns *et al.* (1990a–d) examined 178 patients with AD from a defined area in the United Kingdom. They found the following cumulative prevalences of neuropsychiatric disturbances ranging from 3.5 per cent for mania to 41 per cent for apathy (see Table 6.1).

To date, the largest population based study of neuropsychiatric disturbances in dementia is from the Cache County Study of Memory in Aging (CCSMA): 5092 participants, constituting 90 per cent of the elderly resident population of a particular county in the United States, were enrolled and thoroughly screened for dementia (Breitner *et al.*, 1999); 329 people were diagnosed with a prevalent dementia syndrome, of which 214 (65 per cent) had AD, 62 (19 per cent) had vascular dementia (VaD), and 53 (16 per cent) had another DSM-IV dementia diagnosis. Using the Neuropsychiatric Inventory (NPI)(Cummings *et al.*, 1994), a widely used method for ascertainment and classification of dementia-associated mental and behavioural disturbances, 201 (61 per cent) of the participants with dementia were reported by their caregivers to have had one or more mental or behavioural disturbances in the past month. Apathy, depression and agitation/aggression were the most common (see Table 6.1) (Lyketsos *et al.*, 2000). In participants specifically with AD, delusions were reported in 23 per cent and hallucinations in 13 per cent, whereas for those with VaD, 8 per cent had delusions and 13 per cent had hallucinations (Leroi *et al.*, 2003). The delusions seen in AD are usually quite simple and most often do include the bizarre and complex delusions seen in schizophrenia. Misidentification phenomena and jealous delusions are more common in dementia compared to schizophrenia. Likewise, Schneiderian first-rank symptoms such as voices commenting, commanding

or conversing are not commonly seen in dementia. The most common form of hallucinations in AD are visual hallucinations (80 per cent), which far exceed auditory hallucinations in frequency (20 per cent) (Leroi *et al.*, 2003).

Increasing attention is being focused on the syndrome of mild cognitive impairment (MCI), which involves impairment in memory and possibly other areas of cognition in elderly individuals whose day-to-day functioning is relatively preserved. MCI may be a precursor to AD (Morris *et al.*, 2001) and appears to have, like AD, neuropsychiatric manifestations. As part of the analysis of data from the recent Cardiovascular Health Study (CHS)(Fried *et al.*, 1991), prevalence estimates of neuropsychiatric symptoms of MCI were sought. Of the 320 individuals who were identified as having MCI, 43 per cent (138) exhibited neuropsychiatric symptoms with depression, apathy and irritability being the most common (see Table 6.1) (Lyketsos *et al.*, 2002). Almost 30 per cent of those with symptoms were rated as clinically significant. Almost 75 per cent of those with a full diagnosis of dementia (n = 362) had at least one neuropsychiatric symptom.

In the frontotemporal dementias, unlike AD or vascular dementia (VaD), the behavioural and psychological disturbances are embedded in the diagnostic consensus criteria (McKhann *et al.*, 2001). Earlier diagnostic criteria for the frontal lobe dementias as a group, proposed by Neary *et al.* (1998), outlined one specific behavioural subtype or 'prototypic neurobehavioral syndrome', which is marked by profound personality and behavioural changes. This presentation, namely, frontotemporal dementia (FTD), is distinct from the progressive non-fluent aphasia (PNFA) and semantic dementia (SD) presentations, which constitute other manifestations of the frontal lobe dementias. In FTD, the core changes are characterized by an insidious onset and gradual decline in social functioning, and regulation of personal conduct,

Table 6.1 Population-based prevalence of neuropsychiatric symptoms in dementia

Study	Camberwell Health Authority, UK (Burns <i>et al.</i> , 1990a–d)	Cache County Study of Memory in Aging, USA (Lyketsos <i>et al.</i> , 2000)	Cardiovascular Health Study, USA (Lyketsos <i>et al.</i> , 2002)	Dementia (n = 362)
Condition	Alzheimer's disease (n = 178)	Dementia (n = 329)	Mild cognitive impairment (n = 320)	Dementia (n = 362)
Delusions (%)	16	23	3	18
Hallucination (%)	17	13	1	11
Depression (%)	24 (Major depression)	24	20	32

Disinhibition (%)		9	3	13
Anxiety (%)		17	10	27
Any neuropsychiatric symptom (%)		61	43	75

accompanied by emotional blunting, and loss of insight. Supportive diagnostic features include a decline in personal care, hyperorality, perseverative and stereotyped behaviours, and utilization behaviours. Speech and language changes and executive dysfunction can also be seen.

In the frontal lobe dementias, the presentation of associated neuropsychiatric symptoms can be used to distinguish SD, which involves temporal lobe dysfunction primarily on the left, from FTD presenting with temporal lobe dysfunction primarily on the right. In the former, compulsive behaviours are more common, whereas in the latter, aberrant social behaviour, hyperorality, hypersexuality and changes in self-defining functions such as dress, religious or ideological beliefs are typical (Miller *et al.*, 2001; Mychack *et al.*, 2001).

As with the frontal lobe dementias, neuropsychiatric symptoms are part of the defining characteristics of dementia with Lewy bodies (DLB). Visual hallucinations, fluctuating cognition and parkinsonism, together with progressive cognitive decline, form the core features of the consensus criteria for the clinical diagnosis of DLB (McKeith *et al.*, 1996). The prevalence of visual hallucinations in DLB can be as high as 93 per cent compared to 27 per cent in AD, depending on the sample (Ballard *et al.*, 1997). Phenomenologically, these hallucinations have similarities to those in Parkinson's disease (PD) or Charles Bonnet syndrome, but are usually more complex and involved compared to those seen in AD (Cummings, 1992; Howard and Levy, 1994; Ballard *et al.*, 1997). Delusions, misidentification phenomena and auditory hallucinations are also commonly present in DLB and also occur at higher prevalence rates than in AD patients (Ballard *et al.*, 1995). Depression has been reported in up to 50 per cent of DLB patients and it may be associated with greater severity of parkinsonism (Klatka *et al.*, 1996). Finally, an increasingly recognized syndrome, which may be a harbinger of DLB and other neurodegenerative synucleopathies, is rapid eye-movement (REM)-sleep behaviour disorder (RBD) (Ferman *et al.*, 2002). RBD involves movements associated with dreaming and may involve potentially harmful sleep behaviour, acting out of dreams, and behaviour that continually interrupts sleep.

The degenerative diseases of the basal ganglia, such as Huntington's disease (HD), progressive supranuclear palsy (PSP) and Wilson's disease, have traditionally been classified as movement disorders, with associated cognitive and psychiatric manifestations. However, the confluence of symptoms (the three Ds: dyskinesia, dementia, and depression) seen in these disorders has led to the rubric of 'triadic syndromes' (McHugh, 1989) and underscores the high prevalence of neuropsychiatric manifestations in neurodegenerative movement disorders (Rosenblatt and Leroi, 2000). In particular, the prevalence of major depression in these disorders is high: up to 38 per cent in HD (Folstein *et al.*, 1987) and 20 per cent in Wilson's disease (Denning and Berrios, 1989). Mania is less common and has been reported in up to 10 per cent of HD patients (Folstein, 1989), and even less in PD. There are few reports of mania or hypomania in other basal ganglia disorders, although emotional lability and irritability have been reported in

Wilson's disease and PSP (Denning and Berrios, 1989; Litvan *et al.*, 1996). Psychotic symptoms have been reported in 3–12 per cent of HD patients (Mendez, 1994) but less than 2 per cent of patients with Wilson's disease (Denning and Berrios, 1989). Behavioural disturbances such as obsession and compulsions, sexual disorders, aggression, irritability and apathy are also well-recognized in neurodegenerative disorders involving the basal ganglia (Rosenblatt and Leroi, 2000).

PD, also considered a 'triadic disorder', shares neuropsychiatric features with the other disorders as well as an underlying pathophysiology involving protein abnormalities of α -synuclein. These synucleopathies, which include PD, DLB, multiple system atrophy (MSA) and striatonigral degeneration, appear to share vulnerabilities to a cluster of symptoms including hallucinations, delusions and RBD (Cummings, 2002).

In PD specifically, most patients develop a certain degree of cognitive impairment, which usually manifests as a dysexecutive syndrome (Gabrieli *et al.*, 1996). Depression in PD, with an average prevalence across studies of 31 per cent (Slaughter *et al.*, 2001) can significantly exacerbate this cognitive impairment (Starkstein *et al.*, 1990). Neuropsychiatric symptoms are more common in those with some degree of cognitive impairment, and in the 30–40 per cent of PD patients who develop dementia (PDD) (Aarsland, 1996b), the vulnerability to neuropsychiatric symptoms is even greater (Holroyd *et al.*, 2001; Goetz *et al.*, 2001). The profile of neuropsychiatric symptoms in PDD and DLB is increasingly recognized as being similar, suggesting that these disease processes might exist on a continuum. The symptoms that predominate in PDD and DLB include delusions and hallucinations which may be varyingly related to antiparkinsonian medications (Aarsland *et al.*, 2001).

6.2 CLASSIFICATION OF SYMPTOMS

There have been various classification schemes for the neuropsychiatric symptoms in dementia. These symptoms have been considered as monosymptomatic phenomena, as DSM-IV categories (1994), as separate phenomena based on unique criteria (Jeste and Finkel, 2000; Lyketsos *et al.*, 2001a, b; Olin *et al.*, 2002), and as part of specific behavioural syndromes (Reisberg *et al.*, 1987; Absher and Cumming, 1994; Lyketsos *et al.*, 2001a, b). This rather fragmented approach to the field has hampered efforts at investigation, particularly in the fields of epidemiology and pathophysiology.

The simplest approach is a monosymptomatic consideration of the neuropsychiatric symptoms of dementia. An example of such an approach was adopted by the landmark AD epidemiological study of Burns *et al.*, 1990. In this study, the prevalence of symptoms derived from the Geriatric Mental State Schedule (GMSS; Copeland *et al.*, 1976) – an interview schedule based on the Present State Exam (PSE; Wing *et al.*, 1974) – was examined. These symptoms included: delusions of thought

(including delusions of theft, suspicion, persecutory ideation and 'any disorder of thought'); disorders of perception (auditory hallucinations, visual hallucinations and misidentification syndromes); and disorders of mood (depressed and elevated mood). The final category of examination was disorders of behaviour in which 33 behaviour items from the Stockton Geriatric Rating Scale (SGRS; Meer and Baker, 1966) were sought.

The risk of such a monosymptomatic approach is that it is contrary to current data supporting the frequent co-occurrence of several neuropsychiatric symptoms in a given patient (Lyketsos *et al.*, 2001a, b). This approach also limits treatment to a hypothesis-driven, phenomenological approach rather than moving towards an evidence-driven approach based on disorders, syndromes and frequently co-occurring symptoms.

An alternative, and more widely adopted, approach to categorization is to use the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (1994). This is a heuristically useful approach and has the advantage of reliability, which enables cross-centre comparability. The disadvantage of this approach is that disturbances in AD and the other dementias are frequently phenotypically distinct from primary psychiatric disturbances. Hence, depression in AD severe enough to warrant treatment, may not meet all the criteria for a 'major depressive disorder' in the DSM-IV. In particular, the depression of dementia more commonly presents with anhedonia, irritability, agitation, apathy and non-specific worry, whereas the symptoms of guilty feelings, self-blame, frank sadness, crying and suicidality are relatively rare (Zubenko *et al.*, 2003). Neurovegetative changes are common in both primary and dementia-related depression. Likewise, the psychosis in dementia presents differently from the psychotic syndrome of schizophrenia and primary mood disorders.

The syndromal approach attempts to address several of the methodological liabilities of the monosymptomatic approach. This approach is based on the observation of co-occurrence of several behavioural symptoms in individual patients (Baker *et al.*, 1991; Cohen *et al.*, 1993). In particular, the co-occurrence of aggression and verbal outbursts with hallucinations and delusions has frequently been reported. (Deutsch *et al.*, 1991; Kotrla *et al.*, 1995; Aarsland *et al.*, 1996a). One of the earlier mentions of a behavioural syndrome in dementia was recognition of the Klüver–Bucy syndrome (visual agnosia, hyperphagia, stimulus bound behaviour, hypersexuality and emotional lability) in AD (Sourander and Sjogren, 1970) and in Pick's disease (Cummings and Duchon, 1981). Burns *et al.* (1990a) found the full syndrome to be relatively rare; however, individual items associated with the syndrome appeared to be interrelated. Other syndromes identified include a three-syndrome classification: overactivity (walking more, walking aimlessly, trailing the carer, checking where the carer was); aggressive behaviour (physical aggression, aggressive resistance, verbal aggression); and psychosis (anxiety, persecutory ideas and hallucinations) (Hope *et al.*, 1997).

Several authors have employed a factor-analytical approach to explore the issue of co-occurrence of symptoms and some

have found correlations of factor scores to clinical variables and functional imaging patterns (Devanand *et al.*, 1992; Sultzer *et al.*, 1995). A factor analysis of neuropsychiatric disturbances in an AD clinic population in Italy found three syndromes occurring in isolation in different patients. These were, a 'psychotic' syndrome (high factor loads of agitation; hallucinations, delusions and irritability); a 'mood' syndrome (high loads of anxiety and depression); and a 'frontal' syndrome (high loads of disinhibition and euphoria) (Frisoni *et al.*, 1999). Each syndrome had unique risk factors and associations. The 'psychotic' group tended to be older, of male sex and with poorer cognitive performance and more rapid decline, whereas the 'frontal' group tended to be more educated, have longer disease duration and slower progression. The existence of a 'psychotic' syndrome of delusions, hallucinations, aggression, agitation and disruptive behaviour is supported by the findings of several other groups of researchers (Flynn *et al.*, 1991; Rockwell *et al.*, 1994; Gilley *et al.*, 1997). This syndrome has been shown to be a significant factor in nursing home placement of AD patients (Steele *et al.*, 1990). Finally, factor analysis of a large cross-sectional sample of patients with HD found that the neuropsychiatric symptoms clustered into three groups: irritability, depression and apathy (Craufurd *et al.*, 2001).

A more recent attempt at classifying symptoms based clusters is using a latent class analysis in a population-based study of 198 individuals with AD (Lyketsos *et al.*, 2001a). Latent class analysis differs from factor analysis in that it examines whether *individuals* tend to cluster into groups (classes) based on their clinical profile, as opposed to factor analysis, which examines the grouping of clinical *characteristics* across individuals. Results revealed that, based on analysis of NPI symptom profiles, three groups (classes) of AD patients were evident. The largest class included AD cases with no neuropsychiatric symptoms (40 per cent) or with a monosymptomatic disturbance (19 per cent). A second class (28 per cent) exhibited a predominantly affective syndrome, while a third class (13 per cent) had a psychotic syndrome. This last group presented with hallucinations all of the time, delusions often, and occasionally, apathy, agitation, depression, irritability, aberrant motor behaviour and anxiety.

Unfortunately, investigations of the underlying pathophysiological and neuroimaging correlates have tended to use the monosymptomatic, rather than the syndromic, approach. Hence, we are only in the nascent phases of a deeper understanding of the aetiology of such behavioural syndromes in the dementias. Quantitative neuropsychiatry is one approach that attempts to examine clusters of neuropsychiatric symptoms based on the underlying molecular biology of the type of neurodegenerative disorder.

As described in a recent review of 'quantitative neuropsychiatry' by Cummings (2003), neuropsychiatric phenotypes may be due to regional differences in cell vulnerability to abnormalities of protein metabolism. Most of the neurodegenerative disorders involve abnormalities of protein metabolism, such as the accumulation of α -synuclein protein underlying the *synucleopathies* (e.g. LBD, PD, MSA),

hyperphosphorylated τ protein in the *tauopathies* (e.g. FTD, progressive supranuclear palsy), and β -amyloid protein accumulation in AD (*amyloidosis*). Each proteinopathy appears to be associated with particular neuropsychiatric phenotypes that transcend the actual disease diagnosis. For example, hallucinations, delusions and RBD are commonly seen in the synucleopathies, whereas the tauopathies present more often with disinhibition, apathy and compulsions. AD has a more mixed underlying proteinopathy, including abnormalities of β -amyloid, τ - and α -synuclein, suggesting a neuropsychiatric phenotype that incorporates elements of all three neuropathological categories.

6.3 DIAGNOSTIC CRITERIA FOR THE NEUROPSYCHIATRIC SYMPTOMS OF DEMENTIA

Several authors have recently proposed the need for unique, validated diagnostic criteria for the neuropsychiatric phenomena of dementia (Jeste and Finkel, 2000; Olin *et al.*, 2002). This would provide the reliability endowed by a DSM-IV-type approach, facilitate hypothesis-driven and evidence-based research, and provide a consistent treatment target. Proposed criteria, whose validation is underway, include: 'psychosis of AD' (Jeste and Finkel, 2000); 'depression of AD' (Olin *et al.*, 2002); and 'AD-associated affective disorder' or 'AD-associated psychotic disorder' (Lyketsos *et al.*, 2001b).

Jeste and Finkel (2000) make the case for 'psychosis of AD' being a phenomenon distinct from the psychosis seen in elderly people with schizophrenia. Compared to schizophrenia, in AD, the duration of psychosis is shorter, the dosages of antipsychotic medications required for successful treatment are much lower, the phenomenology is distinct, and the neuropathological basis of the psychosis is different. The DSM-IV provides no specific criteria for this subcategory while proposing additional coding if delusions are a predominant feature of the dementia. The proposed criteria for 'psychosis of AD' (Box 6.1) have reliability and face validity and have been accepted by the United States Federal Drug Administration (FDA) as a specific target for treatment intervention. With further field trials, this classification may eventually be extrapolated to become 'psychosis of dementia' and apply to other dementia types such as DLB, vascular dementia and mixed dementia.

The criteria for 'depression of AD' were proposed in 2002 by a group of investigators with extensive research and clinical experience in late-life depression and AD (Olin *et al.*, 2002). These criteria (Table 6.2) differ from the DSM-IV criteria for a 'major depressive episode' in four ways:

- only three or more symptoms (rather than five or more) of depression are required;
- symptoms do not have to occur on a daily basis;
- criteria for irritability, social isolation and withdrawal have been added; and

Box 6.1 *Diagnostic criteria for psychosis of Alzheimer's disease (Jeste and Finkel, 2000, reproduced with permission)*

A Characteristic symptoms

Presence of one (or more) of the following symptoms

- Visual or auditory hallucinations
- Delusions

B Primary diagnosis

All the criteria for dementia of the Alzheimer-type are met

C Chronology of the onset of symptoms psychosis versus onset of symptoms of dementia

There is evidence from the history that the symptoms in criterion A have not been present continuously since prior to the onset of the symptoms of dementia

D Duration and severity

The symptom(s) in criterion A have been present, at least intermittently, for 1 month or longer. Symptoms are severe enough to cause some disruption in patients' and/or others' functioning.

E Exclusion of schizophrenia and related psychotic disorders

Criteria for schizophrenia, schizoaffective disorder, delusional disorder, or mood disorder with psychotic features have never been met

F Relationship to delirium

The disturbance does not occur exclusively during the course of a delirium

G Exclusion of other causes of psychotic symptoms

The disturbance is not better accounted for by another general-medical condition or direct physiological effects of a substance (e.g. a drug of abuse, a medication)

Associated features: *specify* if associated

- with agitation
- with negative symptoms
- with depression

- the 'loss of interest' criterion has been modified to include a diminished positive response to social interaction.

These criteria are designed to be broad and to rely on clinical judgement.

An alternative set of criteria for Alzheimer's disease affective disorder (AAD) (Table 6.2) has been proposed by Lyketsos *et al.* (2001b). Both sets of criteria are in the process of being validated as part of the DIADS-2 (Depression in AD Study-2) and the Cache County-Dementia Progression Study in the USA.

One of the most extensive studies of the clinical features of depression in AD was that of Zubenko and colleagues (2003). They derived data from structured diagnostic assessments of 243 patients with AD. In the most severely demented patients, major depressive episodes were diagnosed in nearly 50 per cent. The validity of a major depressive syndrome of

<p><i>Specify if:</i></p> <ul style="list-style-type: none"> • Co-occurring onset: if onset antedates or co-occurs with the AD symptoms • Post-AD onset: if onset occurs after AD symptoms <p><i>Specify:</i></p> <ul style="list-style-type: none"> • with psychosis of Alzheimer's disease • with other significant behavioural signs or symptoms • with past history of mood disorder 	<p><i>Specify:</i></p> <ul style="list-style-type: none"> • with or without psychotic symptoms

AD was supported by the finding that the majority of patients who developed depression had no premorbid history of depression. In addition, the depression tended to appear after the onset of cognitive decline, and the clinical presentation differed from that seen in depressed elderly without dementia. Neuropathological and neurochemical changes in depressed AD patients differ from those of their non-depressed counterparts by demonstrating greater loss of aminergic nuclei, particularly in the locus caeruleus, thus

supporting the notion of a distinct depressive entity (Zweig *et al.*, 1988; Zubenko *et al.*, 1990; Förstl *et al.*, 1992).

6.4 PATHOPHYSIOLOGY OF NEUROPSYCHIATRIC SYMPTOMS OF DEMENTIA

Examining the underlying neurophysiology of neuropsychiatric symptoms may lead to the eventual validation of

observations of given symptoms and syndromes. Increasingly, newer modalities of investigation, such as functional imaging and behavioural neurogenetics, will aid in the understanding of these symptom clusters (Assal and Cummings, 2002).

Post-mortem neuropathological and neurochemical studies have shown that, compared with those with no psychosis in AD, those with psychosis have more extensive neurodegenerative changes in the cortex, decreased cortical and subcortical serotonin/5-HIAA and increased subcortical norepinephrine (Zubenko *et al.*, 1991). They also have increased muscarinic M2 receptor density in the orbitofrontal cortex (Lai *et al.*, 2001). Furthermore, psychosis in AD is associated with a significantly increased level of abnormal paired helical filament (PHF)- τ protein in the temporal and entorhinal cortices (Mukaetova-Ladinska *et al.* (1995).

Depression in AD is associated with damage to the locus caeruleus resulting in disturbances in norepinephrine (Reifler *et al.*, 1989; Petracca *et al.*, 1996) and cholinergic deficiency may underlie neuropsychiatric disturbances in PDD and DLB (Kaufer *et al.*, 1998; Kaufer *et al.*, 1996). Agitation in dementia is associated with increased density of tangles in the anterior cingulate and orbitofrontal regions (Assal and Cummings, 2002). Aggression in AD specifically appears to be associated with degeneration of serotonergic areas in the brain accompanied by retained integrity of dopaminergic areas (Katz *et al.*, 1999; Street *et al.*, 1999). Finally, apathy results from deterioration in medial prefrontal, anterior cingulate, and anterior temporal paralimbic structures (Marin, 1996) and may involve disruption in dopaminergic circuits (Marin *et al.*, 1995).

In functional neuroimaging studies, depression in AD has been associated with frontal hypometabolism (Hirono *et al.*, 1998). Depression in PD has been associated with hypometabolism in the caudate and inferior orbital-frontal regions (Mayberg *et al.*, 1990) and medial frontal lobes (Ring *et al.*, 1994). Apathy in AD has been associated with single photon emission computed tomography hypoperfusion in the anterior cingulate (Migneco *et al.*, 2001). Neuroimaging studies in AD with delusions have revealed various findings, including greater dysfunction in the paralimbic areas of the frontotemporal cortex (Seltzer, 1996), and marked right medial posterior parietal hypoperfusion (Fukuhara *et al.*, 2001). In those with hallucinations in AD, hypoperfusion was seen in the right parietal, left medial temporal and left dorsolateral prefrontal cortex (Lopez *et al.*, 2001).

6.5 CONCLUSIONS

The neuropsychiatric complications of dementia syndromes are common and nearly universal. It is becoming increasingly evident that certain neuropsychiatric phenotypes are linked with the underlying pathophysiology of the dementia type. These neuropsychiatric symptoms, which may appear even before the cognitive and functional decline has become evident, have significant consequences, not only for the patients themselves but also for their caregivers. On an optimistic

note, while therapeutic approaches to the cognitive and functional decline remain limited, the neuropsychiatric symptoms remain the most treatment responsive aspects of dementia.

Screening instruments for the detection of cognitive impairment

LEON FLICKER

7.1 Description of tests	66	7.4 Conclusions	69
7.2 Use for these tests	67	References	69
7.3 Using informant-based tests	68		

A frequently used method in the ascertainment of dementia in older people is the performance of a short cognitive test to determine the need to perform further testing to establish the diagnosis. At the time of writing, the case for detection of milder forms of cognitive impairment has not been established, mainly because therapeutic strategies for patients with conditions such as mild cognitive impairment (MCI) (Petersen *et al.*, 2001) have not been proven. Thus, the focus of this chapter remains on the use of short cognitive tests to aid in the detection of older people with dementia. These short cognitive tests are commonly described as 'screening instruments', but this is in fact a misnomer. Screening has been defined as 'an organized attempt to detect, among apparently healthy people in the community, disorders or risk factors of which they are unaware' (Cadman *et al.*, 1984). In reality, these short cognitive tests are used as a means of case-finding in certain clinical situations for which there is a high prior probability of finding individuals with cognitive impairment, usually associated with dementia or, in those individuals who are medically unwell, delirium.

7.1 DESCRIPTION OF TESTS

The type of cognitive testing has varied a little over the last 45 years. A minor change that has occurred in the more recently developed tests is the use of lengthier delayed recall tasks, both cued and non-cued. One of the earliest instruments was the Mental Status Questionnaire (MSQ) (Kahn *et al.*, 1960). In, 1968, Blessed *et al.* described the Information Memory Concentration (IMC) test, which was validated against the

criterion of neuropathology. Hodkinson (1972) described a shortened version of the IMC test and called this the Abbreviated Mental Test Score (AMT). In North America, Pfeiffer (1975) described the Short Portable Mental Status Questionnaire (SPMSQ) and Folstein *et al.* (1975) devised the Mini-Mental Status Examination (MMSE), which has undergone standardization (Molloy *et al.*, 1991). Other short tests that have been developed include Kokmen's Short Test of Mental Status (STMS) (Kokmen *et al.*, 1991), and the General Practitioner Assessment of Cognition (GPCOG) (Brodsky *et al.*, 2002) both of which include the clock drawing test. All these instruments have in common their brevity, taking 10 minutes or less to administer with relatively little training.

One of the main problems with these cognitive tests is the fact that they exhibit both floor and ceiling effects. There have been attempts to develop tests that would be more suitable for testing impaired patients (Plutchik *et al.*, 1971; Albert and Cohen, 1992). Longer tests and word lists have the advantage that they are less prone to ceiling effects. Word list instruments generally require some training. These include the seven minute screen (Solomon *et al.*, 1998), which is a test that comprises a cued recall task, verbal fluency, an orientation test and a clock drawing task. Similarly the Syndrome Kurz Test (SKT) (Lehfeld and Erzigkeit, 1997) has nine sub-tests, which include naming, memory, attention, cued recall and visuospatial functioning. A very short version of delayed free and cued recall tests has been developed called the Memory Impairment Screen (Buschke *et al.*, 1999), which consists of just four items.

Several other survey instruments have been developed which have incorporated both cognitive screening instruments

and diagnostic schedules. These include the Cambridge Diagnostic Examination for the Elderly (Roth *et al.*, 1986), Consortium to Establish a Registry for Alzheimer's Disease (Morris *et al.*, 1989), Geriatric Mental State schedule (Copeland *et al.*, 1976) and a Structured Interview for the Diagnoses of Dementia of the Alzheimer's type, multi-infarct dementia and dementias of other aetiology according to ICD-10 and DSM-III-R (SIDAM) (Zaudig *et al.*, 1991). The cognitive components of the Cambridge Diagnostic Examination for the Elderly (Roth *et al.*, 1986), the Alzheimer's Disease Assessment Scale (ADAS-cog) (Rosen *et al.*, 1984) and the Mental Deterioration Battery (Carlesimo *et al.*, 1996) take longer to administer and are not usually performed as initial brief tests, although the Organic Brain Scale (OBS) from the Geriatric Mental State has been used as a stand alone test (Ames *et al.*, 1992).

7.2 USE FOR THESE TESTS

The need for these 'screening' instruments has arisen because there is good evidence that clinicians will commonly miss dementia in their routine practice without the assistance of formal cognitive assessment (Williamson *et al.*, 1964; Mant *et al.*, 1988).

Even before the arrival of specific symptomatic treatments for the symptoms of Alzheimer's disease (AD), the presence or absence of significant cognitive impairment had major implications for the management of patients. In particular, older individuals with multiple medical problems requiring medications could not be managed appropriately without an assessment for the presence of cognitive impairment and some idea of its severity. Also, there is some evidence that the earlier identification of people with dementia and appropriate referral to support services and counselling can alleviate some of the stresses associated with caring for people with dementia and delay institutionalization (Green and Brodaty, 2002).

These short cognitive tests have limited domains of measurement. Table 7.1 refers to the domains of measurement of the common assessment tools. Orientation figures prominently in most of these tools and is a reflection of recent memory

acquisition. In a longitudinal study of cognitive function in people with AD, it was demonstrated that this dementing process particularly affects remote memory, immediate memory and language function (Flicker *et al.*, 1993). Since memory impairment is a *sine qua non* in the categorization of dementia in both the DSM-IV and ICD-10 criteria, it is hardly surprising that the short cognitive tests focus on this domain. It is also clear that these tests are highly correlated with each other. For example, Stuss *et al.* (1996) observed that the proportion of variance accounted for by a single common component was in excess of 0.80 for the Mattis Dementia Rating Scale, an abbreviated six-item version of the Orientation Memory Concentration Test adapted from Blessed *et al.* (1968), a Mental State Questionnaire and an Ottawa Mental State Examination. Also in this study there was no added benefit from longer tests and the shorter cognitive tests performed as well as longer tests with multiple domains. In another study the correlation between the AMTS and MMSE was greater than 0.85 (Flicker *et al.*, 1997). Similarly correlations between the MMSE and the ADAS-cog have been found to be strong, -0.9 (Burch and Andrews, 1987), although the correlation between the MMSE and the STMS may only be 0.74 (Kokmen *et al.*, 1991).

These short cognitive scales appear robust in many settings. The IMCT has been validated on telephone interview (Kawas *et al.*, 1995) as has the Telephone Cognitive Assessment Battery (Debanne *et al.*, 1997), and the Telephone Version of the MMSE (Roccaforte *et al.*, 1992). The OBS has been found to have good validity in three separate countries (Ames *et al.*, 1992). Some attempt has been made to develop self-administered tests, such as the Early Assessment Self Inventory (EASI) (Horn *et al.*, 1989). There is evidence that the place of testing can cause significant changes in the test score, with testing in a patient's own residence being associated with a higher score (Ward *et al.*, 1990).

These short cognitive screens obviously have their limitations, the most obvious being that they test only limited domains of cognition. Besides the use of full neuropsychological assessment, attempts have been made to develop other short tests of specific functions. An example of this is the Executive Interview (Royall *et al.*, 1992), which attempts to assess executive cognitive function. Also, the ability to draw a

Table 7.1 Cognitive domains in commonly used short cognitive tests

GPCOG		◆	◆			◆

clock has been extensively studied as a short test that examines other cognitive domains. It has been used by itself in conjunction with other cognitive tests such as the SPMSQ or MMSE, or as part of the 7-minute screen, GPCOG or STMS. Clock drawing may miss a quarter of cognitively impaired individuals (Gruber *et al.*, 1997). Clock drawing may be able to detect cognitive alterations not related to delirium or dementia, with abnormal clock drawing being associated with other psychiatric disorders (Gruber *et al.*, 1997). Also it may provide additional information to the MMSE as suggested by Ferrucci *et al.* (1996), where the clock drawing test predicted cognitive decline in older people independently of the MMSE.

Short cognitive tests are known to be sensitive to bias associated with education, but adjustment for this effect does not necessarily improve test performance (Belle *et al.*, 1996). Another consideration is that these tests may not be sensitive to all stages of the disease. Stern *et al.* (1994) demonstrated that there was a quadratic relationship with dementia severity showing that the ADAS-Cog and IMCT show greater deterioration for patients with moderate dementia and that the deterioration is slower for mildly and severely demented patients. This may represent the relative insensitivity of the tests for patients with the least and greatest impairment, or may reveal true patterns of progressive cognitive decline at different parts of the disease process.

Attempts have also been made to shorten these tests even further – for example the 10-item AMT has been further shortened to four items (Swain and Nightingale, 1997) but it does seem to lose some predictive efficiency at this length. The potential problem of inadequate specificity of short cognitive tests for population screening has been revealed in a community study: the Canadian Study of Health in Ageing (Graham *et al.*, 1996). In this study the modified MMSE (3MS Exam) (Teng and Chui, 1987) was used as a community screen before a diagnostic battery. Cognitive impairment, not dementia, was found to be more common than dementing processes, with the prevalence of cognitive impairment not dementia found to be 16.8 per cent, whereas the prevalence of all types of dementia combined was 8 per cent (Graham *et al.*, 1997). The conditions identified within this category of cognitive impairment included delirium, alcohol use, drug intoxication, depression, psychiatric disorders, memory impairment associated with the ageing process and intellectual disability.

7.3 USING INFORMANT-BASED TESTS

Perhaps the most exciting development in the detection of cognitive impairment in older people in recent years has been the refinement and validation of structured tests administered to informants. Examples of this type of test include the DECO Test – Deterioration Cognitive Observée (Ritchie and Fuhrer, 1992) and the Informant Questionnaire for Cognitive Decline in the Elderly (IQCODE) (Jorm and Korten, 1988).

Important advantages of these tests is that they correlate relatively poorly with premorbid function and are relatively insensitive to the effects of education. The other consideration about informant questionnaires is that they have shown lower correlations with the cognitive tests: somewhere in the order of 0.6 (Flicker *et al.*, 1997). The work by Ritchie and Fuhrer (1992) would suggest that they seem to be better able to discriminate mild dementia from normality as opposed to cognitive screens such as the MMSE, although this was not replicated by others (Flicker *et al.*, 1997). This may represent a difference in the choice of informants as much of the sample described by Ritchie and Fuhrer (1992) were recruited through 'France Alzheimer' and may have represented carers who were well attuned to the problems associated with dementia, while the Flicker *et al.* (1997) patients were drawn from attendees at a memory clinic.

A meta-analysis (Jorm, 1997) suggests that informant tests may perform better than short cognitive tests, but it is important to emphasize that there was great heterogeneity within this meta-analysis and clearly the test results were dependent on the subject samples and the samples of informants. Nevertheless Harwood *et al.* (1997) demonstrated a remarkably similar result for both the AMT and the IQCODE in a sample of medical inpatients over the age of 65 admitted to a general medical unit. In that study, the 16-item version of the IQCODE was used with good effect. The IQCODE has been validated by longitudinal changes of cognitive tests (Jorm *et al.*, 1996) and also has been validated retrospectively against post-mortem diagnosis (Thomas *et al.*, 1994).

One of the important considerations for the use of combinations of tests or additional items is that the correlation between individual tests should not be too great. The importance of asymmetry of associations between tests to increase the positive predictive value of combinations of tests has been highlighted (Marshall, 1989). Hooijer *et al.* (1993) found some improvement in diagnosis in using pairs of short screening tests. This was not the case in work by Little *et al.* (1987) where a short AMT score was found to have better predictive value than longer combined tests.

To date, most work has focused on using either informant tests or short cognitive tests separately as a screen for further investigations and management, but clearly the tests can be combined. This was raised by Flicker *et al.* (1997) where the lower correlations and asymmetry of the test properties within different populations could be used so that the combined tests' sensitivity and specificity would be improved. This is quite different to the use of the alteration of cut points, where a trade-off occurs between sensitivity and specificity. The judicious use of the combination of informant and short cognitive tests potentially may result in an increase in both sensitivity and specificity.

This has been demonstrated by Gallo and Breitner (1995) where a telephone administered cognitive status was used as a first screen followed by an informant test. The informant test was falsely described as being more specific, but in fact it was the combination of using the two tests in series that

Table 7.2 Positive predictive values in different clinical situations*

Clinical situation	Prevalence	Positive predictive value	
		AMT 7/8	AMT 8/9 in series with IQCODE 3.79/3.80
1 General population age group 80–84	11%	45%	63%
2 Patients seen through Aged Care Assessment Teams or in geriatric hospitals	44%	84%	92%
3 General patients over the age of 75 years admitted to acute teaching hospitals	26%	70%	83%

* Based on data from Ames and Tuckwell 1994; LoGiudice *et al.*, 1995; Ames *et al.*, 1994. Reprinted with permission from Flicker L, LoGiudice D, Carlin JB, Ames D. (1997) The predictive value of dementia screening instruments in clinical populations. *International Journal of Geriatric Psychiatry* 12: 203–9. Copyright John Wiley & Sons Limited.

resulted in the increased specificity needed for this two-stage screen. Another example of this approach being used in challenging population research is the work of Hall *et al.* (1993, 1996). In these studies a combination of short cognitive tests and informant testing was used in cross-cultural studies of African American, Cree Indian and Nigerian populations, and the relative insensitivity of the informant tests to the effects of culture and education improved the performance of these combinations. The combination of the MMSE and IQCODE has now been evaluated extensively in three separate studies (Mackinnon and Mulligan, 1998; Knafelc *et al.*, 2003; Mackinnon *et al.*, 2003) with the total evidence suggesting that the combination of tests performed better than either test alone, and that the tests could be combined usefully by either a requirement for both or either test to be positive or calculating a new score using a weighted sum rule.

Besides the characteristics of the population being assessed, it is important to realize that the absolute prevalence of the condition will also cause a need for an adjustment in the cut points. Very low prevalence will increase the need for specificity, otherwise there will be a large number of patients to investigate further. This could of course occur in either research or clinical practice. Some illustrative extrapolations have been provided where the positive predictive value of combinations of tests have been calculated across different population groups (see Table 7.2). It is important to emphasize that the cut points used in the combination of these tests in either series or parallel may be quite different from the ones normally employed by the tests in isolation.

7.4 CONCLUSIONS

There is now available a number of short cognitive tests that appear useful in helping clinicians to determine whether individuals require further assessment for the presence of a cognitive disorder. The tests seem to perform in a fairly similar fashion and it is difficult to predict the performance of these tests, either singly, or in combination with informant tests, from one population to the next. This depends on the asymmetry of test results in cases and normals within that

population, and is very much dependent on the characteristics of the population studied. There is now evidence that an improvement in the efficacy of cognitive assessments can be most easily achieved by combining informant and short cognitive tests to a single summative score, or using informant and cognitive tests with specific cut points and rules of combination. Alternative cut points will need to be used when the tests cannot be used together – for example, when there is no caregiver or informant to provide information on a particular subject, or alternatively, where a subject is delirious or dysphasic and is unable to perform cognitive testing to their potential ability.

Measurement of behavioural disturbance, non-cognitive symptoms and quality of life

AJIT SHAH, STEPHEN FOLI AND IAN O NNATU

7.5 BPSD: definition	72	7.9 Disorders of thought content and perception	76
7.6 Disorders of behaviour disturbance	72	7.10 BPSD: conclusions and a way forward	77
7.7 Disorders of personality alteration	73	7.11 Quality of life	77
7.8 Disorders of mood	75	References	78

7.5 BPSD: DEFINITION

Burns and colleagues (1990a–d) originally classified non-cognitive symptoms in dementia into disorders of behaviour, mood, thought content and perception. The International Psychogeriatric Association labelled these as behavioural and psychological signs and symptoms of dementia (BPSD) and defined them as ‘a heterogeneous range of psychological reactions, psychiatric symptoms, and behaviours occurring in people with dementia of any aetiology’ (Finkel and Burns, 2000). We have added a further domain of disorders of personality alteration. The definition of any individual BPSD should be hierarchical and allow discrimination between the cognitive and non-cognitive (BPSD) domains, different BPSD domains, and individual signs and symptoms within a given BPSD domain (Shah, 2000).

7.6 DISORDERS OF BEHAVIOUR DISTURBANCE

7.6.1 Definition

Aggressive behaviour is described as a typical example of disturbed behaviour, but similar arguments can be rehearsed for other disorders of behaviour. There is no generally agreed definition of aggressive behaviour (Shah, 1999a). Varying definitions of aggressive behaviour have been used. The best definition of aggressive behaviour in the elderly is: ‘Aggressive

behaviour is an overt act, involving the delivery of noxious stimuli to (but not necessarily aimed) at another organism, object or self, which clearly is not accidental’ (Patel and Hope, 1992a).

7.6.2 Samples, settings, methods of data collection and measurement instruments

Box 7.1 illustrates the samples studied in several settings including the community, outpatient clinics, residential and nursing homes, acute admission and continuing care geriatric and psychogeriatric wards (Shah, 1999a). More recent studies have largely been prospective and some include a longitudinal component. Methods of data collection are listed in Box 7.2. Essential properties of instruments measuring any BPSD, including aggressive behaviour, are illustrated in Box 7.3.

An important characteristic of some instruments measuring aggressive behaviour is the spontaneous tendency for aggressive behaviour to decline during a period of serial measurement. This has been observed with the Staff Observation Aggression Scale (SOAS) (Palmsteirna and Wistedt, 1987) on psychogeriatric wards (Nilsson *et al.*, 1988; Shah, 1999b). Therefore, a 'run in' period of up to 4 weeks has been recommended in intervention studies (Nilsson *et al.*, 1988; Shah, 1999b).

7.6.3 Comment

Many instruments measure aggressive behaviour, but not all the psychometric and other properties have been adequately evaluated. Individual instruments have been developed for use in specific settings or specific diagnostic groups. One example of this difficulty is the RAGE scale. It was developed for use by the nursing staff on psychogeriatric inpatients with dementia (Patel and Hope, 1992a), but it has also been used in nursing homes (Shah *et al.*, 1997) and psychogeriatric wards (Shah and De, 1997) for all diagnostic groups. Generalizability of instruments to other settings, diagnostic groups and different category of raters is unclear. Given the large number of instruments, with varying properties, there should be a moratorium on the development of new instruments. Research should be directed at comparing different instruments with each other, generating data on all of their properties, refining these instruments to improve their properties, adapting them for use in parallel settings, and developing guidelines and protocols for their use in research and clinical practice (Shah and Allen, 1999). This would ultimately allow measurement of aggression across settings, diagnostic groups and with different modes of data collection in a comparable common currency.

7.7 DISORDERS OF PERSONALITY ALTERATION

7.7.1 Definition

Personality changes in dementia include emergence of new features (Petry *et al.*, 1988; Dian *et al.*, 1990; Siegler *et al.*, 1991; Chatterjee *et al.*, 1992) or an exaggeration of premorbid personality traits.

7.7.2 Samples, settings and methods of data collection

Box 7.4 illustrates the samples and the settings in which personality change has been examined. Studies have included a comparison group of normal aged individuals (Rubins *et al.*, 1987a, b; Petry *et al.*, 1988; Cummings *et al.*, 1990; Dian *et al.*, 1990; Jacoub and Jorm, 1996), Parkinson's disease (Meins and Dammas, 2000), vascular dementia (Sultzer *et al.*, 1993)

Box 7.4 *Sample or setting (with references) in studies of personality change in dementia*

- Undifferentiated dementias Seigler *et al.*, 1991
- Vascular dementia Dian *et al.*, 1990; Sultzer *et al.*, 1993; O'Connor, 2000
- Alzheimer's disease Rubins *et al.*, 1987a, b; Petry *et al.*, 1988, 1989; Bozzola *et al.*, 1992; Chatterjee *et al.*, 1992; Sultzer *et al.*, 1993; Jacoub and Jorm, 1996; Meins and Dammast, 2000
- Frontotemporal dementia Miller *et al.*, 1997
- Community sample Nilsson, 1983; Jacoub *et al.*, 1994; O'Connor, 2000

- Mixed group of psychogeriatric inpatients Pearson, 1990, 1992

Box 7.5 *Methods of data collection (and references) for personality change in dementia*

- Specially designed personality questionnaire administered to relatives Petry *et al.*, 1988, 1989; Chatterjee *et al.*, 1989; Dian *et al.*, 1990; Seigler *et al.*, 1991; Bozzola *et al.*, 1992; Jacoub *et al.*, 1994; Jacoub and Jorm, 1996
- As above and an open interview Rubins *et al.*, 1987a, b
- Specially designed personality questionnaire administered to patients Nilsson, 1983; Pearson, 1990, 1992

and frontotemporal dementia (Miller *et al.*, 1997), and compared Alzheimer's disease (AD) with norms for inpatients (Meins and Dammast, 2000). Comparison with the premorbid personality allows identification of personality changes (Siegler *et al.*, 1991; Chatterjee *et al.*, 1992); and, comparison with normal aged individuals allows exclusion of personality changes as an artefact of ageing (Rubins *et al.*, 1987a, b; Petry *et al.*, 1988; Cummings *et al.*, 1990; Dian *et al.*, 1990). Difficulties in measuring the type, nature and severity of personality change include: reduced insight, judgement and memory preclude use of self-reports (Petry *et al.*, 1988; Meins and Dammast, 2000); accounts from relatives may be biased by their emotional feelings (Dian *et al.*, 1990; Jacoub *et al.*, 1994; Meins and Dammast, 2000) and personality (Meins, 2000); and, a clear retrospective account of premorbid personality may not always be available. Methods of data collection are listed in Box 7.5.

7.7.3 Instruments used to measure personality alteration

The items of irritability and disinhibition on the Neuropsychiatric Inventory (NPI) (Cummings *et al.*, 1994) coupled with case-notes review was used to examine socially disruptive and antisocial behaviour in a comparative study of AD and frontotemporal dementia (Miller *et al.*, 1997). The Brooks and McKinlay (1983) personality inventory, originally used in brain injury patients, with 18 pairs of adjectives, measured on a five-point scale, has been administered to relatives of people with dementia (Petry *et al.*, 1988, 1989; Cummings *et al.*, 1990). The 11 personality items on the Blessed Dementia Rating Scale (Blessed *et al.*, 1968) has been used alone (Bozzola *et al.*, 1992) or in combination with six items from open-ended questions (Rubins *et al.*, 1987a, b). The Eysenck Personality Inventory (EPI) has been used to show that, among elderly psychiatric inpatients and day patients with organic disorder, impulsiveness correlates with extraversion but not psychotism (Pearson, 1990, 1992). Subjects with mild-moderate dementia and neurotic disorders scored highly on the neuroticism component of the EPI in a community sample (Nilsson, 1983). 'Troublesome behaviour' has been reported to be associated with higher scores on the premorbid trait of neuroticism in Alzheimer's subjects (Meins *et al.*, 1998). Instruments measuring personality changes have been developed from the 'personality change' and impaired judgement of impulse control' components of DSM-III-R and ICD-10 descriptions of dementias (Jacoub *et al.*, 1994) and asking clinicians to complete personality inventories on the basis of their experience (Jacoub and Jorm, 1996).

7.7.4 Clinical features

Changes in personality features include coarsening of affect, disinhibition, increase in passivity, apathy, asponaneity, irritability, belligerence, demanding attention, indifference, egocentricity, less conscientiousness, lower extraversion, higher neuroticism and lower openness (Seltzer and Sherwin, 1983; Ishii *et al.*, 1986; Petry *et al.*, 1988, 1989; Cummings *et al.*, 1990; Siegler *et al.*, 1991; Bozzola *et al.*, 1992; Chatterjee *et al.*, 1992; Jacoub and Jorm, 1996; Meins and Dammast, 2000). Patients with AD, compared to normal elderly, have greater changes on 12 personality traits of being more out of touch, less self-reliant, less mature, less enthusiastic, less stable, more unreasonable, more lifeless, more unhappy, less affectionate, less kind, more irritable and less generous after the onset of the dementia (Petry *et al.*, 1988); similar results were observed in vascular dementia (Dian *et al.*, 1990). Subjects with frontotemporal dementias are more likely to demonstrate forensic behaviour like indecent exposure and shoplifting than those with AD (Miller *et al.*, 1997). Four patterns of personality alteration in AD emerge at 3-year follow up: change at onset with little change as the disease continues; ongoing change as the disease progressed; no change at all; and,

regression of previously altered personality characteristics (Petry *et al.*, 1989).

7.7.5 Comment

Some BPSD may be secondary to personality change. However, the relationship between personality changes and other BPSD domains is unclear. They may be part of the same phenomenon, aetiologically linked or discrete entities. Many of the personality change features listed above overlap with features of frontal lobe dysfunction (Dian *et al.*, 1990) and depression (Sultzer *et al.*, 1993). Paucity of data on psychometric and other properties of instruments used to measure personality suggests that research efforts should be directed at rigorous evaluation of existing and new instruments (Strauss and Pasupathi, 1994). There is a clear need to develop instruments that measure personality features in individuals with dementia that are sensitive from the premorbid to the illness state and that allow for personality change as an artefact of ageing alone (Strauss *et al.*, 1997). They should be applicable across different diagnostic categories, settings and informants to measure personality change in a comparable common currency.

7.8 DISORDERS OF MOOD

7.8.1 Definition

These two disorders are common in old age and may occur together by chance. Patients with depression may demonstrate cognitive deficits (Verhey and Visser, 2000), including depressive pseudodementia. Depression may precede the onset of dementia either as an early presentation of incipient dementia or act as a risk factor for dementia (Verhey and Visser, 2000). Furthermore, depressive symptoms and illness in dementia require careful definition due to overlap with features of personality changes and cognitive impairment, especially frontal lobe features (Weiner *et al.*, 1997). Ideally this definition should be identical to that for primary depression.

7.8.2 Samples, settings and methods of data collection

Boxes 7.6 and 7.7 illustrate the diagnostic categories and settings, and methods of data collection used in studies of depression in dementia, respectively. Although no clear gold standard for diagnosis of depression in dementia has been established (Verhey and Visser, 2000), these instruments have mainly been validated against gold standard definitions of depression according to DSM-III (Reifler *et al.*, 1986; Cummings *et al.*, 1987; MacKenzie *et al.*, 1989), DSM-III-R (Burns *et al.*, 1990d; Skoog, 1993; Weiner *et al.*, 1997), DSM-IV (Brodaty and Luscombe, 1996), Research Diagnostic (Alexopoulos *et al.*, 1988) and ICD-10 (Burns *et al.*, 1990b)

criteria for major depressive disorder. Some studies have also included dysthymia (Alexopoulos *et al.*, 1988; Skoog, 1993).

7.8.3 Instruments used to measure depression

Box 7.7 illustrates the self-rated and interviewer-rated scales used for measuring depression in dementia. Data on psychometric and other properties for most of these instruments are limited. These scales are generally less accurate as cognitive

impairment increases and insight decreases (Ott and Fogel, 1992) because good attention, concentration, memory and judgement are required for their completion (Burke *et al.*, 1989). Furthermore, as cognitive impairment increases and insight decreases, the discrepancy between depression reported by patients and carers increases (Ott and Fogel, 1992). The recognition of this problem has led to development of instruments specially designed to measure depression in dementia using collateral sources of information (e.g. family members or nursing staff) in addition to clinical examination. Three such scales exist: the Depressive Signs Scale (DSS) (Katona and Aldridge, 1985); the Cornell Scale (Alexopoulos *et al.*, 1988); and, the Depression in Dementia Mood Scale (DDMS) (Sunderland *et al.*, 1988).

7.8.4 Comment

The prevalence of depressive symptoms and depressive illness in AD are 0–87 per cent (median 41 per cent) and 0–86 per cent (median, 19 per cent) respectively (Wragg and Jeste, 1989; Verhey and Visser, 2000). There are various methodological reasons for the variability in these rates. Instruments used to measure depression may be insensitive in severe dementia or patients with severe dementia may not be able to experience complex emotions like depression (Burns *et al.*, 1990b). Furthermore, depression may not present with the classical symptoms in dementia (Verhey and Visser, 2000), particularly in severe dementia (Burns *et al.*, 1990b). There should be a moratorium on developing new depression scales for use in dementia until all the properties of existing scales are thoroughly evaluated. Moreover, refining these instruments will also allow discrimination from other cognitive and personality features and allow examination of the relationship between depression and functional disability in dementia (Espirito *et al.*, 2001). Efforts need to concentrate on scales that can measure depression across different groups of dementias, settings and informants at varying degrees of cognitive impairment in a comparable common currency.

7.9 DISORDERS OF THOUGHT CONTENT AND PERCEPTION

7.9.1 Definition and classification

Hallucinations and delusions in dementia have the same classical definition as in other psychiatric disorders (Cummings *et al.*, 1987). Presence for at least 7 days is an added requirement to exclude delirium as a cause of these phenomena. Auditory (Cummings *et al.*, 1987; Burns *et al.*, 1990d), visual (Cummings *et al.*, 1987; Reisberg *et al.*, 1987; Burns *et al.*, 1990d) and olfactory (Rubins *et al.*, 1989) hallucinations have been studied. Delusions were divided into four categories by Cummings (1985): simple persecutory; complex

Box 7.8 Samples, settings and methods of data collection (and references) for study of psychotic symptoms in dementia

- Interview with caregiver Cummings *et al.*, 1987; Burns *et al.*, 1990c, d; Brodaty *et al.*, 2001; Lyketsos *et al.*, 2001
- Case-notes Cummings *et al.*, 1987

persecutory; grandiose; and those associated with specific neurological deficits. An alternative classification is of delusions of theft, delusions of suspicion and systematized delusions (Burns *et al.*, 1990c). Four types of misidentification syndromes have been described (Burns *et al.*, 1990d): people in the house, misidentification of mirror image, misidentification of television and misidentification of people.

7.9.2 Samples, settings, methods of data collection and measurement instruments

Box 7.8 illustrates the samples, settings and methods of data collection used. Box 7.9 illustrates common instruments used to measure psychotic symptoms. Several semistructured interviews and specially designed scales measure psychotic symptoms along with several other non-cognitive symptoms and thus produce diluted data on pure psychotic features (Ballard *et al.*, 1995).

7.9.3 Comment

The prevalence of delusions (Cummings *et al.*, 1987; Reisberg *et al.*, 1987; Burns *et al.*, 1990c), hallucinations (Ballard *et al.*, 1995; Burns *et al.*, 1990d) and misidentification syndromes (Ballard *et al.*, 1995; Burns *et al.*, 1990d) in AD and vascular dementia varies from 20 to 50 per cent, 17 to 36 per cent and 11 to 34 per cent respectively. Methodological reasons primarily explain the variability in the rates. The boundaries between hallucinations, delusions and misidentification syndromes are often blurred (Whitehouse *et al.*, 1996) and delusions are difficult to differentiate from confabulations (Cummings *et al.*, 1987). The definitions and descriptions of the psychopathology require refinement and clarity (Trabucchi and Bianchetti, 1996). Psychometric and other important properties of measurement instruments have been poorly studied. A systematized check list of 17 categories of psychotic symptoms is the only pure instrument designed to measure psychotic symptoms, but has been poorly evaluated (Ballard *et al.*, 1995). This and similar instruments should be rigorously evaluated and refined to allow measurement of psychotic symptoms across different diagnosis, settings and informants in a common comparable currency. None of the extant instruments measures the degree of distress to the patient and potential for harm to others or self. Measurement of these two variables is important because clinicians will generally only treat psychotic symptoms if the patient is distressed or there is risk of harm to self or others.

7.10 BPSD: CONCLUSIONS AND A WAY FORWARD

Interrelationships between individual BPSD symptoms within and across BPSD domains has been examined by simple univariate correlations (Brodaty *et al.*, 2001), latent class analysis (Lyketsos *et al.*, 2001) and factor analysis (Hope *et al.*, 1997). Ultimately, such analysis will allow identification of the nosological validity of the empirically derived five domains of BPSD by establishing symptom and syndromal clusters

(Lyketsos *et al.*, 2001) and, in turn, facilitate a greater understanding of the demographic, clinical, genetic, biochemical, neuroimaging, neurophysiological and neuroanatomical correlates of BPSD, and their longitudinal course and prognosis.

These developments should be coupled with a moratorium on development of new BPSD rating instruments in order to allow researchers simultaneously to concentrate on comparing different extant BPSD instruments with each other, generate data on their psychometric and other properties, refine these instruments and improve their properties, adapt them for use in parallel settings, and develop detailed glossary, guidelines and protocols for use in audit, research and clinical practice. The ultimate objective should be to measure BPSD accurately by means of the same instrument across settings and diagnostic groups, using different modes of data collection and differing categories of raters. Using the same scale is important because patients move from different settings in different directions.

7.11 QUALITY OF LIFE

7.11.1 Definition

Quality of life (QoL) has several definitions with variable content and weighting given to different domains (Ready *et al.*, 2002). The problem of definition and quantification lies in the different perspectives of this concept and the individual differences in the perception of QoL (Calman, 1984). This perception has cultural-, subcultural-, social-, societal-, personal- and personality-based facets (Whitehouse *et al.*, 1997). The most comprehensive definition of QoL is from the World Health Organization (WHO): 'as individuals' perception of their position in life in the context of the culture and value system in which they live, and in relation to their goals, expectations, standards and concerns' (WHOQOL, 1995). The International Working Group on the Harmonisation of Dementia Drug Guidelines, defined QoL in dementia as 'the integration of cognitive functioning, activities of daily living, social interactions and psychological wellbeing' (Whitehouse *et al.*, 1997). A simpler definition of health-related quality of life in dementia is: 'the individual's subjective perception of the impact of a health condition on life' (Smith *et al.*, 2000; Banerjee *et al.*, 2002). They proposed examining domains of daily activities and looking after self, health and wellbeing, cognitive functioning, social relationships and self concept. Lawton (1994) proposed examining domains of cognitive function, competence in activities of daily living, socially appropriate behaviour, engagement in positive activities, and the presence of positive affect and absence of negative affect in AD.

7.11.2 Measurement of QoL

Measurement instruments can be generic or specific to dementia. Generic instruments have the advantage of allowing

comparison across different disorders and are appealing to policy makers because comparisons across diagnostic categories can inform allocation of funds. Disease-specific instruments, by measuring items relevant to the disorder, allow measurement of the impact of treatment on the disease.

QoL instruments, specific for dementia, are required because a unique set of symptoms cluster in dementia (Rabins and Kasper, 1997). However, the measurement of QoL in dementia is difficult because cognitive impairment can compromise the subject's understanding of QoL, ability to recall relevant recent events, ability to make comparisons across complex QoL domains and insight (Banerjee *et al.*, 2002; Smith *et al.*, 2003). Moreover, the measurement of validity poses difficulties owing to lack of universally accepted definition and an absence of a 'gold standard' measure. Furthermore, subjects in the early stages of dementia give overtly optimistic ratings (Lawton, 1994). These issues raise the question of whether measurement instruments should be self-rated, proxy-rated or use both rating methods (Banerjee *et al.*, 2002; Smith *et al.*, 2003). Proxy measures, by informal or professional carers, may partly address these issues, and may also be necessary in severe dementia when subjects have poor comprehension and communication skills (Smith *et al.*, 2003). However, it not clear at what severity of dementia should self-reports be replaced by proxy reports (Fletcher *et al.*, 1992). Moreover, objective ratings of QoL by caregivers and health professionals are often inconsistent with subjective self-reports by people with dementia (Albert *et al.*, 1996).

7.11.2.1 EXISTING SCALES

Many existing scales were developed in the field of oncology and chronic physical disorders and used in the evaluation of pharmacotherapeutic agents and other treatment interventions, and development of health economics. They are unsatisfactory for measuring QoL in dementia.

Several scales have been evaluated in dementia including Quality of Well Being Scale in AD (Kerner *et al.*, 1998), Quality of Life in AD (Logsdon *et al.*, 1998), AD-Related QoL (Rabins and Kasper, 1997), Cornell-Brown Scale for Quality of Life in Dementia (Ready *et al.*, 2002), and Health-Related Quality of Life in Dementia (Banerjee *et al.*, 2002; Smith *et al.*, 2003). The later new measure of Health-Related Quality of Life in Dementia with satisfactory psychometric properties, has two separate and autonomous components: self-report by people with dementia (DEMqoL) and proxy report by carers (DEMqoL-Proxy) (Banerjee *et al.*, 2002; Smith *et al.*, 2003). These two measures give different but complementary perspectives on the quality of life in dementia. In most cases both measures would be used; however, in severe dementia, owing to the large amount of missing data on self-reports, DEMqoL-Proxy would be useful, and there may not be a need for DEMqoL-Proxy in those with mild cognitive impairment.

7.11.3 Comment

QoL instruments can be useful in screening and monitoring of psychosocial problems in individual patients, population surveys of perceived health problems, clinical audit, measuring outcome in health services and evaluation research, clinical trials, and conducting cost-utility analysis. However, most existing QoL measures in dementia cannot be considered satisfactory in the absence of an agreed definition of QoL, operational criteria and gold standard, lack of satisfactory data on psychometric and other properties (see Box 7.3), and absence of normative data on the subjective perception of QoL. In dementia, impaired judgement, reduced insight, cognitive impairment, personality changes, affective and psychotic symptoms, physical morbidity and temporary fluctuations may make subjective assessment of QoL difficult. There needs to be a moratorium on developing new QoL instruments for dementia. Existing QoL instruments in dementia should be further developed to measure QoL across different dementias, settings and raters, and for use directly with subject, by proxy or by observational ratings in a comparable common currency. Individual instruments measuring QoL should be compared with each other, and theoretically this can lead to further refinement of these instruments.

This chapter focuses on the clinical and research uses of structural magnetic resonance imaging (MRI) in the study of dementia.

Traditionally, structural neuroimaging in dementia has been used to exclude intracranial lesions that may be responsible for cognitive impairment, especially so-called treatable or reversible causes. Although these causes are relatively uncommon and the cost-benefit of using neuroimaging for their detection continues to be debated, MRI and computed tomography (CT) have an unassailable role in their diagnosis because no combination of first line clinical and laboratory findings (which exclude imaging) can identify all treatable causes (Frisoni, 2001).

In addition, imaging is increasingly used to identify neuro-radiological features that characterize specific dementias. This has become possible because of improvements in image quality allowing subtle anatomical differences to be detected and measured. It also reflects a conceptual shift towards diagnosing dementia using both exclusion and inclusion criteria, and recognition that existing diagnostic criteria have finite sensitivity and specificity. Investigations that improve diagnostic accuracy should also help ensure that new treatments are targeted to patients most likely to benefit. In this way, MRI is being used to optimize diagnostic confidence by detecting the presence, and not solely the absence, of biological features specific to certain dementias. Conceivably, even if findings do not redirect the clinician to alternative diagnoses or treatment strategies, they will facilitate provision of accurate information to patients and their families about diagnosis and prognosis. Indeed, the significance of neuroimaging to patients and families should not be underestimated: the result of a

scan often has a pivotal role in helping individuals understand and adjust to the diagnosis of dementia.

In a research context, cross-sectional and longitudinal MRI studies have been conducted to detect bioradiological markers that could aid presymptomatic diagnosis of dementia. MRI also offers new insights into the biology of dementia. These include understanding the links between pathology and symptoms, how dementia subtypes progress over time, whether pharmacotherapies modify these changes, and the identification of predictors to treatments.

Although the first human MR images were generated in the 1970s, the first systematic study of MRI in dementia dates from as recently as the late 1980s. Indeed, MRI remained niched as a research tool until 1990s, by which time it was recognized as a powerful, versatile and safe imaging modality with a central role in medical diagnostics. By 2002 approximately 22 000 MRI scanners were in operation worldwide, performing more than 60 million investigations per annum. The all-round significance of MRI to medical diagnostic and research was underlined in 2003 when two of the pioneers of MRI, Sir Peter Mansfield from the UK and Paul Lauterbur from the USA, were awarded Nobel Laureates in Medicine. The last Nobel Prize in Medicine in the field of diagnostics was awarded to Alan Cormack and Sir Godfrey Hounsfield for the development of CT in 1979.

8.1 MECHANISM OF MAGNETIC RESONANCE IMAGING

In essence, MRI is a non-invasive chemical probe capable of generating high-resolution three-dimensional images of the

body's internal structures. It uses the electromagnetic properties of hydrogen nuclei (or protons) to construct a spatial representation of tissue. Under the controlled environment of the MR scanner, hydrogen nuclei act like microscopic radiotransmitters and a macroscopic impression of tissue structure is obtained by detecting their signal. Analogies have been drawn comparing the way MR images are assimilated from these multiple signals with how an impression of the structure of a city can be obtained from observing the pattern of street lights at night. MRI scanners use very powerful magnetic fields that are approximately 30 000 times greater than the earth's magnetic field. Alterations in water (or, in effect, proton) content and the molecular motion of water molecules provide a basis for detecting pathological change.

Box 8.1 Main types of MRI sequences

Conventional sequences

- *T1-weighted*: provides good definition of anatomy
- *T2-weighted*: provides high contrast and definition of soft tissue pathology
- *Proton density*: provides good brain/CSF contrast

Newer sequences

- Fluid attenuated inversion recovery (FLAIR): sensitive to changes in white matter
- Magnetization transfer imaging (MTI): sensitive to changes in structural integrity of tissue
- Diffusion-weighted imaging (DWI): provides information about the microscopic diffusion of water molecules and integrity of axons
- Perfusion-weighted imaging (PWI): provides information about the status of brain tissue perfusion
- Diffusion tensor imaging (DTI): identifies white matter tracts

A difference in water content of <1 one per cent is enough to distinguish normal and abnormal tissue.

One of the strengths of MRI is its versatility, and there are a number of imaging sequences which can be used to optimize anatomical and pathological differentiation. These standard or conventional sequences are summarized in Box 8.1 and illustrated in Figure 8.1. In addition, newer MRI sequences have been developed to enable a more detailed examination of white matter tracts, also summarized in Box 8.1. Importantly, they provide higher lesion contrast and can detect and quantify changes that may go undetected by conventional sequences. To date, the vast majority of MRI studies in dementia have used conventional imaging sequences, and only a small number of studies have explored the potential benefits of combining different MR modalities, or indeed structural and functional imaging.

8.1.1 Comparison between MRI and CT

MRI and CT have different advantages and disadvantages as summarized in Box 8.2. The availability of MRI scanners varies considerably from country to country, and by locality. In reality, local service issues such as access, cost and availability often affect the choice to use MRI or CT more than adherence to clinical or scientific considerations.

8.2 INDICATIONS FOR MAGNETIC RESONANCE IMAGING

MRI provides a sensitive method to study atrophy, cerebrovascular disease, white matter abnormalities and certain specific diseases associated with cognitive impairment, such as Creutzfeldt–Jakob disease (CJD). High spatial resolution (<1 mm) and superior soft tissue contrast also provides greater

Figure 8.1 Comparison of FLAIR, proton density (PD) and T2-weighted images from the same individual: note differences in appearance of white matter hyperintensities.

potential for early diagnosis. Moreover, brain structure can be examined in any plane and detailed volumetric quantification of regional and global morphology obtained. Contraindications of MRI are summarized in Box 8.3.

Few studies have directly compared the diagnostic usefulness of MRI and CT. Frisoni (2001) suggested, that in the absence of suitable evidence-based guidelines, CT is sufficient (and necessary) to detect most reversible or treatable causes, particularly those liable to surgical intervention (e.g. brain tumours, subdural haematoma or normal pressure hydrocephalus). MRI, on the other hand, because of the superior image quality, may be more helpful in the differential diagnosis of dementia subtypes and in early/presymptomatic diagnosis. Which format is best suited to detect vascular disease is unresolved, but MRI is probably more sensitive, and CT more specific (especially when the disease process is more advanced).

Box 8.2 Comparison between MRI and CT

MRI

- Higher spatial and anatomical resolution
- Superior soft tissue definition and contrast
- Image in multiple planes; therefore superior views of middle and posterior fossa, pituitary, brain stem, and spinal cord
- Uses non-ionizing radiation
- Wide application for quantitative analysis
- Greater sensitivity to detect white matter pathology and lesions causing epilepsy

CT

- Shorter scan times
- Widely available
- Lower cost
- Better tolerated
- Good for bone abnormalities
- Better for lesions with little or no water content (e.g. meningiomas) and detection of acute intracerebral haemorrhage

Box 8.3 Contraindications to MRI

- Claustrophobia/poorly tolerated (5–10%): MRI scanners can be noisy and feel confined
- Ferromagnetic implants, e.g. pacemakers, intracranial aneurysm clips, cochlear implants, neurostimulators: cardiac pacemakers can de-program and misfire – under these circumstances, structural imaging with CT is the only option
- Ferromagnetic objects in eyes
- Orthopaedic implants are not contraindicated but may introduce local artefacts

8.3 CHOOSING A RATING SCALE AND MEASURING BRAIN ATROPHY

There are a plethora of tools to evaluate the extent and progression of atrophy and white matter pathology. Methods range from very basic visual rating scales to sophisticated computerized programs, requiring back-up from medical physics. Very few studies have compared the clinical usefulness of different tools, leaving the clinician uncertain about which tool to use. As a result they are rarely used routinely outside research clinics.

Nevertheless, tools that assess atrophy have a sensitivity and specificity for distinguishing Alzheimer's disease (AD) from controls of between 70 and 90 per cent, and perhaps in a counterintuitive way, there is little evidence that any method, simple or complex, performs better (Scheltens *et al.*, 2002; Frisoni *et al.*, 2003). The Consensus statement produced by the Neuroimaging Working Group of the European Alzheimer's Disease Consortium (EADC) could find only one MRI tool with evidence showing it had 'added diagnostic value' (Frisoni *et al.*, 2003). This was a visual rating scale of medial temporal lobe atrophy (MTA). In terms of everyday clinical practice, Frisoni (2001) suggested that a visual rating scale (at least) of MTA on MRI (such as Scheltens *et al.*, 1992) (or a linear measure of MTA on CT) should be used in each patient with cognitive impairment. Visual rating scales have the general advantage of being simple and quick to use, and can provide clinically relevant information that correlates sufficiently well with quantitative *in vivo* analysis and post-mortem neuropathology. Limitations include lack of detail and issues of subjectivity, with variable interobserver and intraobserver reliability.

Most research studies now use volumetric analysis for detailed quantification of even small amounts of atrophy. This is, however, time consuming, requires trained operators, high resolution images and, by definition, cannot be obtained from the direct visualization of radiological films. This level of analysis is not currently used in clinical settings, though some automated methods have been developed but require wider validation.

Voxel-based morphometry (VBM) is a new method to evaluate structural change. It combines data from individuals to estimate differences in the pattern and extent of atrophy between the specific groups under investigation. It achieves this by a voxel-based comparison of the local concentration of grey matter between two groups of subjects (Ashburner and Friston, 2000). It is particularly useful at exploring the entire brain without bias and in assessing anatomical differences in areas that would otherwise be difficult to quantify, e.g. total grey matter. However, comparison of individual subjects is not yet developed and VBM lacks the anatomical precision of detailed region of interest (ROI) volumetric studies. VBM has been used to map grey matter density reduction in degenerative dementias, as outlined below.

8.4 CROSS-SECTIONAL AND LONGITUDINAL STUDIES

Brain morphology can be assessed using cross-sectional or longitudinal study designs. The majority of neuroimaging studies so far have been cross-sectional. This design is widely used to compare atrophy in a diseased group with age-related change in an appropriately selected control group. In addition, by the study of age-stratified non-demented healthy individuals, morphological changes across the human life span can be defined in a relatively short time frame.

Longitudinal studies, in contrast, measure the same structure in the same individual at two time points. Differences in volumes between scans is then calculated and used to assess rate of change. Serial scans can be compared using a range of methods, most commonly repeated manual tracing or coregistration, subtraction techniques. Serial scans reduce the variance due to intersubject differences, with each subject acting as their own control, allowing individual changes over time to be precisely assessed. This approach is sufficiently sensitive to detect very small volume changes in the order of a few millilitres or less. There are a number of methodological challenges; atrophy rates can vary considerably between subjects, and serial scanning of patients with advancing dementia can, understandably, be problematic.

Serial MRI was initially used to evaluate whether atrophy rates could improve diagnostic accuracy. The premise, drawn from initial work from CT scanning, was that progressive atrophy over time in an individual patient may be a more sensitive and specific diagnostic marker than a cross-sectional measure obtained from only one scan. Wide variation in normal brain morphology means that within-subject change may discriminate patients with dementia from normal subjects with greater accuracy and at an earlier stage than absolute or group mean volumes. However, results from studies have so far been mixed, and looking ahead, the most exciting role for serial imaging in disease detection is likely to be during the presymptomatic stage of a dementia.

Progression of atrophy in different dementia subtypes can also be explored using serial MRI. Preliminary findings indicate that subjects with degenerative and vascular dementia are losing brain volume at a similar albeit greater rate than normal controls, suggesting serial measurement of global atrophy is unlikely to differentiate the main types of dementia, although, conceivably, measures of regional atrophy rates (such as the hippocampus) could prove to be more discriminating.

Serial MRI also provides a potential paradigm to evaluate the effects of new therapies in dementia. Although evidence is limited, initial studies indicate that this approach is feasible and can provide useful surrogate biomarkers in evaluating the outcome (Jack *et al.*, 2003; Krishnan *et al.*, 2003). Measures of the rate of atrophy have now been incorporated into several trials in MCI and AD.

Box 8.4 Differences between cerebral infarcts and deep white matter hyperintensities on MRI

Infarcts

- Hypointense on T1 and proton density weighted images
- Hyperintense on T2-weighted images
- Well-defined; wedge shape if peripheral
- Often single or low numbers
- Often evidence of cortical extension
- May be associated with focal enlargement of ventricles and sulci

Deep white matter hyperintensities

- Hyperintense on T2 and proton density weighted images
- No change/invisible on T1-weighted images
- Range from punctuate to diffuse confluent lesions
- Often multiple
- Restricted to white matter with no cortical extension
- Ventricles and sulci unchanged

8.5 WHITE MATTER LESIONS

MRI has had a leading role in characterizing white matter abnormalities. The nature and significance of such changes, however, remains an area of uncertainty and controversy, and is perhaps one of the most widely misunderstood and misinterpreted neuroimaging changes.

White matter lesions (WML) that appear as areas of reduced attenuation or leukoaraiosis on CT scanning are hyperintense on proton density and T2-weighted MR images. WML can be divided into those immediately adjacent to the ventricles (periventricular hyperintensities, PVH) and those located in the deep white matter (deep white matter hyperintensities, DWMH). As shown in Figure 8.2, PVH can be further subdivided into caps (frontal and occipital) and bands, and DWMH into punctate foci, early confluent foci and large confluent areas (Fazekas *et al.*, 1987). Box 8.4 summarizes the radiological differences between DWMH and established infarcts (see also Figure 8.3). WML on conventional MRI sequences can be assessed using simple rating scales, semi-quantitative scales and volumetric analysis, although there is currently no universally accepted standardized approach.

WML are clinically and pathologically heterogeneous (see Table 8.1, p. 87). They become more common with advancing age, and can be found in all major forms of dementias as well a host of other conditions, including multiple sclerosis, hydrocephalus, various leukodystrophies, cerebral oedema, neurosarcoid, and conditions such as late life depression. Given the variety of pathologies known to underlie white matter change, it is important not to overinterpret imaging changes (particularly on proton density and T2-weighted MRI) with regard to the vascular contribution to dementia.

The clinical significance of WML continues to be debated. As a general statement, more severe DWMH are more closely

Figure 8.2 Examples of white matter lesions on FLAIR. (a) No periventricular hyperintensities (PVH); (b) mild PVH (frontal and occipital caps); (c) moderate to severe PVH (frontal and occipital caps); (d) punctate deep white matter hyperintensities (DWMH) (in frontal and parietal lobes); (e) large, early confluent DWMH.

coupled to both significant pathologic change (notably ischaemia) and clinical outcome, such as dementia and depression. The ‘disconnection’ of key cortical-subcortical circuits could mediate their effect on brain function. PVH, on the other hand, may have little impact on the clinical outcome. However, uncertainties remain, and the application of newer MRI sequences to this area of study may find links between lesions and symptoms that currently go undetected.

Looking ahead, should WML prove to be clinically significant, then this would have implications for treatment, either directly by opening up new therapeutic options (for example, whether treatment for vascular risk factors modifies ischaemic WML), or indirectly by understanding how WML may modify response to other treatments.

8.6 NORMAL AGEING

With maturity we lose approximately 0.5 per cent of our brain volume every year, and, as our brains become smaller, our ventricles become larger, often at a faster rate. The pace of this

change accelerates with advancing age, particularly after 70 years of age. These age-related changes are common but not inevitable, and there is considerable variation between individuals. Atrophy is observed in most cortical and subcortical structures.

For reasons not yet understood, the hippocampus appears to be particularly sensitive to the effects of ageing, and atrophies at a faster rate than other structures (Scahill *et al.*, 2003). MTA in normal ageing could clinically be linked to mild cognitive impairment (MCI), as discussed in more detail later, and pathologically to AD-type pathology. Preliminary reports have found that increased levels of homocysteine are associated with hippocampal volume loss in non-demented subjects (den Heijer *et al.*, 2003).

Changes in white matter also occur. Indeed, WML are common in late life with a prevalence of between 8 and 92 per cent depending on the study. Across a life span it seems that white matter is in a constant state of change, with processes of maturation continuing into middle age, followed by progressive loss of myelin integrity (Bartzokis *et al.*, 2003).

Figure 8.3 Example of frontal stroke on (a) axial FLAIR, (b) proton density, (c) T2-weighted and (d) Coronal T1-weighted.

8.7 ALZHEIMER'S DISEASE

Earlier MRI studies in AD compared atrophy between patients with established AD and age-matched non-demented controls. Although these studies continue, MRI now has a broader and arguably a more searching role. It is used to see whether subjects with presymptomatic AD, MCI or very early AD can be accurately detected, and in the differentiation of dementias. MRI can also detect biomarkers to track disease progression and predict response to treatment.

8.7.1 Early and established Alzheimer's disease

MTA is the most consistent and recognized structural difference in AD compared with age-matched controls, as illustrated in Figures 8.4 and 8.5. Patients with AD have significantly smaller (by up to 40–50 per cent) amygdalae, hippocampi and parahippocampi, which includes the entorhinal cortex. Lesser degrees of atrophy have also been observed in other temporal structures, including the fusiform gyrus and

Table 8.1 Histopathology associated with white matter lesions in dementias

Pathology	Possible mechanisms
<p>PVH</p> <p>Less extensive PVH: loss of ependymal lining, increased interstitial fluid and gliosis, myelin pallor</p> <p>More extensive irregular PVH which extend into the deep white matter: likely to correspond to areas of reactive gliosis, lacunar infarction, loss of myelin, perivascular spaces and arteriolar thickening</p> <p>DWMH</p> <p>Punctuate WMH: reduced myelination and perivenous damage</p> <p>Early confluent areas: show evidence of perivascular rarefaction of myelin, fibre loss and gliosis</p> <p>Confluent WMH: have a similar histopathology as irregular PVH, including microcystic infarcts</p>	<p>In part secondary to atrophy processes</p> <p>Frontal caps extremely common in late life – could be considered 'normal' and secondary to age-related changes</p> <p>More extensive PVH probably linked to vascular risk factors</p> <p>Punctuate lesions are probably not associated with ischaemia/infarction</p> <p>Ischaemic damage implicated as lesions become larger and more confluent</p> <p>Other possible causes of white matter change include focal cerebral oedema, hypoxia, acidosis, chronic perfusion changes, wallerian degeneration of axons secondary to neuronal loss in neocortex</p>

DWMH, deep white matter hyperintensities; PVH, periventricular hyperintensities

Figure 8.4 (a–d) Examples of graded medial temporal atrophy (MTA): arrows point to hippocampi.

lateral temporal gyri. Indeed, as AD progresses, nearly all limbic structures atrophy. Overall, the distribution of atrophy is symmetrical and more prominent in medial and posterior brain structures than anterior structures. By comparison, there is less atrophy in the frontal lobe, hypothalamus, thalamus, caudate and putamen, and relative sparing of the primary

Figure 8.5 Comparison of medial temporal atrophy in (a) AD, (b) DLB and (c) normal controls.

motor and sensory cortex, inferior occipitotemporal region and cerebellum (Baron *et al.*, 2001). Generalized brain atrophy and ventricular enlargement is common but relatively non-specific.

The pattern of *in vivo* atrophy is consistent with the topographical model of disease progression for AD postulated by Braak and Braak (1991). In this model AD pathology, particularly neurofibrillary tangles, are initially localized to the medial temporal lobe (entorhinal cortex then hippocampus), then extend to other temporal lobe structures, and ultimately beyond to multiple neocortical association areas, finally involving the primary neocortex.

MTA, notably atrophy of the hippocampus and entorhinal cortex, provides the greatest discrimination between AD

and normal subjects with a sensitivity and specificity of 85–90 per cent. Results appear equally good when only very mild subjects are considered (Mini-Mental State Examination [MMSE] >21). This is perhaps not surprising given the extensive loss of neurones in this area of the brain. When measures of MTA are further combined with measures of atrophy involving other brain regions, differentiation is even greater.

Patients with AD are losing brain volume at a faster rate than normal controls. The highest levels of accelerated atrophy are again seen within those structures intimately associated with the disease, particularly the hippocampus (3.98 v 1.55 per cent in controls) and entorhinal cortex (6.5 per cent v 1.4 per cent) (Jack *et al.*, 1998; Du *et al.*, 2003). Increased rates of global atrophy also occur.

MTA is also a biologically relevant measurement, as hippocampal volume loss correlates with symptoms of cognitive impairment, particular memory loss, as well as functional decline and AD-type pathology. However, although MTA provides good discrimination between patients with AD and controls and is a relatively sensitive marker of AD pathology, it is not specific to AD. To lesser degrees MTA is seen in other dementias (as discussed below), Parkinson disease, temporal lobe epilepsy, schizophrenia, depression and certain medical conditions, such as type 2 diabetes (den Heijer *et al.*, 2003).

Studies examining the relationship between measures of regional or global atrophy and variables such as ApoE ϵ 4 allele status, oestrogen replacement and vascular risk factors, have not yielded consistent results. From a limited evidence base, the specificity of MTA as a biomarker for AD appears to decline with age.

In terms of WML, AD tends to have more extensive PVH (prevalence 44–100 per cent) than controls, but findings in relation to DWMH (prevalence 60–100 per cent) are less consistent. Recent evidence indicates a loss of integrity of white matter tracts that is not randomly distributed (Rose *et al.*, 2000). It appears to selectively affect tracts linked to the association cortices (with relative sparing of other tracts), leading to a hypothesis that white matter changes are a downstream consequence to cortical pathology (Bozzali *et al.*, 2002).

In summary, MTA occurs early in the course of AD, and the extent of the atrophy increases with increasing severity of dementia to involve other structures in a way that mirrors the Braak and Braak staging of AD. Indeed, although MTA appears to be necessary for the development of AD, without more extensive atrophy it may be insufficient to cause widespread cognitive impairment (Kaye *et al.*, 1997). Thus, as Jack *et al.* (2002) speculate, MTA is a good marker for early AD, but, as the disease progresses beyond the limbic areas, measures of neocortical atrophy may be better markers of advanced disease. Overall, the diagnostic accuracy of MR volumetry of the hippocampus for distinguishing patients with AD from healthy elderly individuals is comparable to the accuracy of a pathologically confirmed clinical diagnosis (Kantarci and Jack, 2003).

8.7.2 Prognostic significance of medial temporal atrophy in individuals at risk of Alzheimer's disease

The pathogenesis of AD is thought to occur years or possibly even decades before clinical symptoms emerge. Given the expected topographical evolution of pathology, most pre-symptomatic studies have focused on measuring either the hippocampus or entorhinal cortex. Indeed, there is good evidence that atrophy of these structures occurs early in the natural history of the illness, and often before symptoms emerge (Killiany *et al.*, 2002; Scahill *et al.*, 2002). By the time mild symptoms are apparent hippocampal volume reductions exceeding 25 per cent have been reported (Fox and Rossor, 1999).

The prognostic relevance of MTA in predicting cognitive decline and eventual dementia in individuals at risk of AD has been studied in two main groups: subjects with a familial, dominantly inherited form of AD and subjects with MCI.

8.7.2.1 PRESYMPTOMATIC DETECTION OF INDIVIDUALS WITH FAMILIAL AD

Serial MRI studies of families with autosomal dominant forms of AD have shown that atrophy of the hippocampus and entorhinal cortex develops in parallel with the appearance of symptoms and progresses more rapidly in subjects who develop dementia (Fox *et al.*, 1996a, b). Interestingly, by extrapolating back in time, Schott *et al.* (2003) estimated pathological atrophy started at least 3.5 years (95 per cent CI, 0.7–7.5) before symptoms emerged. This raises the exciting and realistic prospect that there are changes that could be detected in due course and enable subjects 'at risk' to be detected. Indeed, this transitional phase from pathology to emerging symptoms may be associated with the most aggressive phase of MTA, raising the exciting prospect that subjects 'at risk' of AD can be detected using serial MRI.

8.7.2.2 SUBJECTS WITH AGE-RELATED MINIMAL COGNITIVE IMPAIRMENT

Subjects with MCI are at increased risk of developing dementia (see Chapter 24). Detection of MCI is therefore important, and the role of neuroimaging in MCI has been extensively reviewed (Kantarci and Jack, 2003; Wolf *et al.*, 2003).

As with presymptomatic studies, significant hippocampal (7–15 per cent) and entorhinal cortex volume (5–32 per cent) reductions are the most consistently described difference between subjects with MCI and cognitively unimpaired controls. Subjects who are moving along the trajectory from normal to MCI are losing more of their hippocampus than those who remain stable. Overall, the results from visual rating of atrophy and cross-sectional and longitudinal volumetric studies have found the changes in MCI are intermediate between normal subjects and AD. The intermediate nature of these results is reflected in the relatively lower sensitivity (60 per cent) and specificity (80 per cent) of measures of MTA in

discriminating MCI and controls compared with their discrimination of AD (Xu *et al.*, 2000).

Currently, opinion is divided as to whether atrophy of the hippocampus or entorhinal cortex best predict conversion from MCI to AD. However, even though atrophy in both structures in MCI is a well-established risk factor for the development of AD, these measures cannot be regarded as being of high predictive value in an individual case (Wolf *et al.*, 2003).

8.8 DEMENTIA WITH LEWY BODIES

Standard ROI and VBM studies consistently find that dementia with Lewy bodies (DLB) and AD have a different pattern of temporal lobe atrophy. The most striking differences relate to medial rather than lateral temporal lobe structures. As shown in Figure 8.5, subjects with DLB have greater preservation of hippocampal, amygdala, and parahippocampal volumes (Barber *et al.*, 2000, 2001). Post-mortem studies back up these findings, and these differences may help explain differences in the profile of cognitive deficits between these disorders. Annual rates of global atrophy in DLB are similar to those in AD and VaD, but greater than normal controls (O'Brien *et al.*, 2001).

Although DLB is associated with visual hallucinations and occipital changes in blood flow and metabolism on single photon emission computed tomography (SPECT), there are no gross structural changes in the occipital lobe on MRI (Middelkoop *et al.*, 2001). Preliminary findings suggest a possible association between DLB and atrophy of the putamen,

but not the caudate nucleus, though there is no link between volumetry and symptoms (Barber *et al.*, 2002; Cousins *et al.*, 2003). Subjects with DLB shares a similar distribution, prevalence and severity of WML to AD on MRI, intermediate in severity between those with VaD and normal controls (Barber *et al.*, 1999).

8.9 FRONTOTEMPORAL DEMENTIA

Frontotemporal dementia (FTD) is characterized by a specific pattern of moderate to severe atrophy of the frontal and temporal lobes. Compared to AD and VaD, atrophy is more severe and has a high specificity for distinguishing FTD from other dementias. The atrophy is also more asymmetrical, and is particularly prominent in the left temporal lobes.

Hippocampal atrophy also occurs but tends to be less severe than in AD, although atrophy of the entorhinal cortex can be equally severe (Frisoni *et al.*, 1999; Boccardi *et al.*, 2003). FTD has increased rates of whole-brain atrophy compared with controls (3.2 per cent v 0.5 per cent per year) but overlaps with AD (2.4 per cent) (Chan *et al.*, 2001a).

The temporal lobe variants of this syndrome include progressive non-fluent aphasia (PNFA) and semantic dementia (SD). PNFA is characterized by asymmetrical, left-sided perisylvian atrophy. Atrophy in semantic dementia tends to be more bilateral, though can be asymmetrical, as shown in Figure 8.6. There is an anteroposterior gradient in the distribution of temporal lobe atrophy (Chan *et al.*, 2001b).

Figure 8.6 Patient with clinical diagnosis of semantic dementia showing bilateral anterior temporal lobe atrophy, Left > right side: coronal and axial T1-weighted images (courtesy of Dr T Griffiths).

Table 8.2 *Structural imaging requirements for current diagnostic systems for dementia*

Diagnosis	DSM-V	ICD-10	Specific diagnostic criteria	Comments
AD	Generalised brain atrophy and enlarged ventricles > normal ageing process	Not specified	NINCDS-ADRDA criteria (McKhann <i>et al.</i> , 1984): ↑ ventricles, gyri are narrowed, sulci are widened; general patterns may not be useful as diagnostic criteria in individual cases	All the major diagnostic criteria for AD focus on neuroimaging <i>excluding</i> competing causes of cognitive impairment and lack reference to possible neuroimaging <i>inclusion</i> criteria for AD, such as medial temporal lobe atrophy
DLB	Not specified	Not specified	Consensus criteria for DLB (McKeith <i>et al.</i> , 1996): recognized lack of definitive evidence about specific abnormalities on imaging (at time of publication); CT or MRI might show generalized cortical atrophy	Growing evidence to suggest neuroimaging criteria should include the relative preservation of medial temporal lobe structures in subjects with DLB compared with those with AD
FTD	Prominent frontal and/or temporal atrophy on structural brain imaging, and localized frontotemporal hypometabolism on functional brain imaging, even in the absence of clear structural atrophy	Not specified	Consensus clinical criteria for frontotemporal dementia (Neary <i>et al.</i> , 1998): abnormalities (structural and/or functional imaging) may be bilaterally symmetrical or asymmetric, affecting the left or right hemisphere disproportionately, although failure to demonstrate these prototypic appearances need not exclude diagnosis	In addition, two neuroimaging exclusion features are described: the presence of multifocal lesions and predominant postcentral structural or functional deficits
VaD	Criteria require 'laboratory evidence of cerebrovascular disease', which may include laboratory evidence such as imaging. Structural imaging 'usually' demonstrates multiple vascular lesions	Not mandatory for the diagnosis, though in some cases it will be needed.	California criteria for ischaemic VaD (IVD) (Chui <i>et al.</i> , 1992): 'Probable' IVD – requires at least one infarct outside the cerebellum. 'Possible' IVD – does not require neuroimaging evidence of infarction. The NINDS-AIREN criteria (Román <i>et al.</i> , 1993): Need to define the extent, topography and severity of vascular lesions. 'Probable VaD' – multiple infarcts or strategic single infarcts or multiple subcortical or white matter lesions (at least 25% of total white matter)	The NINDS-AIREN criteria have the most rigorous neuroimaging criteria. Specifically state that the absence of cerebrovascular lesions on brain CT or MRI makes the diagnosis of vascular dementia unlikely. NINDS-AIREN v California criteria: NINDS-AIREN criteria recognize that a single lesion may cause VaD; radiological lesions regardless of location may be taken as evidence of cerebrovascular disease (excluding 'trivial' infarcts); require vascular change to fulfil criteria for both location and severity

AD, Alzheimer's disease; DLB, dementia with Lewy bodies; DSM: *Diagnostic and Statistical Manual* (American Psychiatric Association, 1994); FTD, frontotemporal dementia; ICD: International Classification of Diseases (World Health Organization, 1992); VaD, vascular dementia.

Provisional findings indicate WML in FTD are common, but as in AD and DLB are less severe than in vascular dementia (VaD) (Varma *et al.*, 2002).

8.10 VASCULAR DEMENTIA

VaD is associated with a wide variety of brain lesions including cortical infarcts, infarcts in strategic brain areas (basal ganglia and thalamus), multiple lacunes, extensive white matter change or combinations thereof. There may be evidence of focal atrophy, either cortical or ventricular, corresponding to focal infarction and subsequent local atrophy. In addition, VaD like AD is associated with relatively non-specific changes such as generalized cerebral atrophy and ventricular dilatation. Hippocampal atrophy can occur but is less severe than in AD.

On MRI, VaD is associated with evidence of infarction and an increased severity of PVH (prevalence 70–100 per cent) and DWMH (prevalence up to 100 per cent) compared with AD, DLB and age-matched normal controls. Large irregular PVH, confluent DWMH and basal ganglia hyperintensities are characteristic of VaD, representing a greater burden of ischaemia.

Several neuroimaging studies have investigated the relationship between dementia and vascular change. The total number and location of infarcts appears to be important, especially left-sided or bilateral lesions and those located in strategic areas such as thalamus and anterior capsule. However, in addition to a 'lesion-based' view of VaD, generalized changes, such as cortical and central atrophy, as well as variables, such as age and level of education, may play an important role in the development of post-stroke dementia.

Table 8.2 summarizes the different neuroimaging criteria for main diagnostic classifications of dementias. Table 8.3 summarizes MRI findings in other conditions.

Table 8.3 MRI findings in other disease associated with cognitive impairment

Disorder	MRI findings
Variant Creutzfeldt–Jakob disease (nvCJD)	Symmetrical hyperintensity in the pulvinar (posterior) nuclei of the thalamus (pulvinar sign). Other features are hyperintensity of the dorsomedial thalamic nuclei, caudate head and periaqueductal grey matter (Collie <i>et al.</i> , 2003). FLAIR more sensitive than other sequences
Sporadic Creutzfeldt–Jakob disease	High signal changes in the putamen and caudate head
Huntington chorea (HC)	Bilateral caudate atrophy – may also have reduce volume of other basal ganglia structures and frontal lobes
Progressive supranuclear palsy (PSP)	Non-specific mild atrophy
Multisystem atrophy (MSA)	Olivopontocerebellar atrophy, pontocerebellar and putamenal hyperintensities on T2-weighted images
Normal pressure hydrocephalus (NPH)	Marked ventricular enlargement, with rounding of anterior horns of lateral ventricles. The enlargement is disproportionate to any sulcal widening (i.e. cortical atrophy not usually present), and there is no significant focal pathology or white matter change.)

8.11 FINAL COMMENTS

From a clinical perspective, a key question remains: 'When should a MRI scan be requested?'. There is, however, no consensus about the threshold or indications for scanning. Instead, there is a spectrum of opinions from the selective to the wholly inclusive, as exemplified in Box 8.5 (see page 92).

Nevertheless, there is a general shift towards the view that all patients with dementia should be scanned at least once during their illness. This position recognizes that there can never be a comprehensive list of all indications for any investigation and, if scanning is combined with accurate clinical information, it offers the highest standard of diagnostic accuracy currently available. Perhaps an alternative question would be: 'If I need to make a diagnosis using a certain set of diagnostic criteria, what sort of imaging do I need to perform?'. A CT will, for cost and practical reasons, usually be the imaging modality of first choice, although an MRI, if accessible, would almost always be the superior imaging modality.

In clinical practice, imaging is not an end in itself but an investigation that contributes information about the biology of the brain, which needs to be interpreted as part of the overall clinical assessment. As with any test or investigation, imaging in dementia is neither perfectly sensitive nor specific, and false negative and positive results will occur. Inevitably, the clinician will need to interpret both the nature and significance of any radiological finding in weighing up its potential contribution to the clinical picture. This is a point of convergence between the art of clinical medicine and science that makes that practice more revealing.

Looking ahead, a more sophisticated blending of MR sequences and measurements could enhance the overall usefulness of MR technology. Indeed, the specific mix of MR tests for optimal diagnostic accuracy could well differ as diseases progress.

Box 8.5 *Examples of guidelines for imaging in dementia***Selective criteria: example from guidelines**

Canadian Consensus Conference on Dementia (Patterson *et al.*, 2001) Recommendations for neuroimaging. Cranial CT scan is recommended if one or more of the following criteria are present:

- A Age less than 60 years
- B Rapid, (e.g. over 1–2 months) unexplained decline in cognition or function
- C Short duration of dementia (<2 years)
- D Recent and significant head trauma
- E Unexplained neurological symptoms, e.g. new onset of severe headache or seizures
- F History of cancer (especially in sites and types that metastasize to the brain)
- G Use of anticoagulants or history of a bleeding disorder
- H History of urinary incontinence and gait disorder early in the course of dementia (as may be found in normopressure hydrocephalus)

- I Any new localizing sign (e.g. hemiparesis or Babinski's reflex)
- J Unusual or atypical cognitive symptoms or presentation (e.g. progressive aphasia, gait disturbance)

All-inclusive criteria: examples of statements from opinion leaders and guidelines

- In elderly demented patients routine neuroimaging with CT or MR is the ideal that should be sought (Rossor, 1994) Practice parameters: diagnosis of dementia (evidence-based guidelines) from the American Academy of Neurology. Recommend:
- Structural neuroimaging with either a non-contrast CT or MR scan in the routine initial evaluation of patients with dementia is appropriate (Knopman *et al.*, 2001)
- Neuroimaging, and MRI in particular, is increasingly regarded as an essential part of the investigation of a patient with dementia (Scheltens *et al.*, 2002)

Functional imaging

KLAUS P EBMEIER, JANE K SUTHERLAND AND NADINE J DOUGALL

9.1 Imaging methods	94	9.6 Imaging neurotransmitter systems	98
9.2 Are there diagnostic patterns?	96	9.7 Brain-behaviour correlates in dementia	98
9.3 What is the 'gold standard'?	96	9.8 Conclusion	100
9.4 Diagnostic accuracy of functional imaging	96	References	100
9.5 Methods of image assessment – PET and SPECT	98		

Functional brain imaging offers a window into the living brain, an organ that is, of course, not usually accessible to direct scrutiny and investigation. Observing functional activity also anticipates any irreversible structural changes and therefore implies treatability of the abnormalities detected. Both aspects make functional imaging of dementing illnesses a fascinating topic.

Radionuclide-based imaging modes, such as single photon emission computed tomography (SPECT) and positron emission tomography (PET) have been available for several decades now, but their impact on daily diagnostic practice has been minimal. The reasons for this will require exploring. Much emphasis will be placed in this chapter on clinical usefulness of imaging, but other aspects of functional neuroimaging, such as the brain-behaviour correlations observed during illness will be equally explored. These themes will be introduced by a short description of the imaging techniques used in dementia research.

9.1 IMAGING METHODS

9.1.1 Single photon emission computed tomography (SPECT)

SPECT uses gamma emitting radioisotopes, which are attached to biologically relevant molecules and injected intravenously to be distributed amongst others to the brain. The three-dimensional reconstruction of the tracer distribution in the brain gives a biologically meaningful map of, for example, blood flow, receptor binding capacity or similar measures. In

order to focus the signal on the gamma camera, collimators are used. These collimators only admit photons coming from a defined direction to the photosensitive crystal (Figure 9.1). By implication, this method of directional filtering only allows for a small proportion of emitted photons to be detected, which limits the sensitivity of SPECT. In addition, scattered photons lose a certain amount of energy, and are therefore excluded with energy filters. The attenuation of gamma rays during their path through brain matter is usually modelled making assumptions of homogeneous attenuation across the brain and head. Some common applications of SPECT are listed in Table 9.1. Gamma emitters with half-lives of 6–12 hours are usually employed, as the tracers tend to be produced some distance from the scanner. Because of this, limited numbers of exposures are possible. The gamma-emitting nuclei employed (^{123}I and $^{99\text{m}}\text{Tc}$) are relatively large and tend to change the pharmacology of the substituted molecule. The extensive pharmacological development work necessary for such tracers may therefore be one of the explanations for the relatively limited number of gamma (SPECT)-ligands available today.

9.1.2 Positron emission tomography (PET)

Positron emission tomography (PET), as the name implies, uses positron emitters to label physiological brain processes. Positrons (positively charged electrons) are not stable elementary particles; within millimetres of travel they react with an electron to generate two photons with a defined energy moving at approximately 180° away from each other. The detection of such coincidence signals with a detector ring thus makes it

Figure 9.1 (a, b) Localization of photon source with PET and SPECT.

possible to identify spatial as well as intensity information (Figure 9.1). Collimators are thus not necessary and signal detection is more sensitive. Positron-emitting nuclei, particularly ^{11}C , are easily incorporated into biological molecules, without changing their chemical characteristics. Positron emission is relatively energetic – only short exposure to radiation is possible, the short decay half-lives require on-site radiochemistry to incorporate the nuclei into physiologically active compounds. In turn, short half-lives allow for repeated application of tracers. Usually transmission scans with a gamma source in the detector rings are used to quantify the attenuation across the brain. Table 9.1 lists a number of commonly used PET-ligands.

9.1.3 Functional magnetic resonance imaging (fMRI)

Functional magnetic resonance imaging (fMRI) uses physical principles completely different from emission tomographies, both for the constitution and the spatial encoding of images (see Chapter 8). The most frequently used, and here the only described principle, is blood oxygen level dependent (BOLD) imaging. Haemoglobin and deoxyhaemoglobin behave differentially within the MRI magnetic field, so that a signal difference of a few per cent can be observed between brain areas

Table 9.1 Some common applications of SPECT and PET

Tracer	Isotope-mode	Physiology	Clinical use
HMPAO	$^{99\text{m}}\text{Tl}$ -SPECT	Perfusion	Yes
EDT	$^{99\text{m}}\text{Tc}$ -SPECT	Perfusion	Yes
FP-CIT	^{123}I -SPECT	Dopamine transporter	Yes
Iomazenil	^{123}I -SPECT	Benzodiazepine receptor	No
Iodobenzamide	^{123}I -SPECT	Dopamine D2 receptor	No
Iodo-QNB	^{123}I -SPECT	Muscarinic receptor	No
5-I-A-85380	^{123}I -SPECT	Nicotinic receptor	No

that are active and those that are not. Paradoxically, the concentration of deoxyhaemoglobin *decreases* in active brain areas, as blood flow *increases* disproportionately to oxygen extraction. The advantage of fMRI over nuclear medicine imaging is that repeated examinations are possible, and within each subject high signal-to-noise ratios can be achieved by repeating scans many times. To identify brain areas associated with a particular function, tasks are compared, which differ only with respect to the function of interest. Alternatively, the variability of behaviour over time can be correlated with the MRI signal of the parallel time series of scans, taking account of the delay equivalent to the 'haemodynamic response function'. Brain lesions are likely sources of error for fMRI, others are head movement and susceptibility artefacts owing to air and boundary effects. For obvious reasons, such artefacts are more likely to occur in older age and in psychiatric patients. The methods of fMRI have only recently been developed, are by no means standardized and have mainly been used in the research context. The clinical use of fMRI in dementia remains to be established.

9.2 ARE THERE DIAGNOSTIC PATTERNS?

As the macroscopic anatomy and natural history of brain changes in the dementias are variable, it is not surprising that there are no generally applicable 'rules' for diagnostic imaging patterns. Alzheimer-like pathology can be found in a substantial proportion of the brains of non-demented patient (Ince, 2001). In addition, the diagnoses of Alzheimer's disease (AD) and vascular dementia (VaD) are not mutually exclusive so that mixed patterns are likely to occur in a significant proportion of patients. Finally, at an advanced stage all dementias tend to involve large portions of the brain, preferentially (and in all likelihood) association cortex, so any differential features will disappear.

AD is said to initially present with posterior cingulate (Minoshima *et al.*, 1997a) or medial temporal (Callen *et al.*, 2002) reductions in brain activity, but soon after bilateral posterior temporoparietal reductions in brain activity intervene (Holman *et al.*, 1992; see Plate 1). During later stages, prefrontal activity reductions are added, so that some authors have suggested computing a ratio of association cortex over primary sensory-motor cortex as a diagnostic index for AD (Herholz *et al.*, 1999). Frontotemporal dementias, i.e. those that initially present with functional impairment of anterior parts of the brain, have a variety of underlying pathologies, from Pick's to AD. VaD is likely to result in patchy lesions of brain perfusion, often asymmetrical in distribution, or localized in 'watershed' regions of the brain (see Plate 1).

Experience with imaging of patients with dementia with Lewy bodies so far suggests little difference in perfusion patterns from Alzheimer's disease, although occipito-temporal changes have been described (Ishii *et al.*, 1999a; Minoshima *et al.*, 2001). More specific pharmacological probes are just now becoming available. Ligands binding to the dopamine transporter (β -CIT, FP-CIT) can be used as markers for dopaminergic cell loss. These radioligands may consequently prove useful in the differential diagnosis of AD and Lewy-body dementia (Walker *et al.*, 2002).

9.3 WHAT IS THE 'GOLD STANDARD'?

As hinted at above and described in more detail in Chapters 1 and 3, the clinical and pathological diagnoses of dementia are not congruent. The question about the true 'gold standard' for the evaluation of imaging studies, therefore, arises: should functional imaging reflect the distribution and severity of brain cell loss, or should it be representative of patients' functional impairment or their symptoms and signs? Either association would be of interest, but the most important purpose of imaging is, of course, the facilitation of effective treatment. Often the predictive validity of imaging methods is not known, but it should be ascertainable using standard empirical methods. This is in contrast to studies trying to validate imaging data with post-mortem results. By the time

the brain comes to histology, a large number of confounding factors will have had a role to play: the time interval and natural history intervening between scan and post mortem examination; additional illness and treatment; the selection bias resulting from low uptake of post-mortem examinations. In the absence of really effective treatments, predictive validity more usually entails follow up within 2–3 years to confirm that the 'gold standard' clinical diagnosis was in fact reliable and that (hopefully) imaging results at baseline predict the observed clinical outcome.

9.4 DIAGNOSTIC ACCURACY OF FUNCTIONAL IMAGING

9.4.1 Guidelines and consensus statements

The role of functional imaging in the diagnosis of the dementias is controversial. Although the characteristic parietal and temporal deficits in AD and the widespread irregular deficits in VaD described above have been acknowledged and confirmed by consensus statement (Small *et al.*, 1997), guidelines have generally not recommended the routine clinical use of PET or SPECT in the diagnostic evaluation of dementia for *all* individuals. This is mainly justified by the lack of sufficient data on validity (Patterson *et al.*, 1999; Knopman *et al.*, 2001). For this reason, the American College of Radiology recommends using SPECT for clinically and diagnostically difficult cases only (Braffman *et al.*, 2000). Similarly, one of the more methodologically stringent systematic reviews recently suggested that there is little evidence to support a role for PET in the clinical evaluation of patients with suspected or established dementia (Gill *et al.*, 2003). In a more positive resumé, an international working group recommended that imaging techniques have an important role to play in the diagnosis and assessment of dementia and specifically AD (Reisberg *et al.*, 1997).

9.4.2 Alzheimer's disease

Bilateral temporoparietal hypometabolism has been frequently reported for AD compared with normal volunteers (Hoffman *et al.*, 2000; Okamura *et al.*, 2001; Alexander *et al.*, 2002a; Herholz *et al.*, 2002a; Volkow *et al.*, 2002). Although a temporoparietal deficit pattern is indicative of AD, it cannot be regarded as specific, but it does discriminate between demented and non-demented individuals (Masterman *et al.*, 1997). A systematic review and meta-analysis of literature in SPECT and dementia (Dougall *et al.*, 2003) found that using data pooled from 27 studies, SPECT successfully discriminated between healthy elderly controls and AD with a pooled sensitivity of 77 per cent against a pooled specificity of 89 per cent.

Additional significant abnormalities have been reported for AD in *posterior cingulate* (Rossor *et al.*, 1996; Minoshima

et al., 1997b) and *hippocampus* (Villa *et al.*, 1995; Ishii *et al.*, 1998; Elgh *et al.*, 2002; Lee *et al.*, 2003). For very early AD, reductions in posterior cingulate tend to be greater than in parietotemporal and frontal association cortices (Minoshima *et al.*, 1997a). Functional imaging in AD increases diagnostic sensitivity at least compared with structural imaging, with blood flow and metabolism first reduced in posterior cingulate gyrus and precuneus, before advancing to medial temporal structures and parietotemporal association cortex (Zakzanis *et al.*, 2003).

Entorhinal cortex and hippocampal metabolic reductions have been successfully used as a classifier in the discrimination of cognitively normal controls from mild cognitive impairment (MCI; De Santi *et al.*, 2001) with a diagnostic accuracy of 81 per cent and from AD using the temporal neocortex with a diagnostic accuracy of 100 per cent (De Santi *et al.*, 2001).

Neocortical metabolic reductions for AD are widely reported (Kumar *et al.*, 1991; Smith *et al.*, 1992; De Santi *et al.*, 2001). In a prospective longitudinal analysis using the ratio of deoxyglucose uptake in association cortex over primary sensory-motor cortex for classification, initial metabolic impairment was significantly associated with subsequent clinical deterioration, thus predicting for patients with mild cognitive deficits the progression to AD (Herholz *et al.*, 1999).

In advanced AD, bilateral parietotemporal perfusion deficits are reported to be more frequent and severe (Nitrini *et al.*, 2000) with a reported odds ratio (OR) of 17.0 (95 per cent CI 3.1–94.2) for severe AD (MMSE <10) and an OR of 5.2 (95 per cent CI 1.1–24.4) for moderate AD (MMSE 0–17). Finally, in a study of 68 AD subjects, metabolism in the cerebellum of a severe AD group was found to be significantly reduced (Ishii *et al.*, 1997) compared with 13 age-matched controls, which is of relevance as cerebellar activity is often taken as a 'normal' reference region (see below).

9.4.2.1 PATHOLOGICALLY CONFIRMED STUDIES

A multicentre study of PET in dementia with diagnostic verification by 3-year clinical follow up (Silverman *et al.*, 2001) concluded that regional brain metabolism was a sensitive indicator of AD. In the same study, a pathologically confirmed diagnosis of AD was predicted by PET with a sensitivity of 94 per cent (91 out of 97 subjects) against a specificity of 73 per cent (30 out of 41 subjects) against other patients presenting with symptoms of dementia. An overall diagnostic accuracy of 89 per cent was achieved for a subset of 55 patients who presented at the time of PET with questionable or mild dementia.

A PET study in a group considered 'diagnostically challenging or difficult to characterize by clinical criteria' (Hoffman *et al.*, 2000) produced sensitivity and specificity values of PET against a histological diagnosis at autopsy of AD of 93 per cent and 63 per cent, respectively. For comparison, clinical diagnosis of probable AD had sensitivity and specificity values of 63 per cent and 100 per cent, respectively, concluding that the overall diagnostic accuracy of PET at 82 per cent was better than clinical diagnosis at 73 per cent.

Two comparable SPECT studies with pathological verification of AD reported sensitivities of 86 per cent and 63 per cent (43 dementia patients v 11 healthy elderly controls) against specificities of 73 per cent and 93 per cent (70 dementia patients v 85 healthy elderly controls), respectively (Bonte *et al.*, 1997; Jagust *et al.*, 2001).

9.4.3 Vascular dementia (VaD)

Typical findings in VD are multiple small areas of reduced perfusion and metabolism extending over cortical and sub-cortical structures and a high diagnostic accuracy has been reported for the discrimination of probable AD and VD using this characteristic metabolic pattern (Mielke and Heiss, 1998). In addition, frontal lobes including cingulate and superior frontal gyri have been reported to be more affected in VD than in AD (Nagata *et al.*, 2000; Lee *et al.*, 2001). On the other hand, temporoparietal brain regions have been said best to discriminate AD from VD with sensitivities reported as high as 90 per cent and 82 per cent against 80 per cent and 82 per cent specificity, respectively (Butler *et al.*, 1995; deFigueiredo *et al.*, 1995). SPECT has been reported to differentiate AD from multi-infarct dementia in a study with a 77 per cent correct classification rate, compared with structural MRI, which correctly classified only 50 per cent in the same subject group (Butler *et al.*, 1995).

9.4.4 Frontotemporal dementia (FTD)

Highly significant metabolic abnormalities have been reported for PET in frontotemporoparietal association cortex, limbic area, basal ganglia and thalamus in FTD compared with normal volunteers (Ishii *et al.*, 1998). In particular, bilateral frontal hypoperfusion is a strong predictor of FTD versus AD in SPECT (Pickut *et al.*, 1997), with sensitivity and specificity estimated at 88 per cent and 79 per cent, respectively (Sjogren *et al.*, 2000). Medial temporal lobe reduction has been suggested as a marker to separate AD from FTD (Sjogren *et al.*, 2000).

9.4.5 Dementia with Lewy bodies (DLB)

An autopsy-confirmed PET study of the differential diagnosis of DLB and AD subjects found occipital metabolic reductions as a potential ante-mortem marker to distinguish DLB from AD, with sensitivity and specificity values determined at 90 per cent and 80 per cent respectively (Minoshima *et al.*, 2001). SPECT studies have confirmed occipital reduction in perfusion as an indicator of DLB (Ishii *et al.*, 1999b; Lobotesis *et al.*, 2001). Medial temporal and cingulate reductions in metabolism have been found to be significantly more pronounced in AD compared to DLB (Imamura *et al.*, 1997), while the occipital deficit in DLB appears irrespective of clinical severity (Okamura *et al.*, 2001).

9.4.6 Depression

SPECT has been reported to be a useful tool for the differential diagnosis of AD and depression, with perfusion deficits in depression lying between those of controls and AD and a reported sensitivity of 52 per cent (against 94 per cent in controls) using parieto-occipital perfusion as a marker (Stoppe *et al.*, 1995).

9.4.7 SPECT v PET

A direct comparison (Herholz *et al.*, 2002b) of SPECT and PET produced an overall significant correlation of abnormal tracer uptake between PET and SPECT across the entire brain ($r = 0.43$) with better correspondence achieved in the temporoparietal and posterior cingulate association cortices. Using quantitative statistical parametric mapping (SPM), the same study reported that PET discriminated between healthy volunteers and AD with greater reliability than SPECT, since PET was less sensitive to threshold effects in SPM. Another study of PET and SPECT compared patients with probable AD and normal controls using temporoparietal reductions as diagnostic criterion and determined a sensitivity for PET of 100 per cent and SPECT of 90 per cent, with the presence of abnormalities in associative cortex outside temporoparietal areas being better evaluated with PET (Messa *et al.*, 1994).

9.5 METHODS OF IMAGE ASSESSMENT – PET AND SPECT

PET and SPECT images can be analysed qualitatively using visual inspection methods or quantitatively using a variety of semiautomated methods. The variability of visual interpretations has been reported as minimal for PET, with a good intraobserver ($\kappa = 0.56$, $P < 0.0005$) and interobserver ($\kappa = 0.51$, $P < 0.0005$) agreement (Hoffman *et al.*, 1996). Good agreement has also been found for qualitative inspection of SPECT (Hellman *et al.*, 1994; Pasquier *et al.*, 1997). Attempts have been made to develop classification criteria according to perfusion deficit patterns on visual assessment (Holman *et al.*, 1992; Sloan *et al.*, 1995).

For quantitative region of interest (ROI) analysis, the brain is divided into areas often approximating underlying structural anatomy. Mean values of functional activity are then averaged within these regions and compared with a dataset of controls (Defebvre *et al.*, 1999). More objective methods have been developed recently, such as statistical parametric mapping (Friston *et al.*, 1995; Soonawala *et al.*, 2002), discriminant function analysis (Mahony *et al.*, 1994; O'Brien *et al.*, 2001; Volkow *et al.*, 2002) and neural network analysis (Chan *et al.*, 1994; Dawson *et al.*, 1994; Kippenhan *et al.*, 1994; deFigueiredo *et al.*, 1995; Page *et al.*, 1996). Three-dimensional stereotactic surface projection images have been found to improve the accuracy of visually detecting AD with PET (Burdette *et al.*, 1996). Finally,

a combination of structural MRI or CT and functional imaging has been found to improve the accuracy of diagnostic classification (Mattman *et al.*, 1997; Scheltens *et al.*, 1997; O'Brien *et al.*, 2001; Callen *et al.*, 2002; Varma *et al.*, 2002).

9.6 IMAGING NEUROTRANSMITTER SYSTEMS

9.6.1 SPECT

Although FP-CIT is now licensed in the UK for the investigation of parkinsonism, its use in DLB is still experimental (Walker *et al.*, 2002). The same applies to all other receptor ligands – be it because of limits in the validation and validity of the imaging protocol or because of doubts about the involvement of the receptor concerned in the pathophysiology of the respective dementia. However, there are now a number of SPECT ligands that can be used as probes into specific transmitter system deficits in dementia: Iodo-QNB and 5-IA-85380 for muscarinic and nicotinic receptors, respectively; FP-CIT and iodobenzamide for dopamine transporter and D2-receptor, respectively; iomazenil for the benzodiazepine/ GABA receptor complex and ^{123}I -MK-801 for the NMDA receptor (Pimlott *et al.*, 2003).

9.6.2 PET

The greater flexibility of PET-ligand creation has made it possible to generate all the above and additional receptor ligands, e.g. for 5HT-2A receptors (altanserin; Meltzer *et al.*, 1999), acetylcholinesterase activity (MP. 4A; Iyo *et al.*, 1997) and, of particular interest in AD, ligands for neurofibrillary tangles and $\text{A}\beta$ -plaques (FDDNP; Shoghi-Jadid *et al.*, 2002). The latter are especially exciting, as the focus of dementia treatment may be shifting away from the selective enhancement of transmitter systems thought to be involved in the Alzheimer pathology, towards the biochemical entities, presumably more at the origin of the pathophysiological cascade leading to cell death and brain atrophy. Such markers could be used both for the diagnosis and 'purification' of patient samples for treatment research, as well as the follow-through of patients in treatment, using ligand binding as a proxy measure of treatment success. On a more fundamental level, if treatment should change ligand binding, the association of changes in ligand binding and clinical improvement could provide causal *in vivo* evidence for the active principle of the treatment concerned.

9.7 BRAIN-BEHAVIOUR CORRELATES IN DEMENTIA

Information from functional imaging modes, such as PET, SPECT and fMRI can be combined with neuropsychological information and be used to investigate the neural correlates

of cognitive and behavioural processes. The use of imaging techniques has led to improvements in understanding of the dementias and their longitudinal course and may lead to further developments for example in evaluating potential treatments.

PET was first used in 1981 to show a global reduction in cerebral blood flow (CBF) in patients with degenerative dementia, which correlated with clinical measures of disease severity (Frackowiak *et al.*, 1981). Since then there have been many studies demonstrating the typical reductions in metabolism and blood flow. These are most consistent and severe in the temporal and parietal association cortices. As the disease advances, the occipital and frontal association cortices are progressively affected (Alexander *et al.*, 2002b). On neuropsychological examination, the typical pattern of AD begins with memory impairment followed by semantic and executive deficits, then deficits in praxis, behavioural problems and so on. These neuropsychological deficits have been correlated with regional metabolic deficits, though as with all 'lesion paradigms' the correspondence between specific cognitive functions and certain brain regions can only be an approximation since it is likely that multiple brain areas are involved in even simple functions. Despite these limitations, functional imaging has been able to add to the understanding of brain-behaviour correlates in dementia.

Neuropsychological testing has shown that the first deficit in AD is episodic memory loss. The first reduction in rCBF has been shown to be in the area of the posterior cingulate gyrus and precuneus which is known to be important in memory (Desgranges *et al.*, 1998). Supporting this correlation, a PET study revealed activation of the retrosplenial area of the cingulate cortex during an episodic memory encoding task, which is also backed by the clinical picture subsequent to other lesions of the retrosplenial cingulate cortex, such as tumours, in this area (Fletcher *et al.*, 1995).

The next area of functioning to show impairment is semantic memory and it is thought that this occurs when neurodegenerative changes extend to the adjacent temporal neocortex (Jobst *et al.*, 1992). It is possible that initial involvement of the transentorhinal region, as indicated by the first histological changes, then leads to disconnection of the hippocampus followed by the limbic structures and isocortical association areas (Hodges and Patterson, 1995). This disconnection hypothesis can also help to account for the variety and progression of symptoms in AD, as different areas become disconnected.

Short-term memory generally has been shown consistently to correlate with metabolism in the temporoparietal association cortex, with the left hemisphere for verbal and right for spatial memory (Trollor and Valenzuela, 2001). Asymmetries in hemisphere metabolism correlate with neuropsychological 'asymmetries' defined by the traditional verbal/non-verbal dichotomy (Haxby *et al.*, 1990). If there is 'asymmetrical' involvement, the left hemisphere is often the more affected side, although reasons for this are unknown. Bilateral parietotemporal hypoperfusion appears to be more frequent in

male patients, those with early onset and patients with severe AD (Nitrini *et al.*, 2000).

Following memory, attention is the next domain to be affected in AD. The anterior cingulate is thought to be involved in attentional function and a particular correlation has been shown between divided attention and anterior cingulate activity (Perry *et al.*, 2000; Matsuda, 2001). This is consistent with the clinical picture – it is thought that impairment of divided attention is responsible for problems in activities of daily living, which occur in AD at a relatively early stage. With regard to psychiatric phenomena, functional imaging has shown that psychotic symptoms in AD correlate with reduced frontal and temporal metabolism (Mega *et al.*, 2000); negative symptoms have been linked to decreased perfusion in the frontal cortex (Galynker *et al.*, 2000), and apathy has been associated with significantly decreased blood flow in anterior temporal, orbitofrontal, anterior cingulate and dorsolateral prefrontal regions (Benoit *et al.*, 1999; Cummings, 2000). With regard to depressive symptoms in AD, there is some evidence of correlation with reduced temporal lobe perfusion (Ebmeier *et al.*, 1998).

9.7.1 Cognitive activation studies

More recently, functional activation studies have demonstrated that in mild to moderately severe AD, a cognitive or sensory challenge task can cause nearly normal levels of activation in areas that are hypometabolic or hypoperfused at rest. However, with increased disease severity the degree of activation declines (Devous, 2002). Furthermore, increased activation may be required in AD patients who perform a task, or indeed activation of additional brain areas which are not activated by healthy controls (Cardebat *et al.*, 1998). It has been hypothesized that functional plasticity may be responsible for such a recruitment of new brain regions in patients. An fMRI activation study compared patients with early AD and FTD during a working memory task in order to try to differentiate between the groups. During performance of the task, there was reduced activation in the frontal, temporal and cingulate cortices in the FTD group compared with the AD group. There was, however, the opposite effect in the cerebellum, a region less consistently activated in functional working memory imaging studies. This cerebellar activation in FTD may reflect successful working memory specific compensation, since test performance of FTD patients were not different from the AD group (Rombouts *et al.*, 2003). Activation studies may, therefore, be useful in helping to reveal subtle changes in brain functioning in the early stages of dementia, as well as improving our understanding of the neural circuits involved in the tasks.

9.7.2 Longitudinal studies

A number of functional imaging studies have investigated cognitive functioning over time. These have shown that

patients with more severe perfusion or metabolic deficits in the temporoparietal cortex at initial evaluation show a more rapid cognitive decline over time (Devous, 2002). In particular a strong correlation has been found between reduction in right parietal rCBF and patient survival (Jagust, 1994). With regard to mild cognitive impairment, significant bilateral rCBF decreases are seen in the posterior cingulate, parietal and precuneus regions of those who later meet criteria for AD. Subsequently, at the stage of a clinical diagnosis of AD, additional rCBF abnormalities are seen in the hippocampus and parahippocampus (Minoshima *et al.*, 1997b; Kogure *et al.*, 2000).

For individual patients, the particular neuropsychological pattern that develops during the progression of AD can be predicted by early metabolic asymmetries in the association cortices (Haxby *et al.*, 1990). This would indicate that there is a functional reserve in the brain, so that neuropsychological dysfunction is likely to follow rather than co-occur with rCBF changes. Similarly, greater premorbid ability is hypothesized to be linked with a cognitive reserve that can reduce the clinical expression of AD. Premorbid IQ and word reading ability have been shown to be inversely correlated with metabolism in AD (Mentis, 2000).

More recently, longitudinal functional imaging studies have been proposed to assess the response to treatments for AD (Alexander *et al.*, 2002b). Such activation studies are of particular interest, as they can help in identifying potentially reversible tissue damage.

9.8 CONCLUSION

One of the authors' central tenets is that the 'gold standard' of all imaging work has to be the patient's clinical state. By implication, 'predictive validity' is the concept of greatest interest: imaging results should *predict* a patient's prognosis and in particular whether they are going to respond to a treatment. This does not contradict the basic notion that diagnosis has to be at the beginning of effective treatment, but it reflects the observation that brain pathological changes are not always specific to a particular illness; that there is a substantial overlap of pathological changes even with health, and that pathological illness 'entities' are likely to be caused by a varying admixture of genotype–environment interactions: AD is really a collective term for a number of conditions resulting in dementia, plaques and tangles. Histological diagnoses merely reflect recognizable final common pathways for a collection of pathological conditions and therefore do not necessarily predict treatment response or prognosis. In evaluating the usefulness of imaging methods, direct comparisons should be made with clinical outcome measures – histopathological follow-through studies are of interest, but will always be confounded by selection bias, intervening illness and other artefacts. The validation of neuroimaging in the dementias is clearly still in its infancy and clinically relevant research is few and far between (Dougall

et al., 2003). One of the binds we encounter is that useful data on sensitivity and specificity, and more particularly positive and negative predictive value, require representative clinical cohorts. If the introduction of a new imaging method is to be evidence based in a national health service and good evidence is only available after the establishment of a service, the creation of pilot services is necessary that are not technology driven, i.e. that are centred in a normal clinical set-up that will generate results transferable to the service in general. The theoretical appeal of imaging methods, after all we believe that the dementias are brain diseases, holds out the promise of visualizing brain changes that are relevant to illness outcome and treatment response.

The neurophysiology of dementia

MICHAEL PHILPOT

10.1 The electroencephalogram	104	10.5 Other technologies	109
10.2 Sleep EEG	107	10.6 Summary	110
10.3 Evoked potentials	107	References	110
10.4 Event-related potentials	108		

During the last 80 years a number of advances have been made in the development of techniques for demonstrating the electrical activity of the brain. Conventional electroencephalography (EEG) was effectively 'founded' in the 1920s when it became possible to record such activity from the scalp. The techniques of evoked potentials were first developed in the 1950s and 'event-related' potentials became available in the 1960s. Quantitative analysis of the electroencephalogram (qEEG) has been possible since the 1970s and recording of the magnetic fields induced by electrical brain activity since the 1980s.

This chapter will deal with clinical and applied research in neurophysiology with regard to ageing and dementia. Technical details are beyond the scope of this review and the interested reader is referred a general text such as Osselton *et al.* (2002).

10.1 THE ELECTROENCEPHALOGRAM

10.1.1 EEG in healthy older people

The prevalence of EEG abnormalities increases with age with an emphasis in the temporal regions (Busse and Obrist, 1965). Using traditional visual methods, there appears to be a progressive slowing of the mean frequency and a reduction in α activity. There is an increase in the frequency and amount of β activity as well as an increase in θ and δ activity (Torres *et al.*, 1983).

Studies employing qEEG have also shown some consistency, in spite of the large number of variables available for measurement. An increase in β activity combined with a reduction in θ and δ power with age has been demonstrated (Polich, 1997; Dustman *et al.*, 1999). Recently, more complex methods

of analysis have examined aspects of the organization of brain activity. These include the following changes with age: a reduction in interhemispheric coherence at rest but an increase in coherence to photic stimulation (Kikuchi *et al.*, 2000), an increase in the complexity of spatial distribution of EEG activity (Pierce *et al.*, 2003), and an increase in slow wave variability (Dustman *et al.*, 1999).

Most studies have been cross-sectional, comparing results in different age groups, but the few longitudinal studies carried out have produced conflicting results. Coben *et al.* (1985) found no change in α or θ frequency over 3 years (or the ratio of δ to θ), although there were significant reductions in β and δ frequency. No changes in any power band were found by Förstl *et al.* (1996) over a 4-year period. Elmståhl and Rosén (1997) performed EEGs 5 years apart in a group of initially healthy elderly women. Those who remained cognitively unimpaired showed an increase in absolute α and θ power, together with a reduction in relative posterior β power.

10.1.2 Mild cognitive impairment (MCI)

Williamson *et al.* (1990) found that healthy elderly subjects who had MCI also had markedly reduced β power in all brain regions. Stevens and Kircher (1998) used a form of temporospatial analysis and found that the duration of stable voltage patterns (known as EEG microstates) was reduced in people with MCI, as was EEG reactivity to eye opening. Grunwald *et al.* (2001) reported that θ activity increased as a function of reducing hippocampal volume. Jelic *et al.* (2000) found that MCI patients who later developed obvious dementia had abnormalities of EEG coherence, α and θ power when compared with MCI patients who remained stable.

10.1.3 Alzheimer's disease (AD)

10.1.3.1 FEATURES AND ASSOCIATIONS OF EEG

Berger (1932) first described the general slowing of the EEG in a patient with dementia. The changes in AD can be summarized as follows: a slowing of the α frequency, amplitude and relative power with a shift towards the anterior frontal regions; a decrease in relative and absolute β power; and, an increasing predominance of diffuse and symmetrical θ and δ waves in posterior regions, reflected by an increase in δ and θ power (Knott *et al.*, 2001). Other changes include a reduction in general reactivity (Visser *et al.*, 1985), and reduced EEG coherence (Stevens *et al.*, 2001; Hogan *et al.*, 2003). These quantitative changes are associated with degree of cognitive impairment (Grunwald *et al.*, 2001; Stam *et al.*, 2003), reduced cerebral blood flow (Ihl *et al.*, 1989a; Rodriguez *et al.*, 1999b; Claus *et al.*, 2000; Mattia *et al.*, 2003) and hypometabolism (Dierks *et al.*, 2000). Abnormalities may also be associated with early onset (Pucci *et al.*, 1999) and psychotic symptoms (Edwards-Lee *et al.*, 2000). Riekkinen *et al.* (1991) reported that reduction in acetylcholinesterase activity in the cerebrospinal fluid (CSF) of AD patients was associated with increased δ power. The same group later reported that patients with the most marked slowing of the EEG had the lowest choline acetyltransferase levels in the frontal cortex post mortem (Soininen *et al.*, 1992). Jelic *et al.* (1998a) found a strong association between CSF τ protein and EEG activity.

Genetic risk factors may also influence EEG activity. Jelic *et al.* (1997) compared EEG coherence in AD patients homozygous for the $\epsilon 4$ allele of apolipoprotein E (ApoE) with patients carrying either one or no $\epsilon 4$ allele. Coherence was reduced in the temporoparietal regions of the homozygotes. Lehtovirta *et al.* (2000) reported pronounced slow-wave activity in AD patients carrying the $\sigma 4$ allele but this did not carry any prognostic significance.

Epileptic seizures and related EEG abnormalities occur in 10–20 per cent of AD patients, usually >6 years into the course of the disease. They are more likely in early onset dementia and may be mistaken for symptoms of the dementia itself (Mendez and Lim, 2003).

10.1.3.2 EEG AND CHOLINERGIC DRUGS

A number of studies have used qEEG as a marker to assess the effects of cholinergic drugs. Modest reductions in δ and θ power and an increase in fast activity (i.e. a shift to more normal EEG) have been reported following the long-term use of tacrine (Riekkinen *et al.*, 1991; Jelic *et al.*, 1998b) and donepezil (Kogan *et al.*, 2001; Reeves *et al.*, 2002; Rodriguez *et al.*, 2002). Changes in the mean frequency of each waveband mirror brain perfusion in the parietal lobe (Rodriguez *et al.*, 2004). Acute administration of nicotine (Knott *et al.*, 2000a) and rivastigmine (Adler and Brassens, 2001) have broadly the same effect. EEG may also be used to identify possible responders to cholinesterase inhibitors after a single drug dose (Knott *et al.*, 2000b; Almkvist *et al.*, 2001). Similarly, a decrease in

θ power after a week of rivastigmine treatment identified those who responded in the longer term (Adler *et al.*, 2004).

10.1.3.3 EEG CHANGES WITH DISEASE PROGRESSION

Patients with EEG abnormalities on visual inspection at the time of diagnosis may have a shorter survival than those whose EEGs are normal when diagnosed (Kaszniak *et al.*, 1978; Soininen *et al.*, 1991). The presence of qEEG abnormalities at diagnosis also has been associated with a more rapid progression of the disorder (Lopez *et al.*, 1997; Nobili *et al.*, 1999) and earlier death (Claus *et al.*, 1998). As the disease progresses there is a gradual reduction in α power and an increase in θ power, or reduction in the α/θ ratio (Coben *et al.*, 1985; Soininen *et al.*, 1991; Förstl *et al.*, 1996; Rodriguez *et al.*, 1999a). Fast activity shifts from a predominance in posterior regions to the frontal region (Ihl *et al.*, 1989b). Mean EEG frequency, θ and δ power correlate with global dementia severity (Penttilä *et al.*, 1985) and more specifically parietal dysfunction (Edman *et al.*, 1998; Matousek *et al.*, 2001). The precise relationship between qEEG markers and disease progression is inconsistent and Förstl *et al.* (1996) have pointed out that EEG measures are so variable that they are less useful in predicting the course of AD than the actual cognitive performance of the patient.

10.1.3.4 DIAGNOSTIC USE OF EEG IN AD

The EEG may be 'visually' normal in the early stages of AD and Robinson *et al.* (1994) reported that a 'normal' EEG ruled out the diagnosis in 83 per cent of cases. Claus *et al.* (1999) used a method of scoring the visual appearance of the EEG and at the optimal cut-point this had positive predictive value of 88 per cent, although it had a relatively modest negative predictive value. Many studies have attempted to use qEEG to discriminate between AD patients and healthy elderly subjects but there has been little overall agreement about the best variables to use. Jonkman (1997) reviewed studies up to 1994 and found a reported accuracy of diagnosis ranging between 54 and 100 per cent. However, sensitivity was low when qEEG was being used as a screening tool in populations with a low prevalence of AD. In general, the diagnostic performance of these measures is reduced in early or mild cases. Table 10.1 shows a selection of studies from 1996 indicating the variability of diagnostic usefulness and discriminator variables.

Nott and Fleminger (1975) found that visual inspection of the EEG did not reliably differentiate between dementia and depression, although this view has been contested (Ron *et al.*, 1979). Non-specific abnormalities of the EEG may be found in up to 40 per cent of patients with affective disorders (Wright *et al.*, 1986). Adler *et al.* (1999) found increased δ and θ power in depressed patients with cognitive impairment when compared with those without, and Dahabra *et al.* (1998) demonstrated that these abnormalities persisted after recovery.

Table 10.1 Performance of quantitative EEG as a diagnostic test (studies from 1996): patients with Alzheimer's disease (AD) versus healthy older people

Study	Year of publication	No. of AD patients (mean age in years)	No. of controls	Positive predictive value (%)	Negative predictive value (%)	Optimal discriminating variables
Jelic <i>et al.</i>	1996	18 (61)	16	100	80	Relative $\alpha + \theta$ power + temporoparietal coherence
Wada <i>et al.</i>	1997	9 (57)	9	80	90	Occipital α power to 10 Hz photic stimulation
Strijers <i>et al.</i>	1997	9 (81)	49	50	93	Absolute θ power
Besthorn <i>et al.</i>	1997	50 (69)	42	95	83	Age + 7 groups of variables (including coherence and α blocking)
Rodriguez <i>et al.</i>	1998	42 (72)	18	94	57	Right temporoparietal relative $\alpha + \beta + \theta$ power
Huang <i>et al.</i>	2000	38 (63)	24	89	80	Relative θ power
Ihl <i>et al.</i>	2000	36 (69)	44	89	93	Topography of β and δ activity + δ power

10.1.4 Vascular dementias (VaD)

Mild cerebrovascular disease is associated with appearance of slow and sharp waves in the temporal region (Inui *et al.*, 2001). The EEG of multi-infarct dementia (MID) is similar to that of AD, but focal and paroxysmal abnormalities are more prominent and there is greater asymmetry of activity (Sloan and Fenton, 1992; d'Onofrio *et al.*, 1996). Slow wave activity correlates with cerebral metabolism (Szelies *et al.*, 1999). Despite this the EEG is likely to be normal, particularly in the early stages (Sloan *et al.*, 1995).

Leuchter *et al.* (1994) found that patients with periventricular white matter hyperintensities had lower EEG coherence in the pre- and post-Rolandic areas. This effect was present in areas connected by fibres crossing the periventricular region, but not in those connected by long corticocortical tracts suggesting that vascular lesions might bring about different types of neurophysiological disconnection depending on their distribution. Indeed, studies of EEG coherence suggest that this may be a useful way of distinguishing between MID and AD (Leuchter *et al.*, 1992).

10.1.5 Parkinson's disease (PD) and dementia with Lewy bodies (DLB)

In cognitively intact PD patients, the EEG is essentially normal, but abnormalities such as slowing of the occipital α frequency and an increase in diffuse fast activity age are present in approximately 30 per cent of patients (Neufeldt *et al.*, 1994). It is now thought that dementia in PD is part of spectrum that also includes DLB (McKeith *et al.*, 2004). The appearance of transient slow waves in the temporal region (Briel *et al.*, 1999) or bilateral frontal intermittent rhythmic δ activity (FIRDA) (Calzetti *et al.*, 2002) may be useful diagnostic markers, although this has been disputed by others (Barber *et al.*, 2000; Londos *et al.*, 2003). Walker *et al.* (2000b) reported the successful use of a battery of attentional and cognitive measures including mean EEG frequency to distinguish between DLB,

AD and VaD. A greater variation of slow wave activity was characteristic of DLB and this correlated with fluctuations in cognition (Walker *et al.*, 2000a).

10.1.6 Creutzfeldt–Jakob disease (CJD)

The characteristic EEG changes of biphasic or triphasic periodic sharp wave complexes (PSWC) occurring at 1–2 Hz appear within the first 3 months of the condition in nearly 90 per cent of cases (Levy *et al.*, 1986). However, runs of frontal δ activity often precede the onset of PSWC (Hansen *et al.*, 1998) and PSWC tend to disappear in the terminal stages of the disease in many cases. The timing of the EEG can therefore be crucial and a study involving serial EEG recordings suggested that PSWC appear in conjunction with the motor symptoms of CJD (Hansen *et al.*, 1998). A large international study has reported that PSWC were present on EEG in 66 per cent of pathologically confirmed cases. The positive predictive value of this marker was 93 per cent (Zerr *et al.*, 2000).

10.1.7 Other dementias

The EEG in Pick's disease is usually normal until the dementia is fairly well established (Gordon and Sim, 1967). Likewise, no specific abnormalities are associated with frontotemporal dementia (FTD). Indeed, a 'normal' EEG is one of the core diagnostic features (Lund and Manchester Groups, 1994). However, qEEG may be useful in distinguishing between FTD and AD (Lindau *et al.*, 2003). In Huntington's disease there is a general poverty of rhythmic activity but an irregular low-voltage slow waveform emerges, which correlates with the severity of cognitive impairment (Bylisma *et al.*, 1994) and the degree of cortical atrophy found at autopsy (Scott *et al.*, 1972).

10.1.8 Delirium

It is sometimes necessary to distinguish between 'organic' and non-organic causes of acute onset mental dysfunction,

the latter being associated with severe depression, mania or acute psychosis. An abnormal EEG generally indicates an organic cause, but the abnormalities identifiable by visual inspection can depend on the underlying cause of the delirium. Generalized slowing may indicate a diffuse encephalopathy, excessive fast activity delirium tremens or a tranquillizer overdose (Binnie and Prior, 1994). Koponen *et al.* (1989) compared elderly delirious patients with healthy subjects and found that the former showed reductions in α power. The mean EEG frequency correlated with the severity of cognitive impairment. The presence of EEG changes during delirium may predict subsequent deterioration in cognitive state (Katz *et al.*, 2001). θ power may be the most sensitive discriminator between delirious and non-delirious patients (Jacobson *et al.*, 1993).

10.2 SLEEP EEG

There is a gradual reduction in total night-time sleep throughout adult life, although much of this occurs before the age of 30. The duration of slow wave or 'deep' sleep (stages 3 and 4) falls and there is an increase in the number of periods of wakefulness (Prinz *et al.*, 1990). The latter occur more frequently in non-REM sleep, particularly stages 1 and 2 (Boselli *et al.*, 1998). There is also a reduction in both amplitude and quantity of δ waves even in healthy adults not troubled by insomnia, but other waveforms and REM sleep are less affected. Sleep spindles and K-complexes fall in number with age (Crowley *et al.*, 2002) and in addition to the relative lightening of night-time sleep there is an increase in day-time napping (Prinz *et al.*, 1990). Overall the changes suggest an increase in cortical activation during sleep (Carrier *et al.*, 2001).

The changes associated with ageing are more pronounced in dementia. There is a reduction in the period spent in deep sleep (stage 4 is often absent), very little REM sleep and frequent awakenings. Sleep spindles and K-complexes are poorly formed and often are absent (Prinz *et al.*, 1982). Montplaisir *et al.* (1998) suggested that the degree of REM sleep EEG slowing mirrored the topographical pattern of cortical abnormalities found in AD. Grace *et al.* (2000) found that sleep disturbances were more severe in DLB than in AD and that treatment with rivastigmine helped normalize sleep in some patients. Indeed, more severe behavioural or motor disturbance during REM sleep may be particularly associated with DLB (Boeve *et al.*, 1998), although disordered sleep is also common in Huntington's disease (Wiegand *et al.*, 1991).

The slowing of the mean frequency seen in the conventional EEG is more prominent in REM sleep and has been used to discriminate between patients with mild AD and healthy subjects (Prinz *et al.*, 1992; Montplaisir *et al.*, 1995). These changes contrast with those found in elderly depressed patients to the extent that measures, such as REM latency or density have been used to discriminate between the two groups (Reynolds *et al.*, 1988; Moe *et al.*, 1993; Dykieriek *et al.*, 1998). Reynolds

et al. (1988) did include a comparison of patients with depressive 'pseudodementia' and those with progressive dementia complicated by depressive features. The combination of four sleep EEG measures enabled correct classification of 64 per cent of patients. It is doubtful, however, whether the sleep EEG has much to offer in clinical practice. A diagnosis of dementia would not necessarily rule out a good response to antidepressants in an individual patient.

10.3 EVOKED POTENTIALS

An evoked potential (EP) is the sequence of EEG changes following a sensory stimulus. If the stimulus is repeated, the specific EEG pattern related to it can be discerned by 'averaging' the responses and removing the effects of spontaneous background activity. EPs are made up of a number of wave forms or components representing electrical activity at different levels in the central nervous system usually occurring within 300 ms of the stimulus. They are numbered by convention or by reference to their latency. EPs are essentially passive responses, requiring no special effort on the part of the subject. This distinguishes them from 'event-related' potentials, discussed below. The topographical distribution of the responses can be 'mapped'.

10.3.1 Visual evoked potentials (VEPs)

Visual potentials are commonly evoked either by flashes of light (FVEP) or pattern reversal, as in checkerboard shifts or multifocal stimulation (PRVEP). These techniques are used to assess the integrity of the optic tract (Aminoff and Goodin, 1994). Potential latency and amplitude may be altered by a great number of factors including gender, head size, systemic disease, visual acuity, accommodation and attention.

10.3.1.1 VEPS IN AGEING AND DEMENTIA

Age is an important factor accounting for the variability of VEPs (Pitt and Daldry, 1988). The change is likely to be due to physical attributes within the eye (Crow *et al.*, 2003). There is an exaggerated or augmented response to increasing the intensity of the stimulus reflecting a reduction in cortical inhibition (Dustman *et al.*, 1981).

A number of studies report the increased latency of components of FVEPs in AD, particularly the P2 wave, which arises in the visual association cortex (Table 10.2). The latency delay of the P2 correlates with dementia severity (Coburn *et al.*, 2003). The early positive peak of the PRVEP (the P1 or P100), which arises in the visual cortex, is usually within normal limits, although later components may also be delayed (Visser *et al.*, 1985; Philpot *et al.*, 1990). A significant P2–P100 latency difference was initially thought to be a specific marker for AD (Harding *et al.*, 1985) but later was shown to be non-specific (Wright and Furlong, 1988; Sloan and Fenton, 1992). The

Table 10.2 Abnormalities reported in visual evoked responses: patients with Alzheimer's disease (AD) versus healthy older people

Study	Year of publication	No. of AD patients (mean age in years)	No. of controls	PR P100 latency delay	Flash P2 latency delay	P2–P100 difference
Harding <i>et al.</i>	1985	20 (64)	20	X	✓	✓
Visser <i>et al.</i>	1985	39 (76)	48	✓	n/d	n/d
Wright <i>et al.</i>	1986	41 (64)	30	X	✓	✓
Pollock <i>et al.</i>	1989	16 (67)	16	✓	X	n/d
Philpot <i>et al.</i>	1990	25 (75)	13	X	✓	✓
Coburn <i>et al.</i>	1991	23 (75)	12	X	✓	✓
Sloan and Fenton	1992	40 (74)	30	X	✓	✓
Swanwick <i>et al.</i>	1996b	16 (71)	15	n/d	✓	n/d
Coburn <i>et al.</i>	2003	45 (73)	60	X	✓	✓

n/d, not done; X, no difference between AD patients and controls; ✓, significant difference between AD patients and controls

diagnostic accuracy of the P2–P100 measure in studies of AD patients compared with healthy subjects is reported as between 60 and 80 per cent though the P2 latency may be a more effective diagnostic measure on its own (Coburn *et al.*, 2003).

Longitudinal studies of VEPs in AD fail to demonstrate progressive delay of components (Sloan and Fenton, 1992; Swanwick *et al.*, 1996a). Consequently, the clinical use VEPs may be restricted to early diagnosis although Moore *et al.* (1996) demonstrated that subjects with mild cognitive impairment also had delayed flash P2 latency. The long-held view that the peripheral visual pathway is unaffected in AD has been challenged. Using electroretinography, an EP technique that records electrical activity in the ganglion cells of the retina, a significant reduction in response amplitude was found in AD patients (Trick *et al.*, 1989; Katz *et al.*, 1989).

PRVEPs are delayed in PD (Nightingale *et al.*, 1986; Calzetti *et al.*, 1990), especially in patients with PD and dementia (Okuda *et al.*, 1996). The PR P100 delay in PD can be reversed by dopaminergic drugs and induced or worsened by anti-psychotic drugs (Onofrj *et al.*, 1986).

10.3.2 Auditory evoked potentials (AEPs)

Repeated clicks or tones are used as the stimulus in AEPs and the major waveforms are generated in the auditory brain stem and the auditory association areas. AEPs are also used in the assessment of demyelinating diseases, acoustic neuroma and coma. Transmission delays are frequently caused by ageing changes in the peripheral auditory apparatus or the brain stem (Amenedo and Diaz, 1998). Delays in major peaks have been reported in dementia (Hendrickson *et al.*, 1979), although the variability of later peaks may be so great that significant delays are not found (Knott *et al.*, 1999). Electrodes may be placed so as to record activity in the brain stem. Green *et al.* (1997) found that the P1 component of this response was missing in about half AD patients tested. These patients also had a delay in the contralateral blink reflex response suggesting that there was a dysfunction of the reticular formation. Tachibana *et al.* (1989a) found increased interpeak latencies in both AD and MID and significant delays were also found in patients with Parkinson's disease and dementia (Tachibana *et al.*, 1989b).

Similar abnormalities have been found in patients with CJD (Pollak *et al.*, 1996) and Huntington's disease (Uc *et al.*, 2003).

10.3.3 Somatosensory evoked potentials (SSEPs)

SSEPs are used in the functional assessment of spinal cord lesions as well as the detection of subclinical lesions in multiple sclerosis. Levy *et al.* (1971) employed ulnar nerve stimulation and showed delayed N35 (or N2) in patients with dementia as compared with those with depression. Amplitudes were also reduced. Huisman *et al.* (1985) confirmed the delay of all peaks after P25 using the more frequently employed median nerve stimulation. Kato *et al.* (1990) reported that SSEP peak latency correlated with the degree of white matter low attenuation in MID, and Okuda *et al.* (1996) found delayed SSEPs in patients with Binswanger's disease but not with PD. Shiga *et al.* (2001) found a reduction in amplitude of N20 in patients with CJD.

10.4 EVENT-RELATED POTENTIALS

Event-related potentials (ERPs) require some 'active' cognitive participation from the subject and therefore demonstrate the integrity of information processing pathways. The most commonly investigated waveform component is the positive peak occurring at around 300 ms after the stimulus or task, the P300 or P3. The subject has to differentiate between two stimuli; for example a frequently presented low tone and an infrequently presented high tone. This is known as the 'oddball' paradigm. The order of stimuli is semirandom so as to increase the unpredictability of the high or 'target' tone. To ensure attention, subjects usually have to register their awareness of the target by pressing a button. Reaction time can thus be measured.

The requirement that the task has to be attended to can be a problem in older, cognitively impaired or unmotivated individuals. Mismatch negativity (MMN) forms part of the negative N2 peak arising at around 200 ms after stimulus offset and is elicited whether or not the subject makes a discriminative response. The 'mismatch' in question occurs between the sensory memory trace of the frequent stimulus and the target.

10.4.1 Auditory ERPs

In cross-sectional studies of different age groups P3 latency increases with age and amplitude reduces (Ford *et al.*, 1997; Anderer *et al.*, 2003). The effect on latency may be more pronounced in men (Hirayasu *et al.*, 2000). The distribution of the reduction has been reported as maximal in the temporoparietal region (Frodl *et al.*, 2000) and the frontal region (Anderer *et al.*, 2003). However, latency, amplitude and distribution all are affected by the nature of task involved (Fein and Turetsky, 1989; Fjell and Walhovd, 2001), the type of auditory stimulus employed and whether effort is required in processing (Squires and Ollo, 1999; Federmeier *et al.*, 2002). MMN amplitudes are reduced in older adults (Kazmerski *et al.*, 1997; Bertoli *et al.*, 2002). In longitudinal studies, P3 latency and amplitude are relatively consistent over periods up to 3 years (Sandman and Patterson, 2000; Walhovd and Fjell, 2002).

Many studies have reported the P3 latency delay and reduced amplitude in AD patients (Goodin, 1990; Williams *et al.*, 1991; Swanwick *et al.*, 1996b; Ford *et al.*, 1997) but others have failed to do so (St. Clair *et al.*, 1985; Kraiuhin *et al.*, 1990; Ruessman *et al.*, 1990). MMN amplitudes are smaller in patients with mild AD than in healthy older people suggesting a degraded sensory memory trace in the early stages of the disease (Kazmerski *et al.*, 1997). P3 abnormalities correlate with the degree of cognitive impairment (Blackwood *et al.*, 1987) and worsen along with intellectual deterioration (St. Clair *et al.*, 1988; Ball *et al.*, 1989; Swanwick *et al.*, 1997). Treatment with cholinesterase inhibitors reduced P3 latency but not amplitude in two recent open studies (Katada *et al.*, 2003; Werber *et al.*, 2003).

Goodin (1990) reviewed 12 studies published up until 1988 and found that the average sensitivity of the P3 latency as a marker of dementia was just 51 per cent, ranging from 7 to 83 per cent. Results of more recent studies, which have included comparisons with depressed patients (Kraiuhin *et al.*, 1990; Polich *et al.*, 1990; Attias *et al.*, 1995; Swanwick *et al.*, 1996b) report sensitivities ranging from 82 to 100 per cent but the positive predictive value of an abnormal result is still relatively modest. Pfefferbaum *et al.* (1990) have cast doubt on the clinical utility of AERPs given the wide range of sensitivity and the fact that abnormalities of latency and amplitude occur in many other neurological and psychiatric disorders, such as PD (Tanaka *et al.*, 2000; Wang *et al.*, 2002). Filipovic *et al.* (1990) were unable to distinguish between patients with AD, Huntington's chorea and PD with or without dementia using AERPs. Patients in this study had been carefully matched for dementia severity and a delayed P3 occurred in two-thirds irrespective of diagnosis. Similarly, the utility of the P3 in distinguishing between MID and AD is contested (Neshige *et al.*, 1988; Yamaguchi *et al.*, 2000).

10.4.2 Visual ERPs

The 'oddball' paradigm can be adapted to the visual modality. Here, a frequently presented pattern, letter or word is displayed

with an infrequently presented one, or words may be paired with pictures (Ford *et al.*, 2001). Increased latency and reduced amplitude of the P3 component (Saito *et al.*, 2001) and attenuation of the error response (Mathalon *et al.*, 2003) have been reported. The visual modality has been used less than the auditory one to investigate AD but Pfefferbaum *et al.* (1984) found that reaction time to the visual stimuli was the best measure for discriminating between demented and depressed patients.

P3 latency and reaction time were significantly longer in a group of non-demented PD patients but the degree of slowing was unrelated to clinical features (Tachibana *et al.*, 1997). Similar abnormalities have been reported in cognitively impaired patients with supranuclear palsy (Johnson, 1995) and Huntington's disease (Munte *et al.*, 1997).

10.4.3 Olfactory ERPs

The sense of smell is particularly prone to the effects of ageing (Doty *et al.*, 1984). It has recently become possible to study olfactory ERPs using measured doses of volatile substances such as amyl acetate. Olfactory neurones take up to 90 s to recover from responding to a single stimulus, making it technically difficult to record responses. However, the major components of olfactory ERPs are delayed in latency and reduced in amplitude in older people (Hummel *et al.*, 1998; Murphy *et al.*, 2000). Initial studies indicate that peak latencies are further delayed in AD and that this correlates with dementia severity (Morgan and Murphy, 2002; Peters *et al.*, 2003).

10.5 OTHER TECHNOLOGIES

10.5.1 Magnetoencephalography (MEG)

During the last 20 years techniques to measure the magnetic fields generated by electrical activity within the brain have been developed. 'Whole-head' MEG can capture magnetic field information from up to 100 locations on the scalp enabling the mapping of the sources of abnormal fields or waveform frequencies and amplitudes (Roberts *et al.*, 1998). The technique has a higher temporal resolution than EEG, despite the tiny fields generated, that may be improved by combination with other imaging methods such as magnetic source imaging or functional magnetic resonance (Roberts *et al.*, 1998). Early studies of AD patients have confirmed the decreased fast wave power, increased slow wave activity and decreased coherence found using conventional EEG techniques (Berendse *et al.*, 2000; Stam *et al.*, 2002; Fernandez *et al.*, 2003). MEG activity correlates with volumetric measures of brain structures, such as the hippocampus (Maestu *et al.*, 2003).

10.5.2 Transcranial magnetic stimulation (TMS)

Traditionally, electrical stimuli have been used to excite cortical areas, either via intracerebral electrodes or during the

course of neurosurgical procedures. TMS employs powerful, rapidly alternating magnetic fields and allows a non-invasive method of electrically stimulating the cortex (George *et al.*, 1996). It has also been used in the treatment of depression (Grunhaus *et al.*, 2003). In AD, interest has centred on the use of TMS to determine motor cortex excitability. When magnetic stimulation is applied to the appropriate parts of the motor cortex, movements of upper or lower limbs can be induced. The threshold (or 'dose' of magnetic field) at which this happens is reduced in AD (De Carvalho *et al.*, 1997; Ferreri *et al.*, 2003). This change correlates with dementia severity (Alagona *et al.*, 2001) and may worsen as the disease progresses (Pennisi *et al.*, 2002). Cholinesterase inhibitors such as donepezil (Liepert *et al.*, 2001) and rivastigmine (Di Lazzaro *et al.*, 2002) have been shown to reverse this abnormality in the short term.

10.6 SUMMARY

Before the advent of brain CT the EEG had a prominent role in clinical practice and probably still does in centres where neuroimaging is not readily available. The conventional EEG remains the most reliable and cost-effective method of neurophysiological investigation in dementia. Its main clinical uses remain the differentiation of organic disorders (including delirium) from non-organic disorders and to support the diagnosis of epilepsy (Binnie and Prior, 1994).

Clinicians have been criticized for their injudicious requests for EEGs in the assessment of dementia, and the low yield of results that affect the patient's management is well known (Binnie and Prior, 1994; Philpot and Pereira, 2002). Nearly all the studies referred to in this chapter have compared well-characterized groups of subjects with each other, rather than including cases in which there have been real uncertainties about the diagnosis. Very few have confirmed diagnosis at autopsy. Perhaps as a result, the technologically attractive techniques such as evoked and event-related potentials, and MEG, do not yet have a place in routine clinical practice and, because of their lack of specificity, do not present the hoped-for short cut to diagnosis. Indeed, neurophysiological methods no longer figure in the latest practice guidelines for the diagnosis of dementia (Royal College of Psychiatrists, 1995; Knopman *et al.*, 2001). However, as research methods they clearly have continuing potential in augmenting knowledge derived from other approaches.

11.7 Protectors from carer distress	123		

There is a maxim that when a person is diagnosed with dementia, there is (almost) always a second patient. Dementia is not just one person's illness. The stone cast sends ripples through families, friends and society. This chapter focuses on informal carers, usually family, sometimes friends.

11.1 WHO ARE INFORMAL CARERS?

There are many definitions of a carer. It may be defined by the:

- relationship – spouse, child, professional;
- primacy – primary or secondary carer;
- living arrangement – with the patient or separately;
- style of care – routine, regular, occasional;
- by job description – unpaid or paid; or
- as formal or informal (Barer and Johnson, 1990).

In the UK and Australia the term carer is used, whereas in North America caregiver is more usual. In India and some other countries, caretaker is a more common term. Pearlin *et al.* (1990) differentiate between caring (the affective part of a relationship), and caregiving (the behavioural component). Both are intrinsic to any close relationship but, with impairment, there is increasing dependency and the restructuring of the relationship so that caregiving becomes dominant and overrides other aspects of the relationship, resulting in a loss of reciprocity. A definition of a caregiver proffered by Zarit and Edwards (1996, p. 334) is 'a family member (or friend), helping someone on a regular (usually daily) basis with tasks necessary for independent living'. The care-recipients, or

patients for the purposes of this chapter, are dependent, disabled and mentally-impaired persons with dementia, most commonly Alzheimer's disease (AD).

The majority of carers, from 33 to over 60 per cent, are spouses (US Congress Office of Technology Assessment, 1987; Brodaty and Hadzi-Pavlovic, 1990; Wells *et al.*, 1990) of whom about 75 per cent are women (Stone *et al.*, 1987; Brodaty and Hadzi-Pavlovic, 1990; Dwyer and Seccombe, 1991; Dwyer and Coward, 1992; Cohen *et al.*, 1997; Tsien and Cheng, 1999), although the proportion does vary according to both the sampling techniques and the country surveyed. Adult children and their partners make up about a third of informal carers, but in Asian countries, such as China, Hong Kong and India, adult children are more often the carers than spouses (Patterson *et al.*, 1998; Tsien and Cheng, 1999; Shaji *et al.*, 2003). Moreover, daughters are far more likely to be primary carers than sons (Horowitz, 1985; Coward and Dwyer, 1990; Dwyer and Coward, 1991; Lee *et al.*, 1993), outnumbering them in a ratio of about 4:1 (Brody, 1990). Likewise, daughters-in-law often inherit the burden of care, particularly in certain cultures such as in Korea, Hong-Kong and India (Choi, 1993; Lee and Sung, 1997, 1998; Patterson *et al.*, 1998; Tsien and Cheng, 1999; Shaji *et al.*, 2003).

About 4 per cent of people with dementia live alone (US Congress Office of Technology Assessment, 1987). Persons living alone are less likely to have a carer, and likely to be institutionalized earlier (Brody, 1981; Mace and Rabins, 1982). There is an enormous difference between living with a person and caring from a distance. Spouses almost always

live with the person with dementia, whereas adult children who are carers often live separately.

There are cultural differences as to who in the family will take on the care. The USA being a more mobile society makes it less likely that offspring will be close at hand to provide care when a parent starts to dement, yet moving the person with dementia to another city can be quite disorientating. There are differences in the ways Caucasian, African American and Hispanic carers cope (see below). In Japan, the tradition is that the wife of the eldest son is responsible for the care of ageing parents. In developing countries and in many rural settings there is more likely to be an extended family network who can provide care. Economic conditions in many rural economies have meant that many of the adult children have migrated internally to cities, leaving older parents stranded. Further, many older people have significant assets, such as a house, but little income, and incur financial hardship when facing the need to provide care for a person with dementia.

11.2 WHY DO FAMILY CARERS CARE?

Eisdorfer (1991) posited that family carers are motivated to provide care for several reasons. It may be out of a sense of love or reciprocity: the bonds of 50 years, the credit points accumulated over a lifetime together, and the recognition that the other partner would provide care were the situation reversed. Caregiving may be seen as spiritually fulfilling. Other carers do it out of a sense of duty because they feel guilt, or in response to social pressure or cultural mores. These latter carers are more likely to resent their role and suffer greater psychological distress than the former carers in the first two groups. Rarely, the motivation is greed: the prospect of financial gain as a result of caring.

11.3 HOW DO FAMILY CARERS CARE?

The concept of care providers and care managers (Archbold, 1981) is useful. The former provide hands-on care – dressing the person with dementia, providing daily supervision, managing finances, or doing whatever else is required. Care managers, on the other hand, arrange for others to provide care: a nurse to attend daily to assist with medications and personal care; an accountant to look after financial matters; personal care assistants to provide companionship. Spouses tend to be care providers; adult children, friends and other relatives tend to be care managers. Care providers are generally more stressed than care managers (Archbold, 1981).

While the negative aspects of caring have received most attention, caring has been associated with benefits and positive feelings, such as a feeling of satisfaction, a feeling that the carer has helped the patient and a sense of meaning (Archbold, 1983; Miller, 1988; Sheehan and Nuthall, 1988; Walker *et al.*, 1989; Cohen *et al.*, 2002).

Recent research has indicated that differences in cultural or ethnic affiliation can influence the way that family carers approach and view their caring role and responsibilities. For instance, it is quite common in African American communities for the extended family to take on the care of persons with dementia, especially in lower socioeconomic groups (Gelfand, 1982; Cantor, 1983; Wood and Parham, 1990). Similarly, in American-Hispanic communities, the extended family typically care for elderly relatives with dementia (Valle, 1988; Mintzer *et al.*, 1992). For some minority groups, such as African American and Asian-American communities, placing an elderly relative in a nursing home is considered abandonment and therefore unthinkable, even in cases of extreme stress and burden to the carer (Wood and Parham, 1990; Yeo, 1996; Wallsten, 1997).

The caregiving role is perceived more positively by African American carers compared with Caucasian carers (Smith, 1996). African American carers tend to report less subjective burden, fewer difficulties in accepting restrictions on recreational activities, and lower levels of depression than Caucasian carers (Gibson, 1982; Lawton *et al.*, 1992; Roth *et al.*, 2001). It was suggested that this is because of greater caregiving support by members of minority extended families but a recent review concluded that minority group caregivers do not have more support than white people (Janevic and Connell, 2001). In developing countries, where levels of caregiver strain appear at least as high as in the developed world despite the extended family structure of care, there appears to be less coresident caregiver burden in larger households (Prince *et al.*, 2004). African American carers appraise caregiving tasks as less subjectively stressful and themselves as having higher effectiveness than Caucasian carers (Haley *et al.*, 1996). Additionally, African American carers tend to use religion and prayer as coping strategies, and view God as an essential part of their support system (Wood and Parnham, 1990).

The beliefs and values of different ethnic groups can furthermore affect the way in which family members appraise and understand dementia, and therefore manage it. For instance, in some cultures there is the belief that behaviours related to dementia are part of normal ageing, rather than a disease process, and therefore may evoke little concern until symptoms are quite advanced (Valle, 1989). Similarly, in some cultures, confusion, disorientation, and memory loss may be viewed as signs of 'craziness' (Yeo, 1996). A cross-national European study found that 2 per cent of overall carer burden was explained by perceived negative social reactions (Schneider *et al.*, 1999).

11.4 EFFECTS OF DEMENTIA ON CARERS

Dementia is an 'unremitting burden' on the family (Anderson, 1987). Caring for a person with a chronic mental condition is more stressful than caring for a person with a physical disorder or disability (Lezak, 1978; Gilleard, 1984; Poulshock

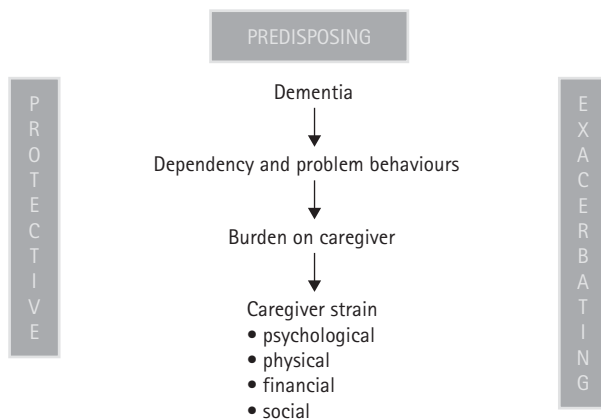

Figure 11.1 Dementia leads to dependency and problem behaviours, which impose an objective burden on the carer. (Adapted from Poulshock and Deimling, 1984).

Figure 11.2 Background and context lead to primary stresses, secondary role strains, and secondary intrapsychic strains (Pearlin *et al.*, 1990, reprinted with permission).

and Deimling, 1984; Mohide *et al.*, 1988). The effects on family carers are diverse and complex and there are many other factors that may exacerbate or ameliorate how carers react and feel as a result of their role.

Two models of the effects of caregiving are shown in Figures 11.1 and 11.2. In the first, adapted from the work of Poulshock and Deimling (1984), dementia leads to dependency and problem behaviours, which impose an objective burden on the carer. Objective burden results in strain, which varies in how it is manifested in carers. Strain may be psychological, physical, financial or social, or may lead to increased use of health services. Carer strain may be influenced by patient, carer, protective and exacerbating variables.

In the second model from Pearlin *et al.* (1990), which overlaps with the first, there are a background and context which lead to primary stresses, secondary role strains, and secondary intrapsychic strains. Several variables can mediate the results of these leading to different outcomes.

11.4.1 Objective burden

Objective burden reflects the dependency of the patient, as evidenced by the loss of activities of daily living, instrumental activities, cognition, other abilities, companionship and communication. Problem behaviours and psychiatric disorders

that commonly accompany dementia are further types of objective burden.

11.4.2 Subjective strain

Subjective burden is the appraisal by the carer. It includes feelings of entrapment, resentment, stress, overload, inability to cope and exhaustion. Activities become restricted, outside relationships diminish.

11.4.3 Psychological morbidity

Numerous studies have demonstrated increased psychological morbidity in carers (Gilleard *et al.*, 1982, 1984; Poulshock and Deimling, 1984; George and Gwyther, 1986; Morris *et al.*, 1988; Brodaty and Hadzi-Pavlovic, 1990; Grafström and Winblad, 1995). Depression levels and rates are also high (Haley *et al.*, 1987; Morris *et al.*, 1988; Gallagher *et al.*, 1989; Schulz and Williamson, 1991; Baumgarten *et al.*, 1992; Pearson *et al.*, 1993; Rosenthal *et al.*, 1993; Mittelman *et al.*, 1995). For example, Gallagher *et al.* (1989) found that amongst carers seeking help, 26 per cent met Research Diagnostic Criteria (RDC) for major depression and 18 per cent for minor depression. Rates among non-help-seekers were 10 per cent and 8 per cent respectively. In a study by Coope *et al.* (1995) of 109 carers of research subjects, 29.4 per cent met GMS-AGECAT criteria for case level depression and 11.9 per cent had sub-case symptoms of depression. Mittelman *et al.* (1995) reported that over 41.7 per cent of carers had a Geriatric Depression Scale score of 11 or greater, the rate being higher amongst women (50 per cent) than men (30 per cent).

A recent meta-analysis of 84 studies comparing caregivers of elderly to non-caregivers found that there were significantly higher levels of depression and stress and significantly lower levels of self-efficacy, general subjective wellbeing and physical health in caregivers. This difference was larger when dementia caregivers were compared with non-carers than with heterogeneous samples of caregivers of elderly patients (Pinquart and Sorensen, 2003).

11.4.4 Physical morbidity

Carers have poorer physical health than non-carer controls (Schulz *et al.*, 1990), higher levels of chronic conditions, prescription medications and doctor visits (Haley *et al.*, 1987) and more physical symptoms and poorer self-rated health (Baumgarten *et al.*, 1992). Those with poor psychological health are even more likely to have physical morbidity (Brodaty and Hadzi-Pavlovic, 1990). The findings of decreased immunological competence in carers of Alzheimer's disease patients (Kiecolt-Glaser *et al.*, 1987) has been supported in an elegant study of response to influenza vaccine. Vedhara *et al.* (1999; 2003) reported that elderly carers of spouses with dementia

have increased activation of the hypothalamopituitary axis and a poorer antibody response to the influenza vaccine, which could be enhanced by cognitive behavioural intervention (see below). They concluded that carers may be vulnerable to infectious disease. A meta-analysis of 23 studies of dementia caregivers found that caregiving was associated with a slightly greater risk for health problems and that this risk was moderated by measure of health (e.g. self-rated global health, medication use, antibodies, cardiovascular measures) and greater in females (Vitaliano *et al.*, 2003).

Other indicators of poorer physical health are increased service use – hospitalization, physician visits, drug use, aggregate use of health service; and less healthy behaviours – increased alcohol intake, smoking more and poorer sleep patterns, eating behaviour and nutrition (Schulz and Williamson, 1997). Further, pre-existing conditions such as hypertension are more likely to be exacerbated by the caregiving role (Schulz and Williamson, 1997). Caregiving has also been associated with a higher mortality rate (Schulz and Beach, 1999).

11.4.5 Social isolation

Dementia is a very isolating condition. At the very time that families need more support, friends feel unsure about what to say on the taboo topic of dementia, are disconcerted by their friend's lack of communicativeness and feel embarrassed by the displays of disinhibition (Brodaty, 1998a). They may feel uncomfortable about the carer's distress and tend to avoid paying visits. Simultaneously, carers abandon their leisure pursuits and hobbies, stop seeing friends and discontinue employment. Their lives become focused on the caregiving role, which takes up most of their time (Brodaty, 1998a). In a survey of Australian carers, we found that half of them had seen a person from outside their home only once a week or less often (Brodaty and Hadzi-Pavlovic, 1990).

11.4.6 Financial

There are considerable financial costs to families looking after persons with dementia. The direct costs are those of medical consultations, investigations, pharmaceuticals, provision of personal and nursing care and later, residential care. Indirect costs comprise loss of earnings by the patient and by family carers if they have to relinquish employment.

Max *et al.* (1995) estimated that the informal care provided to patients with Alzheimer's disease living at home is substantial, averaging 286 hours per month. Even after patients were placed in a nursing home, the number of monthly informal caregiving hours was reported to be 36. For patients at home, primary carers had been caring for an average of 3.7 years; for institutionalized patients, the average length of time carers had been caring was 6.3 years.

Most of the care for patients at home is provided informally by family members and friends (Max, 1999). While the

cost of caring for an institutionalized patient is twice the cost of caring for a patient at home (Hu *et al.*, 1986), the total social costs of care per person were nearly the same in two settings where both paid and unpaid informal care were included (Rice *et al.*, 1993). However, most of the expenses for patients living at home are borne by their families (Gray and Fenn, 1993; Rice *et al.*, 1993; Stommel *et al.*, 1994). As the disease progresses, the cost of care increases. Hu *et al.* (1986) found that severely demented patients required more than twice as many hours of informal care as mildly demented ones. Others have found rates of 1.28–1.63 times greater costs for severely demented patients compared with mildly demented ones living at home (Rice *et al.*, 1993; Souetre *et al.*, 1995). Max (1999) went on to conclude that 'Alzheimer's disease is extremely costly, no matter how it is measured and what cost is included ... for patients cared for at home, most of the care is provided informally by family members and friends and most of the burden of care for patients at home is borne by their families, in the form of out-of-pocket payments for services or in the form of hours of time spent caring for the patients without reimbursement' (p. 367).

In a US survey, families spent the equivalent of \$US18 200 annually (Stommel *et al.*, 1994). Four out of five families in Stommel's sample reported out-of-pocket expenditures averaging \$US2088 (14 per cent of total) but the lion's share (\$US11 560 or 59 per cent) was accounted for by the primary carer's time spent providing care. The US National Longitudinal Caregiver Study estimated the annual cost of providing informal care to elderly community-dwelling veterans with dementia to be \$US18 385 in 1998. The majority of this cost comprised caregiving time (\$US6295) and caregiver's lost earnings (\$US10 709) (Moore *et al.*, 2001).

In Australia in 2002 with a population of 19 million including 165 000 with dementia, the direct health costs for dementia (residential care, hospitals, GPs and specialists, outpatients, research, pharmaceutical and other services) was \$A3236 million, and indirect costs (loss of earnings, absenteeism and mortality burden) were estimated as \$A365 million (Access Economics, 2003). The value of informal care for people with dementia was \$A1713 million, or 32 per cent of the total cost of care (Access Economics, 2003).

11.5 PREDICTORS OF CARER DISTRESS

11.5.1 Demographic variables

Carers who are women, and those who are spouses, have higher rates of psychological morbidity than their counterparts (Fitting *et al.*, 1986; Baumgarten *et al.*, 1992; Collins, 1992; Gallicchio *et al.*, 2002). The spouses of younger patients may have higher rates of psychological morbidity, perhaps because of the high stresses inherent in being married to a younger person with dementia, and the high likelihood of having younger children at home (Luscombe *et al.*, 1998).

Carers who cohabit with patients are more likely to be depressed or psychologically stressed than those living apart (Gilhooley, 1984; George and Gwyther, 1986; Wells and Jorm, 1987; Brodaty and Hadzi-Pavlovic, 1990; Harper and Lund, 1990). The gender of the patient does not appear to affect carer wellbeing once allowance is made for the increased likelihood of behavioural disturbances in men (Brodaty and Hadzi-Pavlovic, 1990).

There have been no consistent associations found between carer age and psychological distress, with higher levels having been reported in older (Fiore *et al.*, 1986) and younger supporters (Gilleard *et al.*, 1984). Such comparisons need to control for the effects of relationship.

11.5.2 Dementia variables

11.5.2.1 TYPE

There is little evidence to suggest that one type of dementia is associated with more psychological stress in carers than another. Similar levels have been reported in carers of patients with vascular dementia and AD (Draper *et al.*, 1992, 1996) and dementia with Lewy bodies and AD (Lowery *et al.*, 2000). On theoretical grounds, one might expect that the increased likelihood of behavioural disturbances and personality changes in frontotemporal dementias might be associated with more carer distress.

11.5.2.2 DURATION

Two possibilities have been hypothesized to account for the lack of consistent link between duration of dementia and carer outcome. The adaptation hypothesis proposes that some carers adapt to the stress of providing care. The sequestration theory hypothesizes that carers experiencing greater stress are more likely to arrange admission of the patient to a nursing home, thus removing these dyads from cross-sectional surveys correlating duration and psychological morbidity.

In support of the adaptation hypothesis, several researchers have found that carers experience less burden over time (Gilhooley, 1984; Zarit *et al.*, 1986; Novak and Guest, 1989; Townsend *et al.*, 1989; Rabins *et al.*, 1990; Brodaty *et al.*, 1997). For example, Grafström and Winblad (1995), in a study limited by a large number of drop-outs and few subjects, reported that, over 2.5 years, spouses and adult children caring for elderly people with dementia reported less burden, decreased behavioural problems in the demented elderly, less conflict with other relatives and close friends, less social limitation and less affective limitations. Additionally, self-rated health improved and the number of visits to a physician decreased. The mean use of psychotropic drugs increased slightly. These effects were still present when analyses were repeated for carers of elderly still living at home. For the relatives of non-dementing elderly, there were no significant differences over time. This is consistent with the findings of Bond and Buck (1998), who found that there were no significant

changes in the General Health Questionnaire (GHQ) scores (a measure of psychological morbidity) of carers over a 2-year follow-up period, and Roth and colleagues (2001) who found that depression scores of caregivers remained constant over a 2-year period. By comparison, the GHQ scores of carers in the control group of an intervention study gradually rose over 12 months (Brodaty and Gresham, 1989). Also, Pot and colleagues (1997) found that over a 2-year period, the psychological wellbeing of carers actually declined and psychological distress increased in terms of depression and anxiety.

11.5.2.3 SEVERITY

The association between dementia severity and carer health is complex (Baumgarten, 1989). Carers may respond quite differently to three manifestations of dementia: cognitive, functional and behavioural decline. Most studies have found no significant correlation between cognitive status and carer psychological health. Functional decline is significantly correlated with restriction in carer activity (Deimling and Bass, 1986) but not with depressive symptoms (Deimling and Bass, 1986; Haley *et al.*, 1987). Functional decline has been linked to increased burden on carers. Haley *et al.* (1987) found that the patient's ability to perform instrumental activities of daily living was highly correlated with the carer's depression score, but not with life satisfaction or self-rated health problems. The difficulty in interpreting the association between patient functional status and carer health, which in any case is not strong, is that patients who have declined functionally are more likely to exhibit behavioural disturbances. Analyses have not allowed for the strong effect of behavioural disturbances on carer health (see below).

The most consistent finding is the strong association between behavioural disturbance and carer distress. Despite differences in outcome measures, methods of assessing behavioural disturbances, populations and countries from which studies are reported, a robust and consistent finding emerges: behavioural disturbances account for about 25 per cent of the variance in carer psychological distress (Mangone *et al.*, 1993; Brodaty, 1996; Cohen *et al.*, 1997; Bond and Buck, 1998). Certain types of behaviour are particularly likely to be associated with distress – incontinence, immobility, nocturnal wandering, proneness to fall, inability to engage in meaningful activities, difficulties with communication, sleep disturbance, loss of companionship, disruptiveness, constant demands and aggression (Gilleard *et al.*, 1982; Greene *et al.*, 1982; Morris *et al.*, 1988; Brodaty and Hadzi-Pavlovic, 1990).

11.5.3 Carer variables

Effective coping strategies can mitigate carer distress (Pruchno and Resch, 1989) and possibly enhance the quality of life for the dementing person. Problem-focused strategies – reframing, problem-solving, developing more social support or a greater social network – are associated with positive effects such as greater satisfaction with life, decreased feelings of burden and

lower depression levels (Pruchno and Resch, 1989). Emotion-based responses (Lazarus and Folkman, 1984) – wishfulness, acceptance and fantasy (e.g. ‘I wish I was a stronger person to deal with it all better’, ‘accept the situation’, ‘fantasies about how things might end out’) are associated with more distress. The more immature the coping strategies and the more neurotic the personality style (Gallant and Connell, 2003), the greater the likelihood of increased burden, decreased satisfaction with life, and increased depression. Of course it may be possible that depression in carers leads to regression and to the adoption of less effective types of coping, which then perpetuates the depression. An association has been found between expressed emotion (EE) and distress in the daughters of people with dementia (Bledin *et al.*, 1990) and carers in general (Fearon *et al.*, 1998).

11.5.4 Relationship factors

Premorbid unsatisfactory relationships are more likely to be associated with carer distress (Brodaty and Hadzi-Pavlovic, 1990). This may accompany the fragmentation of communication between couples, the increase in tension, the loss of companionship, the loss of a confidante, the increase in economic and household responsibilities and the waning of sexual intimacy (Chenoweth and Spencer, 1986; Fitting *et al.*, 1986; Wright, 1991).

11.6 SUPPORT

The relationship between support and carer outcome is extremely complex. There are differences between actual and perceived support, formal (from professionals) and informal (from friends and relatives) support, between psychological and instrumental support, and between how males and females use support (Brodaty, 1994). Enright (1991) reported that husbands were more likely to receive help than wives. There is also the potential for negative effects from so-called supportive figures, i.e. visits from other family members may be more stressful than helpful (Fiore *et al.*, 1986; Edwards and Cooper, 1988).

An association between the number of supports and carer distress might merely reflect an increased likelihood of distressed carers seeking help; while a negative correlation could suggest that support has an ameliorating effect (Brodaty, 1994). A lack of either a positive or a negative correlation might result where both effects occur in the one population being sampled. Also carers who use more informal services may need less professional help and make fewer demands on community services (Fitting *et al.*, 1986; Chesterman *et al.*, 1987). Finally, gender and culture influence the use of informal supports. For example, men, who are more likely than female carers to seek help, and African American carers, who are more likely than Caucasian carers to engage with larger extended networks of family and friends, both have lower levels of psychological distress than their counterparts (see above).

In summary, there is support for a relationship between informal supports and lower psychological distress, but it may be that happier people are more inclined to seek contact in the first place or that lack of happiness and social support are independently related to disturbing behaviours. Carer satisfaction with social support is generally associated with better health (Gilhooley, 1984; Fiore *et al.*, 1986). It may be that unhappy carers perceive the world negatively in general and so rate the satisfaction with their supports in the same way, thus contaminating the results. On the other hand, social support may provide a protective buffer against stress but have little effect on those who are not exposed to stress (Baumgarten, 1989). For instance, it has been shown that paid help buffers the relationship between caregiver stress and burden while perceived availability of social support buffers the relationship between caregiver stress and depression (Majerovitz, 2001).

11.7 PROTECTORS FROM CARER DISTRESS

The corollary to the above studies is that carers who are care managers are able to distance themselves physically or emotionally from the patient, use problem-focused coping strategies, are able to use supports to buffer stress and are able to deal more competently with the care recipient's behavioural disturbances or have them treated well (e.g. Hincliffe *et al.*, 1995) are less likely to experience psychological distress. Membership of a support group, such as the Alzheimer's Association may also be helpful (see Chapter 22).

11.8 NURSING HOME ADMISSION AND CARERS

In general, carer factors are more potent predictors of institutionalization than patient or dementia variables. Having a coresident carer has a 20-fold protective effect against institutionalization (Banerjee *et al.*, 2003). Carer psychological distress has been consistently associated with institutionalization (Colerick and George, 1986; Lieberman and Kramer, 1991; Brodaty *et al.*, 1993; Yaffe *et al.*, 2002). Older carers are more likely to institutionalize (Yaffe *et al.*, 2002). Paradoxically, spouses are less likely to institutionalize dementing partners than children, and carers who express a stronger ‘desire to institutionalize’ are more likely to follow through (Morycz, 1985). Some studies have found that severity of dementia and rate of progression – how ‘far’ and how ‘fast’ – significantly increased the likelihood of institutionalization (Drachman *et al.*, 1990; Brodaty *et al.*, 1993). Institutionalization has also been associated with financial and psychological problems in the carer and family problems (Lieberman and Kramer, 1991). A 3-year study found that caregivers who experience a gradual entry into caregiving (providing care and recognizing

symptoms before obtaining a diagnosis) were less likely to institutionalize their relatives (Gaugler *et al.*, 2003).

11.9 THE FAMILY AND THE MANAGEMENT OF DEMENTIA

The management of the family will evolve and change throughout the course of the illness (Steele, 1994). It is convenient to consider three stages.

11.9.1 Early stage

After assessment, the first opportunity to intervene is when the diagnosis is communicated – a crucial time in the career of caregiving (Fortinsky and Hathaway, 1990). When dementia caregivers were asked what topics they would have liked to learn more about, 25 per cent said they wanted to know about disease progression and 19 per cent said they wanted more information on the disease (Thomas *et al.*, 2002). A routine family diagnostic conference to communicate the diagnosis to the family can allow for clarification of behaviour, explanations of prognosis, and a discussion of current and future needs so that the family can be organized into an effective system of carers and the burden shared (Steele, 1994). We have found that when the family is seen separately to the patient, they are more likely to raise sensitive issues, such as genetic risk, time to nursing home admission and general prognosis. It is also useful to have a large family conference following discussion with the primary family carers, in order to enlist the support and help of other family members and friends.

For the many family carers who resist obtaining help for themselves, it is useful to emphasize that they are the most important element in the continuing management of the patient, and that the carer's wellbeing is critical to the patient's quality of life. In this way, requests for help from family and friends, use of family supports and later use of respite care are seen as positive therapeutic moves rather than admissions of inadequacy and failure.

Carers should be made aware of support groups through the local Alzheimer's Association and encouraged to make use of them, although it is recognized that they are not suitable for all carers. The commonest reason for carers not to access services or support groups is lack of knowledge or failure of health professionals to make a referral (Molinari *et al.*, 1994; Thomson *et al.*, 1997). The local Alzheimer's Association can provide educational materials, counselling, access to a support group or specific training courses. With the arrival of medications for Alzheimer's disease, patients are being diagnosed earlier and more services are being offered for them in tandem with those for carers. For example, there is a computer-based support group for people with dementia (Dementia Advocacy and Support Network; <http://www.dasninternational.com>), support groups for people with early stage dementia (Yale, 1995) and in Australia, the Living with Memory Loss

Program, a 7-week course for people with early stage dementia and their partner, that has been reported by attendees to be extremely helpful.

Another useful concept is the family carer as therapist (Brodaty *et al.*, 1997). This underscores the importance of the carer obtaining as much knowledge as possible about what is happening with the patient, and what to expect and how to manage. Brochures, books and videotapes are available through the Alzheimer's Association. Books such as *The 36 Hour Day* (Mace and Rabins, 1991) have been a boon to families. Carers can be taught behavioural management strategies and how to supervise exercise programmes for patients, which can be beneficial to the physical health and level of depression of the person with dementia (Teri *et al.*, 2003).

Sensitive issues arise: when should the patient discontinue driving, when should the patient stop working (if still doing so) and what are the hereditary risks to relatives of the patient? Financial management, enduring or durable power of attorney, enduring guardianship, advance directives and wills should be considered while the patient still retains competency. The possibility that the carer may suddenly take ill or even predecease the patient should be canvassed. For example, many couples have mirror wills and should the carer die suddenly, the patient, if named as the executor, would be unable to act in this capacity later in the illness. Obtaining durable power of attorney earlier avoids subsequent lengthy court proceedings required to obtain legal guardianship. In many jurisdictions it is possible to arrange enduring guardianship and to provide for advance directives, which only come into effect once the patient loses capacity. These important topics should be discussed with the patient and family separately and together to enable harmonious decisions to be reached.

Drugs are now available for the treatment of AD and other medications may be of assistance in ameliorating some risk factors for vascular dementia. Families are usually well aware of these and are desperate for information and prescriptions. Medications for AD appear to be of benefit for caregivers, as well as for patients. Cholinesterase inhibitors have been reported to reduce the time required for caregiving by about 1 hour per day and to decrease carer burden (Brodaty and Green, 2000). Even so, carers should be appraised of what to expect realistically from drug treatments (Brodaty, 1998a).

Family carers should be advised of their increased risk for depression and psychological stress. As the disease progresses the family carer appears to suffer more than the patient. Carers should be encouraged to meet regularly with their general practitioner, primary care physician or other aged care workers in order to ventilate concerns and seek advice on management. Our own practice is to advise general practitioners to meet with families at least quarterly to review the situation as well as to consult as necessary.

11.9.2 Middle stages

In the middle stage of the illness there is increasing memory loss, language difficulties, agnosia and apraxia, and loss of

planning and other executive functions. Personality changes, apparent from the beginning, now become more prominent and the most common complaint of carers is the loss of companionship and lack of communicativeness (Brodaty *et al.*, 1990). Carers can be taught practical strategies to assist the patient to compensate for cognitive deficits: establishing a routine, keeping a diary, having a whiteboard by the telephone, using visual prompts if verbal memory is more severely affected, capitalizing on old memories (e.g. rereading books from the past, playing familiar music, watching classical movies on television) and pursuing activities that do not rely on memory, such as physical exercise, craft hobbies or games.

Behavioural and psychiatric problems come to the fore as the disease progresses (Carrier and Brodaty, 1999). Behaviours such as wandering, aggression, sexual disinhibition, repeated questioning, 'shadowing' and disrupted sleep patterns, can be quite distressing to the carer. Depression, hallucinations, delusions and misidentification syndromes occur more commonly in the middle and later stages. Their management is discussed in Chapters 38 and 39. Often an explanation about these phenomena and their cause can be very helpful to the carer. For example, it may be that hallucinations are more distressing to the family than they are to the patient, and that once this is explained, carers become more accepting and less stressed.

Carers can be taught behavioural management strategies (e.g. Teri *et al.*, 1997, see below) given practical advice (e.g. using identity bracelets for wandering patients, establishing routines for daytime naps so as to encourage the patient to stay up longer and establish a more normal sleeping rhythm), use of distraction when agitation occurs (e.g. music, physical activity), and establishment of a daily routine to achieve a sense of stability in the patient's life and compensate for memory deficits.

As the dementia progresses, patients become more functionally dependent, requiring assistance with instrumental activities of daily living and supervision with self-care. Carers are more likely to use support services in the middle stages of dementia: day centre; in-home respite; residential respite care; other relatives taking over for short periods of time. It is important that appropriate and timely referral be made to services, as caregivers have reported that general practitioners only referred them to community care services after they had experienced difficulties for a considerable time period (Bruce and Paterson, 2000).

Throughout the course of the disease, regular counselling to discuss problems as they arise and assistance with their management can help carers. Patients have usually lost competency by this stage, and treatment interventions and use of medication require informed consent from the carer. Legal requirements for this consent will vary according to the jurisdiction.

11.9.3 Late stage

In the later stages the patient becomes completely dependent in activities of daily living and requires assistance with bathing,

toileting, dressing and eating. Paradoxically for many carers this stage may become somewhat easier. The demands are purely physical and labour intensive and the emotional strain is less.

At some stage, in most developed countries, institutionalization is considered. Each family has its own threshold for nursing home placement and for many families the answer is never. The financial costs of nursing home care can be a powerful disincentive to admission. Typically, carers decide to institutionalize their dependant when the patient requires more nursing care than one person can provide, when the patient can no longer recognize the carer as someone meaningful, when the patient develops urinary and/or faecal incontinence, when behavioural disturbances become unmanageable, or when the carer becomes physically ill, experiences excessive psychological stress or breaks down. The decision to institutionalize a loved one can induce in family carers powerful feelings of guilt and anguish, which may be mitigated by open discussion. For example, admission can be 'reframed' as an opportunity to provide 'quality time' with the patient and free the carer from the drudgery of physical care and household chores. Sometimes the decision to institutionalize precipitates intense family disagreement. If an extended family interview fails to resolve the issue, usually having the dissenting family member care for the patient over a weekend succeeds.

A study comparing home social services, day centres, expert centres, group living and respite hospitalization in seven different centres in the European Union found that caregivers of AD patients in group living arrangements experienced the lowest level of burden followed by caregivers of patients receiving home social services (Colvez *et al.*, 2002).

Ethical issues arise in the terminal stages of dementia. The family must be consulted about decisions when to withhold treatment or when to institute feeding devices when patients are no longer able to swallow.

11.9.4 After the death of the patient

'The funeral that never ends' finally does so. However, carers do not feel a sense of relief that their ordeal is now over. Often the care of the patient has become the entire focus of the carer's life and the death heralds a black void rather than a new freedom. The grief can be 'remarkably intense' (Steele, 1994). For those considering autopsy, usually for scientific reasons to determine hereditary risk, decisions about post-mortem examination should be made well before death so that these can be arranged expeditiously.

11.10 CARER INTERVENTIONS

While education, support groups and provision of information alone have limited efficacy in reducing carer distress (although they have been demonstrated to result in carer satisfaction with the training and increase in knowledge [Brodaty, 1992]), other carer interventions can reduce carer stress or burden

(Kahan *et al.*, 1985; Zarit *et al.*, 1987; Lovett and Gallagher, 1988; Brodaty and Gresham, 1989; Brodaty and Peters, 1991; Mittelman *et al.*, 1993, 1995; Hinchcliffe *et al.*, 1995), improve physical activity levels (Castro *et al.*, 2002) and increase immune response (Vedhara *et al.*, 2003).

A meta-analysis of 30 studies of psychosocial interventions for caregivers of people with dementia found that there were significant benefits for caregiver psychological distress, caregiver knowledge, any main caregiver outcome measure, and patient mood, but not caregiver burden (Brodaty *et al.*, 2003). Interventions were more likely to be successful if they involved both patients and caregivers (Brodaty *et al.*, 2003). Another meta-analysis, of 78 studies of interventions for caregivers of older adults, found that intervention effects for dementia caregivers (61 per cent of studies) were smaller than for carers of other groups (Sorensen *et al.*, 2002)

Carer interventions can delay nursing home admission (Brodaty *et al.*, 2003). A 10-day intensive, residential, comprehensive and extensive training programme, consisting of counselling, provision of information, practical advice, role plays and skills training for groups of up to four carers and their charges, delayed nursing home admission by almost a year (Brodaty and Gresham, 1989; Brodaty *et al.*, 1997). For the following year the groups of carers were linked by telephone conference calls second-weekly, then fourth-weekly and sixth-weekly. The programme was part of a randomized controlled trial with one group of carers receiving training immediately, a second group receiving training after 6 months' delay and a third group receiving no training at all. For the third or control group, patients were admitted for 10 days and participated in a memory-retraining programme while their carers had 10 days respite. All groups of carers had similar telephone conference links over 12 months (Brodaty and Gresham, 1989). At the end of the 12 months, patients declined uniformly on tests of cognition and function regardless of which group they were in. However, the carers in the immediate training programme had a significant decline in their (GHQ) scores, (a measure of psychological morbidity), over the 12 months, while the GHQ scores of control carers rose. The GHQ score of the delayed training carers remained steady. Rates of institutionalization were significantly lower for both carer training groups over 8 years' follow up. For example, at 4 years 55 per cent of patients in the immediate dementia caregiving training programme, and 40 per cent of those in the delayed programme, were still at home, whereas, only 8 per cent of patients whose carers were in the control group were still at home (Brodaty *et al.*, 1997). Although the programme was more costly than necessary, as it was residential and within a hospital setting, it still resulted in savings of about (in 1987) \$US6000 per couple over 39 months, because of the delay in nursing home admission (Brodaty and Peters, 1991). Over 8 years the odds ratio of surviving patients staying at home was 5.03 (95 per cent CI 1.73–14.7) greater if the carer had participated in training.

Mittelman and colleagues demonstrated almost identical findings using a different modality of intervention (Mittelman

et al., 1993, 1995, 1996). Carers were randomly assigned to receive counselling or standard management. The counselling condition consisted of four family sessions and two individual sessions but *ad libitum* contact and the availability of weekly support group meetings. The counselling programme was effective in reducing depression scores (Mittelman *et al.*, 1995) and delaying nursing home admission (Mittelman *et al.*, 1996). Over 8 years, there was a delay in nursing home admission in the counselling condition by a median 327 days (Mittelman *et al.*, 1996).

Eloniemi-Sulkava *et al.* (1999) and Riordan and Bennett (1998) (and Chu *et al.*, 2000 for more impaired patients) demonstrated a longer median time of home care with interventions. Qualitatively, factors associated with interventions delaying nursing home placement were a continuing relationship between helper and carer, flexibility of the intervention, and a variety of interventions tailored to meet the varied needs of the carer (Brodaty *et al.*, 2003).

The potential for carers to be effective therapists was demonstrated by two elegant multicentre US studies by Teri *et al.* (1997, 2003). The first study (Teri *et al.*, 1997) selected patients with AD who had coexisting depression and were living with a carer. The aim of the study was to investigate whether training carers in behavioural techniques could alleviate patients' depression. Carers were allocated to one of two behavioural interventions: training in problem-solving techniques or training in the use of pleasurable activity schedules; or one of two control conditions, typical care or wait-list. Patients whose carers had participated in the behavioural interventions had significantly reduced levels and rates of depression compared with patients whose carers were in the control conditions. There was no difference in outcome between the two behavioural or between the two control conditions. The benefits were retained at 6 months' follow up. Moreover, the depression scores of the carers fell significantly. In the second study, a randomized controlled trial, behavioural management strategies combined with supervision of a home-based exercise programme for people with dementia improved physical health and depression in patients with AD (Teri *et al.*, 2003). An important lesson emerging from these studies is the ability of carers to be effective therapists, given training and support.

11.11 SPECIAL CATEGORIES OF CARERS

Certain groups of carers face extra levels of isolation beyond that usually experienced by others in this role (Brodaty, 1998b). Migrants are doubly isolated by culture and language and are less likely to use services. Patients tend to lose their acquired languages first, making integration into mainstream care more difficult. Indigenous people tend to have poorer health, inferior health services and more difficulty with access to services. Younger people with dementia encounter special problems as they are more likely to be still working,

have school-age children at home, have heavier financial commitments, have greater concern about heritability, have more difficulty obtaining a diagnosis and have greater difficulty integrating with mainstream services (Luscombe *et al.*, 1997). Patients who are professionals or prominent citizens, often find it difficult to accept community and residential services. Persuading such patients that they are no longer able to continue working can be a particular problem. Where couples dement, problems are more than doubled because of the lack of an informant to obtain a history, a carer to assist in management or anyone to compensate for the patient's cognitive losses. Finally, feelings of obligation and reciprocity in a relationship are not as well developed in second marriages. There is more likely to be resentment and more difficulties and disagreements amongst children from previous marriages with different viewpoints about management, especially about finances.

11.12 CONCLUSION

The management of the carers is integral to good care of a person with dementia. Carers should be regarded as partners, alongside patients, doctors, and other health professionals in the long haul that is the tragedy of dementia. Psychosocial interventions have the capacity to reduce carer distress and delay nursing home admission. They are also cost-effective. Prescription of psychosocial interventions should be made with the same rigour and specificity as in prescribing medications. Doctors recognize that for drugs there are indications and contraindications, side effects, latency periods for onset of action, limited duration of need for the medication and need for constant review of continuing medication. These same considerations apply to psychosocial interventions (Brodaty and Gresham, 1992).

One caregiver's view

EMERSON MORAN

Emerson Moran is a writer in Florida. Pat, his wife, was diagnosed with early onset Alzheimer's disease in 1999. Previously, Mr Moran was a communications executive with the American Medical Association. This article is adapted from his remarks at an AMA scientific news briefing in New York City in January 2004.

The first time Pat didn't know who I was felt like we'd each been kidnapped.

Her early onset Alzheimer's had been at the centre of our life for several years, but I never expected our connection to fracture so soon. After all, I'd just quit a 10-year job to better manage our living with the disease by moving from Washington, DC, to South Florida, where Pat loved the warmth, water, bright flowers and the exotic birds.

That evening, after supper, we'd gone to the ocean to visit Pat's pelicans – when they fly low, she waves and calls them to come 'over here, over here'. At sunset, we headed home, about 15 minutes away. I remember the big thunderheads ahead of us, out over the Everglades, the wind shearing off their tops like anvils. It was like a Frederic Edward Church painting.

Halfway home, Pat was distressed and frightened. She asked who I was, what was I doing to her, where was I taking her. She tried to open the car door to escape. I was scared. Shortness of breath, dry mouth, jumbled thoughts. It was hard to look calm, talk and drive calmly at the same time.

At home, we looked at photos of our Philadelphia Quaker wedding, of trips to Tuscany and Cape May Point, of family and friends. She couldn't recognize the facts of our history, but she cried over our emotional memories. She didn't know my name, but knew we'd loved each other a long time. That was good enough for me then, and still is.

When I first saw Pat 20 years ago it was like in those movies when they freeze the frame. My frame froze. I've been with her in that frame ever since. What I didn't know for years and years was that Alzheimer's was in our frame, too.

Pat's Alzheimer's was diagnosed 5 years ago, but had already been controlling our life for a long time. We just didn't deal with it. Denial is a powerful force.

We had a very tough time at first. After all, a diagnosis of Alzheimer's is a death sentence, isn't it? And that's the first thing I felt: death, despair, deep depression, grief and fear – gripping, chilling, stunning fear. When CS Lewis lost his wife – she was the love of his life, too – he wrote that no one ever told him how much grief feels like fear. Well, yes it does.

We got through that, and, gradually and gratefully, and with a lot of help, we found ways to cope. We also discovered that our ability to deal with Alzheimer's progressed right along with the disease's progression. What we never expected was how far we'd end up going, geographically and spiritually, to manage our living with Alzheimer's before Alzheimer's totally managed us.

We tried to perpetuate our old way of life for a long time, and then reached a point where it made no sense, where our old 'normal' didn't work any more. In the landscape of our life, normal had moved. We had to move with it, by creating a new landscape and a new normal, and by building a new life frame, with Alzheimer's now the biggest figure in our picture.

We began our new way of life Labor Day weekend 2002 when we moved 985 miles from Washington to Florida, leaving behind old job, old home, old normal. It felt like jumping off a cliff. The 2-day drive was easier than I thought it would be. We could never do it today. But, back then, Pat could still handle herself alone in a strange bathroom; eat without help in a crowded, noisy restaurant; feel safe in an unfamiliar motel room. She was happy in the car. She munched M&Ms, and sang along to the Beatles and Sarah Brightman. We stopped in St Augustine – the oldest permanent European settlement in North America – and took the horse and carriage ride to the Fountain of Youth, of all places.

A week later, she didn't know who I was. I'd read the Alzheimer's books, like *The 36 Hour Day*, and knew intellectually that this moment was certain to arrive. But, Lord, I thought, not this day! Please, not this day!

Later, I had one of those dreams where I'm trying to get some place. This time I was struggling to get to the airport in some desolate, desert-like place. I had to climb up a steep

incline, crawl down a deep depression, and back up over rocks and through dust. The airline check-in desk was up above me, to the right, on the edge of a cliff. Out of nowhere, a pickup truck blocked my way, machine gun in the back, like those 'technicals' the Somalian war lords drove in *Black Hawk Down*. There was shooting, confusion. Then I woke up, full of dread and apprehension.

Yes, changing our life was like jumping off a cliff. But we had to jump. It was the only way to break away from our old way of life. I took a family leave from the job I'd had for 10 years. That, plus accumulated vacation, bought 4 months to sort things out, and to just be together. We decided that I'd quit my job. We'd move to Florida, where we had family and friends. Cost of living was going to be much lower, and we figured I could earn enough freelancing to get by. What we hoped to do was carve out a way of living that would:

- keep us together as many hours in each day as possible;
- embrace Pat with care and comfort and laughter;
- allow me to work from home;
- prop me up with enough emotional and physical support to keep us going.

Looking back, I can see how we actually changed the equation of what had been a pretty conventional career-driven middle-class American existence. In our old formula, work was cemented solidly at the centre, with everything else in orbit, around the edges. In our new formula, we put Pat and Alzheimer's in the centre, with work kicked out into an orbit of its own, not quite on the edge, but not in the centre, either.

This is pretty easy to articulate after the fact. But at the time it felt like radical, uprooting, life-altering, mind-boggling, heart-thumping, cliff-jumping change. Some simple things have helped a lot. Here are six that seem real clear to me from where we sit today:

1. Family: **there is a higher power in a loving family** – we feel it and it fuels us every day. When we met, Pat was a widow, I was divorced. She never had the chance to have her own kids. Then along came my crowd. Now it's up to three married sons (one, a Marine Corp F-18 fighter pilot, serving twice in Iraq), six grandchildren, plus three step-grandchildren, my sister, brother, nieces, nephews, cousins and their kids, my own ancient parents – we now live 2 minutes away – and they all love Pat. Even my first wife loves Pat!
2. Early on, in those darkest weeks after 'The Diagnosis,' a colleague told me: '**This is not the end of the world.** You still have years ahead of quality and value and love together.' That stuck like glue. It's my creed.
3. A friend reminded me: 'This is that rainy day they tell you about. **The future is now.**' Whatever you have now, use it for what you need to do now.
4. To best care for Pat I had to **take care of myself** – physically, mentally and emotionally. Early on, I was mad as hell and didn't even know it until I exploded in front of a co-worker and kicked a door so hard that they tell

me it's still dented. By 3.00 pm the next day I was sitting in front of a psychologist with a lot of experience dealing with Alzheimer's families. We made a deal. I'd stick with Dr Jacobek's counselling, and she would help me stay as 'whole' as possible, no matter what happened, all the way to the end, and beyond. That was almost 5 years ago, and we're still at it, 1200 miles apart, over the phone, every 10 days. **Therapy is my gut check**, my outlet of last resort. I'm not sure how Pat and I could carry on without it.

Working out – physical exercise – is therapeutic, too.

I'm not a jock, but today, working out is actually a refuge for me. Neighborhood power walks; the gym's monthly 'geezer discount'; free weights in the garage. The cadence, the repetitions, the breathing are meditative. The endorphins fight depression.

5. **Get Pat all the help we can find.** We've been blessed with skilled, attentive doctors, and we learned that it's a good idea to have the same internist. He treats us as individuals and as a couple. Pat can't be left alone while I work. Handling this defines how we function. A sign on Dixie Highway in our new hometown led us to a local day programme for Alzheimer's. It was a big factor in deciding where to live.

The programme is 10 minutes from home, in a church, next to our local high school. Pat's there from 8.00 am to 4:00 pm Monday through Friday. The morning roundtrip is my commute to work and Pat's time there gives me a chance to get my own job done.

The programme's home is a 40-year-old Lutheran church hall, across a vacant lot from our local high school ('Home of the Gators'). More therapeutic than just day care, it's staffed by professionals, small enough for lots of gentle attention, and full of fun.

At Christmas, one registered nurse brought her kids' pet goat, wearing reindeer antlers. Pat still remembers the 'rein-goat,' a remarkable memory for a woman whose only moment of meaning usually is the one she is in.

One patient, a former golf pro, taught Pat how to putt. Some days, I wouldn't mind being there myself. Then there's Stacia, a crusty, no-nonsense, loving 70-something Polish angel who couldn't stand retirement and seems to find great satisfaction helping people just like us. Stacia brings Pat home in the afternoon, helps around the house, takes Pat to get her hair and nails done, and stays with her when my work takes me away. Stacia's parting words usually are, 'I'll take care of Pat. You take care of yourself'.

6. **Medication to manage and modify Pat's behaviour** is the final factor that holds the whole thing together. Pat has exploded with all the agitation, rage and aggression that can accompany Alzheimer's. It's terrifying when it erupts. I learned the hard way to keep a table between us for protection.

A wise geriatric psychiatrist prescribed a strong antipsychotic that many people with schizophrenia use to help keep their lives in order. This little pill calms the

rage, quiets the aggression and takes away the agitation, without taking away anything else. I don't know how we would get through the day, much less live at home together, without it.

With or without medication, though, Rule Number One is this: You will never win an argument with someone with Alzheimer's. Never. Don't even try.

Rule Number Two is old and golden: Do unto Pat as I would have Pat do unto me. Pat can't bathe herself, choose between red or blue blouse, put on earrings, shave her legs, read the paper, chew steak or pizza, pour herself a cup of coffee, or find our bathroom on her own and in time. She can, however, always find the chocolate chip cookies. We joke about putting the cookies in the bathroom. Thankfully, 'Depends' have taken the crises out of incontinence.

The Pat I fell in love with had a wonderful artistic talent (sketches and watercolours mostly), but the Alzheimer's blocked the path to her creativity years ago. Passion for her art once consumed her. Today she won't even pick up a crayon. We still have her rough drawings and pencilled story line for a children's book on meerkats in the Kalahari Desert, a cherished, unfinished work, frozen in time by her disease, an artefact of Alzheimer's.

Her brain blocks other forms of communications. Most times, she can't find the words to ask for what she wants, tell me about her day, or name who's talking to her on the phone. She says 'Thank me', instead of 'Thank you' – then giggles at the odd sound of it.

What she can do is whistle, as she never did before. It's the first sound she makes in the morning and the last at night. I tell her she's in 'full pucker'. Old movie tunes from the 1940s are favourites. Over Christmas, she was stuck on 'Easter Parade'. Sometimes I whistle with her; it's one of the few things we can still do in harmony; intimacy, redefined.

We've always loved movies, and our own critique afterwards. But now Pat can't follow a movie or TV shows with complex story lines. However, she really likes 'Sponge Bob', and belly-laughs at 'Seinfeld'. We joke a lot. I tell her that, with Alzheimer's, there's no such thing as TV reruns.

Except for 9/11. We lived in DC, on Connecticut Avenue, close enough to hear sirens and see smoke from the Pentagon. Pat experienced 9/11 on TV over and over, each time the first time, each time brand new, on September 11 and September 12: right up to today. She still gets scared when she sees the images. But then, so do I. I'm pretty sure that my own post-9/11 priorities propelled how and when we changed our life so profoundly.

What we are doing has a high cost. Nearly 45 per cent of our income goes for health insurance, medications, the day programme, Stacia helping at home. Just like hundreds of thousands of other American families, we do this on our own.

Much has changed. The kids up North have to pay their own airfare when they come down to see us. We've ended our week-long family vacations at Cape May Point. But then, where we live now sure removes the urge for a mid-winter get-away in the sun. There's no more eating out several nights a week, but my home cooking is improving. I roasted the Thanksgiving turkey over charcoal, with cornbread stuffing and a maple syrup glaze. A pot of chilli is on the stove as I write this.

Shopping is more Sears than Bloomingdales, eBay and web discounts. I clip coupons. I've discovered warehouse shopping – toilet paper in 35-roll bundles, 300-ounce Tide. Plus, a perk of paradise, \$19 orchids in full bloom.

Our favourite time of the day is bedtime, which is earlier and earlier. Pat starts shutting down when the sun starts going down. She seems to settle into her own private peace in bed, curled up, eyes closed, covers pulled into a tight cocoon. She'll lay awake for 2 or 3 hours while I read, watch TV, talk to my family on the phone. We listen to music; New Age Celtic tunes strike her Irish chords. I ask, but she can't tell me, what goes on behind her closed eyes, except to say, 'I'm working on things'.

She doesn't pay much attention to the TV, unless it's the Chicago Cubs baseball team. When we lived in Chicago in the 1990s, Pat loved taking the elevated train to Wrigley Field. One night, the broadcasters cut from the playing field to the cheering fans. Pat seemed sound asleep. It was loud, it was late, I turned off the TV. In the darkness Pat said, 'Put it back. It's fun'.

Pat and I are the lucky ones. Somehow, so far, we are pulling this off, a day at a time and we do have fun. We laugh a lot, and we play a lot.

The great irony is that they tell us that Alzheimer's is a catastrophic disease but, on any given day, we don't feel like we're in the middle of a catastrophe. In many ways, we are happier now than ever before. We talk about it. We agree that surrender, acceptance, and loving each other no matter what are big reasons why.

I've been to the support groups and I've seen that not all Alzheimer's families are as fortunate. There's terrible pain and fierce anger out there. It hurts just to be near it.

I read a terrible news story maybe four years ago, from Washington. Just up 16th Street from the White House, in front of the Capital Hilton, a woman driving a Ford Taurus stopped at the light. Her father was sitting beside her. The paper said he had Alzheimer's, that she took care of him. Before the light could turn green, she pulled a gun, killed him and turned it on herself. The light changed to green, the traffic moved around them, and there they sat, at the bloody end of their own sad road.

I worry how close many other families have gotten to that point. I bet more than we'd like to think, not the point of violence, certainly, but maybe, secretly, wishing the end would come sooner rather than later.

This disease really is different, you know. There is no real treatment yet. Drugs can briefly slow down the clock, but

there will be no remission, no cure, not for Pat and not, yet, for the 4 or 5 million others in the USA just like her.

We hope our 'together' lasts a long time, but, like many Alzheimer's patients, Pat's body has not been kind to her. Doctors call it 'comorbidity' – coronary artery disease, breast cancer, diverticulitis, fibromyalgia, depression – and she's only in her mid-60s. In a medical crisis, do we treat or not treat? What's moral, what's ethical? Do we risk the distress of heart surgery, colostomy, chemotherapy? Or do we let nature take its course? Where's the right and wrong?

Nothing prepared us for issues like these. Pat can't decide for herself. It's up to me. Some nights, when answers don't come, the loneliness of Alzheimer's can be worse than the certainty of how it's all going to end, no matter what we do.

Alzheimer's is a medical Mount Everest that no one has figured out how to conquer. When they do, when they break through to the summit, it'll be too late for us, but not for many of the others. I guess that's the best hope there is with Alzheimer's: that money, hard work, luck and genius will pry

loose the mystery of this disease that is so slowly being unlocked from inside this human genome of ours.

Pat and I work hard every day to just live life on life's terms. One melody Pat whistles is an old Irving Berlin tune called 'Always'. I have no idea where she gets it from. I 'Googled' the lyrics. They're up on our refrigerator door, held there by a tacky magnet from the boardwalk at the New Jersey seashore. This is the refrain:

The days may not be fair – always.

That's when I'll be there – always.

Not for just an hour,

Not for just a day,

Not for just a year – but always.

I can't bear to think of the silence in my life when the whistling stops.

Pat sometimes looks at me, startled, and asks, 'Where's Emerson?' I tell her, 'I don't know, but if you see him, tell him I'm looking for him, too'. And we laugh. Always.

Health economic aspects of dementia

A highly prevalent group of disorders such as dementia presents a challenge for any healthcare and social support system. The combination of a costly care (Ernst and Hay, 1994; Winblad *et al.*, 1997), difficulties in funding health care and an important contribution by informal caregivers focus on the basics in any health economic analysis and has indeed put the costs of dementia and cost effectiveness of dementia care into focus. It has been debated whether ‘the welfare state’ will be able to care for the increasing number of elderly people in general (OECD, 1996), and with dementia in particular (Lovestone, 2002). However, in the light of the enormous economic impact of dementia, it is surprising that the health economics of dementia has such a small scientific base (Jonsson *et al.*, 2000; Gray, 2002). The first (and still the only) basic textbook in this field (Wimo *et al.*, 1998a) was published in 1998 and reviewers have stressed the need for further studies (Salek *et al.*, 1998; Walker *et al.*, 1998; Jonsson *et al.*, 2000; Shukla *et al.*, 2000; Grutzendler and Morris, 2001; Lamb and Goa, 2001; NICE, 2001; Clegg *et al.*, 2002; Gray, 2002; Lyseng-Williamson and Plosker, 2002; Wolfson *et al.*, 2002; Birks and Harvey, 2003; Jonsson, 2003; Leung *et al.*, 2003; Lyseng-Williamson and Plosker, 2003; Olin and Schneider, 2003).

12.1 PERSPECTIVE

An important purpose of economic evaluation is that it should serve as a tool for decision-making regarding allocating of scarce resources (Drummond *et al.*, 1997). There are many

‘players and payers’ involved in delivery and financing of dementia care. Therefore it is essential to define the perspective of any pharmaco-economical analysis. The viewpoint may be a county council, a municipality, the public sector in general, an insurance company, a family member or a patient. The main cost drivers are costs for living (in its wide context, including also care in nursing homes) and informal caring (Wimo and Winblad, 2003b). There is a complex interaction on one hand between those who finance the care and on the other hand those who may benefit from the results of interventions (such as drugs or caregiver support programmes). Therefore, the detection of inoptimal incentives is an essential part of the economic analysis. Limiting the economic analysis only to the healthcare sector or the public sector exclude substantial components from the analysis. Thus, a societal perspective where all relevant costs are included regardless of where they occur and regardless of who pays is often to be preferred.

12.2 TYPES OF STUDIES AND DESIGN ASPECTS

Different types of analyses are presented in Box 12.1.

12.2.1 Descriptive studies

Cost description (CD) describes only the costs (no outcome) of a single treatment/care, without making any comparison between alternative treatments. Thus, CD cannot give any

support in priority discussions but presents a framework for how costs are calculated.

Cost of illness (COI) studies are also descriptive. The COI is equal to what these resources would have been used for if there had been no case of illness (the opportunity cost). Two approaches can be used: an incidence approach or a prevalence approach. With the incidence approach the costs for new cases are estimated where both the annual costs and future (discounted) costs are included. In the prevalence approach the costs for all cases during, for example, a year are estimated – both for those already suffering from dementia and for new cases occurring during the year in question (Lindgren, 1981; Rice *et al.*, 1985). Only exceptionally have both approaches shown the same results. The choice of approach depends on the purpose of the study; if the aim is to illustrate the economic consequences of interventions, the incidence approach is preferable. If the idea is to estimate the economic burden during a defined year the prevalence approach is the option.

Box 12.1 *Different kinds of health economical studies*

Descriptive studies

- COI Cost of illness

Evaluation studies

- CA Cost analysis (incomplete evaluation)
- CBA Cost benefit analysis
- CEA Cost effectiveness analysis
- CMA Cost minimization analysis
- CUA Cost utility analysis
- (CCA Cost consequence analysis)

Another issue is whether to use a top-down or a bottom-up approach. In the ‘top-down’ approach the total national cost for a specific resource is distributed on different diseases. The ‘bottom-up’ method starts from a defined subgroup with, for example, dementia, and registers all cost of illness related to it, followed by an extrapolation to the total dementia population. The problem is that to compensate for comorbidity and net costs may be difficult to estimate. It is also important to specify the included cost categories (e.g. cost of informal care). It is obvious that dementia care is costly, but the great range in cost figures in Table 12.1 illustrates that the costing approaches vary.

12.2.2 Economical evaluations

In a cost analysis (CA), only the costs of different therapies are compared (not outcomes). Thus a CA is an incomplete economical evaluation. A complete economical evaluation includes the incremental costs and outcomes, and comparisons between different treatment alternatives.

In a cost minimization analysis (CMA), the effects of different treatments are assumed to be equivalent and the analysis is focused on identifying the cheapest therapy. The value of CMA is questioned, since the assumption of similar treatment effects is problematic (Briggs and O’Brien, 2001).

In a cost effectiveness analysis (CEA), the effect is expressed as a non-monetary quantified unit such as the cost per nursing home admission averted.

A cost benefit analysis (CBA) expresses all costs and outcomes in monetary units, e.g. dollars or euros. Few attempts have been made to apply CBA to dementia. It has, however, been argued that CBA-approaches such as ‘willingness to pay’ could be of value (Wimo *et al.*, 2002).

Table 12.1 *Cost of illness studies expressed as US\$ 2003 (currency conversions to US\$ by PPPs [purchasing power parities], time transformations by CPI [consumer price index])*

Country	Annual costs per patient US\$ 2003	Cost categories included	Source
USA	57 000	D, IC	Ernst and Hay, 1994
England	6 600	D	Smith and Shah, 1995
Canada	14 300	D, IC	Ostbye and Crosse, 1994
Sweden	24 400	D	Wimo <i>et al.</i> , 1997b (gross costs)
Sweden	16 500	D	Wimo <i>et al.</i> , 1997b (net costs)
Germany	12 800	D	Schulenberg and Schulenberg, 1998
Denmark	10 400	D	Kronborg Andersen <i>et al.</i> , 1999
Italy	64 400	D, IC	Cavallo and Fattore, 1997
The Netherlands	10 800	D	Koopmanschap <i>et al.</i> , 1998
Ireland	13 900	DC, IC	O’Shea and O’Reilly, 2000

Source for PPP and CPI: OECD, data on file: www.oecd.org. Figures are rounded off.
D, direct costs; IC, informal care

In a cost utility analysis (CUA), the effect is expressed as utilities, such as QALYs (Quality Adjusted Life Years) (Torrance, 1997).

It is important to include a discussion of uncertainty in economical evaluations (Briggs and O'Brien, 2001) and important factors should be varied in a sensitivity analysis.

In a cost consequence analysis (CCA), cost and outcomes are analysed and presented separately. The value of CCA is under discussion (Winblad *et al.*, 1997), since results may be difficult to interpret and the selection of outcomes may be biased.

12.3 THE NEED FOR MODELLING

An intervention in dementia may influence the course of the disease (e.g. the deterioration rate in functional ability, the position in a care organization and perhaps survival). Therefore, an economic evaluation has to take into account impacts on costs and outcomes during the whole lifespan. Most clinical studies last for 6–12 months. Owing to practical and ethical issues, single studies covering the whole disease period will probably never be undertaken. One option to determine long-term effects is to extend ongoing studies. In randomized controlled trials (RCTs) it is difficult to maintain the original design for many years, but open follow-up studies have been used on tacrine (Knopman *et al.*, 1996) and donepezil (Geldmacher *et al.*, 2003). However, there are several drawbacks, such as selection bias, patients lost to follow up and problems in defining controls.

Therefore, there is a need for modelling approaches (Buxton *et al.*, 1997). The basic idea is that results from a short core period are extrapolated to a longer period. Inputs from several sources, e.g. efficacy, costing and progression, are used. Markov models are frequently used for this purpose (Sonnenberg and Leventhal, 1998). Other approaches, such as decision tree models (Weinstein and Fineberg, 1980) and survival models (Fenn and Gray, 1999) can also be used. Discounting of costs (and perhaps outcomes) is recommended. The discount rate is often 3–5 per cent (Siegel *et al.*, 1997), but it can be varied in a sensitivity analysis.

Models are controversial. Long-term effects, such as exhaustion of carers and staff, which do not occur in the core period, and symptoms that do not have a linear progressive course, such as BPSDs (Behavioural and Psychological Symptoms in Dementia) (Ferris and Mittelman, 1996), are difficult to model. A model is also linked, implicitly or explicitly, to a specific organization of care. The drug authorities are often sceptical to models, since such studies are not 'empirical'.

12.4 FAMILY MEMBERS AND INFORMAL CARE

Informal carers (mostly spouses or children of demented patients) are of great importance in dementia care. An informal carer is often part of a 'dementia family'. In that sense, their

situation can be analysed in terms of, for example, burden, quality of life, coping, stress, social network and morbidity (Max *et al.*, 1995; Jansson *et al.*, 1998; Schulz and Beach, 1999; Wimo *et al.*, 1999b; Almgren *et al.*, 2000).

They are also often producers of an extensive amount of unpaid informal care (Rice *et al.*, 1993; Stommel *et al.*, 1994; Langa *et al.*, 2001; Moore *et al.*, 2001; Wimo *et al.*, 2002), which constitute a great part of the societal costs.

Measuring caregiver time is problematic. Support in personal activities of daily living (ADL) and instrumental activities of daily living (IADL) are rather well-defined activities. However, a substantial part of caregiver activities is linked to supervision to manage behavioural symptoms or to prevent dangerous events (Wimo *et al.*, 2002). The assessments of supervision and surveillance in terms of minutes and hours may, however, be difficult.

Two other important factors are care productivity and joint production. A formal caregiver is probably more efficient and takes less time to support ADL tasks than an informal caregiver. This must be considered if a replacement approach is used (see below). Joint production means that the patient and the caregiver are doing things together, for example shopping.

Costing informal care is a complicated and controversial issue (Koopmanschap, 1998; Jonsson *et al.*, 2000). There are two frequently used methods: the opportunity cost approach and the replacement cost approach.

Whether the caregiver is paid or not is not of interest for the economic valuation. Payment has an impact on the distribution of the economic burden but not on the total societal cost. The relevant cost is the opportunity cost, i.e. the benefits that are forgone because a resource – in this case caregiver time – is not put to its best alternative use. Thus, the question is to identify the alternative use of the caregiver's time. If the alternative is working on the labour market, the cost for informal care should be valued to the production loss owing to absence from work.

However, more problematic is the costing of leisure time and caregiver time during retirement. There is no consensus on how this should be performed. The cost for the caregiver's time may be the value of the time used as leisure time (Karlsson *et al.*, 1998). However, there is no such market price available. Survey methods (for example the contingent valuation method – Johannesson *et al.*, 1992) is an option.

With the replacement cost approach it is assumed that the informal carer should be replaced with a professional carer on a 1:1 ratio. The informal caregiver's time and the professional caregiver's time are regarded as perfect substitutes. However, we do not know if there actually will be a complete replacement with a professional carer.

12.5 OUTCOME MEASURES

Cognition is considered as the mandatory primary efficacy outcome in most dementia trials. There are, however, other

outcomes that are probably more important for the patients and the caregivers. Quality of life, ADL-capacity, mood-depression or BPSDs may be of greater interest than cognition in the long run. ADL-capacity and BPSDs are also essential in care planning.

Surrogate end points are inappropriate to use in CEA (Johannesson *et al.*, 1996). Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975) is often used in dementia studies as well as other measures of cognitive capacity such as the ADAS-cog (Alzheimer's Disease Assessment Scale – cognitive subscale) (Rosen *et al.*, 1984). However, in our view, they should be regarded as surrogate end points. Since MMSE is highly correlated to costs (Ernst *et al.*, 1997; Hux *et al.*, 1998; Wimo *et al.*, 1998c; Jonsson *et al.*, 1999b), and also to other, more relevant outcomes, such as ADL-capacity, position in care organization and severity of dementia, it has frequently been used in economic evaluations of dementia. MMSE is also used in most longitudinal population based studies and thus it may be useful as a link between clinical studies and population studies in the discussions of efficacy versus clinical effectiveness.

However, delay in progression in terms of severity presents a broader outcome than cognition and severity scales such as clinical dementia rating (CDR) (Berg, 1988) and the global deterioration scale (GDS) (Reisberg *et al.*, 1988) or multidimensional instruments such as Gottfries–Brane–Steen scale (GBS) (Brane *et al.*, 2001) are therefore more relevant to use than cognition.

Postponing or preventing nursing home placement has also been suggested. A study by Knopman *et al.* (1996) indicated that nursing home care can be postponed about by about 1 year with tacrine treatment. Sano *et al.* (1997) showed similar effects with vitamin E/selegiline treatment. A study on donepezil indicated an even longer postponing of institutionalization (Geldmacher *et al.*, 2003). However, the situation is more complex regarding caregivers. On the one hand, it may be an advantage that spouses can go on living together, but on the other hand, a prolonged period at home may be more stressful for the caregiver (Max, 1996). This potential risk was, however, not confirmed in the two published RCTs where the amount of informal care has been measured (Wimo *et al.*, 2003a, b).

Quality of Life (QoL) of both patients and caregivers is considered as a relevant outcome. Health-related QoL includes several dimensions, such as ADL, social interaction, perception, pain, anxiety, economic status, etc. One potential problem in QoL assessments is the patient's difficulties in evaluating his or her own health state (Stewart and Brod, 1996). Thus, proxies (mostly caregivers) are often used. Proxies *per se* is not necessarily a problem. The US Panel for Cost-Effectiveness recommends that the general public should value the health states and, in that sense, an indirect measurement is not disqualified (Siegel *et al.*, 1997). If the proxy is a family member, the answers partly may reflect the situation and interests of the proxy, which must be considered. Some attributes may be difficult for proxies, such as 'pain', whereas others, such as

'mobility' are less problematic. Interestingly, in a project where proxy-rated and self-rated QoL were used simultaneously, great differences between the two approaches occurred (Jönsson, 2003).

In principle, two kinds of instruments can be used: diagnostic specific or generic instruments (Bowling, 1995; Spilker, 1996; Salek *et al.*, 1998; Walker *et al.*, 1998).

More or less dementia-specific instruments such as DQoL (the Dementia Quality of Life instrument) (Brod *et al.*, 1999), QoLAD (Quality of life-Alzheimer's disease) (Selai *et al.*, 2001; Logsdon *et al.*, 2002) and Quality of Life Assessment Schedule (QoLAS) (Selai *et al.*, 2000; Elstner *et al.*, 2001) may be useful in CCA-trials but are inappropriate for complete economic evaluations since these instruments not are preference based (Torrance *et al.*, 1996; Siegel *et al.*, 1997).

There are a great number of generic QoL scales, such as the Sickness Impact Profile (Bergner *et al.*, 1981), the Short Form 36 (SF-36) (Ware and Sherbourne, 1992), the QLA-scale (Blau, 1977), the Health Utilities Index (HUI) (Torrance *et al.*, 1996; Neumann *et al.*, 2000), the EuroQoL/EQ-5D (Coucill *et al.*, 2001) or the Quality of Wellbeing Scale (QWBS) (Kerner *et al.*, 1998). HUI, EQ-5D, QWBS and the caregiver quality of life index (CQLI) (Mohide *et al.*, 1988) can be used to calculate QALYs (Torrance, 1997).

QALYs are used in CUA and reflect both quantity and quality of life (Torrance, 1996; Torrance *et al.*, 1996) and give opportunities for comparisons with other diseases. Utilities are expressed as a figure between 0 (death) and 1 (perfect health). QALYs are not uncontroversial (Tsuchiya *et al.*, 2003). Chronic incurable progressive disorders may be disfavoured when compared with, for example, curative surgical treatment, such as cataract surgery or hip replacement surgery.

There are also other approaches, such as DALYs (Disability Adjusted Life Years) (Allotey *et al.*, 2003) and HYE (Healthy Years Equivalents) (Dolan, 2000). However, DALYs focus on productivity more than quality of life and HYE require a great number of health scenarios (Torrance, 1996).

Burden scales, such as the Burden Interview (Zarit *et al.*, 1980) can to some extent be used as indicators of caregiver QoL, but the interplay between patient status, caregiver QoL and burden is complex (Deeken *et al.*, 2003).

In conclusion, the choice of outcome measure in economic evaluation in dementia is not an obvious one. As different outcome measures give different pieces of information, several outcome measures can be used.

12.6 RESOURCE UTILIZATION IN DEMENTIA

The costing process usually consists of two phases: first, resource utilization is expressed in terms of physical units (such as nursing home days), and second, the resource utilization figures are calculated into costs by the use of unit costs for each resource. RUD (Resource Utilization in Dementia) (Wimo *et al.*, 1998b) is an example of a framework

assessing the use of formal and informal resources, aiming at calculating costs from a societal perspective (Box 12.2). RUD has been used in several studies (Wimo *et al.*, 1999a; Wimo *et al.*, 2000; Wimo *et al.*, 2003a; Wimo *et al.*, 2003c). A comprehensive battery can be time-demanding and thus a short version, the RUD Lite (Wimo and Winblad, 2003b) was developed. It was possible to limit the number of variables in the RUD considerably without losing the societal perspective in the analysis (RUD Lite covers about 95 per cent of the costs resulting from the complete RUD – Wimo and Winblad, 2003b). One part of the RUD is the caregiver time subscale. Other instruments that assess caregiver time are the CATS

(Caregiver Activities Time Survey) (Clipp and Moore, 1995) and the CAS (Caregiver Activity Survey) (Davis *et al.*, 1997).

Since the organization of dementia care varies between countries, any resource use battery must be adapted to the specific situation in a country.

12.7 PHARMACO-ECONOMICAL STUDIES

Even if it would be advantageous to design studies purely for health economical purposes, pharmaco-economics will probably be part of comprehensive phase III/IV studies (Hill and McGettigan, 1998). It is, however, important to refine the methods used (Briggs and O'Brien, 2001). It has also been debated whether pharmaco-economic aspects are best included in phase III or phase IV studies (Schneider, 1998).

Several pharmaco-economical evaluations have been published, mainly on the cholinesterase inhibitors (one on memantine) with various approaches. The early tacrine studies focused on costs and they are also based on the same efficacy study (Knapp *et al.*, 1994). Even if treatment seems to be cost saving, the range is large in these studies, from about 1 to 17 per cent, indicating not only different methodological approaches but also problems. Few studies are empirical (Table 12.2) and most evaluations are based on models (Tables 12.3 and 12.4). In the donepezil models, Markov models have been used with QALYs or severity (avoided) as outcome, while survival analysis have been used in the rivastigmine models. In the galantamine studies, the AHEAD (assessment of health economics in Alzheimer's disease) concept is used (Caro *et al.*, 2001). In general, the results favour drug use, but sensitivity analyses show a range in the results, indicating uncertainty.

Drug trials are often criticized regarding representativeness. Schneider *et al.* (1997) showed that study populations in dementia drug trials only reflect about 7 per cent of a general dementia population. The progression rate of cognition is slower in placebo groups in most clinical studies than in

*A positive value indicates net savings with treatment

population-based studies. Another issue is whether study populations reflect the dementia care organization that the results are generalized to.

12.8 MILD COGNITIVE IMPAIRMENT

Health economical effects on mild cognitive impairment (MCI) can be divided into short-term and long-term effects (Wimo and Winblad, 2003a). In the short-term perspective, an

intervention can perhaps result in a reduction of informal care in terms of IADL. Thus it is questionable whether the costs of a drug will be offset with a short-term viewpoint. In the long run, the question will be whether survival is affected and whether there will be any transitions of symptoms and resource use during the course of the dementia. To design studies to answer these questions is not easy. A synthetic approach with RCTs covering segments of the dementia course, modelling studies and open follow-up studies will probably be needed, resulting in some kind of 'best guess' judgement.

Table 12.3 Cost analysis models. Costs are expressed as US\$ 2003 (PPPs). Figures are rounded off.

Drug	Model length (years)	Cost difference*	Cost difference (%) v comparator	Range in sensitivity analysis	Comment	Ref
Tacrine	4.4	2900	17.3	US\$113–6595	Costs effects annualized by study's authors	Lubeck <i>et al.</i> , 1994
Tacrine	5.3	11 500	7.5	US\$698–26 687		Henke and Burchmore, 1997
Tacrine	9	2600	1.3	0.6–5.2%		Wimo <i>et al.</i> , 1997a

12.9 PHARMACO-ECONOMICS AND DRUG AUTHORITIES

New drugs go through several steps within drug authorities before entering the market. These steps are not necessarily handled within the same authorities. While the registration process in the European Union is being harmonized through EMEA (CPMP, 1997¹), focusing on cognition, ADL and a global effect (Hill and McGettigan, 1998), decisions about pricing and reimbursement remain on the country level. Furthermore, there may be different forms of budget restrictions on various levels in the care organization.

In the USA, the specific guidelines for antidementia drugs presented by the FDA demands 'clinically meaningful effects' (Leber, 1997).

The drugs that are used in dementia are rather expensive and the fact that a drug is registered in a country does not mean that the drug will be available for all patients. The critical issue is the reimbursement decisions (Drummond, 2003). For example, in Sweden the cholinesterase inhibitors are reimbursed as other drugs. However, in Sweden a new authority has just been founded to handle questions about reimbursement on a national level. The drug authorities in Australia and Canada demand health economical evaluations as part of the reimbursement decision process (Hill and McGettigan, 1998). The Canadian Health Technology Assessment Guidelines for Pharmaco-economics (CCOHTA), focus on meta-analysis and epidemiological data and emphasize the use of cost benefit and cost utility analysis (CCOHTA, 1997).

12.10 INTERNATIONAL COMPARISONS

The way care is financed and organized as well as the relative supply of different forms of care, the general taxation level and the economical strength of countries are factors that make comparisons between countries difficult.

Comparing currencies also present problems. Usual currency exchange rates reflect trade between countries rather than purchase power. PPPs (purchase power parities) (OECD website), are probably better to use than exchange rates. Comparisons over time both within and between countries are also linked to uncertainty. Consumer price indexes are often used, but an index that reflects changes in the health-care sector is better.

In multinational studies, the results should be aggregated in terms of resource use (and not in monetary terms) from every country. The cost calculations should then be performed in one currency, based on aggregated resource use. However, if there are great differences in care organization

between countries, aggregation of resource use results may also be problematic. For example, the concept of 'nursing home' can include a wide range of resources in terms of number of staff and their competence, physical environment, technical equipment, leading to different costs. There are also care concepts that are used just in one or only a few countries, such as DOMUS care in the UK (Beecham *et al.*, 1993), Group Living in Sweden (Wimo *et al.*, 1995) and Special Care Units (SCU) in the USA (Maas *et al.*, 1998). Home care may be dealt with by social services with poorly qualified staff, but also by specific teams focused on dementia. Even if a care organization can be roughly divided into levels (such as nursing home care – intermediate care alternatives – home care), such a simplistic division questions the validity of multinational intervention studies.

12.11 SEVERE DEMENTIA

Several years can pass in the stage of severe dementia (Winblad *et al.*, 1999). In a model of a Swedish cohort, the course of dementia with an estimated survival up to 9 years was simulated (Wimo *et al.*, 1998c). About 75 per cent of the total costs occurred in severe dementia, indicating that the total span for benefits during the total course in terms of cost reduction is only 25 per cent, if efficacy only is shown for mild to moderate dementia. The results indicate that severe dementia must be the focus for improved care and research. Many of the instruments we use today for outcome research show floor effects in severe dementia and they are not sufficiently sensitive to detect clinically relevant changes (Winblad *et al.*, 1999). Currently (March 2005) there is one drug, memantine (Reisberg *et al.*, 2003), approved for severe dementia, but studies on the cholinesterase inhibitors are underway.

12.12 CONCLUSION

The health economics of dementia is still in a premature state, even if the number of published studies is increasing. There is a great need for methodological improvement. There is also a great interest in the pharmaco-economics of dementia among the drug authorities in different countries and in the pharmaceutical companies who are engaged in antidementia drug research, illustrating that it is a hot topic.

Cross-cultural issues in the assessment of cognitive impairment

AJIT SHAH, JAMES LINDESAY AND IAN O NNATU

13.1 Demography	147	13.5 The differential prevalence and incidence of the different subtypes of dementia in different cultural and national groups	154
13.2 The epidemiology of dementia among ethnic groups in the UK	147	13.6 Future directions	158
13.3 The concept of pathways to care	152	References	159
13.4 The concept of multiple jeopardy	154		

Two types of cross-cultural studies will be discussed: cross-community studies comparing two or more ethnic groups in a single country, and cross-national studies comparing populations across two or more countries. We will focus on cross-community studies of ethnic groups within the United Kingdom (UK), using the Goldberg and Huxley (1991) model of pathways into care, and the significance of cultural factors. Cross-national studies will be examined with particular reference to methodology, aetiology and risk factors.

13.1 DEMOGRAPHY

13.1.1 International demographic changes

The size of the elderly population is increasing both in developed and developing countries, particularly the 'old old' (i.e. those >80 years) in developed countries (Ogunlesi, 1989; Zhang *et al.*, 1990; Kalachie, 1991; Jorm and Henderson, 1993; Snowdon, 1993). It is estimated that 90 million people live outside their country of birth (Bohning and Oishi, 1995).

13.1.2 National changes in ethnic minority demography in the UK

The proportion of ethnic minority individuals >65 years in Britain has increased from 1 per cent in 1981 to 3 per cent in 1991 (OPCS, 1983, 1993); this figure is likely to increase when the figures from the 2001 census become available in the near future. This contrasts with 17 per cent of the indigenous

population being over 65 years in 1991 (OPCS, 1993). In 1991, the composition of the ethnic elderly group was 41 per cent of 'Indian Subcontinent' origin, 34 per cent of 'Black Caribbean', 'Black African' and 'Black other' origin, 5 per cent of Chinese origin and 14 per cent from other ethnic groups (OPCS, 1993). Closer political and economic union with Europe may also lead to increased migration of elderly people between neighbouring states (e.g. English elderly retiring to Spain, France or Italy).

13.1.3 Implications of these demographic changes

The prevalence of dementia doubles every 5.1 years after the age of 60 (Jorm *et al.*, 1987; Hofman *et al.*, 1991). Thus, internationally, with the predicted increase in the elderly population (particularly of those >80 years), the absolute number of dementia cases will increase (Shah, 1992a, b; Jorm and Henderson, 1993; Ames and Flynn, 1994). There is, therefore, both a need and an opportunity to study the epidemiology, aetiology and risk factors, phenomenology, diagnosis, long-term outcome and prognosis of dementia cross-nationally and across different ethnic groups, to improve our understanding of dementia and enable adequate planning of services.

13.2 THE EPIDEMIOLOGY OF DEMENTIA AMONG ETHNIC GROUPS IN THE UK

There are several methodological difficulties related to epidemiological studies of dementia in different ethnic groups,

notably the definitions of age and ethnicity, diagnostic issues, and lack of appropriately validated screening instruments.

13.2.1 Age

Epidemiological studies of dementia in developed countries usually focus on those aged 60–65 years and older. Some ethnic groups have a shorter life span, retire early and assume the social role of an elder at a younger age (Rajkumar *et al.*, 1997). Thus, an age cut-off in the range of 40–55 years has been used in some studies of ethnic groups in the UK (Barker, 1984; McCallum, 1990; Manthorpe and Hettiaratchy, 1993) and in developing countries (Yu *et al.*, 1989; Zhang *et al.*, 1990; Ganguli *et al.*, 1995; Vas *et al.*, 2001). Similarly, for indigenous Australians, old age has been officially defined as starting at age 50 years (Commonwealth Department of Health, Housing and Community Services, 1991). Use of younger age cut-offs makes comparison with studies of indigenous populations more difficult (Rait and Burns, 1997), but does allow for the generation of larger sample sizes. Using the same cut-off age will facilitate development of psychogeriatric services alongside those for the indigenous population, and avoid confusion and fragmentation of service delivery. However, study sample sizes will be smaller as ethnic minority populations are generally younger than their indigenous counterparts. Another issue is the difficulty in ascertaining the precise age of some ethnic elders (Chandra *et al.*, 1994; Rajkumar and Kumar, 1996; Rait *et al.*, 1997). This can be overcome to some extent by using an ‘events calendar’ (Rajkumar and Kumar, 1996).

13.2.2 Race, culture and ethnicity

Race, culture and ethnicity are often used interchangeably. Guidelines on the use of ethnic, racial and cultural definitions for research, audit and publication are emerging (Anonymous, 1996; Singh, 1997). Race is a phenomenological description based on physical characteristics (Bhopal, 1997). Culture describes features that individuals share, and which bind them together into a community. It is possible to be racially different but culturally similar. The definition and identification of ethnicity can pose difficulties (Lloyd, 1992; McKenzie and Crowcroft, 1996; Pringle and Rothera, 1996) because it incorporates some aspects of race and culture, and other related characteristics including language, religion, upbringing, nationality and ancestral place of origin (Rait and Burns, 1997). It may be a personal expression of identity influenced by life experience and place of habitation, and can change over time (Senior and Bhopal, 1984). Ethnic minority individuals have been defined as those with a cultural heritage distinct from the majority population (Manthorpe and Hettiaratchy, 1993). This definition may be appropriate in the UK where the indigenous white population forms the majority, but poses difficulties in countries like Australia where the indigenous population is a minority.

Using the above definitions, individuals of Indian subcontinent, African-Caribbean, African, Chinese, Irish, Jewish, South African and East European origin can be described as UK ethnic elders. Thus, ethnic elders comprise a heterogeneous group with unique individual and collective experiences (Barker, 1984; Manthorpe and Hettiaratchy, 1993; Rait and Burns, 1997); they should not be amalgamated (Livingston and Sembhi, 2003), and consideration should be given to individual subgroups.

13.2.3 Other methodological issues

Epidemiological studies of dementia among ethnic elders in the UK are few in number. They are fraught with difficulties such as: ascertainment of age (Rait *et al.*, 1997); illiteracy (Lindesay *et al.*, 1997a, b); innumeracy; small sample sizes (Bhatnagar and Frank, 1997; Lindesay *et al.*, 1997b; Rait *et al.*, 1997); inappropriate sample frames (Richards *et al.*, 1996; Richards and Brayne, 1996; McCracken *et al.*, 1997); non-response (Bhatnagar and Frank, 1997; Lindesay *et al.*, 1997b; McCracken *et al.*, 1997) and refusal to participate (Bhatnagar and Frank, 1997); lack of valid tools to identify and quantify dementia (Lindesay, 1998; Shah, 1998); and lack of comparisons with the indigenous population (Bhatnagar and Frank, 1997).

Problems with sampling include: using an amalgamation of heterogeneous groups of ethnic elders (Bhatnagar and Frank, 1997; McCracken *et al.*, 1997; Livingston and Sembhi, 2003); an assumption that general practice patient lists are accurate and up to date (Bhatnagar and Frank, 1997; Lindesay *et al.*, 1997a, b; McCracken *et al.*, 1997); and the fact that many ethnic elders may be abroad for much of the time and only return to the UK when ill (Richards and Brayne, 1996; Bhatnagar and Frank, 1997).

In addition to using GP lists, sampling yield can be increased by means such as door knocking and snowballing, a technique whereby local community groups and ethnic elders themselves are asked to nominate other ethnic elders (Richards *et al.*, 1996; McCracken *et al.*, 1997; Rait *et al.*, 2000a, b).

13.2.4 Diagnostic issues

Psychiatric illnesses, including dementia, can be difficult to recognize among ethnic elders (George and Young, 1991). Cultural factors complicating diagnosis include: communication difficulties (George and Young, 1991; Shah, 1992c, 1997a, b; Livingston and Sembhi, 2003); taboo topics (Shah, 1992c); stigma attached to mental illness (Barker, 1984; Livingston *et al.*, 2002); bias and prejudice of clinicians (Solomon, 1992); institutional racism (Solomon, 1992); unfamiliarity with symptoms of mental illness by relatives (Manthorpe and Hettiaratchy, 1993); and illness being viewed as a function of old age. Another problem is the paucity of suitable screening and diagnostic instruments for dementia in this group (Shah, 1998). Cognitive tests standardized in

one ethnic group may not be appropriate for another because they may be influenced by culture (Gurland *et al.*, 1992; Chandra *et al.*, 1994; Teresi *et al.*, 1995; Livingston and Sembhi, 2003; Prince *et al.*, 2003), education (Chandra *et al.*, 1994; Teresi *et al.*, 1995; Stewart *et al.*, 2003; Kim *et al.*, 2003a, b; Livingston and Sembhi, 2003; Prince *et al.*, 2003), language (McCracken *et al.*, 1997; Livingston and Sembhi, 2003; Prince *et al.*, 2003), literacy skills (Chandra *et al.*, 1994; Kabir and Herlitz, 2000; Livingston and Sembhi, 2003; Prince *et al.*, 2003), numeracy skills (Prince *et al.*, 2003), sensory impairments (Lindesay *et al.*, 1997b), unfamiliarity with test situations (Chandra *et al.*, 1994; Richards and Brayne, 1996) and anxiety (Lindesay, 1998).

Education can influence performance on cognitive tests like the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975; Escobar *et al.*, 1986; Li *et al.*, 1989; Salmon *et al.*, 1989; Yu *et al.*, 1989; Phanthumchinda *et al.*, 1991; Tombaugh and McIntyre, 1992; Stewart *et al.*, 2003; Kim *et al.*, 2003a, b), and probably accounts for much of the difference in MMSE scores between immigrant groups and indigenous elders (Lindesay *et al.*, 1997b). The Chinese MMSE has developed different cut-off scores predicting dementia for different levels of education in respondents with good sensitivity and specificity (Katzman *et al.*, 1988; Zhang *et al.*, 1990; Sahadevan *et al.*, 2000); this has also been suggested in other ethnic groups (Murden *et al.*, 1991; Gurland *et al.*, 1992). An alternative approach that avoids using selective cut-off scores for two-stage population-based studies is to use operationally defined concepts of 'cognitively impaired' and 'cognitively declined' (Chandra *et al.*, 1998, 2001). For example 'cognitively impaired' has been defined as a score below the 10th percentile of the sample on a given cognitive test and is based on the reported 5 per cent average prevalence rate for dementia in Western countries. Illiterate subjects may be unable to complete tests that require reading, writing and drawing (Katzman *et al.*, 1988; Chandra *et al.*, 1994; Rajkumar and Kumar, 1996); illiteracy may also reduce access to information related to orientation in time and general knowledge (Lindesay, 1998). Innumerate subjects may be unable perform tests involving calculations (Chandra *et al.*, 1994; Livingston and Sembhi, 2003). A study of ethnic elders in Liverpool reported a higher prevalence of dementia in subjects unable to speak English (McCracken *et al.*, 1997); this may have been an artefact of their inability to speak English. Lack of education may also pose difficulties for the subject in understanding the nature of the test and therefore feeling that the questions are irrelevant and of little practical value (Chandra *et al.*, 1994; Richards and Brayne, 1996; Bhatnagar and Frank, 1997). Even if educational levels appear to be similar, there may be sociocultural inequality in access and quality (Bohnstedt *et al.*, 1994).

Tests identifying the discrepancy between age and date of birth (Bhatnagar and Frank, 1997; McCracken *et al.*, 1997) disadvantage ethnic elders born in remote villages with poor birth registration facilities, and those who have altered age and date of birth to facilitate migration and entry into institutions

(Rait *et al.*, 1997). Culture-specific questions (e.g. about royalty or politicians) also disadvantage ethnic elders (Bhatnagar and Frank, 1997; McCracken *et al.*, 1997), although these can be modified (e.g. dates of independence of the country of origin) (Chandra *et al.*, 1994; Rait *et al.*, 1997). Cultural concepts of orientation in time and place (Escobar *et al.*, 1986; Ganguli *et al.*, 1995; Lindesay *et al.*, 1997b) and preferential use of the Western or traditional calendar (Kua, 1992; Bhatnagar and Frank, 1997; Lindesay *et al.*, 1997b; Rait *et al.*, 1997) can also influence performance. Orientation items work well within the dominant culture but less well in some minority cultures (Rait *et al.*, 1997; Livingston and Sembhi, 2003); this was the case among Singaporean Chinese (Kua, 1992), but not in the Liverpool Chinese (McCracken *et al.*, 1997).

13.2.5 Developing new instruments for screening

There is a need to develop instruments that allow the subject to perform at their best without the influence of the extraneous factors listed above. Either new instruments can be developed, or existing instruments can be adapted and refined. Modifying existing instruments makes empirical and economic sense, and most research with well-developed techniques has adopted this strategy (Chandra *et al.*, 1994, 1998; Ganguli *et al.*, 1995; Hall *et al.*, 1993; Rait *et al.*, 1997).

Detailed knowledge of relevant cultural factors and their influence on ageing is required (Dein and Huline-Dickens, 1997). A Delphi panel of experts from the culture of interest or a more widespread consultation technique to examine each item for cultural relevance, translation, adaptation and modification has been used, with the aim of producing a culture-fair, education-free and analogous instrument (i.e. comparable meaning, difficulty, familiarity and salience) (Hall *et al.*, 1993; Chandra *et al.*, 1994, 1998; Graves *et al.*, 1994; Richards and Brayne, 1996; Richards, 1997). Both approaches can be combined (Rait *et al.*, 1997). The Delphi panel technique can use structured interviews, semistructured interviews, questions or vignettes (Rait *et al.*, 1997). The consultation approach involves professionals and/or lay members working closely, perhaps focusing on separate issues initially, and sharing them later (Rait *et al.*, 1997); this approach has been successfully used in developing a depression screening instrument for African-Caribbean elders in London (Abas, 1996).

Both translation and back-translation by separate groups of bilingual translators is necessary to ensure accuracy of translation (Brislin, 1970; Katzman *et al.*, 1988; Yu *et al.*, 1989; Chandra *et al.*, 1994; Lindesay *et al.*, 1997b). In addition, bilingual translators can ensure that the meaning and significance of the items are preserved as far as possible (Lindesay *et al.*, 1997b); this could be achieved by a Delphi panel when panel members originate from the same culture. Translation should endeavour to ensure content, semantic, technical, criterion and conceptual equivalence with the parent version of the scale for every item (Flaherty *et al.*, 1988; Rait *et al.*, 1997).

A sophisticated statistical technique employing item characteristic curves can be used to develop tests that are functionally equivalent (Gibbons *et al.*, 2002). Ideally, field pretesting is required to identify variations in dialect, logistic and conceptual problems, and practical difficulties (Li *et al.*, 1989; Yu *et al.*, 1989; Zhang *et al.*, 1990; Hall *et al.*, 1993; Chandra *et al.*, 1994, 1998; Ganguli *et al.*, 1995). Several rounds of field pretesting may be required (Chandra *et al.*, 1994; Ganguli *et al.*, 1995). This should, ideally, be followed by pilot testing to determine the distribution of scores (Chandra *et al.*, 1994; Ganguli *et al.*, 1996; Rait *et al.*, 2000a, b; Stewart *et al.*, 2001a, 2002) and their ability to discriminate between dementias of different severity (Chandra *et al.*, 1994; Lindsay *et al.*, 1997b).

Clear validation against a gold standard diagnosis of dementia is needed (Livingston and Sembhi, 2003). Ideally, this should be achieved by a standardized clinical interview (perhaps video or audio taped) with evaluation at two time points (Chandra *et al.*, 1994; Shah *et al.*, 1998) to confirm cognitive decline. Translated versions of the Geriatric Mental State Schedule (GMS) (Copeland *et al.*, 1976) have been used among older Asians, Chinese, Somali, African-Caribbean and British black people in Liverpool (Blakemore and Boneham, 1994; McCracken *et al.*, 1997), Indian subcontinent elders in Bradford (Bhatnagar and Frank, 1997), Chinese in Taiwan (Tsang *et al.*, 2002), and among respondents from India, China and southeast Asia, Africa, Latin America and the Caribbean (Prince *et al.*, 2003). An 'ad hoc' translated version of the Cambridge Cognitive Examination (CAMCOG) section of the Cambridge Mental Disorders of the Elderly Examination (CAMDEX) (Roth *et al.*, 1986) and the first part of the Schedules for Clinical Assessment in Neuropsychiatry (World Health Organization, 1992) have been used to gather systematic data to facilitate a clinical diagnosis of dementia in Gujarati elders (Lindsay *et al.*, 1997b; Shah *et al.*, 1998). Information from the CAMDEX interview and the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) interview (Morris *et al.*, 1989) have been used by a panel of physicians to make consensus DSM-III-R diagnosis of dementia among Cree Indians and English-speaking Canadians (Hall *et al.*, 1993). In most studies, the accuracy of the 'gold standard' instrument in diagnosing dementia has not been adequately examined; one useful method of validating such instruments is by serially following up dementia cases, whereupon true dementia cases are likely to demonstrate continuing decline in cognition (Shah *et al.*, 1998). The need for an assessment of functional impairment in the diagnosis of dementia in ICD-10 and DSM-IV can pose major problems in some cultures because of major conceptual difficulties in its definition and measurement across different cultures (Chandra *et al.*, 1994; Pollit, 1996; Richards and Brayne, 1996). Nevertheless, good interrater reliability between clinicians from six different countries in diagnosis of dementia using DSM-III-R and ICD-10 criteria has been reported (Baldereschi *et al.*, 1994), suggesting that these diagnostic constructs can be used in cross-cultural research.

Important properties of instruments measuring features of dementia are listed in Box 13.1. Data on the sensitivity to

Box 13.1 *Important properties of instruments measuring features of dementia (Katzman *et al.*, 1988; Chandra, 1994; Zaudig, 1996)*

- Patient characteristics
- User characteristics
- Type of instrument

- Training needs
- Duration of administration
- Availability of operational manual with glossary and definitions
- Qualification of users
- Costs

change are very important in incidence studies, because serial examination should be able to identify change in cognition as a measure of dementia (Chandra *et al.*, 1994). Ideally, most of these properties in the newly developed scale should be similar to or better than those of the parent version. In developing countries, either trained lay personnel or para-professionals are most likely to administer these instruments; even in developed countries, owing to limited research budgets, trained lay personnel may need to be used.

Versions of the MMSE have been developed in several languages, including Chinese (Serby *et al.*, 1987; Katzman *et al.*, 1988; Salmon *et al.*, 1989; Yu *et al.*, 1989; Xu *et al.*, 2003), Korean (Park and Kwon, 1990; Park *et al.*, 1991), Finnish (Salmon *et al.*, 1989), Italian (Rocca *et al.*, 1990), Yoruba (Hendrie, 1992), Spanish (Escobar *et al.*, 1986; Anzola-Perez *et al.*, 1996), Thai (Phanthumchida *et al.*, 1991), Cree (Hall *et al.*, 1993), Hindi (Ganguli *et al.*, 1995; Rait *et al.*, 2000a), Punjabi (Rait *et al.*, 2000a), Urdu (Rait *et al.*, 2000a), Bengali (Rait *et al.*, 2000a), Bangla (Kabir and Herlitz, 2000), Malayalam (Shaji *et al.*, 1996), Gujarati (Lindsay *et al.*, 1997b; Rait *et al.*, 2000a) and Sinhalese (de Silva and Gunatilake, 2002). However, comparisons between all these different versions are problematic as not all studies have followed a rigorous procedure for the development of screening instruments, and/or evaluated the psychometric and other properties adequately.

The abbreviated Mental Test Score (Quereshi and Hodkinson, 1974) has been developed in several south Asian languages for use among Gujaratis and Pakistanis and in

English for use among African Caribbeans in the UK (Rait *et al.*, 1997; Rait *et al.*, 2000a, b). A Korean version of the Alzheimer's Disease Assessment Scale (Rosen *et al.*, 1984) has been developed (Youn *et al.*, 2002). The MMSE, selected items from the CERAD neuropsychological test battery (Morris *et al.*, 1989) and the CAMCOG component of the CAMDEX interview (Roth *et al.*, 1986) have been evaluated in older African Caribbean people (Richards and Brayne, 1996; Richards *et al.*, 2000). Orientation items of the MMSE, selected items of the CERAD battery and the clock drawing test have been further evaluated in elderly African Caribbeans and normative data are available (Stewart *et al.*, 2001a). The 10-word list learning task from the CERAD battery has been shown to be successful in establishing a diagnosis of dementia in study populations from India, China and southeast Asia, Africa, Latin America and the Caribbean (Prince *et al.*, 2003). The Alzheimer's Disease Risk Questionnaire (Breitner and Folstein, 1984), which obtains information on history of cognitive impairment among first-degree relatives, has been translated into Chinese and Spanish, and has been administered by bilingual workers (Silverman *et al.*, 1992). The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) (Jorm *et al.*, 1991) has been developed for use in illiterate Chinese populations (Fuh *et al.*, 1995). A dementia screening instrument, the Community Screening Interview for Dementia (CSI-D), with a cognitive test for the subject and an informant history, has been developed for use among Cree Indians in Canada (Hall *et al.*, 1993; Hall *et al.*, 2000), English-speaking Canadians (Hall *et al.*, 1993; Hendrie *et al.*, 1993; Hall *et al.*, 2000) and Yoruba Nigerians in Ibadan (Hendrie *et al.*, 1995a; Hall *et al.*, 2000), African Americans in Indianapolis (Hall *et al.*, 2000), Jamaicans (Hall *et al.*, 2000) and in study populations in India, China and southeast Asia, Africa, Latin America and the Caribbean (Prince *et al.*, 2003), with good psychometric and other properties. The Chula Mental Test, developed for elderly Thais by selecting and adapting items from several existing screening tests, has been found to reduce the influence of illiteracy on scores (Jitapunkul *et al.*, 1996). A Spanish version (for use among Mexican Americans) (Royall *et al.*, 2003) and a Brazilian version (Fuzikawa *et al.*, 2003) of the clock drawing test have been evaluated; the Spanish version is reported to be education-free and acculturation-free.

A unique approach involving use of three instruments (the GMS, the CIS-D and the 10-word list-learning task from the CERAD battery appropriately translated into native languages) and an algorithm derived from these instruments has been shown to have high specificity and sensitivity in the diagnosis of dementia in culturally diverse populations from India, China and southeast Asia, Africa, Latin America and the Caribbean (Prince *et al.*, 2003). Furthermore, this approach allows for educational bias.

Some commonsense rules should be followed when you are administering cognitive tests to ethnic elders. First, any sensory impairment should be corrected if possible; some ethnic groups, like the Gujaratis, have a higher prevalence of visual impairment (Lindesay *et al.*, 1997b). Second, the nature,

purpose and duration of the test should be carefully explained and the instructions should be explicit and simple. This may need further facilitation by unscored trial runs on selected examples to ensure that the nature and purpose of the test is understood by the subject (Chandra *et al.*, 1994, 1998). The latter may be particularly helpful in subjects who are not used to being examined in this way, or who are reluctant to share intellectual skills with a stranger (Richards and Brayne, 1996). Third, a calm, patient and reassuring approach by the assessor may help reduce anxiety and obtain the best possible performance. Finally, if possible, the individual should be assessed in their mother tongue (Shah, 1992c, 1999).

13.2.6 Prevalence studies of ethnic elders in the UK

Only a few prevalence studies have been carried out; there are no incidence studies. The literature suggests that the prevalence of dementia among ethnic elders of Indian subcontinent origin in the UK is either similar (Bhatnagar and Frank, 1997; Lindesay *et al.*, 1997b; McCracken *et al.*, 1997) or higher (McCracken *et al.*, 1997) than among indigenous elders. A community study from Bradford, using the Hindi version of the GMS administered to Indian subcontinent elders, reported a dementia prevalence rate of 7 per cent (95 per cent CI 2.9–13.8 per cent) (Bhatnagar and Frank, 1997). However, using clinician's diagnosis, the prevalence was only 4 per cent (95 per cent CI 1.1–9.9 per cent), and there was poor agreement between the two diagnoses.

A two-stage community study from Leicester, using a Gujarati MMSE administered by trained personnel in Gujarati, a clinical interview and an *ad hoc* translated version of the CAMDEX and the SCAN interviews administered by a Gujarati-speaking psychiatrist, found prevalence rates of 0 per cent and 20 per cent (95 per cent CI 5.3–48.6 per cent) in the 65–74 and 75+ years age groups respectively (Lindesay *et al.*, 1997b). This study included a comparison group of indigenous elders and the prevalence of dementia was higher in the Gujaratis, although this was not statistically significant. The stability of the diagnosis of dementia was confirmed at 27-month follow up by another Gujarati-speaking psychiatrist using similar diagnostic techniques (Shah *et al.*, 1998).

A community study from Liverpool of African, Caribbean, Asian, Chinese and Middle Eastern elders used the GMS either in English or an *ad hoc* translation during interview (McCracken *et al.*, 1997). The prevalence rates (95 per cent CI) of dementia in English-speaking individuals of black African, black Caribbean, black other, Chinese and Asian origin were 8 per cent (4–15), 8 per cent (4–15), 2 per cent (0.1–12), 5 per cent (1–26) and 9 per cent (2–41) respectively, similar to the 3 per cent (2–4) found in the indigenous population. Prevalence in the black African and Chinese who did not speak English was 27 per cent (10–50) and 21 per cent (11–33) respectively; these figures were higher than those for the indigenous population. The comparison group of

indigenous elders was taken from another study that did not have the same complicated sampling frame. It is unclear whether the higher prevalence in the non-English speakers was real, or an artefact of communication or translation difficulties.

A community study in Islington used the shortened version of the Comprehensive Assessment and Referral Evaluation (Short-CARE) (Gurland *et al.*, 1984) in those born in the UK, Ireland, Cyprus, Africa and Caribbean and Europe (Livingston *et al.*, 2001). The prevalence of dementia in those born in the UK, Ireland, Cyprus, and Africa and the Caribbean was 10 per cent, 3.6 per cent, 11.3 per cent and 17 per cent respectively. Logistic regression analysis revealed that living in a residential home, age, being African or Caribbean and years of education were the only significant predictors of dementia. The Short-CARE interview was not translated and back-translated using any of the principles illustrated earlier and no information was provided about how the interview was administered to those who did not speak English.

A small pilot study of only 45 subjects reported a prevalence rate of 34 per cent for dementia in an African Caribbean group compared with 4 per cent in a white group (Richards *et al.*, 2000).

13.2.7 Other epidemiological issues

Most diagnostic systems emphasize the cognitive features of dementia (Fairburn and Hope, 1988), and non-cognitive features such as personality change, behaviour change, affective features, psychotic features and functional disability have been sparsely studied among ethnic groups (Jitapunkul *et al.*, 1996; Shah and Dighe-Deo, 1998). Data on the clinical presentation, natural history, risk factors, incidence rates, quality of life and carer stress are also sparse.

13.3 THE CONCEPT OF PATHWAYS TO CARE

In the UK, general practitioners (GPs) are traditionally the first port of call for patients requiring medical attention. Moreover, GPs act as gatekeepers for secondary services. Pathways into care encompass all stages from the first appearance of an illness in the community, patients consulting their GP, identification of the illness by the GP, management of the illness by the GP, referral by the GP to secondary care services, and the identification and management of the illness in secondary care (Goldberg and Huxley, 1991).

Ethnic elders and their carers in the UK, particularly from the African-Caribbean, Asian, Chinese and Vietnamese ethnic groups, are well aware of services provided by GPs and use them effectively (Bhalia and Blakemore, 1981; Barker, 1984; McCallum, 1990). Moreover, they have high general practice consultation rates (Donaldson, 1986; Balarajan *et al.*, 1989; Gillam *et al.*, 1989; Lindsay *et al.*, 1997a; Livingston *et al.*, 2002); up to 70 per cent have consulted their GP in the preceding month (Lindsay *et al.*, 1997a). However, there is a

Box 13.2 Possible reasons for discrepancy in high general practice consultation rates but low service prevalence of ethnic elders in the UK

- The prevalence of dementia may be low
- Dementia may be less severe
- Dementia may lack non-cognitive features that lead to clinical presentation
- Patient factors may influence primary care consultations
- Family factors may influence primary care consultations
- General practitioner factors may influence primary care consultations
- Secondary care services may not be ethnically sensitive

low prevalence of ethnic elders in contact with community or hospital mental health facilities (Blakemore and Boneham, 1994). This has more specifically been observed with dementia in psychogeriatric services (Lindsay *et al.*, 1997a; Rait and Burns, 1997; Jagger, 1998; Shah and Dighe-Deo, 1998). Several possible reasons for this discrepancy, as listed in Box 13.2, are systematically examined below.

13.3.1 The effect of patient and family factors on primary care consultations

The discrepancy between high GP consultation rates and low secondary psychogeriatric service use for ethnic elders may be influenced by factors related to patients and their families. Family members may not recognize symptoms of mental illness and dismiss dementia as a function of old age. Traditionally very few ethnic elders have reached old age and younger family members may be unfamiliar with symptoms of dementia (Manthorpe and Hettiaratchy, 1993; Rait and Burns, 1997). Moreover, both the DSM-IV and the ICD-10 diagnostic criteria for dementia require evidence of functional impairment, and this raises the possibility that different cultures may have different thresholds for diagnosis, depending upon the social roles and cognitive demands placed upon elderly people (Zhang *et al.*, 1990; Pollit, 1996). This may be enhanced if the patient is unable to communicate symptoms of mental illness to family members or the GP owing to lack of vocabulary or other language barriers (George and Young, 1991; Shah, 1992c, 1997a, b). Both family members and the patient may believe that nothing can be done; be unaware of existing services (Bhalia and Blakemore, 1981; Age Concern/Help the Aged Housing Trust (ACHAHT), 1984; Barker, 1984; McCallum, 1990; Lindsay *et al.*, 1997a); be unaware of the application procedure for these services (Lindsay *et al.*, 1997a); feel existing services are inadequate, inaccessible and culturally insensitive (Hopkins and Bahl, 1993; Lindsay *et al.*, 1997a); have had poor previous experience of services (Lindsay *et al.*, 1997a), and fear the stigma attached to mental illness (Barker, 1984; Manthorpe and Hettiaratchy, 1993; Livingston *et al.*, 2002).

The position of ethnic elders in some communities may be more advantageous than that of their white counterparts. In some cultures, notably Muslim, Sikh, Hindu and Jain, elderly people are well respected, and have a status and a role to give their life meaning and purpose. This applies to both men and women, and the latter can acquire a considerable degree of authority and independence with age. Family members may, therefore, feel obliged to look after the person with dementia at home. Thus, both the patient and family members may choose not to consult their GP. However, these hypotheses have not been systematically examined.

This gloomy situation may be changing in some areas. In two recent cross-sectional studies of UK psychogeriatric service users, ethnic elders received both health and social service resources at the same frequency as indigenous elders, despite having more individuals in the household and more children than indigenous elders (Redlinghuys and Shah, 1997; Odutoye and Shah, 1999). Similar findings were reported in a population-based community study for use of primary and secondary health services (excluding psychiatric services) and social services (Livingston *et al.*, 2002). Thus, the traditional belief that ethnic elders do not access psychogeriatric and social services and are looked after by the extended family (Barker, 1984; Boneham, 1989; Manthorpe and Hettiaratchy, 1993) is changing, perhaps because younger family members lead a culturally different life style; work long hours and are busy (Barker, 1984); may have lived in the UK longer than their elders (Barker, 1984) and their elders may have migrated to join them contrary to their wishes (Silveira and Ebrahim, 1995); may experience family tensions (Boneham, 1989; Silveira and Ebrahim, 1995), and may experience financial hardship. Such factors may make it difficult for an extended family to provide support (Redelinghuys and Shah, 1997), thereby encouraging referral to services.

The clinical presentation of ethnic elders is influenced by their complex personal histories. Migration may have been enforced (e.g. from trauma and hardship) or elective (e.g. to join the family). First-generation migrants are less likely to assimilate into the host culture than subsequent generations, and may have greater problems with adjustment. This can lead to family conflicts and expose the individual to racist attitudes. The impact of these factors and that of the degree of acculturation on the clinical presentation of dementia is unclear.

13.3.2 The effect of GP factors on consultations

In the UK up to 70 per cent of Asians register with Asian GPs (Johnson *et al.*, 1983). This, coupled with high GP registration and consultation rates among ethnic elders, should theoretically enable easier diagnosis and access to psychogeriatric and social services. The statutory offer of an annual physical and mental examination to all patients over the age of 75 (Secretaries of State for Health, Wales, Northern Ireland and Scotland, 1989), and the emphasis on the single assessment

process and diagnostic protocols for dementia in primary care in the National Service Framework for Older People (Department of Health, 2001) should further facilitate this. However, it appears that relatively few ethnic elders receive this annual examination (Lindesay *et al.*, 1997a). There are several reasons why dementia may not be identified during a routine GP consultation:

1. The prevalence of dementia among ethnic elders consulting their GPs may be low; some possible reasons for this were explored in the last section.
2. Even if the prevalence is similar or higher in ethnic elders consulting their GP than in the rest of community, then the severity of the dementia may be lower.
3. Non-cognitive features, which often lead to clinical presentations, may be less frequent or different to those in indigenous patients.
4. Data on clinical presentation, diagnostic features and natural history of dementia among ethnic elders are sparse, and GPs may lack the diagnostic skills to diagnose dementia in ethnic elders (Shah and Dighe-Deo, 1998).
5. Because ethnic elders with dementia are seen infrequently (Shah and Dighe-Deo, 1998), GPs lack experience of this condition in these groups; even psychiatrists experience this difficulty (Lindesay, 1998; Shah and Dighe-Deo, 1998; Shah, 1999). These difficulties may be further complicated by language and communication difficulties, the age and sex of the assessor, the context and setting of the assessment, attitude and expectations of both the patient and the family, and status of the patient in the family and the community (Lindesay, 1998). A careful informant history and assurance of confidentiality can help with this (Lindesay, 1998).
6. As discussed above there is a paucity of screening instruments with good psychometric and other properties. Diagnostic difficulties may lead to a lower rate of referral to secondary care services as shown in younger mentally ill primary care attenders of Indian subcontinent origin (Odell *et al.*, 1997; Jacob *et al.*, 1998).
7. The bias, prejudice and experience of clinicians (Solomon, 1992) can result in consultation difficulties. None of these hypotheses has been systematically studied.

Informant histories with ethnic elders can provide valuable information (Shah *et al.*, 1998; Shah, 1999), but there are pitfalls. Well-intentioned family members may withhold valuable information if they feel it will present their family member in a 'bad light' (Shah, 1997a, b, 1999). Similarly, they may not volunteer any difficulties and problems for fear of being accused of failing in their duty of care.

Good communication between patients and professionals is paramount (Bhalia and Blakemore, 1981; ACHAHT, 1984; Jones and Gill, 1998; Shah, 1992c, 1999), as many ethnic elders do not speak English (Barker, 1984; Manthorpe and Hettiaratchy, 1993; Lindesay *et al.*, 1997a). This has important

consequences for the process of psychiatric assessment and for the communication of information about treatments and services. This problem can be minimized if staff members are able to speak the patient's language (Shah, 1992c, 1999). However, bilingual health workers are uncommon (Phelan and Parkman, 1995). Translation services, therefore, are usually required to communicate directly with patients (Shah, 1992, 1997a, b; Phelan and Parkman, 1995). Relatives, non-clinical staff, clinical staff and professional translators with and without special training in mental health can be used (Phelan and Parkman, 1995; Shah, 1997a, b). Translations can be done in person or via a three-way telephone conversation (Pointon, 1996; Jones and Gill, 1998). Ideally, professional translators should be used in person. The inherent difficulties and limitations in using translators in dementia (Shah, 1997a, b) and other mental disorders (Marcos, 1979; Kline *et al.*, 1980; Shah, 1997a, b) are well described. For illiterate patients and carers, audiotapes, videos and diagrammatic representation with cartoons giving information on management and service related issues may be helpful (Lindesay *et al.*, 1997a).

If dementia is identified it may or may not be treated. It may not be treated because the GP believes that nothing can be done, or considers that ethnically sensitive health and social services in the catchment area are inadequate, or has had poor response for previous referrals or be unaware of the procedure to access these services. If dementia in ethnic elders presenting to the GP is less severe and lacks troublesome non-cognitive features, the GP may consider that onward referral is unnecessary. The GP may feel that he or she can communicate better with the patient, particularly if they share the same ethnic background. Finally, the GP may wish to refer patients to secondary services, but the patient and/or family members may be reluctant. Reasons for this reluctance are similar to those discussed for patients or family not wanting to consult their GP in the first place.

13.3.3 Factors in secondary care that may influence diagnosis and management of dementia

There is a paucity of studies examining ethnic elders with dementia in psychogeriatric, geriatric and social services. Almost all the criticisms applied to primary care also apply to secondary care services. There are only two published studies of psychogeriatric service users (Redlinghuys and Shah, 1997; Oduoye and Shah, 1999), and both of these services may have been particularly accessible to elders of Indian subcontinent origin because of local service development factors.

13.4 THE CONCEPT OF MULTIPLE JEOPARDY

The difficulties faced by ethnic elders with dementia can be explained in terms of multiple jeopardy. The concept of

double jeopardy owing to age- and race-related disadvantages was first developed in the USA (National Urban League, 1964) and later introduced to the UK (Dowd and Bengston, 1978). Sexism (Palmore and Manton, 1973) and social deprivation (Norman, 1985) have been added to develop a model of triple jeopardy. Boneham (1989) has developed a model of multiple disadvantages, which can be applied to all ethnic elders (Rait *et al.*, 1996). Six factors contribute to this model of multiple jeopardy: ageism, racism, gender disparities, restricted access to health and welfare services, internal ethnic divisions and class struggle. These bring together all the issues discussed in earlier sections into a final common pathway, illustrating the difficulties that ethnic elders with dementia face in reaching secondary services. However, these models of disadvantage, whilst tantalizing, have been criticized and have not been systematically studied among ethnic elders with dementia.

13.5 THE DIFFERENTIAL PREVALENCE AND INCIDENCE OF THE DIFFERENT SUBTYPES OF DEMENTIA IN DIFFERENT CULTURAL AND NATIONAL GROUPS

Published studies of the prevalence of dementia in UK ethnic elders do not report on the relative prevalence of individual dementia subtypes. Anecdotally, it is believed that vascular dementia is more common than Alzheimer's disease (AD) among Indian subcontinent elders (Bhatnagar and Frank, 1997) and African Caribbeans (Richards *et al.*, 2000; Stewart *et al.*, 2001a; Livingston *et al.*, 2001; Livingston and Sembhi, 2003) in the UK. Some risk factors for vascular dementia are more prevalent in these ethnic minority groups than in the indigenous population, such as diabetes in Asians (Mather and Keen, 1985; Samanta *et al.*, 1987), and hypertension and cardiovascular disease in Asians and African Caribbeans (Balarajan, 1996; Ritch *et al.*, 1996).

The prevalence rates of dementia in ethnic groups in other countries are also variable. A study of Chinese residents in USA nursing homes reported a prevalence rate of 95 per cent for dementia (Serby *et al.*, 1987); the ratio of vascular dementia to AD was estimated as 4.4 to 1 (Serby *et al.*, 1987), but there was no indigenous comparison group. Studies in the USA have reported a higher prevalence of dementia among African Americans (Still *et al.*, 1990; Heyman *et al.*, 1991; Perkins *et al.*, 1997) and Hispanics (Perkins *et al.*, 1997) than white Americans, although one study of severe dementia in African Americans did not find this (Schoenberg *et al.*, 1985). The North Manhattan Ageing Study reported significantly higher prevalence and incidence rates of dementia in Latinos and African Americans compared with non-Latino white Americans (Gurland *et al.*, 1995, 1999); however, these ethnic differences in prevalence and incidence disappeared after controlling for age and educational attainment. Also, there were no significant differences between the three groups

for individual subtypes of dementia. Another study reported a higher prevalence of vascular dementia coupled with a higher prevalence of strokes and high blood pressure in African Americans (Heyman *et al.*, 1991; Perkins *et al.*, 1997).

In an American postmortem study of 144 cases of dementia, AD and dementia owing to Parkinson's disease were more common in white Americans, and alcohol-related and vascular dementias were more common in African Americans (de la Monte *et al.*, 1989). Another USA study, using an informant questionnaire (Alzheimer's Disease Risk Questionnaire) administered to non-demented elderly day centre attenders, reported a significantly increased risk of dementia in first-degree relatives of Jews and Italians compared with Chinese and Puerto Ricans (Silverman *et al.*, 1992). This raises the possibility of discrepant environmental exposure to risk factors, as the first two groups had migrated to the USA significantly earlier.

In one Canadian study, the prevalence of all dementias and AD was 4.2 per cent and 0.5 per cent respectively in Cree Indians, and 4.2 per cent and 3.5 per cent respectively in English-speaking Canadians (Hall *et al.*, 1993). An Israeli study of presenile dementia, using hospital discharge diagnosis as a proxy for incidence rates, reported age- and sex-adjusted incidence rates of presenile dementia of the Alzheimer's type to be higher in European and American Jews than those from Africa or Asia (Treves *et al.*, 1986), raising the possibility of both environmental and genetic risk factors. Pollit (1997), quoting Zann (1994), reported that the prevalence of dementia in Aborigines in Northern Queensland was 20 per cent, with alcohol-related dementia accounting for the majority of cases.

Some of the characteristics of prevalence studies of dementia from Asian and African countries are listed in Table 13.1. Although the rates are variable, the overall theme is one of low prevalence in these countries. The exceptions are studies from Shanghai (Zhang *et al.*, 1990), Korea (Park *et al.*, 1994), South Africa (Ben-Arie *et al.*, 1983) and Singapore (Lim *et al.*, 2003). The prevalence of AD in these countries is generally lower (Hasegawa *et al.*, 1986; Shibayama *et al.*, 1986; Li *et al.*, 1989, 1991) and that of vascular dementia generally higher (Hasegawa *et al.*, 1986; Shibayama *et al.*, 1986; Jorm *et al.*, 1987; Li *et al.*, 1989). Almost universally, the prevalence of dementia was reported to increase with age, and generally it was more common in women. Two incidence studies of AD in Japan showing an annual incidence of 1.1 per cent have been quoted in a review (Graves *et al.*, 1994). A meta-analysis of the world literature on incidence studies reported that the incidence of AD and vascular dementia exponentially increased with age (Jorm and Jolley, 1998); eastern countries had a lower incidence of AD and there was no difference in the incidence of vascular dementia between European and eastern countries.

The variable prevalence rates of dementia and its subtypes across different ethnic groups in a given country and across different countries may be due in part to methodological factors. These include differences in: the sensitivity of screening instruments and case-finding techniques (Jorm *et al.*, 1987; Amaducci *et al.*, 1991; Osuntokun *et al.*, 1992; Hall *et al.*,

1993; Prince *et al.*, 2003); diagnostic criteria (Jorm *et al.*, 1987; Amaducci *et al.*, 1991; Osuntokun *et al.*, 1992; Silverman *et al.*, 1992; Hall *et al.*, 1993); sampling frames and procedures (Jorm *et al.*, 1987; Amaducci *et al.*, 1991; Osuntokun *et al.*, 1992; Silverman *et al.*, 1992); screening personnel (Hall *et al.*, 1993) and interrater reliability (Osuntokun *et al.*, 1992); age and demographic characteristics of study populations (Li *et al.*, 1989; Yu *et al.*, 1989; Zhang *et al.*, 1990; Osuntokun *et al.*, 1992); educational attainment and literacy (Hall *et al.*, 1993; Prince *et al.*, 2003); and cultural factors. Some studies do not differentiate between different types of dementia (Kua, 1992).

13.5.1 Effect of life expectancy

Prevalence rates are influenced by several factors (Graves *et al.*, 1994; Suh and Shah, 2001). The overall incidence (and therefore overall prevalence) will be low in societies where life expectancy is short because fewer subjects will reach the age of risk. In general, socioeconomically less developed societies have shorter life expectancies than more developed societies. The selective survival of those not at risk of dementia may further compound such a trend. It is possible that early mortality selects for genetic and/or constitutional factors that protect against neurodegenerative disorders (Suh and Shah, 2001). Mortality and survival after the onset of dementia also influence prevalence rates. In regions where survival after the onset of dementia is short, the prevalence may be low even if the incidence is not (Suh and Shah, 2001). Consequently, lower prevalence in some countries may be due to reduced life expectancy, shorter survival from onset, or reduced age-specific incidence (White, 1992; Chandra *et al.*, 1994, 1998; Vas *et al.*, 2001). This difficulty can be reduced by using age-stratified samples to compare prevalence rates; however, the resulting sample size for older age groups is likely to be small in some developing countries. Another explanation for a low prevalence rate in an urban Indian area is selective migration, whereby people with dementia may return to their 'native' rural area (Vas *et al.*, 2001). An alternative approach is to compare incidence rates (Hendrie *et al.*, 1995a; Richards, 1997; Suh and Shah, 2001). However, incidence studies are time consuming, require large numbers of subjects and are expensive.

13.5.2 Genetic and environmental influences

If the differences in prevalence (or incidence) persist after these methodological problems are overcome, then cross-cultural and cross-national studies would allow investigation of underlying genetic and environmental risk factors and the interaction between them (Amaducci *et al.*, 1991; Osuntokun *et al.*, 1992; Silverman *et al.*, 1992; Brayne, 1993; Hall *et al.*, 1993; Chaturvedi and McKeigue, 1994). If the risk of dementia were solely due to genetic factors, then migrants would have the same incidence rate as in their country of origin (Graves *et al.*, 1994). Thus, comparison of the same ethnic group in different

Table 13.1 Prevalence studies from African and Asian countries

Country	Study	Sample size	Prevalence	Age	Stratified by age	Design	Gold standard
Nigeria	Osuntokun <i>et al.</i> , 1992	326	Overall 0%	65+	?	Two-stage	DSM-III-R dementia
Nigeria	Hendrie <i>et al.</i> , 1995a	2494	Overall 2.29%; AD 1.41%	65+	Yes	Two-stage	DSM-III-R and ICD-10 dementia

communities, at different stages of economic development and differing environments, whilst maintaining genetic homogeneity, may allow identification of environmental risk factors (Graves *et al.*, 1994; Richards and Brayne, 1996). Environmental changes that accompany migration include dietary change, acculturation, occupational change, educational change and differences in water, air, pollution and climate, etc. (Graves *et al.*, 1994). The identification of genetic and environmental factors predisposing to dementia will allow better understanding of causal mechanisms, leading to improved treatments and, ultimately, preventative strategies (Graves *et al.*, 1994).

Cross-national and cross-cultural incidence and prevalence studies designed to overcome these methodological difficulties, using screening and diagnostic instruments that are culture-fair, education-free and analogous, with similar case-finding methods in age- and sex-stratified samples, are now emerging (White, 1992; Prince *et al.*, 2003). The 10/66 Dementia Research Group (2000a, b) of Alzheimer's Disease International has developed an algorithm using appropriately translated (into native languages) and validated (culture-fair and education-free) versions of the GMS, CIS-D and the 10-word list-learning test from the CERAD battery with high degree of sensitivity and specificity in the diagnosis of dementia in culturally diverse populations from India, China, southeast Asia, Latin America, Africa and the Caribbean (Prince *et al.*, 2003). Population-based prevalence studies using this algorithm in the same diverse populations and using similar methodology are currently underway. The findings of this large study will be of great interest because it will compare prevalence from many different and culturally diverse countries using the same culture-fair and education-free instruments and methodology.

13.5.2.1 ENVIRONMENT

Despite comparable rates of dementia in Japan and USA, prevalence of vascular dementia is highest in Japan, intermediate in Hawaii and lowest in the mainland USA and an opposite trend is observed for AD (Graves *et al.*, 1994). These rates are being systematically studied in a cross-national studies: the Ni-Hon-Sea study of Japanese in Japan, Hawaii and mainland US (Graves *et al.*, 1994, 1996), and the Honolulu-Asia Aging study of Japanese in Hawaii, Japan and Taiwan (White *et al.*, 1996). The prevalence of AD among Japanese Americans in Washington (Graves *et al.*, 1996) and Honolulu (White *et al.*, 1996) is closer to that of white Americans suggesting an environmental aetiology. A prospective cohort study of Japanese Americans has reported that those who lead a traditional Japanese life style had a slower decline in cognition over a 2-year period (Graves *et al.*, 1999), also suggesting the importance of environmental factors. However, a study of first-generation Japanese migrants from Miyagi prefecture in Japan to Brazil (Meguro *et al.*, 2001a) reported a similar prevalence of dementia, AD and vascular dementia to that in Miyagi prefecture in Japan (Ishii *et al.*, 1999) despite the migrants having a higher prevalence of

diabetes mellitus and cerebrovascular disease (Meguro *et al.*, 2001b). The authors concluded that the prevalence of dementia was not affected by the environment.

The Indo-USA cross-national study reported a prevalence of 0.84 per cent for all dementias among rural Indians near Delhi, a lower figure than in a community sample in Pennsylvania (Chandra *et al.*, 1998). An incidence study in the same geographical area reported one of the lowest incidences of AD in the world (Chandra *et al.*, 2001). A study of Singapore Chinese and Malays revealed a higher prevalence of dementia among Malays than the Chinese (Kua and Ko, 1995); this difference was largely accounted for by an increased prevalence of multi-infarct dementia among Malay women when compared with Malay men and Chinese women. A prevalence and incidence study comparing rates among Yoruba Nigerians in Ibadan and African Americans in Indianapolis has reported a lower prevalence and incidence for dementia and AD among the Nigerians (Hendrie *et al.*, 1995b, 2001).

13.5.2.2 GENETICS

An early pilot population-based prevalence study has reported a strong association between apolipoprotein E (ApoE) $\epsilon 4$ allele and AD in African Americans (Hendrie *et al.*, 1995a) suggesting that ApoE $\epsilon 4$ is a risk factor independent of ethnicity. However, this was not observed in Yoruba Nigerians in Ibadan (Osuntokun *et al.*, 1995), despite a high prevalence of $\epsilon 4$ allele in the community. This discrepancy was explained by differences in the expression of ApoE alleles or of ApoE receptors, interaction with unidentified modifier genes, or environmental factors interacting with genes. Furthermore, there was lower deposition of A β amyloid in post-mortem brains of Nigerian subjects without dementia compared with a similar series in Melbourne, Australia (Osuntokun *et al.*, 1994). Both these factors may be important in explaining a lower prevalence and incidence of AD in Nigeria.

A strong association between ApoE $\epsilon 4$ homozygous status and AD has been observed among Caucasians (non-Hispanic white Americans), African Americans and Hispanics in America in population-based prevalence studies (Maestre *et al.*, 1995; Tang *et al.*, 1996; Sahota *et al.*, 1997); despite these associations, the relative risk of developing AD was the highest in Caucasians compared with African Americans and Hispanics suggesting a gene-environment interaction. However, when considering heterozygous ApoE $\epsilon 4$ status, this relationship was either weaker (Maestre *et al.*, 1995) or absent in African Americans (Tang *et al.*, 1996; Sahota *et al.*, 1997) in comparison with Caucasians and Hispanics.

A population-based incidence study, controlling for education, family history of AD and other risk factors such as hypertension, demonstrated a strong association between combined homozygous and heterozygous ApoE $\epsilon 4$ status and AD in whites, African Americans and Hispanics in America (Tang *et al.*, 1998); unfortunately, separate data on homozygous and heterozygous ApoE $\epsilon 4$ status were not available owing to a small number of individuals homozygous for ApoE $\epsilon 4$ in the

three ethnic groups. Furthermore, in the presence of at least one ApoE $\epsilon 4$ allele, the cumulative risk of developing AD up to the age of 90 years was similar in each of the three ethnic groups. However, in the absence of the an ApoE $\epsilon 4$ allele, the cumulative risk of developing AD up to the age of 90 years was higher in both the African American and the Hispanic groups when compared with the white group (Tang *et al.*, 1998). These observations taken together suggest that the effect of ApoE $\epsilon 4$ on AD is weaker and 'dose dependent' in African Americans compared with white Americans and to a lesser extent Hispanics. It is possible that the presence of other environmental factors or modifier genes may reduce the ApoE $\epsilon 4$ -associated risk of developing AD in people of African origin (Sahota *et al.*, 1997; Tang *et al.*, 1998). These environmental factors or modifier genes may be able to alter the risk of one dose of ApoE $\epsilon 4$ more easily than two doses of ApoE $\epsilon 4$ (Maestre *et al.*, 1995).

Another explanation for these findings is that there may be differential linkage disequilibrium between an unidentified AD susceptibility gene and ApoE $\epsilon 4$ alleles in different ethnic groups (Maestre *et al.*, 1995). A further explanation is the differential survival of those with ApoE $\epsilon 4$ alleles, although this observation is not supported by reports that ApoE $\epsilon 4$ frequency in white subjects is unchanged with age (Maestre *et al.*, 1995; Tang *et al.*, 1996), and either unchanged (Tang *et al.*, 1996) or increased (Maestre *et al.*, 1995) with age in African American subjects. Also, the frequency of ApoE $\epsilon 4$ in white and African American AD patients is reported to decline (Maestre *et al.*, 1995) or remain unchanged (Tang *et al.*, 1996) with age. However, despite a decline in ApoE $\epsilon 4$ frequency in AD patients with age, other genetic or environmental factors may increase the risk of developing AD in African Americans and Hispanics in the absence of this allele (Tang *et al.*, 1998), including ApoE allele, $\epsilon 4$ which has been reported in a population-based study to increase the risk of AD in African Americans compared with white Americans (Maestre *et al.*, 1995). A population-based incidence study of Japanese American men reported a significant association between ApoE $\epsilon 4$ and AD (Havlik *et al.*, 2000).

Chandra and Pandav (1998) have speculated that high serum levels of cholesterol may interact with ApoE $\epsilon 4$ alleles to produce AD based on evidence of the low serum cholesterol levels in rural Indians near Delhi and a low prevalence of AD (Chandra *et al.*, 1998). However, their observations were not supported by the ApoE typing in the same population-based Indo-US prevalence study (Ganguli *et al.*, 2000). The frequency of ApoE $\epsilon 4$ in the Indian sample was significantly lower than in the USA sample. However, the strength of association between ApoE $\epsilon 4$ and AD was similar in both samples. These findings taken together may be one explanation for one of the lowest prevalence rates for AD in the world to be reported in India (Chandra *et al.*, 1998). The authors concluded that the different prevalence in the two samples cannot be explained by differential risk or modifier risk pertaining to ApoE polymorphism, and they speculated that there may be additional risk or protective factors, survival effects or contributory environmental factors.

In a convenience sample of Cherokee Indians in Texas the risk of developing AD declined with an increase in the genetic degree of Cherokee ancestry and this relationship was independent of ApoE $\epsilon 4$ status (Rosenberg *et al.*, 1996); however, the protective effect of Cherokee ancestry declined with increasing age. These findings suggest a complex interaction between genetic and environmental factors and critical examination in population-based studies is needed.

13.5.3 Education

The role of educational attainment as a risk factor for dementia is controversial. However, examination of the role of education as an environmental factor across different ethnic groups may shed further light on the role of environmental factors or gene-environment interaction. In two USA studies of Latinos, African Americans and non-Latino white Americans, levels of education were strongly correlated with the prevalence of dementia (Gurland *et al.*, 1995, 1999); however, the differences in prevalence rates across the three ethnic groups disappeared if age and education were controlled for (Gurland *et al.*, 1999), suggesting education may be an important environmental risk factor independent of ethnicity. In a community study of African Caribbeans in London, hypertension and diabetes were specifically associated with cognitive impairment in those with low levels of education (Stewart *et al.*, 2001b). In a South Korean study, a similar association was found between cognitive impairment and systolic blood pressure, previous diagnosis of diabetes and non-fasting glucose levels in subjects with no formal education (Stewart *et al.*, 2003).

These collective findings may be explained by several hypothesis which could be rigorously tested in epidemiological studies:

- Subjects with lower levels of education may have less well-controlled hypertension or diabetes (Gurland *et al.*, 1995, 1999; Stewart *et al.*, 2001b, 2003).
- Cognitive test batteries may not be sufficiently sensitive to measure cognitive impairment accurately in those with high levels of education (Stewart *et al.*, 2001b).
- Third, those with high levels of education may have developed sufficient cognitive reserve to be less vulnerable to the effects of hypertension and diabetes (Gurland *et al.*, 1995, 1999; Stewart *et al.*, 2001b, 2003).
- Cerebral damage owing to hypertension or diabetes may be more severe in those with lower levels of education (Stewart *et al.*, 2003).

13.6 FUTURE DIRECTIONS

Most cross-cultural studies have concentrated on cognitive impairment. BPSDs have to date received little attention in cross-cultural settings and in developing countries (Shah

and Mukherjee, 2000). Measures of BPSD that are culture-fair and analogous to those currently used in Western countries are emerging from developing countries (see Chapter 7b on measurement of non-cognitive symptoms of dementia). BPSD require close examination in cross-sectional and longitudinal studies of the prevalence and incidence of dementia in cross-cultural and cross-national settings; these studies should also be designed to examine genetic and environmental risk factors (and the interaction between them) for both cognitive impairment and BPSD. The 10/66 Dementia Research Group (2000a, b; Prince *et al.*, 2003) from Alzheimer's Disease International is in a strong position to conduct such research. They have developed measurement instruments and a methodology that can be applied across cultures, and studies of prevalence and BPSD are in progress in India, southeast Asia, China, Africa, the Caribbean and south America.

Similarly, very few cross-cultural studies have examined neurochemical, neuroanatomical and neurohistological changes in post-mortem brains (Amaducci *et al.*, 1992), and structural and functional neuroimaging techniques have not been used at all. These techniques should be applied in rigorous population-based cross-cultural studies of cognitive impairment and BPSD; this would be a further powerful means of exploring environmental and genetic risk factors, and the interaction between them. The clustering of less common dementias, such as Huntington's disease, prion dementias and Parkinson's dementia complex of Guam, in some cultural groups may shed light on the genetic and environmental aetiological factors (Graham *et al.*, 1998). The development of these elaborate and sophisticated research programmes will require considerable development of specialist services for these groups in both developed and developing countries if they are to be feasible.

A theoretical model of the epidemiological transition in dementia has been developed using incidence and prevalence data from different countries (Suh and Shah, 2001). According to this model all societies sequentially move through four hierarchical stages:

1. low incidence–high mortality society;
2. high incidence–high mortality society;
3. high incidence–low mortality society; and
4. low incidence–low mortality society.

Several factors contribute to the prevalence of dementia:

- The overall incidence (and thus the prevalence) will be low in societies where life expectancy is low, as few individuals will reach the age of risk.
- Mortality and survival after the onset of dementia will also influence the prevalence rate. Thus, in regions where survival after the onset of dementia is short, the prevalence will be low even if the incidence is high.
- The incidence itself is very important because uneven geographical distribution of protective or risk factors of AD and vascular dementia will vary the incidence. In socioeconomically less developed societies, infectious

diseases associated with poor socioeconomic factors will reduce life expectancy with fewer individuals reaching the age of risk for dementia. Such a society has been described as a low incidence–high mortality society. With improvement in basic medical care the average life expectancy will increase and reach the threshold age of risk for dementia. This will lead to a gradual transition from a low incidence–high mortality society to a high incidence–high mortality society. Furthermore, in socioeconomically more developed societies the mortality associated with dementia may decline because of greater availability of medical care and advances in medical care and technology. This will lead to a gradual transition to a high incidence–low mortality society.

- In socioeconomically well developed countries, efforts to improve the control of risk factors (such as those for vascular dementia) may reduce the incidence of dementia leading to a low incidence–low mortality society. The transition from a low incidence–high mortality society to a low incidence–low mortality society may unfold in several ways depending upon availability of medical services, advances in medical care and technology, public health policies and efforts undertaken to control risk factors for dementia in a given society.

A detailed discussion of all the evidence to support this hypothesis is beyond the scope of this chapter. However, cross-national and cross-cultural population-based prevalence and incidence studies, data on mortality and survival after the onset of dementia, and 'proxy' measures (such as infant mortality rates) of the quality of medical care can be used to rigorously examine this hypothesis.

Helping staff and patients with dementia through better design

MARY MARSHALL

14.1 Problems for nursing and care staff caused by poor design	165	14.4 Conclusions	168
14.2 Design that helps patients	167	References	168
14.3 Some key design principles	168	Additional reading	169

Nursing and care staff are the most precious resource in dementia care. Theirs is a challenging job, which requires them to be able to really focus on their relationship with the patient. They need to be able to relate at an emotional and practical level at the same time, all the time. They need to be able to keep patients stimulated whilst also keeping them safe. They need to be able to care for them, while also maintaining as much of the patients' independence as possible. They need to offer an environment that reinforces identity, while also offering group care. They also need dignity, privacy and choice in their work environment where they spend much of their lives.

We cannot expect nursing and care staff to value the individuals in their care if they do not feel valued. The buildings in which they are required to work can speak volumes about the extent to which their work is seen as valuable and important.

To enable nursing and care staff to give of their best requires buildings that are supportive. They need buildings, which, as far as possible, tell patients what is expected of them and how to find their way. They need buildings that make it easy to keep patients busy but also well supervised. They need it to be easy to modify buildings to reinforce identity.

This chapter will explain how buildings can be designed or modified to help nursing and care staff to provide the best possible care.

Unnecessary disability is a useful concept. A lot of buildings cause patients to be more disabled than they need to be and add to the burden of care for staff.

14.1 PROBLEMS FOR NURSING AND CARE STAFF CAUSED BY POOR DESIGN

If problems are clearly identified, design solutions are very obvious.

As far as staff are concerned there are many kinds of problems that make their lives difficult.

14.1.1 Front doors

Conspicuous front doors encourage patients to try to get out. Patients are constantly reminded that there is somewhere else to go by the constant traffic of people and trolleys in and out of the front door. Patients are mistaken for visitors and accompany people leaving. They also hang around the doors making everybody else feel bad about the fact that they can come and go, whereas the patients are trapped inside. We need to protect staff from the constant exposure to emotional pain that this causes (Samut, 2003).

14.1.2 Fire doors

Conspicuous fire doors, often at the end of corridors, keep everybody busy as patients depart through them and staff have to drop what they are doing to run after them. People with dementia often move towards light, so fire doors with windows in a dark corridor are very enticing.

14.1.3 Storage space

Lack of storage often means that bathrooms do not have the function that they should have because they are full of hoists, wheelchairs and zimmers. This is confusing for patients and infuriating for staff who need space to work. Patients need bathrooms to be places of calm and multisensory stimulation and instead they are full of rather frightening contraptions. Lack of storage can also mean that staff are unable to allow personal furniture in bedrooms because there is nowhere to put the furniture that belongs to the provider. Summerhouses and sheds, built to provide activities for men, are sometimes full of beds and chairs.

14.1.4 Dining rooms

Dining rooms that are too big are full of noise and distracting activity. Noise to people with dementia is as disabling as stairs are to people in wheelchairs (Hiatt, 1995). Given the levels of undernutrition in many establishments for older people (Walker and Higginson, 2000), every effort needs to be made to make dining a congenial experience where the patients can concentrate on eating without becoming stressed and agitated by other patients. Dining rooms need to be as small as possible (see Plate 2). Staff find it much easier to ensure that the atmosphere is calm and patients are getting individual attention if there are fewer than 10 people eating together at the one time. The lack of any sound-absorbing ceiling tiles, and other fabrics also makes it very hard for staff to ensure a quiet and calm atmosphere.

14.1.5 Household spaces

The lack of everyday household spaces and objects means that anxious old people, with no motivation to do anything or who spend the whole day running their hands across tabletops, have nowhere familiar to do what they have always done to pass the time. They simply exasperate staff and other residents. Given a kitchen they can happily spend hours keeping the surfaces clean or mopping the sink. Yet few units provide even the rudiments of a kitchen except for the occupational therapy activity kitchen and then it is behind closed doors and only available to certain patients at certain times. Washing poles and a line in the garden with an adjacent sink can keep some patients very happy (see Plate 3). An old car in the garden can be very good for older men to sit in or fidget in the engine.

14.1.6 Toilets

Out of the way or poorly identified toilets make it difficult for patients to find the toilet themselves. Levels of incontinence mean that staff spend much of their time taking people to the toilet and this can be very wearing and unrewarding. Many

staff can use this as an opportunity for individual interaction but motivation wears thin if you do little else. Yet a good part of the incontinence may be because patients cannot find the toilet. One nursing home reduced its use of incontinence pads by half when they painted the doorframe red and put a large sign on it with a picture and the words 'Toilet' (personal communication) (see Plate 4). Another home relocated their en-suite toilet doors to face the bed and again reduced incontinence (personal communication). Wilkinson *et al.* (1995) found the most effective sign was words and a picture.

14.1.7 Walking areas

Many places have little appropriate space for meaningful walking. Patients who walk a lot can be very wearing for staff and other patients. There can be many reasons for this. Allan (1994) lists the following possibilities:

- continuation of life style patterns
- occupation
- leisure
- response to stress
- neurological damage
- anxiety/stress/anger
- boredom
- need for toilet
- pain
- other physical/psychiatric illness
- loss of goal-directed behaviour
- faulty goal-directed behaviour
- need for exercise
- form of communication
- medication side effects.

Several of these are ameliorated by design. If a person needs exercise there ought to be healthy, positive ways that they can go on a walk, ideally through a garden so they can get fresh air and vitamin D. The design of the unit should take them on a journey that includes a pathway outside and back in again. Sadly too many buildings offer only corridors where patients go up and down, which is depressing for everybody. In other racetrack style units they go round and round, again making staff feel inadequate because it is demonstrably such a poor experience.

Faulty goal-directed behaviour could mean that the person could not find the toilet or their bedroom. Good basic design would mean that patients could see all the doors in their unit. If this is not possible, then good quality individual signage on bedroom doors can be very helpful. It is hard for staff to provide this if the basic name holders are not in place. Nothing looks worse than selotaped bits of paper or photographs. Fixed notice boards, picture frames or perspex holders make individualizing rooms very easy for staff. Better still is the glass-fronted cupboard by the door to hold much-loved objects and photographs.

Some people walk about because they are too hot or too cold. Staff need to be able to control the temperature of individual rooms so that people can have at least one place where the temperature suits them.

14.1.8 Observation

Poor design can make it very wearing for staff to keep an unobtrusive eye on all the patients. Many staff walk miles on each shift, at the expense of their backs and feet, in order to keep an eye on a population dispersed throughout a unit. It is much better for them to work on smaller units with everything watchable. This can be achieved with a more open plan. Clearly a completely open plan is impossible given fire safety regulations, but a great deal can be achieved if this is the starting point. Glazed walls on sitting/dining/kitchen rooms; kitchen areas with shuttering for when they are not in use; waist-high furniture acting as a room divider, alcoves rather than completely separate lounges; all help facilitate unobtrusive observation. It can be very hard for staff if the unit is full of little dogleg corridors and passages to fire doors. Patients can become invisible and cause great anxiety.

14.1.9 Garden access

Poor access to the garden can cause additional work for staff or can mean that patients rarely go out. Gardens need to be very accessible so that patients can go out without supervision. They also need to be safe, which means having a fence but concealing it behind planting so that it is not an invitation to climb over. Many gardens are only accessible through fire doors out of the way of the main body of the unit, thus depriving staff and residents of an important therapeutic resource. Gardens are an important place to benefit from vitamin D from sunlight, as well as a place for activities and normal exercise. Staff are only too well aware of the importance of exercise but some residents do not respond to organized groups.

14.1.10 Chairs

People with dementia sit in chairs for long periods. The chairs are sometimes lacking in support and cause pain or discomfort to the patients with dementia. This means that staff have to deal with patients who walk about to loosen up their limbs or lash out because they are stiff and sore. Staff often have to pack pillows around patients because the chairs offer no side support. More fit and active patients can fail to recognize their chair because they are all the same colour. Chairs have the potential to provide a positive touch experience; one which is seldom provided.

14.1.11 Staff facilities

Poor quality staff facilities can be very demoralizing. Nursing and care staff need places where they can laugh, cry, shower

or put their feet up in private. These need to be of a decent quality so that they feel valued. Dignity, privacy and choice for staff means, in part, a space where they can get away to recharge their batteries. They also need offices, which are not near patient areas, so they can do their paperwork in peace. They need somewhere for training, counselling relatives and having meetings, space that is not invaded by patients.

14.1.12 Flooring

Flooring that is difficult to keep clean is a real source of exasperation to nursing and care staff as well as cleaning staff. Flooring is one of those issues where there is no right answer partly because the ideal flooring does not exist. The ideal would be a speckled carpet, which did not show every crumb and did not look as if it had crumbs on it. It would be a carpet because this feels safer to many people with dementia who are frightened of slipping. Carpets also provide a softer landing for people who do fall. Carpets are ideal because they soak up sound, they look domestic, do not reflect light and make the place look less clinical. But they are very difficult to keep stain- and smell-free. Some people are concerned that they can be a source of infection because they are so hard to wash. They rarely live up to the sales hype about being easy to wash. They often allow urine to penetrate and soak into the floor or concrete below. As a consequence staff prefer a hard floor surface that is easy to keep clean, and this is perfectly understandable. Ideally all floor covering would be the same colour because people with dementia cannot see the difference between a step and a change in floor colour.

14.1.13 Colour

Lack of differentiation between units means that patients often end up in the wrong place. Colour is often used with the intention of differentiating between units without a full understanding of the increasing impairments in colour differentiation that occur with age. Brawley (1997) has a good chapter on this. As we age we get less and less able to differentiate between pastel shades, initially, and this impairment starts at the blue end of the spectrum. Objects are much better than colour to orientate people with dementia. Strong colour contrast can be useful but it is best reserved for really crucial aspects such as toilet doors.

14.2 DESIGN THAT HELPS PATIENTS

Clearly staff are going to be most helped in their care activities if the patients are helped to function as well as they can, both because it means less work for staff and there is more job satisfaction. A therapeutic design for people with dementia will compensate for the following disabilities in every aspect:

- impaired memory
- impaired reasoning

- impaired learning
- high levels of stress
- increasing dependence on the senses.

In the same way that buildings can compensate for mobility problems and visual impairment, so they can compensate for these main disabilities of dementia and thereby help the person to remain as independent as possible. Some examples may illustrate how this thinking is applied.

14.2.1 Memory

If you have an impaired memory, it is helpful if you can see everywhere important that you need to go. You need to be able to see the toilet door and ideally the toilet itself; you need to be able to see the sitting or the dining room. Corridors are really difficult unless they are very short and very wide, because you cannot see the doors. For the same reason you need a lot of light, so that all available information is visible.

14.2.2 Learning

If you have impaired learning, you need lots of cues, so signage must include pictures and words. It also needs to be low enough for people who do not look upwards easily. If you find it difficult to learn where to go, you find it equally difficult to learn where you cannot go. Painting those doors that are not accessible the same colour as the walls, even to the extent of putting the handrail and skirting across them, can be helpful.

14.2.3 Reasoning

If you have impaired reasoning it is important that everything is understandable. The items that you are likely to use most often are those in the toilet: the tap, the flush handle and the paper holder. All need to be very easy to understand. A cross-head tap for example is much easier to understand than most lever taps especially the mixer versions (see Plate 5).

14.2.4 Stress

High levels of stress are much reduced by quiet, so acoustic tiles in the ceiling and lots of soft fabric surfaces can be very helpful, as can the availability of quiet sitting rooms and gardens.

14.2.5 Sensory abilities

Designing to take advantage of remaining sensory abilities for orientation is a real challenge. Impaired vision might mean using smell, touch or noise. Smell of disinfectant can lead people to a toilet and smell of food to a dining room, for example. The sense of smell can be very helpful in stimulating appetite, which is such a problem in people with dementia, so a kitchen or servery where toast can be made or bacon

grilled can be very helpful – food generally arrives smell-free in trolleys. Impaired hearing means that everything possible needs to be done to make things visible.

14.3 SOME KEY DESIGN PRINCIPLES

There is not a great deal of research on design features. Day *et al.* (2000) provide an analysis of current research. Most of the literature is based on practice. It is tempting to give a checklist of design tips but this can never cover every aspect of a building, particularly when they have to be designed to help such a range of age groups and levels of disability. More helpful are principles against which actual buildings or proposed modifications can be judged. Many authors have presented design principles, starting with Uriel Cohen's book (Cohen and Weisman, 1991). There is a fair degree of international consensus (Judd *et al.*, 1997), which, if pulled together, gives a list of design points.

- Design should compensate for disability.
- Design should maximize independence.
- Design should enhance self-esteem and confidence.
- Design should demonstrate care for staff.
- Design should be orientating and understandable.
- Design should reinforce personal identity.
- Design should welcome relatives and the local community.
- Design should allow control of stimuli.

These principles are used as part of an audit tool to gauge the degree of 'dementia friendliness' of a building (Stewart and Page, 2000).

14.4 CONCLUSIONS

Buildings where people with dementia spend their days are also where nursing and care staff spend much of their lives. It is possible to design buildings to help nursing and care staff in their very complex and challenging work. It is also possible to design to help people with dementia to function at their best, which is clearly of assistance to staff. Perhaps the most important message of a building that takes staff needs properly into account is that the staff are valued and their work respected. This is a crucial message given the demands that are made of them.

It is in a primary care setting that most of the care for those suffering from one of the dementia syndromes will be delivered. Changes in the demography of the population in association with changes in social and health policy mean that, in the United Kingdom (UK) at least, the burden of provision of health care will increasingly be that of the general practitioner or primary care physician. The population is ageing; by the middle of this century over one-quarter of the population will be aged over 60 years, with the over 85s being a significant proportion of those. The age-specific prevalence of dementia doubles every 5 years from 60 onwards and this presents a daunting prospect for those planning as well as those providing health and social care. Women are more at risk at all ages, and it has been speculated that this is due to an increased incidence of apolipoprotein E ϵ 4 in women. Dementia is not just confined to the elderly, however, and there is a prevalence of 0.35/1000 in those aged 45–64 (Newens *et al.*, 1993).

Putting these numbers into a primary care context, the general practitioner with an average list size of 1800 people can expect to have perhaps 20 cases of dementia at any one time, although this will vary both by chance and the local age/sex distribution of the registered practice population. This is a similar order to those patients with other chronic diseases such as diabetes, past and present epilepsy and rheumatoid arthritis, almost all of whom will be known to the practice. With regard to the people with dementia, the general practitioner will know only of about 60 per cent of cases, and those at the more serious end of the disease spectrum. There is

great variation, however, and in one study (Illife *et al.*, 1991a) only about 8 per cent of those with severe cognitive impairment or depression were known to their general practitioner.

At present the role of the general practitioner with regard to dementia care will vary according to interest and perceived skills. General practitioners often do not seem to be active in the treatment of the dementias, probably owing to a form of therapeutic nihilism; feeling that there is nothing to be done.

Recent scientific developments, particularly with regard to the genetics, chemistry and treatment of Alzheimer's disease and vascular dementia have heightened the profile of the dementias. An increasing pressure from the public responding to the knowledge that there are drugs available that ameliorate some of the symptoms of some dementias will fuel this process. In the UK the National Service Frameworks for Older People has defined a care pathway for dementia and evidence-based best practice; by April 2004 all general practitioners should be using protocols agreed with their primary care organization (PCO) and local specialist services.

It is important that a person with dementia has their illness recognized by their general practitioner as soon as possible in the disease process. By early recognition it is possible to be proactive and plan a package of disease management to optimize the patient's quality of life, and perhaps modify the progress of the disease. The NMDA receptor antagonist memantine has a licence for use in moderate–severe Alzheimer's disease but the cholinesterase inhibitors donepezil, rivastigmine and galantamine are only

licensed for use in mild–moderate cases. Dementia patients with this mild level of disease are just those cases of whom the general practitioner is not usually aware. At present the inception of a patient with dementia into primary care will usually be when a crisis occurs. This can happen when intercurrent illness produces a rapid deterioration in mental state or a carer is taken ill or dies, and a person with dementia becomes visible to the general practitioner for the first time. Patients with dementia often present to the Accident and Emergency department. In one study (Shaw *et al.*, 1996), 24 per cent of those people over the age of 65 presenting to a casualty department after a fall were found to have cognitive impairment. This demonstrates the need for good liaison systems to be in place to alert primary care services to possible new dementia cases.

15.1 SCREENING FOR DEMENTIA

The general practitioner and the primary healthcare team will need to consider what strategies they wish to adopt in order to optimize dementia care by the early detection of the illness. There are no true screening tests to detect impending dementia in a presymptomatic latent phase at present, apart from those cases caused by relatively rare autosomal dominant gene defects. The ethical impact of such tests, if eventually developed, will be enormous, affecting many fundamental facets of life ranging from the ability to get employment to health and life insurance (Anonymous, 1996). For the foreseeable future, however, the general practitioner will have to rely upon early case finding coupled with a high index of clinical suspicion in order to detect cases of dementia. In UK general practice there was until recently a contractual framework in which registered patients aged 75 and over were offered an annual health assessment, including mental health. There is evidence, however, that this process is not very effective; it is also very demanding in resource terms. To ‘screen’ the average general practitioner’s list of those over 75 years would take approximately 150 hours of face-to-face contact (Illife *et al.*, 1991b). One study (Hallewell and Pettit, 1994) only found eight previously unknown cases of dementia and 16 previously identified cases in a screened population of 232 patients over the age of 75.

To date there is little evidence that cyclical population-based case finding produces much yield, particularly on a 12-monthly basis, owing to the relatively low incidence as opposed to the relatively high prevalence of the disease. It is becoming the norm for the use of computers in the clinical setting of the consultation in general practice. At a minimum this means that, for each encounter, a disease code and prescribing information is recorded in the computer databases. The end result of this is, over time, the generation of coded disease registers for a practice population. In the UK it is planned that such information will eventually be collected and shared on a PCO basis. In those practices where the disease register showed a lower than expected prevalence of dementia, then a

stronger case for one cycle of case finding could be made. As the general practitioner will see up to 90 per cent of the practice population aged 75 and over in the setting of a consultation either at home or in the surgery in one year (Williams, 1984), case finding could be done on an opportunist basis; it could be said that this is good clinical practice. It is also quite feasible to seek out the 10 per cent not seen and administer rating scales to them. This does not have to be done by the general practitioner; community nurses of all disciplines can undertake this role, as could suitably trained lay people.

The type of practice population profile may well influence the approach taken to maximizing the number of dementia cases known. In socially deprived areas there tends to be a preponderance of patients from social classes III, IV and V. It is known that these groups use their general practitioner less than those from social classes I and II (Victor, 1991), despite having higher levels of morbidity for many diseases. In this sort of area, there is a stronger argument for active rather than opportunistic case finding, again for at least one cycle. As stated earlier, at present people with dementia often only become visible to primary care teams when the patient’s support systems fail, perhaps owing to the death or illness of an elderly spouse. There is a need for primary care to be more proactive; the ‘managed care’ approach that some PCOs may adopt in the UK could be a vehicle for this. There will be many competitors for resources, however.

15.2 CASE FINDING

Although a question to a patient about their memory may be helpful, those patients presenting themselves with a complaint of memory loss are often found to be depressed rather than demented, even though depression and dementia coexist in up to 40 per cent of cases. Family and friends’ comments about memory loss are much more significant, as are their comments about subtle problems with the instrumental activities of daily living (IADL). Deterioration in IADL, e.g. managing medication, using transport, handling finances and using the telephone, are significantly associated with cognitive impairment.

The general practitioner has a wide range of dementia-detecting or rating instruments that they can use as part of the consultation. There is reluctance for general practitioners to use these instruments, possibly as they feel the questions may be embarrassing. They are not alone in their reluctance: it has been reported that geriatricians have a similar attitude (Dunn and Lewis, 1993). This sense of embarrassment is misplaced; patients do not find the administration of the instruments intrusive (O’Connor *et al.*, 1993; Hallewell and Pettit, 1994). The Abbreviated Mental Test Score (AMTS), clock face drawing and Mini-Mental State Examination (MMSE) are easy to use in a primary care setting, and take only a few minutes to administer. There are instruments such as the PHOTOS test (part of the CAMDEX and Rivermead behavioural memory test), that have been validated in a primary care

setting (Hallewell and Pettit, 1994) and consist of seven photographs to be recognized and remembered. This test is even less intrusive, but will only detect cases and not measure severity. The MMSE offers severity rating, covers several domains and can be used serially, thus measuring rate of cognitive decline. It seems to be disliked by many general practitioners as it is thought to be a long instrument to administer. This is not so at all, and software versions are available for palm-top computers for the cost of a few pounds. At the moment simple instruments are being piloted as part of computer-aided decision-making software packages for use on primary care clinical computer systems. The patient's demographic information and past history, already held on the system, prompt the clinician to ask questions of the patient and enter the response into the computer, which will then score the responses and suggest if there is evidence of cognitive impairment. Until better instruments, perhaps with measures of ordinary and instrumental activities of daily living included in them, are developed, the MMSE may well be the instrument of choice. The main requirement is for the general practitioner to make the use of an instrument of their choice a regular part of routine clinical practice.

15.3 DIAGNOSIS

Having found a possible case of dementia, general practitioners can either refer to the specialist services at that point, or try to identify the type of dementia themselves. The natural history and clinical patterns of the dementia syndromes have been well described, particularly with regard to Alzheimer's disease (AD), which has a remarkably consistent natural history. The search continues for diagnostic markers of AD that do not require the neuropathological study of brain biopsy material, and so may be more accessible in a primary care setting. Blood tests such as analysis of the serum iron binding protein p97 (Kennard *et al.*, 1996) showed early promise, but a truly sensitive and specific test has yet to be found. Magnetic resonance imaging of entorhinal cortex has been shown to be a potentially useful method of diagnosing early AD (Bobinski *et al.*, 1999). This modality of investigation will not be in the primary care armamentarium for the foreseeable future!

Local shared care policy, where it exists, may influence the diagnostic input of the general practitioner. By taking a good history and carrying out a few investigations along with a physical examination, a general practitioner could make a diagnosis of dementia and probably the type of dementia syndrome in many cases. Most general practitioners would approach the diagnostic problem by excluding the reversible forms of dementia, and then trying to identify characteristic features of the remaining common dementia syndromes, those being AD, vascular dementia (VaD) and dementia with Lewy bodies (DLB). The other rarer causes of dementia such as neurosyphilis and Creutzfeldt-Jakob disease are very much in the specialist domain.

To aid diagnosis, a thorough history is essential – the more detailed the better. In the case of dementia this will need to be obtained from a relative or carer who knows the patient well, and has done so over a period of time. It is not sufficient to rely upon the patient alone for a history. The clinician will try to identify characteristic patterns of disease. In AD the indeterminate onset and insidious progress may be noted. Many areas of cognition are affected including memory, aphasia (loss of ability to understand the spoken or written word), apraxia (inability to perform familiar activities), agnosia (inability to recognize familiar objects) and disturbances in executive function (sequential organization, attention and planning). Functional disability results in deterioration in social and occupational activities. Early in AD, problems arise in the IADLs. As the disease progresses, the basic activities of daily living (ADL), including dressing, grooming and bathing, become restricted. In addition, behavioural changes are common and may include mood swings, wandering and agitation. In VaD a stepwise decline may be seen. There may be a history of transient ischaemic attacks or strokes. Other evidence of vascular disease history, such as angina, may be evident. It is important to remember that elements of VaD and AD may coexist. There is evidence to suggest that atherosclerosis is associated with both AD and VaD, and that there is an interaction between apolipoprotein E and atherosclerosis in the aetiology of AD (Hofman *et al.*, 1997).

Visual hallucinations are more common in DLB, with up to 70 per cent of patients experiencing them, as is less severely impaired recent memory (Graham *et al.*, 1997). DLB has a characteristic fluctuation in cognitive function, which may appear similar to a confusional state. Some 80 per cent of patients with DLB will demonstrate clouding of consciousness. It is very important that the general practitioner considers this diagnosis carefully, as patients with DLB are very sensitive to neuroleptic agents and administration of these agents may indeed prove fatal. The history itself should help distinguish the acute onset of a confusional state from the slow onset of any dementia syndrome. It is, of course, necessary to try to identify depression and delirium, and treat accordingly.

15.4 CLINICAL EXAMINATION

Examination will obviously include a dementia rating scale such as the MMSE. Evidence of disease in the cardiovascular system, such as ischaemic heart disease, hypertension and arterial bruits, would tend to support a hypothesis of VaD, although as previously stated, AD and VaD can coexist. A brief neurological examination may show evidence of extrapyramidal signs found in DLB. Evidence of cerebrovascular accident may be evident, such as focal neurological signs. A physical examination may reveal evidence of a reversible cause of dementia such as hypothyroidism or profound anaemia. It is stated that, overall, 5–10 per cent of dementias are reversible, but this is only true in about 1 per cent of dementia presenting

in the elderly population. A younger patient presenting would increase clinical awareness of the possibility of a reversible dementia or one of the rarer dementia syndromes, and referral to a neurologist may be more appropriate than referral to old age psychiatry or memory clinic services.

15.5 INVESTIGATIONS

Laboratory tests will include glucose, full blood count, erythrocyte sedimentation rate, vitamin B₁₂ and folate, thyroid function tests and biochemical profile. It has been traditional to undertake syphilis serology, but this is probably not cost-effective in primary care.

Neuroimaging is helpful in diagnosing a dementia, the cheapest option being a computed tomography (CT) brain scan without contrast. This will demonstrate structural changes in the brain typical of AD or VaD, and other abnormalities that may be a cause of cognitive decline such as tumours, haemorrhages and normal pressure hydrocephalus. Whether or not open access to CT imaging for general practitioners is practical is a matter for debate. The use of magnetic resonance imaging (MRI), functional MRI, single photon emission computed tomography (SPECT) and positron emission tomography (PET) are clearly not in the domain of primary care.

15.6 REFERRAL

Interestingly, almost three-quarters of UK general practitioners in one survey felt that a specialist opinion was not necessary to diagnose dementia (Grace, 1994). Now that drugs to ameliorate some of the symptoms of the dementias have a product licence or their equivalents are available for prescription, there has been a financial and clinical imperative in many areas to allow only initiation of prescribing by specialist clinicians. It is clearly essential that an accurate diagnosis of the type of dementia is needed to allow effective use of drugs. When considering specialist referral, the general practitioner will need to decide if he or she is going to refer and to whom. To aid this decision the practitioner needs to define and clarify purpose in referring: is it for diagnostic help, management help, prescription or a combination of these things?

The answers to these questions will make the type of referral clear. A neurologist may be appropriate for the younger or atypical case. The old age psychiatrist and their teams may be the most appropriate for cases where the patient is older and the diagnostic probabilities are more defined. If there is going to be a need for ongoing support, then the old age psychiatry teams will be the obvious choice; this is almost always the case. If the general practitioner is confident about the diagnosis, and the primary healthcare team is able to arrange appropriate support, then, arguably, no specialist referral is needed.

15.7 DRUG TREATMENT

It is probable that a patient with dementia will have other diseases also requiring treatment with drugs. It is important to review therapy to simplify the regimen as much as possible. The advice of the community pharmacist can be helpful regarding type of preparation and aids to compliance, such as 'dosette' boxes. Medication can be made up into blister packs with days and time of day clearly marked. Many people with dementia live on their own, and whilst it may be possible for someone to visit once daily to supervise medication, more frequent visits become problematic. If possible, once-a-day dosing with long-acting or modified-release agents should be arranged. There are several classes of drugs used in dementia, ranging from disease-modifying agents to those drugs used to modify behaviour. Donepezil, galantamine and rivastigmine have a UK product licence for the treatment of mild–moderate AD and memantine for moderate–severe AD. Prescribing guidelines such as those issued by the UK Standing Medical Advisory Committee (1998) and others (Lovestone *et al.*, 1997) exist for these agents. Initiation of this form of therapy is not, as yet, a primary care function, although continued prescription can be, as part of a shared care protocol. Other non-cholinergic agents are being developed and might be indicated in VaD as well as AD, but early results have been disappointing so far.

Aspirin therapy should be initiated in VaD to help prevent further ischaemic damage. Hypertension and atrial fibrillation should be treated vigorously. Other antiplatelet treatment, such as combined modified-release dipyridamole and aspirin may have a role if transient ischaemic attacks have been identified.

Wandering, agitation, aggression and insomnia are seen in dementia and can cause great distress to the carer. Aggression is often associated with delusions, and the general practitioner should try to identify the presence of this phenomenon. Non-drug interventions should be tried if at all possible, but there may be a need to prescribe medication at some stage. Small doses of a neuroleptic agent work well, but should be initiated carefully and the dose titrated to response. Patients with dementia are very susceptible to extrapyramidal side effects of these agents and, as has been previously stated, reactions can be fatal in those with DLB (Anonymous, 1994). In early 2004 it was reported that there was a two- to three-fold incidence of stroke in elderly patients with dementia treated with atypical antipsychotic agents. The Committee on the Safety of Medicines recommended that risperidone and olanzapine should not be used for the treatment of behavioural symptoms of dementia. Extrapyramidal side effects can be countered with agents such as orphenadrine, but these can cause confusion, delusions and hallucinations, so caution is required. Almost half of dementia patients may be depressed at some stage. Depression responds well to treatment in many cases; suitable agents are lofepramine, imipramine or a selective serotonin reuptake inhibitor (SSRI). The SSRIs have

a better safety profile, and may be preferred if there are doubts about supervision or compliance.

15.8 FURTHER MANAGEMENT

There is no excuse for the continuing management of dementia in primary care to be one of crisis management. There has been a general interest in developing evidence-based guidelines for proactive management (Anonymous, 1995), especially in chronic disease management, and these well-described processes and principles for the management of chronic disease in primary care can be adapted for the dementia syndromes. Some excellent examples of evidence-based guidelines exist: *Interventions in the Management of Behavioural and Psychological Aspects of Dementia* produced by the Scottish Intercollegiate Guidelines Network in 1998, and the North of England evidence-based guidelines for the primary care management of dementia (Eccles *et al.*, 1998) are good examples. National guidelines are an excellent starting point, but need to be adapted and adopted locally in order to be 'owned' by a group of practitioners; anecdotal evidence suggests that 'top-down' guidelines tend to be ignored, whereas locally developed guidelines tend to be adhered to.

Dementia management should be anticipatory and there needs to be a system for regular review of the patient including some measure of disease progression and functional ability, with clearly defined triggers for carers to seek clinical help identified. There may be dedicated dementia care teams available or the primary care team may undertake the task itself. Computerized disease registers that can be associated with algorithms for care should make the task easier, but are not essential. The most important thing, as has been stated, is to develop a system for periodic review, including a definition of roles and responsibilities for the primary care team members. A package of care should include as much support for carers as possible; this has been shown to delay the admission of a patient with dementia to a nursing home (Mittleman *et al.*, 1996). In another study it was found that carers identified reliable, competent respite care, on a planned basis, as the single most important service to prevent premature long-term nursing home placement (Heagerty *et al.*, 1988).

A range of options for the care of the dementia patient in primary care exists, very much locally determined, however. This can vary from care at home by a spouse or other carer, with varying degrees of input from health professionals, to intensive home-based care from a community mental health team as an alternative to inpatient care (Stokes *et al.*, 1998). Other patients will attend day hospital or community facilities on a regular basis. The general practitioner should make sure that there is access to occupational therapy and the other non-drug therapies if felt appropriate. A holistic approach such as 'person-centred dementia care' (Thacker, 1998) is well suited to a nursing or residential home setting.

It should be remembered that a sudden deterioration in function may be due to a 'silent' intercurrent illness such as a chest infection, urinary tract infection or myocardial infarction and not part of the underlying dementia. Recognition of this is important as treatment of the intercurrent illness will restore cognitive function to its previous level.

15.9 CARERS AND THEIR SUPPORT

The vast majority of the burden of caring falls upon relatives, usually the spouse, of the patient. These carers are themselves often elderly and frail, and may also be ill. Research has confirmed that this is so, with only a minority of patients getting support from the statutory bodies (Luker and Perkins, 1987). The Alzheimer's Society found in a survey of UK health authorities (Anonymous, 1997) that there was inequality of service provision and access for people with dementia and, disturbingly, very little consultation with users and carers about how needs should be accessed and what services should be commissioned. It is to be hoped that changes in the structure of the UK National Health Service (NHS) in 1999, such as the formation of PCOs and the National Institute for Clinical Excellence (NICE), may go some way to mitigating this.

Along with the unremitting 24-hours-a-day, 365-days-a-year physical task of looking after a relative with dementia, there are other burdens that the carer will have to adapt to. Carers may have feelings of guilt or anger about the way they feel about the very different person they used to know, and may suffer from a form of grief reaction about the 'death' of an intellect when the body remains all too apparent. None of these things should be unexpected, and the primary care team should be able to anticipate problems and act in a proactive way.

One of the single most useful things that a general practitioner can do as soon as a diagnosis of dementia is made is to put relatives and carers (and also the patient, if appropriate) in contact with the local dementia self-help group. In the UK this would probably be the Alzheimer's Society or Alzheimer Scotland Action on Dementia. These organizations can provide a wealth of information and support, and are often able to provide literature and advice about topics such as sexuality, aggression, wandering and other emotive areas. Other voluntary groups such as Crossroads (the Association of Crossroads Care Attendant Schemes) in the UK can provide someone to sit with a person with dementia on a regular basis, allowing the caregiver time to him/herself. This can greatly improve the carer's quality of life.

15.10 LEGAL AND ETHICAL ISSUES

Dementia has an enormous impact on all aspects of life, and advice will be sought from the general practitioner about these. Sensitivity is needed when giving advice, particularly in

the light of recent evidence (Meyers, 1997) that the majority (80 per cent) of carers feel that a person with AD should not be told the diagnosis. Interestingly, though, the carers themselves (70 per cent) felt they would want to know if they had the disease themselves. It is important that the person does know the diagnosis and prognosis in order to be able to put his/her affairs in order and consent to treatment whilst the intellectual capacity to do so remains. Relatives and carers do need to be given as much information as possible. Magazines, radio, television and the Internet have placed vast amounts of information about dementia in easily accessible form, but information overload is a risk and the quality of data variable, ranging from reputable science to dangerous quackery.

There are many major changes in the life of the person with dementia and his/her carers ahead and they need to be alerted to these to allow action to be taken. The doctor needs to be aware of legalities in order to alert the patient and carers, but it would be a foolish doctor or other member of the primary healthcare team who purported to give legal advice; this should be left to lawyers. Driving can be a cause of much concern, especially if the person and family rely on this form of transport. This is especially so in rural areas. The doctor may feel conflicts of interest when giving advice, not wanting to isolate the person with dementia and their dependants, but also not wanting to put the general public at risk. The patient should be advised to notify the vehicle's insurers of the nature of the illness. The British Medical Association suggests that any question from an insurance company regarding an opinion about whether a patient with dementia is fit to drive should not be answered by a family doctor in order to avoid risk of a charge of negligence in case of an accident. The person with dementia should be told to advise the competent authorities on the nature of the disability. The authorities will then gather such information as they require to make a decision about driving. A yearly licence may be issued, or the licence may be revoked. There is no doubt that people with mild cognitive impairment do drive, apparently safely. It is interesting to note, however, that in one study (Johansson *et al.*, 1997) it was found that post-mortem evidence suggested a higher number of elderly drivers dying in a road traffic accident had evidence of Alzheimer's disease than age-matched controls. It would be advisable for the physician to contact the relevant professional organizations for expert advice, if needed. The general rule should be that, however uncomfortable a decision it may be, society's safety outweighs an individual's rights.

With regard to advice about making a will, the person with dementia will need to make a will while capable of understanding what a will is, what property there is to dispose of, and to whom. In order to satisfy these criteria, the family doctor is going to have to make absolutely sure that the person understands the nature of the illness, and its natural history, early on in the illness before cognitive impairment is fully established.

As the disease progresses, the need for Enduring Power of Attorney may be necessary. This gives another person (the attorney) the right to act for the patient (the donor). With

ordinary Power of Attorney, this power becomes invalid if the donor becomes mentally incapable. Enduring Power of Attorney will allow the attorney to deal with the donor's affairs no matter what their mental state, as long as the donor had insight when appointing the attorney.

The general practitioner may also feel an ethical dilemma as he/she will often be caring for the dementia patient and the carer and family. Is facilitating the nursing home placement of a patient with dementia, perhaps against expressed wishes, in order to protect the mental and physical wellbeing of an exhausted carer the 'ethical' thing to do? Is it ethical to allow a crisis to develop by withholding support when a dementia patient is living alone and refusing help, in order to facilitate hospital admission and thus support the patient, perhaps by using statutory powers? There are no easy answers to any of these questions, but discussing the matter with colleagues and other members of the primary health-care team sometimes make the solutions clearer.

15.11 PREVENTION

Until recently it would be unheard of for the subject of the prevention of dementia to be dealt with in a primary care context; indeed, very little about dementia *per se* was to be found in the primary care literature. There has been a sea of change, however. Much more is known about the pathogenesis of the dementia syndromes; although the evidence is not always based on robust randomized controlled trial work, there is mounting evidence that lifestyle modification and therapeutic interventions may be possible in the primary prevention of some of the dementia syndromes (Whalley, 1998). The general practitioner will need to be aware of this as an increasingly informed public may well require information from them. Recent published work regarding the adequate control of hypertension demonstrated in the elderly that, if hypertensive elderly people were treated for 5 years, 19 cases of dementia per 1000 of the population could be prevented (Forette *et al.*, 1998) and these were cases of AD, rather than VaD, as may seem initially intuitive. Reducing vascular risk factors such as hypertension, obesity, hyperlipidaemia and smoking will reduce the risk of cerebrovascular accident and cognitive impairment.

There have been a number of robust trials, some (Forette *et al.*, 1998) with the onset of dementia as an end point in its own right rather than transient ischaemic attacks and stroke used as proxy markers. The Study on Cognition and Progress in the Elderly (SCOPE) (Sever, 2002) looked at 5000 hypertensive patients aged between 70 and 89. At enrolment all subjects had a MMSE equal to or greater than 24. The subjects were randomized to placebo or angiotensin-converting enzyme (ACE) inhibitor plus other agents to control blood pressure. After 3.5 years there was a 24 per cent drop in stroke incidence in the treatment group and, although both arms showed a similar decline in MMSE, more sophisticated tests

of cerebral function showed increased speed of cognition, increase in attention, improvement in episodic and working memory and better executive function in the treatment group compared with the controls. In the PROGRESS trial (PROGRESS Collaborative Group, 2001) over 6000 subjects with a history of transient ischaemic attack or stroke were enrolled. Importantly the inclusion criteria did not include hypertension, so normotensive subjects were included as well as hypertensive subjects. There was a reduction of cognitive decline of almost 20 per cent in the treatment group, which was more marked in the subgroup who did have another stroke. After 4 years the risk of dementia after a stroke was reduced by 34 per cent. The Antihypertensive and Lipid Lowering Treatment to prevent Heart Attack (ALLHAT) (ALLHAT Collaborative Research Group, 2002) introduced lipid lowering treatment as well as anti-hypertensive therapy with a favourable outcome in terms of cardiac and neurological events in the treatment groups. Other studies on statins have shown a reduction in AD in the treatment group (odds ratio 0.26) but only in subjects younger than 80. The available evidence suggests not only a reduction in VaD, which would be expected, but also AD, though the 'pure' form of either entity is probably rare and most cases sit on a continuum stretching between AD and VaD.

Diabetes is also associated with vascular problems and there is a relative risk for AD of 2.3 for men and between 1.4 and 2.0 for women who are diabetic. Good control of diabetes should help prevent both VaD and AD.

There was some evidence that the use of hormonal replacement therapy (HRT) may help prevent AD (Bonn, 1997); however, this is offset by the increased risk of breast cancer in users of HRT (Beral *et al.*, 2003) and by the knowledge that HRT increases the relative risk of stroke by 1.41 after 5 years of use (Writing Group for the Woman's Health Initiative Investigators, 2002). More recent work has shown stroke itself is a risk factor for AD (hazards ratio for AD with a history of stroke 1.6) (Honig *et al.*, 2003) so the role of HRT as protector against dementia is becoming clouded and may do more harm than good.

It has been suggested (Whalley, 1998) that a dementia prevention programme is possible. It should seek to lower the risk of dementia by reducing vascular risk factors, for example, by treating diabetes and hypertension, stopping tobacco use and normalizing lipids by drug therapy and diet. It is becoming increasingly likely that AD is a manifestation of insulin resistance (Rasgon and Jarvik, 2004) (Strachan M, 2003) and this theory gives a logical basis for the above approach. It has been suggested that a pill containing a statin, three blood pressure drugs (perhaps beta-blocker, ACE inhibitor and a thiazide all at half standard dose), low-dose aspirin and folic acid (to reduce serum homocysteine) be administered to persons over 55 years of age (Wald and Law, 2003). Using existing data, it is estimated that one-third of people so treated would gain an additional 11 years of life free from an ischaemic heart disease (IHD) event or stroke. It is true to say that there is considerable controversy about this proposal,

but the concept of IHD and stroke prevention is so similar to a dementia prevention programme that the two may really be the same thing. Only large-scale properly designed trials over some period of time are going to give the answers. The use of antioxidants and anti-inflammatory agents such as non-steroidal anti-inflammatory drugs (McGeer and McGeer, 1999) may have their place in the prevention of dementias by their actions as neuroprotectors.

Diet plays a role, especially in AD. Obesity itself is a risk factor for dementia independently of other comorbid factors with up to 74 per cent increased risk of dementia developing if the body mass index is greater than 30 (Whitmer *et al.*, 2005). There is evidence (Grant, 1997) that a high fat and high calorie diet is associated with an increased prevalence of this disease, perhaps by adding to oxidative stress; conversely, fish consumption is associated with a reduced incidence. Vitamin C may protect against cognitive impairment in the elderly (Gale *et al.*, 1996) as, indeed, does education (Ott *et al.*, 1995). Modification of all these varied factors could potentially form part of a primary prevention package, but there is still a need for firmer, long-term prospective evidence before this can be recommended and such evidence may be hard to gather.

In primary care, especially in the UK, the same team will look after the same cohort of individuals over long periods of time. This means that they have the ability to note those people who are more at risk of developing a dementia syndrome, and there should be a raised index of clinical suspicion when dealing with these individuals. For example, in AD, about one-third of cases are familial. Risk factors for AD include previous Parkinson's disease (relative risk of 2.4), advanced parental age (relative risk 1.6) and head trauma (relative risk 1.8). Interestingly, a history of depression more than 10 years ago is said to carry a relative risk of 1.7 and more recent work (Green *et al.*, 2003) in a large study shows a doubling of risk of AD in patients with a history of depression. We know that diabetes and hypertension are risk factors.

Primary care is now becoming highly computerized with many practices' 'paperless' and comprehensive disease databases being generated containing (when complete) most, if not all, of the information above. It has been suggested (Holt and Ohno-Machado, 2003) that there should be a nationwide adaptive prediction tool for coronary heart disease prevention. Adaptive predictive models are computer based and 'learn' to classify cases according to patterns. They include algorithms as well as more complex models such as neural networks. These systems are used in industry for pattern recognition and process control. Data collected under the new General Medical Services contract in the UK, along with pre-existing data, could populate an adaptive predictive tool and in essence stratify risk for each individual allowing targeted intervention for those highest at risk of coronary heart disease. By adding some of the dementia risk factors to this information, it would in theory allow the construction of a similar adaptive prediction tool for dementia prevention, especially as there is great overlap in the characteristics of the 'at CHD

risk' and the 'at dementia risk' populations, again allowing for targeted intervention to 'prevent' dementia.

The prevalence of AD will quadruple by the year 2047 to 8.64 million cases in the USA unless effective preventive interventions can be developed. If the disease onset can be delayed by as little as 6 months then it is projected that in 50 years, 380 000 fewer people will be affected (Brookmeyer, 1998). This would have enormous resource implications.

15.12 THE FUTURE

The future of primary care is uncertain. There is a general trend for as much clinical and social care to be delivered to the patient as close to home as possible, hence firmly in the primary sector. There is also a trend for the introduction of managed care. The introduction of PCOs in the UK, with their similarities at trust level to US-style health maintenance organizations will accelerate this trend.

A main feature of health provision in primary and secondary care is the introduction of clinical governance. Clinical governance has been described as a system through which NHS organizations are accountable for continuously improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish (Scully and Donaldson, 1998). It involves standards, performance and quality review. It seems logical that patterns of care will be increasingly guideline-based and be capable of being audited both for process and outcome. The development of guidelines will no doubt be influenced by national guidelines, but need to be locally modified to be practical, as has been previously noted. Developing protocols and guidelines must not be taken lightly, and must be firmly evidence based. There can be apparent contradictions in the evidence, however. For example, with regard to the risks of smoking and dementia, one small study in the UK found the relative risk of AD in patients who smoked was 0.68 (Salib and Hillier, 1997), whereas a large population study in Rotterdam (Ott *et al.*, 1998) showed the relative risk to be 2.2. The difference may well be due to the presence or absence of the apolipoprotein E ϵ 4 allele, but this example of apparent conflict in evidence demonstrates the need for expertise and care in developing a robust evidence base on which guidelines for care are based.

One of the outcomes of the introduction of care trusts has been a unification of clinical budgets with social care budgets. When this has truly happened, then the true cost of care (including clinical and social elements) is of prime importance. At the moment the fact that a modest outlay on anti-dementia drug costs might delay a patient entering very expensive residential or nursing care homes tends to be ignored, as different organizations are responsible for drug and social care budgets – the opportunity for overall cost saving is thus lost. With a unified or pooled budget this would not be the case. There is good evidence that the integration of

medical and social care can result in reduced costs and reduced functional decline in the elderly (Bernabei *et al.*, 1998). A certainty is that patients of increasing levels of dependency will be cared for in the community in increasing numbers and this trend will continue (Stern *et al.*, 1993). Some general practitioners have found the increase in workload to date unmanageable (Williams *et al.*, 1992). The new General Medical Services contract introduced in the UK in April 2004 allows for enhanced services to be provided by some practices to special patient groups. This could be used as a mechanism for interested primary healthcare teams to develop a special interest in caring for people with dementia in a locality, including those registered with other practices.

16.3 Communication	182	References	184

Dementia presents with a progressive deterioration of cognitive abilities, increasing dependency on others for self-care and an emerging need for supervision. The role of nursing can be pivotal in that nurses work in a continuum of settings in which they provide care for the individual with dementia and their families. Nursing professionals have the benefit of face-to-face contact, be it in the clinic, home, or institution. The nurse may be the person who is most readily accessible and can coordinate the patient's care needs. Nurses are a valuable resource for understanding the difficulties of caring for the patient at home. Their role may be to observe changes in health status and to communicate these changes to the other members of the health team. It may be the nurse who talks most frequently to the family providing counselling and support. As a resource for assistance in day-to-day care, nurses can identify problems and give practical advice in caring for problems ranging from bathing to catastrophic reactions (Sloane *et al.*, 1995).

The challenge of caring for patients with dementia is to become vigilant in identifying the range of symptoms of cognitive decline in the early stages to the more troubling behavioural symptoms of the later stages. Current research emphasizes the need for early identification. Backman and associates (2004) found that in preclinical dementia there is decline in cognitive functioning 3 years before diagnosis. These researchers observed that with increasing age and numbers of recent diseases there is a more rapid decline (Backman *et al.*, 2003). Early identification of dementia is imperative. Individuals with mild symptoms may be eligible for cholinesterase inhibitors or inclusion in drug research trials that may delay the progression of the disease.

Though each setting in which the nurse provides care has specific issues, the care of patients with dementia falls into several components that are pertinent to all settings. These

components are assessment with emphasis on self-care abilities and communication abilities; therapeutic interventions and symptom management; and support systems and resources. In addition, each stage of dementia presents unique challenges to nursing care. The overarching philosophy of care is to provide individualized care that enhances self-care abilities and encourages autonomy in the least restrictive setting for as long as possible. The patient with dementia requires a thorough and holistic evaluation including physical, psychiatric, psychosocial and environmental assessments. This chapter emphasizes assessment.

16.1 ASSESSMENT

Ongoing assessment is an essential part of the care of the patient with dementia. Geriatric prepared nurses have knowledge and understanding of age-related changes and common disease processes, as well as behavioural symptoms that can afflict the elderly patient. People with Alzheimer's disease (AD) have a full range of symptoms from those who have not yet come to medical attention, the mildly affected, to those with advanced symptoms (Albert *et al.*, 1998). The progression of dementia symptoms jeopardizes the individual's ability to remain in an independent living situation.

All patients need to be evaluated for changes in cognition and functional abilities. The nurse's responsibility is to complete and continue a thorough nursing history to assess the stage of the disease, comorbid medical conditions, activities of daily living (ADL) and instrumental activities of daily living (IADLs), self-care abilities and competency to self-medicate. Various tools are available to document baseline abilities and change or decline (Katz *et al.*, 1963, 1970; Lawton and Brody,

Box 16.1 Mnemonic for dementia evaluation

Drugs on board
 Emotional disorders
 Metabolic disorders
 Ears, eyes – perception
 Nutrition and normal pressure hydrocephalus
 Infections
 Arteriosclerosis and atherosclerosis
 Sundowner's syndrome

1969). A review of systems is indicated owing to the high prevalence of comorbid medical conditions and susceptibility to delirium, particularly infections, inadequate nutrition and polypharmacy, being mindful of drug–drug interactions (Inouye, 1998). As noted previously, nurses should be suspicious of subtle declines in individuals not yet diagnosed but with the risk factors of increased age and numbers of recent medical conditions (Backman *et al.*, 2004).

Since dementia is to some degree a diagnosis of exclusion, specific reversible causes must be ruled out. Use of a mnemonic for evaluation of potentially treatable causes may be helpful (Box 16.1). Once the diagnosis is established, identification of the stage of disease development can be helpful in anticipating needs and to help the family plan for care.

Several authors have developed scales to stage dementia in general and AD in particular, such as the Global Deterioration Scale (GDS) (Reisberg *et al.*, 1982), the Clinical Dementia Rating scale (CDR) (Berg, 1988), the Blessed Memory-Information-Concentration Test (Blessed *et al.*, 1988), the Functional Assessment Staging (FAST) (Reisberg, 1988), and the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975). In the outpatient setting, the 'SCOPED' assessment tool is a quick assessment of functional abilities (Dohrenwend *et al.*, 2003; Beck *et al.*, 1994). The questions revolve around the patient's safety, asking questions about spending, cooking, operating automobiles, pill taking, everyday activities and decision-making.

All of these scales quantify the specific functional losses that occur with AD and in association with ageing. These scales plot symptoms from normal to severe and help clinicians track the course of the disease. This tracking helps identify where the individual is in the disease progression. Staging, used correctly, can assist the family in anticipating and preparing for problems rather than waiting until a crisis occurs, but if used inappropriately, can depersonalize the patient and limit options for therapeutic interventions (Cole *et al.*, 1998).

16.1.1 Mental health assessment

The nursing psychiatric assessment includes observation for depression, psychosis and behavioural change. The goal of the psychiatric assessment is to gather and integrate biological,

psychological and socioeconomic data to provide comprehensive understanding of a person's psychosocial status.

Crucial information includes past ways of coping, identification of chronic and acute stressors, personality styles, family roles and dynamics, decision-making history, and past and family psychiatric history. Besides observing and documenting symptoms of depression and other psychiatric behaviours, nurses spend much time with the patient and can elicit pertinent information about the meaning and significance of behaviours and symptoms. An important hint in understanding the patient's current behaviour is to obtain information concerning who the patient was and behavioural styles prior to the onset of dementia. This information can give the clinician insight into and understanding of some of the behaviours exhibited by the patient. For example, a patient who worked nights may not have nocturnal wandering; a domineering personality may not respond to directives but needs to be 'in charge'.

16.1.2 Caregiver assessment

Holistic assessment of the patient with dementia includes evaluating how well the family or professional caregiver is handling the impact of the disease and the behaviours presented by the patient (see Chapters 4 and 11a). Caregiver burden is defined as the physical, emotional, social and financial challenge of providing care (George and Gwyther, 1986).

Caregivers have more stress symptoms, use more psychotropic medications and have less social activities. Depression and worsening behaviours in the person with dementia adversely affect the caregiver (Saad *et al.*, 1995). As part of the patient encounter, the caregiver's stress and issues with the person with dementia need to be assessed. The nurse can evaluate caregiver burden based upon the risk factors noted above and with one of the tools that measure caregiver burden such as the Zarit Burden Inventory (Zarit *et al.*, 1980) or the Screen for Caregiver Burden (Vitaliano *et al.*, 1991).

16.2 ENVIRONMENT AND SAFETY

Use of the milieu or environmental manipulation is a primary intervention for confused people. Important aspects of using the environment are for observation of behaviour, therapeutic interventions and to evaluate the efficacy of psychopharmacological options. The nurse in any setting is responsible for developing a therapeutic environment for the patient. Safety surveillance is emphasized, providing for the patient's needs and developing ways to tolerate their behaviours in a safe environment. Helping the family to remove safety hazards, toxins, inedibles, cords and throw rugs can ensure a more streamlined and safer habitat for the confused patient.

In a nursing facility (as well as the home), the environment should be streamlined to decrease confusion but stimulating enough to encourage the patient with dementia to be

Box 16.2 *Environmental strategies for dementia*

- Use of calendars, pictures and maps for visual and cognitive cueing
- Space for safe wandering, both inside and outside
- Use of wandering gardens (Hoover, 1995)
- Use of colour and signs to help with orientation and way-finding
- Use of light and small areas for conversation and quiet pursuits
- Decrease distracting, confusing noise levels
- Add appropriate music (Tabloski *et al.*, 1995)
- Comfortable home-like furniture
- Provision of activities that allow the patient success and interaction
- Use of electronic alarm systems and/or design to deter elopement, such as camouflaged doors, use of directional street signs, or dutch doors
- Assessment of area for fall prevention
- Good definition between walls and floors
- Availability of activities throughout the day and evening
- Access to portable foods and liquids for wanderers
- Physical activities to divert aggression

involved and interested. Teri and Wagner (1992) demonstrated that participation in pleasurable activities decreases depression in demented patients and lessens agitation. In designing the environment, several considerations need to be addressed. Box 16.2 refers to environmental considerations that benefit people with dementia and can provide a more therapeutic atmosphere for the confused.

The family trying to understand the disease may not consider changing the home environment as part of the treatment. The nurse can provide helpful, practical suggestions to assist the family to provide an optimal environment at home. Many family caregivers feel helpless and welcome practical advice that encourages their involvement in caring for their loved one.

16.3 COMMUNICATION

Language abilities deteriorate with dementia. Often the early symptoms include word-finding, receptive aphasia, derailing mid-sentence, confabulation (filling in missing gaps of information), tangentiality and circumstantiality. Many AD victims demonstrate remarkable conversational skills and social graces that fool the clinician. Family and caregivers need to be interviewed to validate patients' reports and abilities.

Techniques of communication require changes in approach and style. Conversation must be streamlined. Most sentences are too long and confused patients are not able to follow several thoughts or directions in one sentence. Slower paced conversation with fewer and more concrete words is indicated. Using as many of the senses as possible may imprint

the message more effectively – for example, using gentle touch to get a patient's attention; pointing to concrete objects like a water glass when asking to drink, or handing the glass with the request. Offering forced options, such as, 'Do you want an apple or an orange?' can help with decision making and foster autonomy. Repetitive questions can aggravate caregivers and upset patients. Sometimes ignoring or redirecting can help. Other patients need more reassurance and the nurse should attempt to divine the meaning behind the repetitious questions (Landreville *et al.*, 1998).

Asking the family about the patient's communication style or special language is necessary to continue to communicate and incorporate into treatment plans. Gathering this information can be instrumental in preventing frustration and agitated behaviours. Observation of the patient's non-verbal language and interpretation of its meaning can provide the nurse with insight into the patient as well as establishing more empathetic responses. Validation therapy proposed by Feil (1993) encourages interpretation of the patient's non-verbal behaviour as a way of validating feelings and emotions the patient can no longer express. Rocking behaviour can be interpreted as agitation or anxiety if vigorous but if it occurs in a gentle, relaxed fashion can be explained as comforting. In essence the nurse interprets to the patient his or her understanding that the behaviour may be expressing a positive or negative emotion, striving for a connection with the patient.

16.4 THERAPEUTIC INTERVENTION AND SYMPTOM MANAGEMENT

As dementia progresses, symptoms worsen and more troubling behaviours may present. These behaviours include agitation, aggression, wandering, sleep disorders, and inappropriate sexual behaviours.

Behavioural interventions designed for target symptoms can be instrumental in minimizing or defusing the escalation of those behaviours. They are the first line in handling milder behavioural and psychological symptoms of dementia (Cohen-Mansfield and Werner, 1995). The more aggressive or problematic behaviours may require a combination of pharmacological and non-pharmacological interventions (see Chapters 38 and 39). Patients with dementia require and benefit from more labour-intensive approaches, i.e. interventions and strategies that can be done by lay and professional caregivers and are easy to implement with widespread application to the home setting or the long-term care facility. As problematic behaviours arise, there is a need and opportunity for nursing intervention with the caregivers and the patient. Basic principles of behavioural intervention are summarized in Box 16.3. The rule of thumb of instituting behavioural approaches is based on the seven Rs – Reassess, Reconsider, Reassure, Rechannel, Redirect, Remove and Rethink (Kuhn, 1993).

Box 16.3 *Assessment of a problem*

- Identify behaviour
- What is the behaviour?
- When does it occur?
- Where does it occur?
- With whom does it occur?
- What is the caregiver's response?
- Identify what was tried and how successful it was
- Was any one person successful and what did they do?

Box 16.4 *Risk factors associated with a person with dementia becoming lost*

- Inability to remember one's own name, address or phone number
- Inability to state why one is in a given location
- Inability to state where one is going or who one is with
- Inability to follow a conversation
- Inappropriate behaviour for the setting
- Inappropriate responses or confusion when asked questions
- Inability to recognize common symbols such as police uniforms or directional signs

Adapted from Rowe (2003)

16.4.1 Problematic behaviours

The nurse's role in managing agitation and aggressive behaviour is assessment of potential triggers and early intervention. Identification of individuals, situations and activities that provoke can prevent escalation and redirection to more appropriate activities. The nurse should evaluate how the patient is being approached. Is the approach calm and slow? Is the patient spoken to firmly and gently in advance so as not to startle and precipitate a spontaneous aggressive reaction? Is the use of touch helpful or counterproductive? Ryden and Feldt (1992) found that intrusive touching behaviours, which nurses and nursing assistants are likely to perform such as bathing and toileting, are likely to be perceived as threatening. Non-verbal behaviour and authoritarian postures can also set off aggressive responses. Use of redirection and reassurance can be the nurse's most valuable weapons. Assessing the reality of the situation and backing off to avoid escalation may be the most effective strategy. Helping the caregivers assess if the activity needs to be done now or if it can wait can prevent caregiver frustration and aggressive reactions. Assessing the patient's environment for too much stimulation and offering suggestions to provide quiet and less stimulating activities will help decrease outbursts. Prediction of possible behaviours and addressing the 'how to handle' before the behaviour occurs gives the family caregivers techniques to use and lessens their sense of helplessness. The potential for danger always needs to be addressed and treatment planning should include what to do and how to get help in whatever setting the patient is in.

Points to consider when assessing wandering and sleep disturbances include assessment of the environment for triggers that stimulate or induce the behaviour. Assessment of types of wandering helps define the appropriate intervention. Nurses need to ask the following questions. What was the patient like before dementia? Was the patient a high-energy person who never sat still and was always on the move? Is the current wandering a problem that requires intervention because of elopement concerns, striking out, a search for home and comfort or a risk to others? Is the confused patient upset because he/she knows where he/she is not? Or is the wandering purposeless, benign and tolerated in a safe environment (Butler and Barnett, 1991)?

Algate and colleagues (2003) have studied wandering and its meaning to the person with dementia. These researchers

found that by observing the pattern, duration and frequency, the nurse could differentiate between healthy and problematic wandering. By looking for the meaning of the wandering, the nurse is more apt to design an intervention that is more successful and relieving for people with dementia.

Related to wandering is the likelihood of becoming lost. The Alzheimer's Association of the United States predicts that 60 per cent of people with dementia will wander and become lost in their community (Rowe, 2003). This statistic highlights a potential public health problem. Nurses have the unique opportunity to educate families, law enforcement and the public of this potentially deadly behaviour. Educational information includes not leaving the person with dementia alone; securing the home environment to prevent inadvertent leaving; use of motion/tone detectors and alarms and security systems. Another resource is the Safe Return Programme of the Alzheimer's Association in the United States, which registers and photographs people with dementia and distributes vital information to local authorities if the need arises. Specific risk factors to be assessed are listed in Box 16.4 (Rowe, 2003).

Similarly for sleep disturbances, assessment of previous sleep patterns or occupational habits need to be incorporated into treatment plans. Assessment of environmental problems that interfere with sleep need to be addressed. Several studies (Hopkins *et al.*, 1992; Satlin *et al.*, 1992; Nelson, 1995) report that sleep patterns change with dementia, resulting in fewer hours of sleep and increased fragmented periods of sleep. Programming may need to be created to provide around-the-clock activities to provide for these changes. Nurses who provide 24-hour care have the opportunity to create innovative programming for patients on all three shifts from bedtime quiet time and snack activities to late-night groups and breakfast. It may be appropriate in future to provide institutional care more like a cruise ship with midnight buffets and recreation. Basic consideration includes avoidance or limited usage of caffeine, alcohol, or nicotine; evaluation of medication and avoiding night-time use of diuretics or stimulating medications; and establishing quiet, comforting, and regular bedtime rituals (Hopkins *et al.*, 1992; Rader and Tornquist, 1995; Rantz and McShane, 1995).

To treat sundowning, increased staffing, structured activities and environmental manipulation are indicated. Having one-on-one staffing or use of family and volunteers at shift change can decrease agitation, fear of abandonment and disorientation. Use of light and uncluttered rooms will decrease the patient's misinterpretation of the environment or illusions. Rescheduling of therapies from 3.00 to 5.00 pm can provide additional security and redirection (Rantz and McShane, 1995; Landreville *et al.*, 1998).

New research on bright light therapy (BLT) indicates that morning BLT can delay evening agitation in patients with milder forms of dementia. BLT is less effective in more severe dementia because of more degeneration and deteriorating circadian activity rhythms. Bright light boxes for 2 hours of exposure 2500 lux every morning can be helpful in many patients with dementia (Ancoli-Israel *et al.*, 2003).

Inappropriate sexual behaviours are troubling and difficult to deal with for both the nursing staff and the family. Medical conditions, such as urinary tract and vaginal infections, incontinence, chafing, rashes and other skin conditions can cause inappropriate sexual behaviours. Treating these conditions can prevent premature use of antipsychotics or other drugs used to lessen sexually inappropriate behaviour. Regular toileting schedules can lessen preoccupation with genitalia and voiding in inappropriate places. Choosing appropriate clothing that buttons from the back or jumpsuits can decrease embarrassing public scenes.

Information about the patient's past and present sexual functioning helps the nurse to provide opportunities for intimacy with spouse or partner, or at least to ensure privacy for masturbation or other intimacy needs. Assessment of loneliness and loss of companionship is a part of providing holistic care for the Alzheimer patient and family. In situations of inappropriate behaviours in public places, use of redirection and distraction is useful.

Education and information about sexuality and handling sexual behaviours is an important aspect of treatment for the staff, family and significant others, including ongoing in-services concerning acceptance, as well as their own reactions to sexual behaviours. There should be frank discussion of normal sexuality and self-assessment of individual practices that can encourage inappropriate behaviours or give the patient mixed messages. For example, some nursing staff are quite comfortable giving hugs and holding patients' hands whereas other staff would interpret a patient's hug as threatening and act accordingly. Staff need guidance and consistency in identifying intimacy needs versus inappropriate behaviours (Szwabo, 1998, 2003).

16.5 PSYCHOTHERAPEUTIC AND SUPPORTIVE THERAPIES

Alzheimer patients can remain physically active and may not exhibit frailty or disability until late stages of the disease.

Their abilities to walk and wander about seeking stimulation challenge nurses to provide structured programming in the home or nursing facilities.

Use of the music therapy with groups and with individuals may soothe and calm. Music with the same beat as a normal heart rate of approximately 76 beats per minute has been found to calm agitation (Tabloski *et al.*, 1995). Music can also stimulate memory and encourage participation in the present. A variety of 'touch' therapies and self-soothing techniques have been used widely for self-enhancement and to stimulate the senses as well as a tool for relaxing.

Small group work has proven successful with demented individuals. These groups range from leader-facilitated reminiscence therapy; current event discussion groups; object-oriented groups; supportive psychotherapy; breakfast groups that prepare food and encourage communication; task groups that develop successful 'jobs' and workplaces; and reduced stimuli activities. A variety of therapies – art, pet, exercise and spiritual – have a role in the treatment of patients with dementia.

The nurse can be the one professional who has the most contact with the person with dementia in multiple settings. This is a unique opportunity and challenge to provide ongoing assessment, interventions, education and therapeutic options to patients, caregivers and the treatment team involved in caring for the Alzheimer family throughout the course of this disease. Keeping abreast of innovative and cutting edge research interventions are at the nurse's fingertips to share with families and other caregivers designing approaches to help people with dementia. Many successful therapies and interventions have found their way into recommended treatment strategies because nurses and the interdisciplinary team members continue to try to develop strategies to keep the demented patient as active, involved and independent as possible in the safest situation that can be provided.

Social work and care management

DAVID CHALLIS, JANE HUGHES AND CAROLINE SUTCLIFFE

16.6 Current patterns of practice	187	16.8 Conclusions	189
16.7 Intensive care management	188	References	189

Social work, like any professional or occupational group, is inseparable from the organizational and legislative context in which it takes place since this defines the parameters of practice. Prior to the introduction of care management, descriptions of social work in services for adults, including older people, tended to focus on professional specific activities, to the neglect of outputs such as the function of linking the individual to networks of care. Moreover, social work with older people, including those with dementia, was typically short term (Hunter *et al.*, 1990). Assessments were often undertaken in a relatively narrow and service-oriented fashion (Social Services Inspectorate, 1987), followed by an allocation of service prior to closure. Continuing management of long-term problems for people living in the community was neglected. The advent of care management has required a useful redefinition of social work in relation to long-term care of older people. It can be most simply defined as a strategy for organizing and coordinating care services at the level of the individual client/patient. Care management therefore involves mobilizing and influencing various agencies and services to achieve clearly formulated goals, rather than each provider pursuing separate and perhaps diverse goals (Challis, 1993). It is helpfully understood in terms of six criteria: the performance of core tasks; effective coordination; explicit goals; a specific target population; a long-term care focus; and an impact on service development as well as individual cases. This is summarized in Box 16.5.

The Health Act 1999 has introduced new flexibilities that allow for pooled budgets, delegated commissioning and integration between services. Subsequently, the Health and Social Care Act 2001 was introduced to promote more integrated organizational structures for the delivery of health and social care through integrated care trusts to improve service delivery (Cm 4169, 1998; Cm 4818-I, 2000). More

Box 16.5 *Key characteristics of care management*

- **Core tasks:** case finding and screening; assessment; care planning; monitoring and review
- **Functions:** coordination and linkage of care services
- **Goals:** providing continuity and integrated care; increased opportunity for home-based care; make better use of resources; promote wellbeing of older person
- **Target population:** long-term care needs; multiple service requirements; risk of institutional placement
- **Differentiating features of long-term care:** intensity of involvement; breadth of services spanned; lengthy duration of involvement with older person
- **Multilevel response:** linking practice-level activities with broader resource and agency level activities

generally, with respect to the provision of health and social care for vulnerable older people, the National Service Framework for Older People (NSFOP) (Department of Health, 2001) has endorsed targets for the reform and development of particular services relevant to conditions more common amongst this group people, for example falls and stroke. Standard Seven of the NSFOP, which is specific to older people with mental health problems, advocates a multi-disciplinary approach to a specialist mental health service, including social work input, with a core team member acting as a care coordinator for each older person referred for specialist care. These developments are important since research has demonstrated that the appropriate provision of services, such as day care, can have a positive impact upon the care of older people with dementia (Andrew *et al.*, 2000; Moriarty and Webb, 2000). Furthermore, respite care which can include day care, day or night sitting services in the older person's

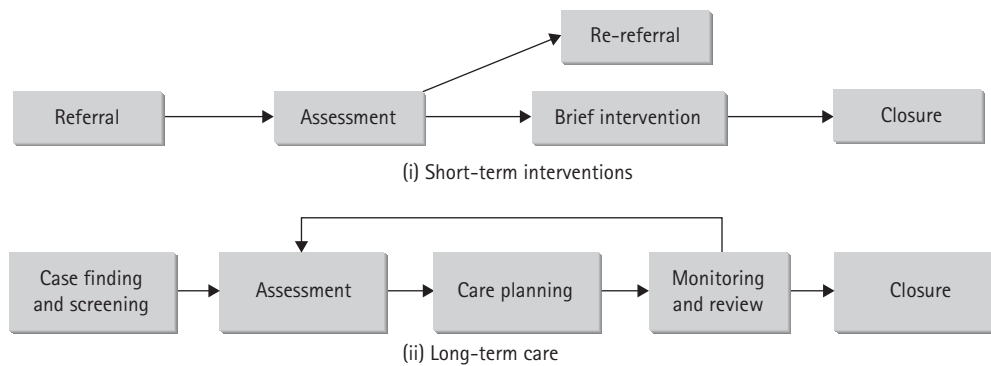

Figure 16.1 A model of care (Challis et al., 1990).

home, or relief care in a care home, has an important role in the context of community care (Levin and Moriarty, 1996).

16.6 CURRENT PATTERNS OF PRACTICE

Examination of existing services suggest there is considerable potential for development. A Department of Health inspection of services in the community for older people with dementia examined the core tasks of care management arrangements (Social Services Inspectorate, 1997a). In terms of assessment and care planning, formal links between health and social care were noted to be poor, although some evidence of good interprofessional collaborative working arrangements was observed. Furthermore, there was a lack of ongoing monitoring of people with dementia and their carers, and the monitoring and review of care plans were seen to be given insufficient priority. The report concluded that a more integrated approach to health and social care was required in order to meet the long-term care needs of people with dementia. More recently, concern has been expressed about the lack of specialist provision to support older people with mental health problems at home, and also regarding shortfalls in the long-term care sector for this group of people (Social Services Inspectorate, 2003).

The core tasks of long-term care embodied in care management, detailed in Figure 16.1, offer an approach suitable for the community-based care of vulnerable people with chronic conditions. Since older people with dementia typically have complex health and social care needs, it is important that agencies have in place procedures and protocols within care management arrangements that facilitate an appropriate response – a feature more likely to be associated with a differentiated approach to care management with procedures specific to those with complex needs. This is an approach in which a distinction is made between older people with complex needs often requiring a multiservice response and those with less complex needs, which are often met by a single service response provided by one agency. However, research has suggested that little progress was made in the development of a differentiated approach to care management immediately

Box 16.6 Differentiated approach to care management

- Specialist assessment documents: only 5 per cent for older people
- Intensive care management for high-risk individuals requiring high levels of support: rare and most not focused on older people

Source: Challis et al. (1999)

after the introduction of the community care reforms. Rather, care management services were, in the main, provided for the majority rather than for a selected group of older service users (Challis et al., 1999; Weiner et al., 2002). This is illustrated in Box 16.6. Nevertheless, a more differentiated approach to care management has been recommended by central government in order to assist social services departments in managing the volume of work and targeting resources on those in greatest need, such as people with dementia (Social Services Inspectorate, 1997a, b). It has identified three types of care management arrangements, each necessary to an integrated and comprehensive approach:

- a predominantly administrative type providing information and advice;
- a coordinating type that deals with a large volume of referrals needing either a single service or range of fairly straightforward services;
- an intensive type where there is a designated care manager who combines the planning and coordination of services with a more therapeutic, supportive role for a much smaller number of users with complex and changing needs.

The Single Assessment Process (SAP) (Department of Health, 2002) is consistent with the development of a differentiated approach to care management. At the outset, it was anticipated that comprehensive assessment would be the most appropriate for older people with dementia since it is specified as a prerequisite for residential and nursing home placements and intensive community support, where substantial packages of care at home are required. It will be undertaken by a range

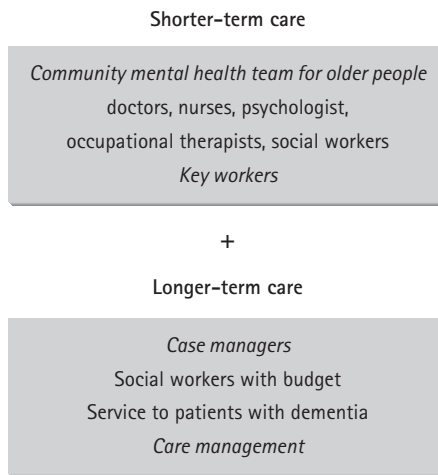

Figure 16.2 *Lewisham Case Management Scheme: setting and roles (Challis et al., 1997).*

of professionals or specialist teams, although geriatricians and old age psychiatrists are expected to take a prominent role in comprehensive assessment, particularly with regard to the development of approaches to assessment.

16.7 INTENSIVE CARE MANAGEMENT

The Lewisham Case Management Scheme offered a practical demonstration of care management designed to provide intensive community support to enable older people with dementia to live at home. It was one of a family of intensive care management studies designed to offer a community based alternative to institutional care (Challis and Davies, 1986; Challis *et al.*, 1995, 2002a, b). Specifically, it was established in a multidisciplinary setting to develop a model of intensive care management for a target population of individuals with a diagnosis of dementia, identified as having unmet needs and likely to be at risk of entry to institutional care, despite input from statutory services (Challis *et al.*, 1997, 2002a). The aim of the scheme was to provide effective integrated community-based long-term care that spanned the health and social service interface. The service was provided by social services case managers based in a community mental health team for older people. Most importantly, case managers were able to purchase care in response to identified need within defined parameters. This enabled the development of a specialist paid helper service that was available to those in the experimental group, receiving case management input. The service setting and roles are summarized in Figure 16.2. An evaluation of the scheme was undertaken using a quasi-experimental approach, where individuals in one community mental health team for older people received case management, the experimental group, and were compared with those in a similar community mental health setting without a case management service, the control group. A range of indicators were used covering aspects of needs, quality of

care, quality of life and wellbeing, encompassing the perspectives of the older person, carers (including family, friends and paid carers) and the assessing researcher.

Box 16.7 details the process of assessment and case management as it developed within the scheme. With regard to implementing the care plan, the goals of intervention in case management were identified by retrospective analysis of 80 care plans. These were analysed under seven categories: supportive, therapeutic, practical, preventive, social, destination and organizational. The most frequently reported were supportive (68 per cent), therapeutic (66 per cent) and practical (56 per cent). Supportive goals were almost exclusively intended for the benefit of informal carers, the most frequently reported categories were to relieve carer burden, provide respite and assist carers. Therapeutic interventions were most often directed at devising strategies to reduce problem behaviours associated with the client's deteriorating state. Practical goals were directed towards the assistance of the client, with personal care, health care and domestic care being the most frequently mentioned. These demonstrate that the prime objective of case managers was to support, sustain and enhance the quality of life of the client in his/her own home, and thereby to assist the carers.

In the second year of the Lewisham Case Management Scheme its effects began to show in a lower rate of admission to care homes for older people with dementia in the experimental group, than under standard arrangements for those in the control group, also resulting in lower associated costs for residential care for the former. Hence the community tenure effect in this study appeared more muted than in other case management studies (Challis *et al.*, 1995, 2002b). However, at 6 months, older people in the experimental group were more satisfied with their lifestyle at home, and there was evidence of a reduction in their needs specifically associated with activities of daily living. No differences were found between the groups in levels of depression, and there was no impact on levels of problem behaviours. With regard to the carers of the older people with dementia, there was a significant reduction in the amount of care input and distress at 12 months for carers in the experimental group.

It was, however, apparent that both experimental and control group clients were receiving support from a relatively resource-rich community-based old age psychiatry service, untypical of that to be found in most of the UK. Costs were higher for the group of older people receiving case management, in particular those accounted for by the social services department, since case manager visits and the paid helper service were not available to those receiving standard services. On the other hand, for carers of those in receipt of case management there was a positive gain, since financial and other costs were lower for this group compared with the carers of those receiving standard services. Moreover, when all costs to society were accounted for, including informal care, the weekly cost of supporting older people with dementia and their carers was not significantly higher for those receiving intensive case management, although the main component for statutory services was greater.

As demonstrated above, this specialist scheme was successful in providing care to older people with dementia to enable them to remain at home rather than be admitted to long-term care and provided effective support to their carers. This approach is consistent with other evidence relating to the provision of specialist care for this group of older people. Levin and colleagues (1994) noted factors that could make for improved care for people with dementia. These included a specialist integrated dementia care service, offering long-term care management to provide sufficiently intensive support, enabling a person to remain at home where appropriate and reflecting the wishes of cared for and the carer. This latter factor is particularly important since the centrality of support for carers remains a constant theme in policy and this service model is endorsed in the NSFOP (Cm 849, 1989; Cm 4169, 1998; Department of Health, 2001).

16.8 CONCLUSIONS

The change in the role, focus and setting for social workers and other professions in the UK working with people with dementia with the enactment of the community care legislation has been made more explicit in government guidance both at the inception of the community care reforms and subsequently (SSI/SWSG, 1991; Department of Health, 2001). A key theme in these has been the development of community-based multidisciplinary teams similar to those operating in mental health and learning disability services, as part of the move away from institution-based care. In order to fulfil the changed role accorded to UK social work, it is essential that arrangements are in place to facilitate the multidisciplinary assessment of people with dementia and particularly to ensure that specialist clinicians contribute to this process. A number of studies in the UK suggest potential gains from greater integration of secondary health care with the decisions made in the context of care management (Brocklehurst *et al.*, 1978; Peet *et al.*, 1994; Sharma *et al.*, 1994; Challis *et al.*, 2004). The experience of Australia, which has the community

care reforms most analogous to those in the UK, gives credence to this type of arrangement (Challis *et al.*, 1995; Howe and Kung, 2003).

It is anticipated that the effective care of people with dementia will benefit from the new service configurations, which pay less attention to traditional boundaries whether professional or organizational than hitherto. Within this, social work and care management have a distinct role in relation to the provision of long-term community-based care. The emergence of dementia-specific services as an outcome of the partnership initiatives may lead to further interprofessional role blurring which, if managed correctly, could be the basis of improved care for people with dementia and their carers. However, as distinct from similar developments in Ireland (Department of Health and Children, 2001), policy guidance in England requires that specialist dementia services develop within the more general framework for older age mental health services.

For social work there are two challenges consequent on these changes. First, the profession-specific contribution to the care of older people with dementia and their carers has changed to primarily that of responsibility for the care for people living at home and, by virtue of changes for the funding of long-term care, gate-keepers for admission to residential or nursing home care. There is now greater standardization in the process with recent guidance emphasizing the importance of assessment, care planning, monitoring and review. Second, and in antithesis to this clarity, the role of the social work profession in respect of the care of people with dementia has become less profession specific. Within multidisciplinary teams there are more opportunities for the sharing of tasks offering informal small-scale opportunities for service substitution. Research has found that the process of assessment of older people referred to a specialist mental health team for older people can be undertaken by any members of the professions within it (Lindesay *et al.*, 1996), and more recently, increasing evidence of community nurses working within such teams for older people (Weiner *et al.*, 2003). There is thus a tendency for there to be less specificity of role for staff as services become more community based. This leads unsurprisingly to a degree of insecurity among professional groups, because each derives their unique quality from a training and occupational function. Roles come to be negotiated rather than simply professionally defined within groups to a greater extent in community-based services and therefore may be seen as less clearly defined by individual professions. This process may well occur to a greater extent as the process of closer integration between health and social care develops.

16.11 Observations	192	References	194
16.12 Standardized tests	192		

The clinical practice of occupational therapy (OT) involves the treatment of physical and psychiatric conditions through specific selected activities in order to help people reach their maximum level of function in all aspects of daily life (Hopkins and Smith, 1993). Fundamental to the philosophy of OT is the belief that purposeful activity is required to promote wellness and prevent disability (Rogers, 1994). It draws on a broad range of theoretical models, which is particularly useful in aged care where there is a significant interaction of biopsychosocial factors affecting the individual's functional status.

The OT process involves assessment, treatment planning, implementation and evaluation. Occupational therapists working in the field of dementia focus their approach on the maintenance of skills and the prevention of functional deterioration owing to the progressive nature of the disorder. The maintenance of a sense of self-worth is also a major consideration when working with people with dementia. Owing to the obvious debilitating symptoms of dementia, individuals can subsequently experience depression, anxiety, apathy and discouragement, which can have a detrimental effect on the dementing process (Pool, 1997). Therefore, in both areas of assessment and intervention, occupational therapy will encourage the individual's sense of wellbeing by allowing them some control over their personal life, and providing opportunities to achieve meaningful roles and to enjoy social interaction.

16.9 ASSESSMENT

16.9.1 Purpose of the occupational therapy assessment

Assessment is a major role of occupational therapy and is used to identify the impact of dementia on an individual's

general daily functioning. Occupational therapists aim to assist older people to be as independent as possible, but first it is necessary to assess the individual's abilities, problems, wishes and interests (Pool, 1997). This information can then be used to plan and implement relevant therapeutic interventions.

OT assessments can provide specific information in the following areas:

- *activities of daily living (ADL)*: eating, dressing, grooming, bathing, toileting, medication management, home and money management, leisure, telephone use and transport;
- *cognitive function*: memory, judgement, problem solving, concentration;
- *perceptual and sensory function*: visual, auditory, proprioceptive sensation, stereognosis and praxis;
- *motor function*: balance, mobility and transfers, hand function, coordination;
- *communication skills*: verbal and non-verbal social skills, receptive and expressive dysphasia;
- *psychological state*: mood, anxiety and motivation.

Throughout the assessment process, therapists use both their physical and their psychiatric knowledge within the framework of the natural ageing process (Vincent, 1997). The information gathered from an OT assessment often overlaps, yet should also complement that gained from other professionals within the multidisciplinary team. However, the unique skills of the occupational therapist in dementia care usually lie in the area of ADL. That is, the therapist will assess the impact of a person's physical, cognitive, psychological and social disabilities on their day-to-day function (Atler and Michel, 1996).

In identifying an individual's functional ability in their living environment, the information may then be used in any of the following ways:

- assist in the formulation of a diagnosis;
- recommend support services to maintain the individual in their preferred living arrangement;
- recommend alternative accommodation options appropriate to the individual's level of functioning;
- advise on adaptive equipment to assist in maintaining independence;
- recommend leisure interests that can be maintained, adapted or introduced to promote quality of life and maintain self-esteem over the course of dementia;
- determine the individual's needs, and priorities for intervention, and to involve the person with dementia and family/carers in this process.

16.9.2 The process of the occupational therapy assessment

The progressive nature of dementia indicates that the process of assessing individuals is one that is ongoing and will change focus with the changing needs of the individual. In the early stages of dementia, the primary focus of assessment may be ADL and maintenance of individuals in their home environment. The later stages of dementia may call for the assessment of basic self-care tasks to determine the level and/or the type of residential care required. When an occupational therapist undertakes assessments of people with dementia, special considerations are required to ensure the assessment of performance is accurate. The use of simple language and repetition of instructions may be necessary to ensure that the person with dementia has sufficient time to process information and to respond to requests. The alleviation of the person's anxiety within the assessment situation is a consideration, particularly when there is some degree of self-insight into deficits. Building a trusting and supportive relationship with individuals prior to the assessment process is important, as is providing positive feedback for the tasks that are done well, with less focus on problem areas.

Assessment may include one or all of the following techniques, and will be tailored to meet the needs of the individual and the overall purpose of the assessment.

16.10 INTERVIEW

The therapist will attempt to ascertain the individual's own perception of their skills and deficits. A person's ability to recognize difficulties in day-to-day functioning will be dependent on the level of dementia. It is therefore necessary to liaise with the family or a caregiver who may be able to provide a more accurate reflection of the person's current functional level. Family and caregivers can also provide

details of the life history, which can be used to promote communication and assist in the development of therapeutic relationships.

16.11 OBSERVATIONS

It is common for people with dementia to be poor historians and to embellish their current skill level. Observation of an individual's activity performance is used to enhance the information gained through the interview process. Observation of a person during activities can provide general information on many aspects of that person's functioning, such as cognition, motor, sensory and perceptual function, psychological state and skills in communication and ADL (Alexander, 1994).

The therapist may observe a person with dementia in a variety of different settings, both in groups and individually. In terms of the assessment of ADL, the specific activities assessed are selected according to their relevance to the individual's living situation, and where possible are carried out in a familiar environment. This aims are to reduce anxiety and limit the effects of the need to learn new skills and to orientate to new environments. Ideally, the assessment of a person's home management skills should occur in the home. The presence of unpaid bills, poor cleanliness of the house, and lack of evidence of fresh food may provide further evidence as to whether a person is managing daily tasks independently. Assessments over time provide a more accurate picture of a person's functioning than a single assessment, particularly when anxiety and performance deficits are observed.

16.12 STANDARDIZED TESTS

Assessment tools are often used by occupational therapists in conjunction with interviews and observation to gain a more specific picture of a person's performance in a particular area. Such tools can be used to determine a baseline functioning and can be used at a later date to monitor any change in performance that may have occurred.

There is a wide range of tools available for use with people who have dementia; however, many have not been designed specifically for this group. Commonly used ADL assessment tools suitable for use with dementia include the following:

- The Barthel Index (Mahoney and Barthel, 1965) is a simple index of independence to rate the self-care ability of individuals. It includes items on feeding, dressing, toileting and showering. Scores are determined by the amount of physical assistance a person requires to perform self-care tasks.
- Domestic and Community Skills Assessment (DACSA) (Collister and Alexander, 1991) may be used to assess an individual's knowledge of and practical skills in a variety of instrumental ADL (IADLs). It includes items such as

banking, bill-paying, shopping, meal preparation and house keeping. The assessment process involves both interview and observation of task performance.

- Assessment of Motor and Process Skills (AMPS) (Robinson and Fisher, 1996) measures a variety of motor and cognitive abilities during an individual's performance of IADLs. It involves the observation of an individual performing two or three tasks that are familiar and relevant to their living situation. They are then rated in the areas of motor skills and process (organizational adaptive) skills necessary for competent task performance.
- Assessment of Living Skills and Resources (Williams *et al.*, 1991) is an IADL assessment tool that evaluates an individual's skill, and resources or support available for daily activities. The assessment determines the likelihood of an individual being able to carry out specific tasks given his/her current skill and resources in the home setting.

16.13 INTERVENTION

16.13.1 The use of activities

Performance in activities, which is the core of OT assessment, is also the major focus of intervention. OT treatment and techniques differ according to the individual and the stage of the disorder. Interventions aim to preserve a person's dignity and self-esteem while maximizing abilities and enabling improvement in quality of life. The occupational therapist achieves this through the medium of 'meaningful activities' that are selected also to be pleasurable, restore roles and enable friendship (Mace, 1987). A person with dementia has impaired learning ability, and so familiar and overlearned activities tend to be most effective in treatment programmes (Zgola, 1987; Conroy, 1992; Vincent, 1997). However, individuals should also have the opportunity to be involved in a variety of both familiar and novel activities. Blair and Glen (1987) classified activities for people with dementia into four categories:

- *Activities designed to involve sensory stimulation.* The use of sensory activities is particularly useful when an individual's cognitive and communication abilities are severely impaired, and involvement in other activities is limited. Useful sensory activities include: visual (outings, photos, movies); tactile (massage, gardening, cooking, craft); auditory (appropriate and varied music, spending time outdoors); gustatory (different food experiences); and olfactory (flower collecting and arranging, cooking, aromatherapy).
- *Activities based on self-care and life skills.* Maintaining independence in daily living is a central activity for all people, and attention to these tasks helps to build self-esteem. These tasks can be structured and simplified to ensure that a person can still complete at least part of the activity. For example, verbal reminders can be used to

initiate bathing; or having essential ingredients and utensils on a kitchen table can assist a person to cook a simple meal.

- *Activities designed around realistic physical exercise.* Physical activity helps to maintain both physical and psychological wellbeing (Simpson, 1986). Physical exertion can also have beneficial effects on behaviour and sleep disturbances. Exercise programmes should be designed around enjoyable indoor and outdoor gross motor activities. These may include walking, bowling and dancing.
- *Activities designed to increase social interaction.* For many people with dementia, the use of group activities helps to promote social skills and verbal interaction. With the presence of impaired memory and concentration, small groups are more effective in facilitating communication. Activities useful for group settings include cooking, gardening, music and reminiscence. For example, reminiscence can be used as a social activity that encourages discussion as individuals recall past roles and interests.

16.13.2 Environment adaptations

The use of environmental modifications is an important non-pharmacological approach to the management of behavioural and psychological symptoms of dementia. Environmental modifications have been introduced in residential facilities, in hospitals as well as in home situations. Gitlin and colleagues' (2003) paper on the research in this area noted that, although 90 per cent of 63 studies reviewed reported positive findings, most studies were methodologically flawed, involved small samples, and were conducted in nursing homes. Environmental principles gleaned from these studies include:

- reducing environmental complexity by relaxing rules and expectations, and minimizing distractions;
- increasing orientation and awareness;
- creating a low stimulus, comfortable environment; and
- providing predictability, familiarity, and structure.

The environment can also be adapted for appropriate cuing. Objects can be placed in the environment to provide orientation; for example, laying out clothes cues a confused person to dress, or a night-light aids a person to locate the toilet. Objects can also be removed because of safety concerns; for instance, no longer hanging the car keys by the door eliminates a visual cue to drive (Gitlin and Corcoran, 1996).

Besides designing interventions to maximize a person's competency, the therapist also modifies the environment to facilitate the performance of daily activities. Changing immediate surroundings through home alterations, removal of objects, and simplification of tasks may reduce the external stressors that produce excess behavioural disturbances and disability in people with dementia (Gitlin and Corcoran, 1996).

Adding items to the environment can make the performance of activities easier. For example, the installation of a grab rail can assist a person to get in and out of the bath safely.

Environmental modifications should, where possible, be tailored to the requirements of the individual. They also need to be monitored on a regular basis to ensure that they are still assisting the current problem, or are replaced to address the individual's changing needs.

16.13.3 Working with families and carers

The family plays a crucial role in the care of the person with dementia. An occupational therapist can assist in identifying the remaining strengths of the person with dementia. The therapist and the family can use this information to plan strategies jointly to maximize function and at the same time minimize the burden of care. Through education and support, carers are taught to support continued engagement of the person with dementia in meaningful activities (Baum and Edwards, 2003).

16.14 CONCLUSION

The specific role of occupational therapists in dementia care will be determined by the setting in which they work and the severity of the individual's dementia. Therapists may work as part of aged care assessment services, aged psychiatry community teams, day hospital or centres, acute inpatient units or long-term residential care facilities. It is therefore likely that therapists will be involved in the assessment and treatment of dementia anywhere from the very early to the late stages of the disorder. The general OT principles of practice will remain consistent across settings and disease stages, and will have an emphasis on maintenance of functional ability and attention to social and psychological needs to promote quality of life.

This chapter was originally written by Fiona Moffatt and Michael Loh and appeared as chapter 19c in the second edition of Dementia. It was updated by Michael Loh for this third edition.

16.15 Speech and language changes in dementia	195	16.19 Eating in dementia	200
16.16 Language assessments used in dementia	197	16.20 Conclusions	201
16.17 Optimizing communication in dementia	197	References	201
16.18 Environmental barriers to communication	200		

Communication is integral to successful living (Lubinski, 1991); however, its breakdown in dementia is well documented (e.g. Hopper and Bayles, 2001; Bourgeois, 2002). Eating and swallowing can also become problematic in this condition (Logemann, 2003). In 1991, Bourgeois reviewed dementia articles in the journals of the American Speech-Language-Hearing Association (ASHA). These articles focused strongly on how cognitive-linguistic profiles contributed to dementia diagnosis. Furthermore, in 1995 Clark observed that although ASHA advocated optimizing functional communication in older people, most clinicians still restricted themselves to assessment of Alzheimer's disease (AD). People with dementia, who can live for up to 20 years after diagnosis, also need help with communication to optimize quality of life (Bourgeois, 2002) and ease carer burden (Enderby, 2002). Hence, involvement of a speech and language therapist (SLT) in the diagnosis of dementia should be only the beginning of the clinical relationship. For a little over a decade, research exploring strategies to facilitate interactions in those with dementia has begun to emerge (e.g. Bourgeois, 1992; Baker, 2001; Spilkin and Bethlehem, 2003). It is appropriate that this chapter includes information about cognitive-linguistic difficulties observed in dementia and assessment tools used to examine these. In addition, it is imperative that it explores how SLTs can work with people who have dementia, significant others and care staff, in optimizing communication. Issues around the SLT's role in facilitating swallowing in dementia will also be explored.

16.15 SPEECH AND LANGUAGE CHANGES IN DEMENTIA

Reisberg *et al.* (1999) used the term retrogenesis to describe strong parallels between language acquisition and the loss of language in AD. Fried-Oken *et al.* (2000) noted that most research into communication difficulties in dementia relates to AD. Nonetheless, they concluded that many language changes seen in AD may also occur in other forms of dementia. As such, this section will refer primarily to language features of AD, according to stages of the Global Deterioration Scale (GDS) (Reisberg *et al.*, 1982). Information regarding features of vascular dementia (VaD), dementia with Lewy bodies (DLB) and primary progressive aphasia (PPA) will then be outlined.

16.15.1 Alzheimer's disease

16.15.1.1 EARLY/MILD STAGE AD (GDS 3 AND 4)

Word-finding difficulties are commonly encountered early in AD (Bourgeois, 2002), affecting most recently acquired and least frequently used words (Haak, 2002). Conversation is therefore slightly empty with fewer ideas in the same amount of words (Bayles and Tomoeda, 1995). Communication is usually successful for brief interactions, but breaks down when lengthy (Haak, 2002). Comprehension of language sometimes remains intact (Bayles *et al.*, 1992) or may decline for longer grammatically complex sentences (Clark, 1995), or

material requiring inference (Fried-Oken *et al.*, 2000) or abstraction (Haak, 2002). Failing memory and executive function impact on adherence to conversational rules around repetition, topic maintenance and turn-taking (Watson *et al.*, 1999). There are often aborted phrases; however, talking may also be excessive (Bayles and Tomoeda, 1995). Oral reading and reading comprehension (Bayles *et al.*, 1992) along with spelling and writing are often relatively preserved, but ability to generate written passages is reduced (Haak, 2002).

16.15.1.2 MIDDLE/MODERATE STAGE AD (GDS 5)

Intention to communicate and general message frameworks are still evident; however, utterances are depleted of content words (Haak, 2002), less concise and more repetitious with reference errors abounding (Bayles and Tomoeda, 1995). Content words are often replaced by indefinite labels (e.g. 'thing') consistent with pervasive lexical retrieval difficulty (Bourgeois, 2002). Sounds, syllables and whole phrases are repeated and the person often speaks excessively or withdraws (Clark, 1995). Automatic and social phrases are retained, but the person frequently forgets what he or she wishes to say (Haak, 2002). Paraphasias and confabulations begin to appear and discourse breakdown increases with poor propositional topic development, difficulty changing topic and maintaining discourse flow (Mentis *et al.*, 1995; Fried-Oken *et al.*, 2000). Expression and comprehension of complex grammar (e.g. embedded clauses or passives) is limited and abstract interpretation is lost, whilst comprehension of one (Haak, 2002) and sometimes two stage (Fried-Oken *et al.*, 2000) commands is preserved. Reading aloud and mechanics of writing are relatively spared, but reading comprehension and writing are often limited to single words (Haak, 2002) and accuracy is markedly reduced (Bayles *et al.*, 1992).

16.15.1.3 LATE/SEVERE STAGE AD (GDS 6 AND 7)

Initially use of automatic and social phrases may continue (Haak, 2002). Often utterances contain strings of non-words with occasional real words interspersed, but message form, simple grammar and intonation are basically present (Bayles and Tomoeda, 1995). There is failure to adhere to speaker-listener conversational discourse roles (Clark, 1995). There may also be difficulty initiating speech, articulatory breakdowns and dysphagia (Clark, 1995). Eventually the person becomes completely non-verbal (Bourgeois, 2002), although conceptual knowledge may be preserved until very late (Fried-Oken *et al.*, 2000). There is also failure to comprehend spoken or written language (Bayles and Tomoeda, 1995) and people rely increasingly on non-verbal cues and emotion to aid comprehension (Haak, 2002). Vocalizations may become disruptive – sometimes because of failure to access specific words describing basic needs and emotions, people, activities or objects wanted (Bourgeois, 2002). Resistance may reflect failure to understand verbal direction.

16.15.2 Vascular dementia

VaD occurs following multiple small infarcts occurring progressively over time (Hopper and Bayles, 2001) and can only be diagnosed where cardiovascular disease is documented (Tomoeda, 2001). Rather than the gradual language changes of AD, deterioration is usually stepwise with new deficits becoming evident suddenly after each new infarct (Hopper and Bayles, 2001; Tomoeda, 2001). As such, individual deficit profiles (depending on infarct locations) are often less uniform across different language areas than with AD (Hopper and Bayles, 2001). Nonetheless, Vuorinen, *et al.* (2000) found little difference, on average, in degree of language deficit across comprehension, naming and picture and object description tasks between individuals with mild to moderate AD versus VaD. Stevens *et al.* (1996) did find some heterogeneity in scoring between mild VaD and mild AD on a range of cognitive-linguistic tasks. Nonetheless, both groups were clearly differentiated from the 'worried well' on verbal fluency, naming, paragraph reading and immediate and delayed story recall. Powell *et al.* (1988) also reported greater motoric speech involvement in VaD (e.g. dysarthria and changes in intonation).

16.15.3 Dementia with Lewy bodies

DLB is possibly the second most common dementia after AD (Hopper and Bayles, 2001). To complicate diagnosis, many people with DLB also have AD lesions (McKeith *et al.*, 1995). Most commonly reported characteristics are insidious in onset, beginning with forgetfulness, then word-finding and calculation difficulties and then other cognitive skills (McKeith *et al.*, 1995). Fluctuating cognition (with periods of lucidity in early- to mid-stages), often mild extrapyramidal features (e.g. dysarthria and dysphagia) and a more rapid progression than AD are also observed (Tomoeda, 2001) – early on people with DLB often have more difficulty with visuospatial, problem solving and verbal fluency tasks (McKeith *et al.*, 1995).

16.15.4 Primary progressive aphasia

In 1982, Mesulam described a syndrome of slowly progressive aphasia without generalized dementia. Gradually both number and severity of aphasic symptoms increase with sparing of non-language executive function for at least 2 years after onset (Weintraub *et al.*, 1990). The most common problem is word-finding difficulty, followed by reduced comprehension with speech hesitancy, phonemic paraphasias, dysarthria, with slowed speech and stuttering also sometimes occurring (Westbury and Bub, 1997). Semantic dementia is a subtype of PPA where syntactic abilities are spared whilst naming, single word comprehension and reading are affected (Westbury and Bub, 1997). Phonology and comprehension of complex commands may also be intact in this condition (Stevens and Ripich, 1999). Progressive non-fluent aphasia (PNFA) is also another subtype of PPA (Thompson *et al.*, 1997). Although it

often also begins with word-finding difficulties, it progresses to reduced phrase length and complexity and then to telegraphic agrammatic output (Thompson *et al.*, 1997).

16.16 LANGUAGE ASSESSMENTS USED IN DEMENTIA

Individual profiles of cognitive-linguistic functioning ideally form part of a comprehensive memory clinic evaluation (including medical history and investigation, performance in activities of daily living and neuropsychological testing) (Ames *et al.*, 1992). Results of such assessment facilitate accurate diagnosis of presence and type of dementia for review upon repeated assessment(s). Appropriate cognitive-linguistic normative data help to distinguish those with early dementia from the 'worried well' (Bryan *et al.*, 2001). Such data also contribute towards differential diagnosis of depression, characterized by reduced concentration and slowed processing speed (Tomoeda, 2001) without primary verbal memory or language impairment (Stevens *et al.*, 1996). Accurate early dementia diagnosis is important in identifying any appropriate drug therapies and in providing informational counselling. Carers of those with AD are often more relaxed when they understand that language unravels sequentially (Haak, 2002). Furthermore, assessment allows for development of effective care plans (documenting impaired and spared abilities) and establishment of baselines for intervention effects or decline over time (Tomoeda, 2001). Other factors contributing to poor performance such as low hearing, vision or premorbid educational level (Tomoeda, 2001) as well as cultural biases (Lydall-Smith *et al.*, 1996) should also be noted.

Recently, several tests assessing cognitive-linguistic function in dementia have emerged. Perhaps best known is the Arizona Battery for Communication Disorders of Dementia (ABCD) (Bayles and Tomoeda, 1993), which assesses performance in mild to moderate dementia across five constructs: linguistic comprehension, linguistic expression, verbal memory, visuospatial skills and mental status (orientation). It has norms from 86 people with probable AD (as described by McKhann *et al.*, 1984) and 86 normal elderly and takes 45–90 minutes to administer. Summary scores for each subtest indicate results in the high normal, low normal, mildly impaired or moderately impaired range. Results are averaged within constructs and a profile obtained to examine deficit pattern. The ABCD was developed in the USA, but norms have also been found to be appropriate with UK (Armstrong *et al.*, 1996) and Australian (Moorhouse *et al.*, 1999) samples.

Time taken to administer the ABCD in poorly resourced clinical settings may be excessive (Bryan *et al.*, 2001). Where only brief screening is possible, ABCD Story Retelling and Word Learning subtests are most sensitive to dementia (Tomoeda, 2001). Additionally, the Boston Naming Test has been found to detect early dementia (Stevens *et al.*, 1992). The Barnes Language Assessment (BLA) (Bryan *et al.*, 2001)

has also been developed to screen for dementia, assessing areas of expression, comprehension, reading and writing, memory and executive functions. It has items adapted from existing tests and includes a manual and set of test materials. It takes 40–60 minutes to administer and can be used with mild, moderate and, sometimes, severe dementia. Norms reported by Bryan *et al.* (2001) were preliminary.

Recent research into pragmatic or conversational abilities in dementia has used protocols rather than standardized assessments – for example, Watson, *et al.* (1999) who used Conversational Analysis (CA) to examine 'Trouble Indicating Behaviour' (TIB) and patterns and types of conversational repair trajectory. There are no dementia-specific protocols investigating function in this area. The only standardized dementia assessment touching on these abilities is the Functional Linguistic Communication Inventory (Bayles and Tomoeda, 1994). It assesses functional communication in moderate to severe AD. It takes 30 minutes to administer and includes items examining ability to greet, answer questions, reminisce and participate in conversations.

16.17 OPTIMIZING COMMUNICATION IN DEMENTIA

Interventions enhancing communicative success in AD will be grouped into three categories: direct, indirect (for caregivers) and environmental interventions (Clark, 1995). As some interventions overlap categories, they will be placed where they fit best. Although many findings cited below relate to intervention in AD, it may be helpful for the SLT to use or adapt this information for people with other dementia types – focusing on functional needs rather than diagnosis. Given relative sparing of executive function in PPA, additional strategies drawn from aphasia therapy may be used in optimizing communication. (For further ideas in this area see Graham *et al.* [1999]; Graham *et al.* [2001] and Rogers *et al.* [2000].)

16.17.1 Direct strategies

Direct interventions involve the SLT (or workers trained by the SLT) intervening face to face to modify communication in a person or group who have dementia. Some studies report on techniques devised by SLTs to target relearning or maintenance of ability to name specific word groups or learn key information in early to middle dementia. Spaced retrieval (SR) (involving rehearsal and recall at gradually increasing intervals) (Abrahams and Camp, 1993; Brush and Camp, 1998) or repeated exposure and questioning (by students) about related semantic properties (Arkin *et al.*, 2000) facilitated performance on specific tasks with some maintenance over several weeks (Abrahams and Camp, 1993). Potential functional communication improvements were not measured, however, Brush and Camp reported some functional use of learned information to achieve speech-language goals.

Some direct interventions devised by SLTs have targeted communicative processes that decline in early to middle AD. Arkin and Mahendra (2001) compared experimental ($n = 7$) and control ($n = 4$) groups over 20 weeks. All participants went to twice weekly exercise programmes. During one weekly exercise session students presented language and memory exercises, such as picture description, word association, simple discourse role plays and word category assignments. Controls experienced unstructured conversation with students. There were no significant differences between groups on the ABCD or on discourse meaningfulness; however, the experimental group had a significantly higher ratio of different nouns to total nouns at post test.

Clark and Witte (1991) advocated clinician training of those with early AD in the use of adaptive communication strategies to prolong effective communication – for example, learning when to use statements such as ‘Please repeat exactly what you just said’ or ‘Say what you said more slowly’, or ‘Give me a little time. I’m having trouble finding the exact words’, or, ‘I forgot what we were discussing’. Clark and Witte also suggested teaching facilitation strategies to assist self-cueing – for example, using circumlocution or a semantically related word. Furthermore, they suggested teaching a script strategy for simple storytelling (e.g. theme, characters, setting and events) to improve cohesion and topic maintenance. Clark and Witte recommended groups as ideal in early AD for practising these adaptive and facilitative strategies. In addition, they argued that sharing of useful conversational strategies and discussion of difficulties would help to reduce communicative stress. Clark (1988) (cited in Clark and Witte, 1991) used the above strategies with a group of eight people with mild to moderate AD. Carers reported maintained or increased functional communication, and scoring on aphasia test batteries was stable over six months.

Clark and Witte (1991) also advocated group programmes in later dementia with the clinician facilitating use of residual communication strengths by introducing tangible stimuli of interest to group members. Santo Pietro and Boczko (2001) used intact procedural memories to facilitate communication in groups for people in residential care with mild–moderate to moderate–severe AD. ‘Breakfast Clubs’ were run each working day for 12 weeks and involved members using greetings, discussing and choosing food for breakfast, helping one another prepare ingredients, setting the table, general conversation (e.g. ‘The homes we grew up in’), cleaning up and then saying goodbye. Initially, speech–language clinicians and later trained facilitators provided visual and semantic cues, paired choices and trigger phrases to help members communicate choices and ingredients required. Participants reclaimed procedural memories for actions such as pouring, cutting, stirring and breaking eggs. Breakfast Club participants improved significantly with performance on the ABCD and had more self-initiated on-topic comments per session, more cross-conversation exchanges and increased initiation of procedural memories. Anecdotally, participants were observed laughing and singing together and had increased

involvement with activities of daily living and social pursuits, along with decreased agitation and wandering. Matched controls attending a conversation group, showed either no gains or slight declines over the same period.

Sonas aPc (activating potential for communication) is a multisensory packaged programme designed to activate communication and reduce social isolation in older people (mainly those with moderate to severe dementia – some non-verbal) (Threadgold, 2002). A group of eight older people meet once weekly with a trained facilitator – an SLT or other worker. Care staff have been trained in over 200 sites in Ireland and the UK (Connors 2001a). As participants arrive, a signature tune plays to trigger memories of previous meetings followed by sung individual greetings. There is then a sequence of gentle exercises with stimulation of the sense of smell, relaxing music during which taste and smell are stimulated, lively music for clapping, dance or percussion use, poetry reading (including opportunities for participant presentation), a singalong, sung individual leave-taking and final signature tune. Connors (2001b) evaluated the Sonas programme on 27 people with dementia over a 6-month period. They improved significantly with communication and cognition after 3 months. Initial gains were not maintained at 6 months; however, cross-programme difference scores approached significance for communication. Observation of videotaped sessions also indicated increased participation across the 6 months.

Fried-Oken *et al.* (2000) discussed the use Augmentative and Alternative Communication (AAC) to facilitate communication in late dementia. Although protocols guiding such work are still emerging, they suggested intervention over time would best meet individuals’ complex and changing communication needs. They highlighted need for longitudinal studies to determine most appropriate use of intervention time (e.g. examining whether people benefit from learning to communicate with symbols and pictures when they can still read). They also asserted that cognitive-linguistic strengths and weaknesses would need to be carefully assessed to develop appropriate AAC input and/or output systems (e.g. instead of devising appropriate motoric access, determining if an alternative route could be found into the lexicon). They stressed the importance of also accommodating caregivers’ needs, to increase chances of communication success.

In later dementia, SLTs can develop personal communication dictionaries to assist carers to interact with individuals with dementia – even with non-intentional communicators. Communication dictionaries were originally developed for early communicators (Siegel and Whetherby, 2000). Development of a communication dictionary requires careful observation and documentation of consistent non-verbal ways in which an individual behaves when wanting something. The SLT may involve carers in recording observations in specific categories – ‘What Fred does’ (e.g. takes your hand and pulls it towards his mouth), ‘What it might mean’ (e.g. ‘I’m hungry or thirsty’), ‘What you should do’ (e.g. Give food or drink if appropriate or distract with another activity if not). A personal

communication dictionary is useful in institutional settings where carers may not know the person. It should be easily accessible (e.g. a poster or notebook) for both reference and amendment. In addition, the dictionary may be helpful to familiar carers in structuring observations to best meet the person's needs.

16.17.2 Indirect strategies

Conversation is collaborative. Where one partner has AD, the other can use strategies to facilitate communication (Kessler *et al.*, 2001). Enderby (2002) recommended SLTs' involvement in role play and group practice with carers to reinforce new techniques.

There are numerous documented strategies for optimizing comprehension in dementia. Generally, a person, when speaking to a partner with dementia, should try to match language complexity to individual levels (Haak, 2002). In early dementia, using slightly slower speech with strategic pausing and reduced information is recommended (Bayles and Tomoeda, 1995; Bourgeois, 2002). As dementia progresses, it is best to converse about tangible things, simplify vocabulary, use non-verbal cues and restate when a message is not understood (Bayles and Tomoeda, 1995) or has been forgotten (Enderby, 2002). Before beginning, it may also be useful to orient the person to topic and then maintain and extend it (Kessler *et al.*, 2001). In middle to late dementia, questions with alternatives (e.g. 'Do you want fish or chicken?'), short utterances and full names (rather than pronouns) are helpful (Haak, 2002). Demonstration to aid comprehension, avoidance of sarcasm and innuendo, use of native language and familiar wording (e.g. respectful title or maiden name) should also boost conversation. Where confusion is likely, carers should reintroduce themselves (Haak, 2002). Important topics should also be avoided where people are upset or tired (Enderby, 2002). In late dementia, sensory stimulation (e.g. tone of voice, smell, touch) can also be used to aid comprehension (Bourgeois, 2002) without patronizing or talking in front of the person as if they were absent (Haak, 2002).

There are fewer documented strategies for facilitation of expression in dementia. People with mild AD should be allowed to speak even when having word-finding difficulties (unless assistance is requested) and should be encouraged to use spared communicative abilities to reinforce self-worth (e.g. reading to a grandchild or writing letters to friends) (Haak, 2002). They may also benefit from encouragement to verbalize actions – for example, 'I'm going to have my dinner' (Haak, 2002). In keeping conversation flowing, Watson *et al.* (1999) found hypothesis formation more effective than requests for more information. Knowing the background of the person is also helpful in optimizing communication in institutional care settings (Enderby 2002; Haak, 2002). Greater response may be evoked if topics of interest are found. Sensitivity to use of words, gesture, tone of voice and context all help those with later dementia to feel comfortable making

communicative attempts (Enderby, 2002). Although people speak jargon or are mute, they still have a message to communicate (Haak, 2002).

Despite the numerous strategies recommended regarding communication in dementia, there has been little work investigating frequency of use. Recently, Kessler *et al.* (2002) examined this question in five men with mild probable AD and their wives and a corpus of identified strategies. Videotaped 10-minute interactions indicated the strategies used by all wives – yes/no questions, facial expression, eye contact, allowing time to respond, showing as well as saying and cueing to topic. Further strategies were used by most, some or none. Overall, wives spontaneously used 60 per cent of identified strategies. This study provides a beginning in examining natural strategy use by carers. Watson *et al.* (1999) provided some insight into this complex question, observing that where a person has AD, interactants did not always repair misunderstandings, but rather preserved dignity of the speaker with AD. The following studies have all examined how education by SLTs might change carers interactions.

Bourgeois *et al.* (1997) trained seven home caregivers over 12 weeks to modify repetitive verbalizations in spouses with probable mild to moderate AD. In weekly 1-hour sessions, most troublesome verbalizations were identified and caregivers trained by the clinician to record behavioural baselines and to provide simple cue cards (e.g. with orientation information) in response. After baseline (2–7 weeks), the programme was implemented and spouses recorded additional data (4–10 weeks). Time series data indicated that four spouses recorded lower rates of repetitive verbalizations during intervention. Another recorded a low baseline, whilst the other two least consistently used the intervention. Follow-up data (recorded monthly rather than weekly) appeared quite similar to intervention. Seven control participants (whose caregivers recorded data without implementing strategies) showed increased repetitive verbalizations across phases.

Bourgeois (1992) explored introduction of personalized memory wallets to enhance communication in six people with mild to moderate AD. Using explanations of response definitions and role play, she trained carers in wallet use. Wallets contained individualized simple written information, drawings and photographs. Carers used the wallet daily across 4 or 5 days with participants to facilitate discussion about 'day', 'family' and 'yourself'. During this training and a maintenance period, participants made more novel on-topic statements and fewer ambiguous utterances. A further three participants also appeared to benefit from introduction of wallets even with minimal carer training. Most participants also used their wallets spontaneously to initiate conversations. Similarly, Baker (2001) reported on the use of life story books (LSBs) with people who had severe dementia and some retained language skills (verbal or non-verbal). SLTs compiled LSBs and trained relatives and staff (e.g. in pace of presentation and cueing). LSBs were initially monitored and changes made following feedback. After 6 months, reports from carer questionnaires indicated more focused and shared

conversation, revived spousal involvement and changed staff attitudes towards the person. Staff also had greater understanding of the SLT's role and increased interest in future collaborations.

Spilkin and Bethlehem (2003) extended memory book use a little further. They collected two 10-minute baselines of interactions between a person with moderate to severe dementia and his daughter using a memory book. Initially, the daughter was given only a handout on basic strategies for book use. Spilkin and Bethlehem then used CA to analyse turn-taking, topic management and conversational repair. Results were used to identify breakdowns and the daughter was trained to use strategies (e.g. more close-ended and single-part questions, tolerating silences for longer, speaking about the pictures and elaborating) to modify interactions with her father. Immediately after training and 1 week later, they recorded two further 10-minute samples. After intervention, CA revealed the father used less minimal turns (e.g. 'mm'), more on-topic responses and he introduced and maintained more topics, whilst perseverating less. He was also more able to repair utterances and, overall, assumed a more active role, probably because his daughter provided more structure in conversation.

SLTs have a role in formal training of care staff to optimize communication in dementia. The FOCUSED programme emphasizes strategies based on an interactive discourse model – F – face to face, O – orient to conversation topic, C – continue the topic, U – unstick communication blocks, S – structure questions, E – exchange conversation and D – direct short sentences (Ripich and Wykle, 1996). Presented over several sessions, it involves role play, discussion and home assignments. In addition, Bryan and Maxim (1998) described communication training strategies used with care staff in the UK. Furthermore, Maxim *et al.* (2001) discussed factors that contribute towards SLTs successfully delivering workshops to care workers, and Pietro (2002) emphasized the importance of evaluating training outcomes on communicative behaviour in the real world.

16.18 ENVIRONMENTAL BARRIERS TO COMMUNICATION

As language devolves, the person with dementia relies increasingly on the environment as a dynamic contributor towards functioning (Clark, 1995). Given increasing problems with hearing and vision, it is critical that these problems be corrected optimally (with encouragement to wear aids) and that environments have limited background noise (e.g. using sound absorbing materials, turning televisions off) and good lighting (Enderby, 2002). In addition, good management of other medical conditions and drug regimens can affect communication positively (Clark, 1995). Although physical space is often quite limited and opportunities for solitude or intimacy rare, social interaction can also be minimal (Lubinski, 1991).

Use of space is important – for example, placing chairs and beds in proximity for comfortable interaction or using round tables at meal times (Morse and Intrieri, 1997). There are also sometimes attitudes that need to be challenged, such as ignoring those with severe communication problems (Lubinski, 1991), or inadequately trained staff speaking to residents only about physical care and failing to use effective communication techniques to reduce aggression (Pietro, 2002). If people have independent mobility, the environment needs to be set up (e.g. colour coding) so that they can find their way to spaces where they can interact (Lubinski, 1991). Unfortunately, when facilities are being designed or renovated, political will to prioritize communication-friendly environments can be lacking when features like cost, physical care and security are considered (Lubinski, 1991). Because more primitive senses of smell and taste may be relatively preserved in later dementia, stimulation of these senses via spice jars, scratch and sniff books, ethnic foods or texture of garden loam can also trigger conversation (Lubinski, 1991; Bourgeois, 1991). Recent studies have also suggested that having a pet or even a toy present can facilitate communication (e.g. Hopper *et al.*, 1998).

16.19 EATING IN DEMENTIA

In later dementia changes in swallow physiology and sensory loss often affect eating and swallowing (Logemann, 2003). Even in early AD, changes in duration of swallow phases have been noted (Priefer and Robbins, 1997). As such, SLTs have a role in optimizing swallowing and reducing the risk of aspiration pneumonia. Logemann observed that people can sometimes be taught strategies to upgrade food and drink consistencies that they can swallow safely, while others may be helped without learning, for example by changing consistencies to prevent aspiration, by triggering pharyngeal swallowing using certain intense tastes or bolus temperatures, or by positioning (Gillick and Mitchell, 2002). To reduce guesswork, it is important for SLTs to use an instrumental examination where pharyngeal dysphagia is suspected (Logemann, 2003). Nonetheless, people with advanced dementia cannot cooperate with such procedures (Gillick and Mitchell, 2002). Where people can no longer swallow safely, a percutaneous endoscopic gastrostomy (PEG) tube is sometimes inserted to administer liquid food directly into the stomach (Gillick and Mitchell, 2002). SLTs also have a role in recommending when this procedure may be considered. However, this decision is not just about swallowing status, but also PEG side effects (of diarrhoea and nausea in 10 per cent of people), likelihood of people pulling the tube out and findings that people with advanced dementia may well not benefit from PEG feeding in terms of survival or comfort (Gillick and Mitchell, 2002; Logemann, 2003). If there is no living will regarding medical intervention, guardians may have to make this difficult decision based on what people would choose for themselves (Gillick and Mitchell, 2002); however, in reality, PEG use can vary between countries or even doctors within the same hospital.

16.20 CONCLUSIONS

Communication, amongst other things, allows elderly people to vent anxieties, relieve loneliness, describe medical symptoms and stimulate cognition (Lubinski, 1991). As such, it seems obvious that SLTs should be increasingly involved in fostering communication in dementia. Nonetheless, in 2002 Bryan and Maxim observed that, in the previous 10 years, there had only been a very small rise in the numbers of SLTs specializing in dementia – despite the proportion of people over age 60 rising astronomically in coming decades. They advocated for SLTs becoming more committed to improving dementia services and gave four major reasons why this is timely – interest shown by the government, older people's increasing awareness of health issues, advances in understanding dementia and increasing evidence to support intervention. Exploring intervention has been a focus of this chapter. In addition to dementia assessment and dysphagia work, there is certainly evidence to support the SLT's role in working directly with those who have dementia, in educating carers and other professionals and in advocating for communication-friendly environments. Nonetheless, many studies reviewed have small sample sizes or generally lack methodological rigour. Future research should address issues such as: what constitutes success in these degenerative conditions and how, for whom and for how long communication interventions are effective in the real world. To address these issues effectively, single-case investigations require collection of lengthy baseline as well as intervention data, whilst group studies require strict selection criteria and well-matched control groups (see Lum, 2001). Given that future SLT resources are unlikely to be bountiful, research also needs to address where resources are best expended.

Physiotherapy is based upon a comprehension of the human being as a dynamic whole with motor function as a part of an optimal psychosocial function. The body is the relation to the world (Merleau-Ponty, 1986) and it is seen as both a subject and an object. Through movements the human communicates knowledge and correlation to the environment, but movements are also a goal-directed solution of functional tasks and thereby a precondition of creating and maintaining a social life, an important topic when you are dealing with dementia.

The physiotherapist examines the body from an understanding of the mutual action between body and emotions, the body expressing and regulating emotions while being a biological and biochemical phenomenon, and evaluates the type and level of strain and resources in the patient. This information about the physical function contribute to diagnosis and therapy (Thornquist, 1992).

Elderly people with dementia often suffer from various somatic illnesses, neurological or musculoskeletal problems, that on the one hand may affect their motor function and state of mind, and on the other hand are reinforced by their mental and cognitive dysfunction.

Physiotherapy for demented people can take many forms with different foci depending on the severity of the illness and the purpose of the physiotherapeutic contribution.

In the early stage of dementia the object of physiotherapy is promoting awareness of the body and its possibly hidden resources working consciously with experiences of the body as a part of the whole identity. Later in the course the physiotherapy can be aiming at decreasing anxiety and depressive symptoms that may follow the progress of the disease.

Gradually, as the dementia develops and the patient's functions decline, the treatment focuses on activating the patient and establishing an environment that maintains and motivates movement and activities of daily living.

Owing to great variation in symptoms in patients with dementia, the physiotherapy must be directed to the individual's functional ability in order to stimulate and support the patient in making the most of their potential. This chapter will describe how physiotherapy is applied in the psychiatric field and how the discipline may contribute to the general management of dementia.

16.21 THE DEMENTED PATIENT

Dementia produces an appreciable decline in intellectual functioning and usually some interference with personal activities of daily living (World Health Organization [WHO], 1992). The decline affects different patients differently and must be managed individually depending on the patient's memory, thinking and reasoning capacity, emotional control, perception of stimulus and ability to orientate and learn, understand and communicate. However, all patients respond positively when treated with common courtesy, kindness and respect (Laerum, 2003).

Dementia patients are exposed to personality and behavioural changes and the progressive nature of the illness affects them psychologically. Their physical functions, however, are not debilitated necessarily concurrently with the other functions and here patients can use their remaining resources and gain a feeling of success, adding quality to their lives.

16.22 BODY AWARENESS THERAPY

Psychiatric physiotherapy has a short tradition, but in recent decades there has been an increasing acknowledgement of how the mind and the body influence each other, and the use of basic body awareness therapy (BAT) has been steadily growing in physiotherapy practice (Gyllensten, 2001).

BAT is the common name for a number of physiotherapeutic approaches using a holistic physiotherapy treatment (Roxendal, 1985). In the 1970s Gertrud Roxendal, physiotherapist and doctor of philosophy, established BAT in Scandinavian countries, integrating a number of techniques which inspired her. After meeting the French psychoanalyst and movement teacher Jacques Dropsy she recognized the value of his movement practice and theories and integrated his work in physiotherapy practice under the name of Basic BAT. In this branch of 'body awareness' the patient works with the basic functions of movements related to posture, coordination, free breathing and awareness (Roxendal, 1987). This work with the body constitutes the basis for the quality of movement in action, the expression of the self, interaction with others and involvement in activities in life (Dropsy, 1975, 1988; Roxendal, 1987). The treatment also inspired the creation of an assessment scale, the Body Awareness Scale (BAS), an instrument that measures the functions of grounding, posture, coordination, breathing and flow, that are the targets of Basic BAT practice.

Roxendal developed the theories of the body ego, an expression first used by Freud (1923), and she defined this as the bodily aspect of the inseparable unit body/mind that is the human being, or total identity (Roxendal and Wahlberg, 1995). She pointed out four cornerstones of important aspects in treatment:

- the encounter or interaction between the patient and the physiotherapist;
- the activation of the motivation of the patient;
- the conscious view of the human being; and
- the movement praxis of Basic BAT.

In this way Roxendal was a pioneer in establishing a broader view of factors active in physiotherapeutic treatment and the outcome of treatment (Gyllensten, 2001). Psychiatric physiotherapy has developed both theoretically and methodologically from Roxendal's work and is now practised outside Scandinavia.

16.23 CLINICAL PRAXIS OF BAT

In BAT one uses movements, breathing, massage and awareness to try to restore balance, flexibility and the unity of body and mind, working with the resources of the body as a whole. The therapist coordinator encourages the patient to move in better ways to attain postural control, balance, free breathing and coordination, using both body and words to guide the

patient. The relation to the ground, vertical balance in the centre line, centring of movements and coordination from the solar plexus area, breathing, flow and awareness are seen as important aspects of the body ego trained in Basic BAT (Gyllensten, 2001). The movements in BAT are quite simple, fundamental and easy to learn, which makes them very suitable for demented patients, who often lack the ability to understand and perform more complicated exercises.

Basic BAT consists of movements of the body as a whole in lying, sitting, standing and walking positions. The work usually starts with stretching exercises on the floor or on a couch, and breathing exercises aimed at letting go of old compensations and control of the breathing and just letting it be. The patient progresses to the sitting or standing position in order to not get trapped in a regressive state. Here the work of becoming more aware and in contact with the antigravity muscles continues. The three basic coordinations starting in the trunk are practised:

- flexion-extension around the centre of movement in the solar plexus area;
- rotation around the vertical axis; and
- trunk rotation and counter rotation as seen in walking.

Mental presence and awareness are key words taught from the very first exercise – the person is stimulated by turning the attention both to doing and to what is experienced in the movements (Roxendal, 1987; Dropsy, 1988; Gyllensten, 2001).

Focusing on activating health promoting resources rather than on physical symptoms and limitations, BAT is a useful approach in the treatment of patients with dementia. The features of dementia include disturbances of cognitive functions and the sensorium as well as changes in physical functions (e.g. reduced trunk rotation); by initiating BAT at an early stage the basic elements of the body ego are stimulated and may help the patient to maintain functional skills and an experience of identity.

16.23.1 The role of the physiotherapist

The professional role of the physiotherapist is to guide and support the patient in the process of deepened awareness, and pictures and images can be used to facilitate the experience associated with the movement. Most of all, the physiotherapist is there to stimulate the search to become aware of dormant resources associated with vertical balance, freedom of breathing, movement and action. The therapist is able to support and give help only in accordance with their own level of awareness (Roxendal, 1987; Dropsy, 1988; Gyllensten, 2001).

16.24 MASSAGE, TOUCHING

The treatment is often supplemented by massage. The skin is the largest and most important sensory organ, and physical touch stimulates inner mental and physiological processes

(Mattson, 1998). Massage reduces muscle tension and rhythmic stroking of the skin has a medical effect in consequence of secreting oxytocin: reduced pain sensitivity, anxiety level, blood pressure and pulse indicating a calm wellbeing (Pettersson *et al.*, 1996a, b).

The human being has a lifelong need for physical touch, and massage is an important form of communication. Touching is an intimate kind of contact that creates a connection between human beings (Montagu, 1986). Through the hands the therapist is in contact with respiration, emotionality, movements, tension and changes in tension in the patient. BAT incorporates special massage techniques that can activate both postural and autonomous reflexes (Mattson, 1998). Tactile stimulation of the skin evokes a more distinct sensation of the body and its centre, diverting attention from unpleasant thoughts and emotions and perhaps diminishing agitation and motor restlessness. Elderly demented patients are in physical contact with nursing staff when washing, dressing, feeding and having their personal hygiene attended to but, beyond that, massage can be given with the one purpose of yielding a positive bodily experience. Caregivers can profitably be instructed in therapeutic touching techniques to make nursing situations mutually pleasant.

16.25 INTERACTION

The importance of interaction between patient and physiotherapist is a central feature in clinical practice and studies have focused on the most important factors for successful treatment. Thornquist (1991) indicates the importance of the physiotherapist continuously using his or her body to communicate throughout the whole physiotherapy encounter. She argues that this communication is a central aspect of patient-centredness, and she also points to the problem of interpreting body language as an observer, since a gesture or a posture is dependent on the specific context (Thornquist, 1990). Self-experience and clinical experience develop knowledge in the cognitive, affective and psychomotor domains, and when working with demented people one has to deal with all these domains. According to Watzlawick *et al.* (1967) all behaviour in an interactional situation gives out messages and is thereby communication. Even nonsense, silence, withdrawal, immobility (postural silence) or any other form of denial is itself a communication. If the patient presents in this way, one should attempt to understand the underlying messages.

Establishing and maintaining contact focusing on the patient's resources are important aspects of the interaction and are vital for outcome (Gyllensten *et al.*, 1999, 2000). These might, however, be complicated in the treatment of demented patients if their motivation fluctuates. Clinical experience and reflecting on communication and the therapeutic process are important tools in interaction, as well as in forming an alliance.

The sooner in the dementia course the physiotherapy is implemented the easier it will be to develop an alliance

with the patient, which can be maintained through subsequent years.

16.26 DEPRESSION AND ANXIETY

Changes in mood or emotion are prevalent in the spectrum of dementia (WHO, 1992). Having a depression is not just a matter of the mind but also affects the body. Patients with depression in comparison with non-depressed persons have more muscular tension, pain complaints, negative attitudes towards their own physical ability, restrained breathing and less freedom of movement (Jacobsen *et al.*, 2003). These symptoms are easily mixed up with and mistaken for symptoms owing to somatic illnesses and physical decline owing to ageing. However, they are the manifestation of depression in the body. In combination with depressive symptoms, a higher level of anxiety appears causing pain, provoking tension and unpleasant bodily symptoms. Clinical experience in physiotherapeutic treatment of depression and anxiety shows that patients benefit from BAT, which includes calming massage and relaxation techniques (e.g. stretching and releasing the body alternately). Treatment pays attention to normalizing the tension level and building up ego-forces, and the patient's focus on body management to be able to control the symptoms and use the body in a more harmonious way.

There are several studies showing that physical activity has a positive effect on the mental state, decreasing anxiety and depressive symptoms. Blumenthal *et al.* (1999) found that exercise training in older depressed patients accelerated the effect of medical treatment and follow up showed a significant decrease in depressive symptoms and a reduced number of relapses. The physical training must be individualized and supervised to include aerobic training and progressive resistance training (Veale *et al.*, 1992; Singh *et al.*, 1997; Lawler and Hopker, 2001).

16.27 PROMOTING MOBILITY

Physical ability deteriorates with increasing years and the physiological and pathological responses to ageing have a direct effect on movement and function. People with dementia may live a sedentary lifestyle and reach the limit of their physical ability simply in the performance of normal activities of daily living. Inactivity results in increasing dependency on the help of others. A number of age-induced changes that affect movement or function can be prevented, slowed down or even reversed by doing exercises (Trew, 1997).

Patients with dementia should be given opportunities for goal-directed movements in a plain and systematic way to maintain mobility and transfer skills (Oddy, 1998). Movement/mobility/transfer can be defined as movements that enable the patient to perform activities of daily living and to move around in their usual environment. These movements comprise

standing up, walking inside/outside and on stairs, sitting down and getting in and out of bed.

The results of goal-directed physical training on impaired elderly people with dementia are significant improvements in the ability to walk and transfer, mobility and balance (Toulotte *et al.*, 2003). Earlier studies providing physiotherapy, including music and movement groups, body awareness and functional mobility training, also showed significant improvements in the mobility skills of elderly people with severe dementing illness (Pomeroy, 1993, 1994). An intervention study providing resistance exercise training proved that neuromuscular strength and function can be rehabilitated in elderly demented people (Thomas and Hageman, 2003).

From clinical experience weight resistance training is an effective, structured method to mobilize physical resources. Records should be kept to motivate patients showing progress and illustrating what they are capable of doing. Training and maintaining mobility skills may postpone the time when the demented patient needs personal care and social services.

16.28 COMMUNICATION

To initiate a movement or a transfer, the dementia patient needs to understand the purpose of the action. Using the voice and body in a certain way, the therapist can facilitate communication and get a successful result. Approaching the patient slowly from in front prevents them from being surprised or scared, and a friendly smile while keeping a distance can make them feel safe.

Verbal commands must be short, concise and simple, instructing the patient in positive phrases, e.g. 'Keep standing!' instead of 'Don't sit down!' because the patient may understand only some of the words (Laerum, 2003). In verbal explanation the words must accurately describe what is to be done. Demonstrating the movement using gestures, signs and touching may clarify to the patient how to move in the right way and in the right direction (Charman, 1997).

Throughout the session it is important to observe the facial expression and body language of the patient to receive an impression of how they respond to the treatment. Strategies for helping patients in daily activities are essential to promote mobility. Nursing staff and relatives are often without sufficient knowledge of techniques for activating the patient, but through instructions from a physiotherapist they can help arrange facilities creating a safe, stimulating environment drawing on the resources of the patient. Guidance and advice for the practical daily care of people with dementia are described in detail by Oddy (1998).

16.29 GROUP ACTIVITY

In some psychogeriatric wards and nursing homes movement groups are practised and have proven very useful to demented

patients with similar mobility levels. The activity must be structured in an atmosphere that encourages spontaneous movements: adequate lighting, no interrupting background noises and no big empty spaces around the circle in which the patients are placed. Music can be used to give rhythm and an opportunity to join in the tunes. The patients may not remember the activity from one session to another and must be prepared and invited to participate.

Words and movements applied during the session must be recognizable for the patients, e.g. movements that are related to activities of daily living and that awaken memories. The elements include simple exercises stimulating muscle strength, mobility, balance, body awareness and spatial perception. Long instructions must be avoided in case patients are over-stimulated with more information than is necessary. In order not to make patients uncomfortable or insecure, several repetitions are carried out for each exercise and the programme is repeated from one session to another comprising:

- *mobility training*: simple, soft movements related to activities of daily living functions performed at a moderate speed and with the sufficient time during and inbetween the exercises;
- *light aerobic training*: in order to increase the patient's circulation and staying power;
- *simple balance, stability and strength exercises*: such as weight transfer sideways sitting on chairs and pushing a medical ball around a circle;
- *body awareness and spatial exercises*: in which the physiotherapist designates the specific body part and direction for the movement;
- *non-verbal interaction between patients*: by rolling, throwing and kicking a ball or a balloon.

There are both medical and economical benefits of mobility groups. The social contact in the group is essential to prevent isolation and a passive life that usually follows reduced motor skills. The patients dare more in the group and, through visual stimulation, it is easier for them to revive the pleasure of movements. Staying in good physical shape may reduce the consumption of medicine and medical costs. In this way it is possible to avoid side effects and improve quality of life of patients.

16.30 SUMMARY

The demented population is a large and diverse group of patients who present various symptoms of the illness, different somatic symptoms and varying function levels. There is no recipe or formula for physiotherapy and the treatment must be based on individual ability, capacity and interest. A physiotherapeutic assessment contributes to a broader view of the patient in the multidisciplinary arena and, with the therapist's knowledge of the human body and the declining functions owing to ageing and dementia, attention can be focused

on preventing the consequences and mobilizing existing physical possibilities. The patients benefit from the simplicity of basic BAT applied in individual treatment and exercise groups, activating physical resources and maintaining their motor skills. Positive sensations of the body can be evoked while the dementia causes loss of functions; promoting mobility and stimulating activities of daily living increases the patient's ability to cope with the dementia. The quality of life gained through physical training results in both personal and economic benefit.

17.1 SEX AND NORMAL AGEING

Many publications about sexuality and sexual behaviour in older people begin with the same message, that it is time to dispel the stereotype that older people are asexual. Although many older people have an active sex life, this age group is more at risk of sexual dysfunction. Furthermore, age is a major risk factor for dementia and the impact a diagnosis of dementia has on sexual behaviour is complex and profound. This chapter outlines the sexual problems faced by individuals with dementia, and the effect that this has on partners and professional carers.

17.1.1 Sexual activity in older people

Although sexual activity appears to decline with advancing age (Schiavi *et al.*, 1990; Kaiser, 1996), sexual activity does not stop, at least among many older individuals. One study of people attending a community centre in the USA (age range 42–82) found over two-thirds reported having a sexual partner (Wiley and Bortz, 1996). Over 90 per cent of this (self-selected) sample, including those over 70, desired sexual activity at least once a week, although less than half achieved this. Retrospective assessment of change in sexual activity over the previous 10 years in this study found no change in the pattern of preferred activity among women (kissing > intercourse > masturbation > oral sex), whereas men reported a decline in desire for intercourse over the same period (Wiley and Bortz, 1996). Bortz *et al.* (1999) surveyed 1202 community-dwelling men (mean age 74, range 58–94) attending luncheon clubs in California. Sixty-four per cent of men over 80 in this

sample continued to masturbate, and 12 per cent reported intercourse at least weekly. Although the median frequency of intercourse fell from 3.6 episodes per month in men aged 55–59 to 1.3 per month in men aged 85–94, this is still a significant figure! Matthias *et al.* (1997) reported a large community survey of sexual activity and satisfaction based in the USA. They found that nearly 30 per cent of the sample (mean age 77, range 70–94) had experienced sexual activity in the past month; 69 per cent were reported to be ‘satisfied’ or ‘very satisfied’ with their sex life. In a small UK-based qualitative study of sexual satisfaction using purposive sampling, 13 of 21 participants over 70 rated their sex life as at least moderately important, with a few reporting that sex was more pleasurable or of increasing importance as they got older (Gott and Hinchliff, 2003). It appears sex does not even stop when people enter residential homes. In a study of residential home residents, again based in the USA, 62 per cent of men and 30 per cent of women had recently had intercourse (Bretschneider and McCoy, 1988).

17.1.2 Sexual dysfunction in older people

Older people are at risk of psychosexual dysfunction including loss of sex drive, erectile disorder and vaginal discomfort (Masters and Johnson, 1981). Loss of sex drive is commonly due to a mixture of psychogenic and organic factors, and may be related to a reduction in sex hormone levels in both sexes with age (Masters, 1986). Men are at risk of a number of age-related changes including: erectile disorder owing to organic causes including neuropathy and vasculopathy, and delayed ejaculation and longer refractory times (Masters, 1986; Carbone and Seftel, 2002). Older women may notice less

effective vaginal secretion, reduced vaginal accommodation, fewer orgasmic contractions and vaginal irritation. Despite these difficulties in the mechanics of the sexual act, sexual activity remains important to many older people.

17.2 EFFECTS OF DEMENTIA ON SEXUALITY AND SEXUAL BEHAVIOUR

The onset of dementia may have a significant effect on the sex life of the individual and their partner, although the evidence base for changes in sexual behaviour in dementia is small. Wright (1991) undertook a controlled study of the impact of Alzheimer's disease (AD) on marital relationships. Eight of the 30 (27 per cent) couples of the dementia-affected group were sexually active, compared with 14 of the 17 (82 per cent) controls. In those individuals still sexually active, compared with controls sex took place more often in couples where one partner had dementia.

Derouesné *et al.* (1996) reported the findings of two surveys of married couples, where one individual had a diagnosis of possible or probable AD (Mini-Mental State scores 0–29). The first, a survey of 135 couples found that 80 per cent of spouses reported a change in the patient's sexual activity. This was not linked to degree of cognitive impairment or gender of the patient. The second study reported the results of a questionnaire about sexual relations before and after onset of AD. Indifference to sexual activity was common (63 per cent of respondents). Most respondents who reported a change in sexual activity noted a decrease, only four (8 per cent of respondents) reported an increase in sexual activity.

Although increased sexual demands were rare in this study of individuals with AD, this problem may be more common in other forms of dementia, especially frontal lobe dementias, which are often characterized by disinhibited behaviours. Furthermore, increased sexual demands may be underreported as they are particularly upsetting for carers, and very difficult to discuss with others.

In a survey of 40 partners of people with mild–moderate dementia, Ballard *et al.* (1997) found all nine (23 per cent) of the sample who continued to have sex were satisfied with their sexual relationship. Twelve (39 per cent) of the remaining sample who had ceased sexual activity were dissatisfied with this. There was a trend for continuance of sexual activity to be associated with better cognition scores.

17.2.1 Effects on the individual

Concerns over the diagnosis and prognosis, awareness of the stigma and likelihood of development of depression will all diminish sexual interest in an individual with dementia. There are few published studies on the impact of dementia on sexual function. Zeiss *et al.* (1990) in an uncontrolled survey of 55 men with AD, found that 53 per cent reported erectile

dysfunction. This was not related to age, degree of cognitive impairment or medication. The high rate of erectile disorder in partners of patients with dementia may be due to the additional stress placed on the relationship by the diagnosis (Litz *et al.*, 1990). Dementia may also reduce libido and cause functional difficulties that adversely affect maintaining a sexual relationship (Jagus and Benbow, 2002). No published studies assess the prevalence of female sexual dysfunction in dementia.

17.2.2 Effect on the partnership

Changes in the balance of the relationship, especially a shift of role from partner to caregiver, may decrease sexual desire in the partner. Carers of individuals with dementia are also vulnerable to depression and anxiety as the carer burden increases. Apparent lack of interest, wandering, forgetting technique, incontinence and poor self-care also are likely to have an adverse effect on the sex life within a dyad. Despite this there is relatively little research in this area (Baikie, 2002). Although not all dementia-affected couples experience a change in sexual activity, an altered sexual relationship is a difficulty many people face after the onset of dementia within a dyad. The onset of dementia should not be assumed to herald cessation of an active sex life, and couples should be encouraged to think and act flexibly in order to adjust to the impact of the disorder (Davies *et al.*, 1998).

Partners of individuals with dementia may confine themselves to celibacy at a time when the rewards of caring for the patient are becoming increasingly scarce. Some partners who retain their sex drive may seek sexual satisfaction elsewhere, through masturbation, visiting prostitutes or longer-term relationships outside the partnership. This may lead to guilt, especially if the patient is still living at home. This is a particularly difficult area to manage as partners are understandably reticent to talk about this. If they do, it is vital to have a non-judgemental supportive approach. Partners will often blame themselves for the cessation of a sexual relationship. Counselling about the reasons for the patient's altered sex drive and an explanation that this is related to the dementia may help to reassure partners. It is important to stress to patients and carers that a lack of sexual activity should not preclude physical intimacy, and that physical intimacy, such as cuddling is unlikely to result in sexually inappropriate behaviour by the patient (Davies *et al.*, 1992).

17.2.3 Sex in residential settings

Two principal issues should be considered when you are assessing the sexual behaviours of individuals in residential and nursing settings: (a) are the needs for appropriate sexual activity addressed and (b) are inappropriate activities identified and managed?

In an observational study of sexual behaviour in 40 men with dementia living in long-term care facilities, Zeiss *et al.*

(1996) found appropriate (defined as sitting close to someone, kissing or stroking face hands or arms) sexual behaviours were present in 20 per cent of the sample, compared with 35 per cent manifesting inappropriate or ambiguous behaviours. Mayers (1998) surveyed 33 professional caregivers working in medical facilities caring for people with dementia: 10 respondents reported observing consensual activity between patients. It is likely that, even if it is desired, sexual activity among couples will stop when one of them enters a residential setting. This may be due to a lack of facilities and privacy, perceived disapprobation of staff and professionals' concerns about defining what activities are 'consensual'.

17.2.4 Inappropriate sexual activity

Figures on the rates of inappropriate sexual activity among people with dementia consistently show that these behaviours are relatively uncommon, and rarely result in criminal proceedings. In one survey of 101 elderly sex offenders, only 1 per cent of the sample was diagnosed as having dementia (Fazel, 2002). Devanand *et al.* (1992) reported rates of sexual disinhibition of under 3 per cent in a survey of 106 individuals with AD. Burns *et al.* (1990) reported sexual disinhibition to be present in 7 per cent of a sample of 178 patients with AD in the UK with men and women affected equally. Inappropriate sexual behaviours (defined as sexually explicit comments, touching someone other than a partner on the breasts or genitals or exposing breasts or genitals in public) were recorded in 7 (18 per cent) of 40 subjects with dementia living in long-term care and were less common in patients with AD than other dementias (Zeiss *et al.*, 1996). In a further study, Tsai *et al.* (1999) reported inappropriate sexual behaviour (overt sexual contact, self-exposure, hypersexuality or public masturbation) in 20 (15 per cent) of 133 individuals with dementia. No significant differences were noted with differing types of dementia. The largest study to date on individuals with dementia in care, involving 730 residents with dementia from 180 separate residential units, reported that inappropriate sexual behaviours were present in 5.3 per cent of the sample; far lower than other behavioural disturbances (Matsuoka-Hattori *et al.*, 2003).

A large number of so-called inappropriate sexual behaviours have been reported. Mayers (1998) in her survey of professional caregivers for people with dementia found the most commonly reported sexualized behaviours observed over 1 year included touching breasts (85 per cent of respondents), buttocks (79 per cent) or genitals (73 per cent). Attempted intercourse by a patient was reported by 10 (30 per cent) respondents. Staff and other patients were both recipients of unwanted sexual activity in this survey. Interpretation of research into sexual problems is hampered by methodological limitations including sampling bias and the difficulty in coding the behaviour types. Despite this, it appears that oversexualized behaviours are not particularly common in individuals with dementia.

17.2.5 Summary

Given the extensive evidence of the frequency and importance of sex among older community-dwelling and care-home residents and the physiological impact of ageing on sexual function, assessment of the impact of the diagnosis on the sexual life of the individual with dementia, their spouse or partner and wider contacts becomes paramount. Ongoing reviews are necessary as dementia progresses, as difficulties may wax and wane as cognitive problems progress or with the advent of behavioural and psychological symptoms of dementia. Discussions about sexual difficulties should be initiated by clinicians, as people are often reluctant to volunteer to talk about their sex life. Older people may feel that sexual disorders are part of the ageing process, or that they are not a priority if they or their partner has dementia. If a sexual problem is suspected, then taking a history in a confident but sensitive manner can be very helpful.

17.3 ASSESSMENT

Most people faced with a sexual problem probably will discuss it first with their general practitioner, although many individuals are reticent about this and prefer an entrée in the guise of a physical complaint (d'Ardenne, 1988). Although there have been few studies about older people communicating their sexual problems, it is likely that they will be even more reluctant to discuss psychosexual difficulties. Therefore, it is often left to the clinician to elicit whether there are any sexual problems. Taking a psychosexual history is a delicate task that requires sensitivity and timing. With older couples, it may take more than one interview, and is probably best left altogether until a rapport has been established. Opinions differ about how to take a psychosexual history, particularly about whether to interview people separately or together. There are no hard and fast rules, and to a large extent, the method of history-taking depends on how advanced the dementia is. Where the dementia is mild to moderate, it probably is best to see the couple together and then see the informant alone. People respond to an open interviewing style, irrespective of their generation. Using euphemisms may lead to confusion and generate a sense of embarrassment among the interviewees.

17.3.1 Aims of taking a psychosexual history

There are several domains to a psychosexual history. First, an idea about how frequently a couple had sex before the onset of dementia and any pre-existing difficulties is useful. The next step is to elicit the presenting problem. This may be dysfunction of some sort (erectile difficulty, vaginismus), an increase or decrease in sexual drive (libido), sexual behaviour that the partner finds unwelcome or troublesome or infringes social/legal standards. The views of the individual with dementia and their partner about what outcomes are desired are also important.

17.3.2 Presenting problem

A comprehensive history may give useful clues as to whether the presenting problem has an organic or psychological basis. However, this organic/psychological dichotomy is often misleading, as many older individuals have a mix of aetiologies. Identify the presenting problem, its time scale, precipitating or alleviating factors and whether the problem is situation specific. For example, if a man presents with loss of erectile function, explore whether this is intermittent or sustained, and whether it occurs in all situations including masturbating alone, or only when having sex with a particular partner.

17.3.3 Current relationship

A detailed assessment of the current relationship (if any) is important. This includes quality of communication between the partners, the perceived strengths and weaknesses of the relationship, the impact the diagnosis of dementia has had on the relationship, and identifying issues of guilt or resentment. The nature of the sexual relationship and frequency of intercourse (if any) before the onset of the presenting problem should also be assessed.

17.3.4 Sexual development and past experiences

It is important to attempt a full assessment of the developmental history, whatever the age of the person. The scope may be limited by the dementia, but many patients may recall earlier details of their sexual development, and this part of the history often provides clues to the aetiology of the presenting problem. Attempt to seek information on age of puberty or menarche, first sexual experiences, length and quality of past relationships. It is important not to make assumptions about an individual's sexual orientation and it is possible to explore this sensitively by asking the first names of past partners. Asking about sexual abuse is another very sensitive task, but couching the question in terms of 'unwelcome sexual experiences' may help.

17.3.5 Assessment of risk

Altered sexual behaviour in the context of a dementia confers increased risk to the patient, carers and others. Although sexual disinhibition seems relatively rare, increased sexual appetite may occur as a result of frontal lobe damage, or increased demand for intercourse may result from forgetfulness of normal etiquette and conventions (Haddad and Benbow, 1993). Disinhibited sexual behaviour may result in conflict with others, and even in charges of assault. Rarely, a sexually disinhibited individual may commit rape (within or outside a marriage). Therefore an assessment of risk in cases of increased sexual arousal is mandatory, and treatment with antiandrogens or other sexual suppressants such as antipsychotic drugs

should be considered. Another area of risk for partners arises from delusions of infidelity. These may be intense and result in physical violence, so should be taken seriously.

17.3.6 Examination and investigations

All patients presenting with psychosexual difficulties should undergo a physical examination. Examination may reveal evidence of systemic disorders that are causing the sexual difficulties such as Parkinson's disease, diabetes or vascular disease. Assessment of the severity of dementia is useful in helping to plan treatment. Investigations for patients presenting with loss of sex drive or erectile dysfunction should include fasting glucose, prolactin, testosterone and sex hormone-binding globulin.

17.4 MANAGEMENT

17.4.1 Managing common sexual dysfunctions

Erectile disorder (ED) may be treated by behavioural and/or pharmacological approaches. Sensate focus (Masters and Johnson, 1966) is a graded programme of behavioural exercises that involves the couple engaging in mutual erotic exercise stopping short of intercourse. This change in focus of the sexual act away from intercourse may help reduce spectatoring (self-monitoring of erectile capacity) and performance anxiety. Applying this technique requires commitment and may be difficult for individuals with dementia.

Oral phosphodiesterase inhibitors such as sildenafil (Viagra) and vardenafil (Levitra) are an oral treatment for ED which is effective in most patients. Older age does not appear to be a contraindication *per se*, although these drugs should be avoided in patients with cardiovascular or hepatic disease, recent stroke and those on vasodilators (especially nitrates). Vaginal discomfort during intercourse is often related to atrophy and dryness of the vaginal mucosa, secondary to low oestrogen levels. Initially, these may respond to simple water-based lubricants or topical oestrogen creams.

17.4.2 Managing inappropriate behaviours

A variety of strategies to reduce unacceptable sexual behaviours has been suggested (Jensen, 1989; Howell and Watts, 1990). Most rely on behavioural modification, including removing reinforcement during the undesired behaviour and increasing reinforcement of appropriate alternative behaviours, allowing masturbation in private or using modified clothing that makes it difficult for the patient to undress. The utility of these approaches has not been established.

Drugs may help reduce the sexual response. Cyproterone acetate, medroxyprogesterone, conventional antipsychotics and beta-blockers all have an antilibidinal effect. Cyproterone

acetate is a steroid analogue that is effective at reducing sexual drive and sexual responsiveness and has been advocated in treating older people with sex-offending behaviour (McAleer and Wrigley, 1998). It is a competitive antagonist of testosterone and reduces gonadotrophin release. Antipsychotics probably work by inducing hyperprolactinaemia, but may also increase confusion through their anticholinergic effects. The utility of these drugs in people with dementia is not established.

There are complex ethical considerations when antilibidinal drugs are used in patients unable to provide informed consent. However, the common law doctrine of necessity may be valid when capacity is lacking, especially where there is significant risk to the individual or others. Under these circumstances, clinicians should ensure they could justify that the sexual behaviour may result in significant risk to the patient or others, that they have attempted to discuss this with the patient, that they have discussed the proposed use of antilibidinal drugs in a multidisciplinary setting and documented the decision carefully. If the patient is unable to give informed consent, treatment with antipsychotic drugs rather than cyproterone, should probably be considered first.

17.4.3 Managing admission to nursing and residential homes

When an individual with dementia enters a residential facility, the sexual needs of that individual and their partner require assessment. This should include the provision of facilities for sexual expression and exploration of the needs of the partner who remains in the community (Kaplan, 1996). A survey of 300 health professionals about sexual expression of individuals with dementia in nursing homes showed a generally positive attitude (Holmes *et al.*, 1997). Although interpretation was hampered by a low response rate (38 per cent), respondents were generally in favour of encouraging sexual expression among residents. Respondents appeared to favour masturbation rather than intercourse between residents. Training programmes for professional carers exist, focusing on exploring attitudes and information needs of carers, residents' rights and issues of capacity (Mayers and McBride, 1998; Heymanson, 2003). These workshops appear popular but their impact on managing sexuality in care settings has yet to be evaluated.

Some nursing and residential homes now provide married residents with double beds and shared facilities, although stricter rules exist for people developing new relationships and some have draconian rules prohibiting sex (in keeping with acute hospitals of all disciplines). This suppression of sexual activity probably stems from a number of reasons, including a belief among staff that older people are, or at least should be, asexual and that a diagnosis of dementia automatically invalidates the ability to consent to have sex. Neither is correct (Dickens, 1997). The former belief is strongly acculturated in the Western world and is difficult to shift. In an attempt to

obviate the problem about consent, Lichtenberg and Strzeppek (1990) developed a structured assessment technique to aid decisions about patients' ability to consent to sexual relationships. This includes ascertaining the patient's awareness of the relationship, the ability to avoid exploitation and the awareness of potential risks. Although this instrument needs further evaluation, it provides a good framework for clinicians to make decisions about competency regarding sexual matters. In cases where consent to engage in sexual activity is established in both individuals, appropriate facilities (a double bed, privacy, time, condoms and water-based lubricants) should be provided by residential facilities for their residents.

There is sometimes a fine line between appropriate and inappropriate sexual behaviour, which is often dependent on the values of the staff and relatives of the individual concerned. However, some sexual behaviours are more clearly 'unacceptable'. These include masturbating or intercourse in public and sexual advances that are indiscriminate or clearly unreciprocated. In addition to the advice about controlling these behaviours it is helpful for staff on the unit to meet to discuss the issues. This not only allows a consistent approach from all staff members, but also allows individuals to vent their own anxieties. Explaining behaviours to other residents may help to reduce their anxiety.

17.5 GAY AND LESBIAN ISSUES

Specific problems faced by lesbian and gay couples include less understanding and tolerance by other family members and professional carers. If the dementia is HIV related, this may result in the patient and partner having to come to terms with being HIV positive, as well as the diagnosis of dementia. Gay partnerships may be discriminated against in terms of not being offered treatment for psychosexual disorders. In many countries, including the UK, gay partnerships still have no legal status and gay partners may not have the same pension and tenancy rights as heterosexual couples, leading to further worries for the partner.

17.6 SEXUAL ABUSE

Although much has been written about elder abuse, there is scant recognition of the potential of sexual abuse in older people with dementia. Estimates of the prevalence of all forms of elder abuse vary, but one study found rates of 16 per cent of a survey of 126 patients in a geriatric psychiatry service had experienced some abuse (Vida *et al.*, 2002). There was a trend for individuals with dementia to experience more elder abuse. Sexual abuse was not classified in this study. In a state-wide survey of elder abuse in Texas, of the 39 658 cases of abuse identified in individuals over 6592 (0.3 per cent) were cases of sexual abuse – nearly all of them women (Pavlik *et al.*, 2001). This is likely to be a significant underestimate owing

to lack of reporting and recognition. Benbow and Haddad (1993) highlighted the risk of sexual abuse of individuals with dementia, which is exacerbated by lack of definitions and awareness of the issue. Elder sexual abuse may occur at home or within residential or nursing homes, perpetuated by formal or informal carers or other residents. People with dementia may be physically frail and unable to resist sexual advances, and may not be able to report abuse when it occurs. Without a high index of suspicion, sexual abuse will be missed. Any suspicion of elder sexual abuse should be discussed within the multiprofessional team and the police, if appropriate.

17.7 CONCLUSIONS

Several issues about sexuality and dementia need to be considered. First, the impact on the individual with dementia in terms of altered sexual interest and comorbid psychosexual difficulties needs assessment. Second, inappropriate sexual behaviours, although uncommon, can result in misery for professional and family carers. Professionals of all disciplines need to be alert to these problems and offer support and help when necessary.

18.4 Measures of quality of life in dementia	217	References	226

Quality of life (QoL) is a state of being as determined by the evaluation of important aspects of an individual's life based on a set of values, goals, experiences and culture. While there is general agreement that QoL is a multidimensional concept, there is no consensus on how to define it or on what aspects of life should be considered when appraising one's QoL. For example, the World Health Organization's definition of QoL is 'the individual's perceptions of their position in life in the context of the culture and value system in which they live, and in relationship to their goals, expectations, standards and concerns' (WHO QoL Group, 1995). However, as Faden and German (1994) note, there are multiple valid and competing conceptions of the good life, that the meaning of QoL changes over the course of a lifetime and that adaptation to circumstances at the moment affect one's perception of QoL.

Health-related QoL (HRQoL) is a more narrow concept that focuses on aspects of life that are affected by a person's health conditions and treatment of those conditions (Kane, 2003). Though more specific than QoL, HRQoL is also a multidimensional concept that refers to one's social, psychological and physical wellbeing consonant with the individual's values and culture. This construct is broader than concepts such as mood and function and has attracted attention in recent years because its primary focus is on individuals' subjective global assessment of their situation as opposed to measures that assess standardized outcomes such as depression or activities of daily living. Although HRQoL is conceptualized as a broad construct, most researchers have concluded that it can be shown to be constructed of several domains, most commonly physical health, psychological wellbeing, function and social activity (Patrick and Erickson, 1993).

Lawton (1997) argued that QoL can and should be assessed both subjectively and objectively. He defined QoL as 'the multidimensional evaluation, by both intrapersonal and social-normative criteria, of the person-environment system of the individual' (Lawton, 1991; p. 6). He believed that there is a need for a frame of reference against which an individual's subjective assessment can be compared and that often there are consensual standards of quality (Lawton, 1997). Lawton suggested that subjective aspects of QoL (e.g. psychological wellbeing) and objective domains (e.g. physical safety) should be assessed in parallel to examine congruence and incongruence between the two approaches.

While HRQoL is conceptualized as a global construct and often examined using generic instruments such as the Quality of Wellbeing (QWB) scale (Kaplan and Bush, 1982) and the SF-36 (Ware and Sherbourne, 1992), many researchers have taken the approach of developing instruments specific to certain diseases because of the conclusion that the characteristics of those diseases have a significant impact on measurement of the construct. This approach can be particularly advocated in the case of dementia because the disease ultimately robs a person of the ability to express oneself owing to the progressive debilitating nature of most dementing illnesses and because of the unique value placed on thought and cognition, especially in the West.

QoL can contribute uniquely to the assessment of treatment interventions for persons with dementia. For example, agencies that approve pharmacological agents have chosen to emphasize cognitive improvement as a necessary attribute for drugs approved to treat cognitive disorders. However, these diseases also universally impair function and social capacity.

Therefore, it is plausible that effective treatments might improve the non-cognitive aspects of dementia more than the cognitive aspects. This suggests that QoL is potentially a unique approach for examining treatment outcomes. Brod and colleagues (1999) note that disease-specific instruments focus on domains most relevant to the disease and characteristics of the patients and their specificity increases the likelihood of capturing change over time.

18.1 GOALS OF QUALITY OF LIFE MEASUREMENT

In a general review of the concept of QoL and its measurement in dementia, Jennings (2000) delineates several broad issues. First he outlines the objections to the construct. These include the claim that it is so vague and so prone to misapplication that it is either useless or dangerous. Another objection is that it attempts to measure aspects of human existence that are ineffable and unmeasurable. Third, the construct can be seen as narrowing rather than expanding individual values since it claims to define a norm or a narrow view of QoL. Finally the term has within it some implication of judgement. Jennings concludes, however, that the value of the construct is that it can be used to improve aspects of life of the disenfranchised and that if we keep in mind the term's drawbacks they can be minimized.

Jennings concludes his analysis by suggesting that QoL has the great strength of setting positive goals and that this counteracts its negative application as a ranking and comparison of individuals or of the states of individuals. Ultimately, Jennings (2000) and Hughes (2003) conclude that the examination of QoL in persons with dementia emphasizes those with the disease and that this great strength counteracts the inherent drawbacks of the concept.

Measuring QoL can serve several important purposes. As Kerner and colleagues (1998) note, determining QoL increases our understanding of the impact that Alzheimer's disease (AD) and other dementias have on individuals over the course of their illness. Beyond specific aspects of the dementia syndrome, such as cognitive and functional impairments, QoL provides a more global indicator of how dementia influences wellbeing. Because dementia affects large numbers of people, has multiple causes and is non-linear in progression, Mack and Whitehouse (2001) suggest that QoL provides a common language for evaluating the effects of interventions. As new medications and other therapies become available, reliable measures of QoL are important for comparing pharmacological agents in terms of both benefits and side effects, for comparing non-pharmacological interventions with each other and for comparing pharmacological with non-pharmacological interventions (Rabins and Kasper, 1997). QoL is a key consideration in evaluating service programmes and in developing clinical guidelines (Brod *et al.*, 1999). For those whose lives have been altered significantly by moving to

long-term care facilities for healthcare reasons, Kane (2003) believes that we have a moral responsibility to understand and to improve QoL in nursing homes and other residential facilities. QoL also is a major consideration near the end of life when decision makers are often faced with choosing between more aggressive interventions or palliative approaches to care. Finally, we must also keep issues of QoL in mind not only when considering outcomes of treatment but also when allocating scarce resources at both the individual and societal levels (Whitehouse *et al.*, 1997; Brod *et al.*, 1999; Selai and Trimble, 1999).

18.2 THE CHALLENGES IN MEASURING QUALITY OF LIFE IN DEMENTIA

We have previously noted three challenges in assessing QoL in persons with dementia (Rabins and Kasper, 1997). The first is whether there are domains of QoL that are unique to dementia as opposed to other illnesses. Some of the hallmarks of dementia are that it impairs memory, it can affect attention, insight, judgement, problem solving, behaviour, personality, communication skills and it can lead to other non-cognitive symptoms (e.g. agitation, anxiety, depression, delusions, hallucinations) (Whitehouse *et al.*, 1997). This constellation of possible features unique to dementia can markedly influence QoL. As Howard and Rockwood (1995) note, AD has many manifestations, not all of which are present in all patients. They emphasize the need to employ QoL measures that discriminate between patterns of symptoms across the course of the illness. The environment also has an influence on functioning and opportunities for social interaction which impacts HRQoL. Measures of QoL must be sensitive to the settings in which people with dementia reside, including at home in the community, in assisted living environments and in skilled nursing facilities.

A second issue relates to the subjective nature of the construct. Clearly, in the earlier stages of dementia when symptoms are mild to moderate and individuals can conceptualize the construct and express their opinions, the determination of self-rated QoL is most appropriate and informative. There is a growing interest in capturing the perspectives of those who have dementia, and there is a body of evidence that it is feasible to assess QoL directly from those with mild or moderate levels of severity (Logsdon and Teri, 1997; Brod *et al.*, 1999; Logsdon *et al.*, 1999; Selai *et al.*, 2001a, b). However, since some individuals lose capacity to self-assess QoL, they must either be excluded from measurement or methods must be developed by which other individuals can rate the person's QoL. Reliance on others to determine an individual's QoL raises important concerns. Does another person have the right to make judgements about an individual's state of wellbeing from the rater's perspective? Concordance between patient and proxy responses are influenced by the nature of their relationship, time spent together, the degree of objectiveness of the questions and the patient's level of impairment (Brod *et al.*, 1999). Albert and colleagues (1996) note that

a proxy's rating of the frequency of an activity does not tell us if the person with dementia is engaging in the activity in a meaningful way or if the person is actually enjoying the activity. While many instruments used to measure QoL in dementia rely on proxies, proxy ratings have the drawback of filtering a subjective measure through the opinion of another person who may or may not share relevant values. This is a limitation that may be unavoidable, especially for those in the later stages of the illness. However, measures consisting of items that describe observable behaviours and expressions can help to minimize this limitation (Rabins and Kasper, 1997).

The third issue is establishing validity and reliability of instruments measuring QoL in a disorder in which some individuals are unable to conceptualize the construct. Establishing the validity of a measure (i.e. that it accurately measures what it purports to measure) is a challenge when there is no universally accepted definition of QoL and any definition is subject to an individual's interpretation and values (Rabins and Kasper, 1997). While criterion validity may not be possible, most developers seek to establish face validity and content validity by demonstrating the relevance and comprehensiveness of their instrument. Reliability of a measure can more readily be established than validity by demonstrating that its items have internal consistency, that it has good repeatability across administrations and that its use by multiple observers produces similar results. Another psychometric challenge for instruments measuring QoL in dementia is to demonstrate its responsiveness or sensitivity to change. This is a critical characteristic for its usefulness as an outcome measure.

In a thoughtful analysis, Hughes (2003) also identifies three somewhat overlapping problems assessing QoL in dementia. One is a determination of domains, second is the subjective-objective problem and third is how QoL should be assessed in the incapacitated person. Hughes suggests an ethical solution to these dilemmas. He identifies the construct of 'personhood' as the solution to these issues. In defining a person as a 'situated embodied agent' he suggests that both prior and current values and wishes of the person should be considered and that a person's social context of family, friends, neighbours and moral/spiritual values be incorporated.

18.3 METHODS AND INSTRUMENTS

Numerous approaches have been used to measure QoL in people with dementia. Differences relate to the general type of instrument used (i.e. generic versus disease-specific), the scope of the instrument (i.e. the domains of QoL examined) and the type of scores it produces and the method used for data collection. The approach selected by an investigator will depend on several factors. First, the purpose for measuring QoL may determine whether a generic or disease-specific instrument is most appropriate. While a disease-specific measure of QoL is most sensitive to the unique characteristics of dementia and its impact on people's lives, it cannot be used to compare the wellbeing of people with dementia with that

of those with other types of illnesses. If QoL is being used as an outcome measure, it is important to consider whether the instrument's content will provide an appropriate measure of effectiveness of the therapy, intervention or programme being examined. Since most agree that QoL is multidimensional, investigators wanting to examine relationships between an intervention and particular aspects of QoL may prefer an instrument that provides subscale scores rather than one that provides only a single summary score. Instruments also vary in how items are scored. In many cases, the items of an instrument contribute equally to either a subscale score or the total score, while other measures have weighted scores based on the assumption that the issues reflected by different items vary in their contributions to the individual's QoL.

Characteristics of the study sample can influence the choice of methods and instruments. Some instruments have been designed to assess QoL of people across the course of their illness. These usually rely on proxy raters, such as family members or formal healthcare providers. Other instruments have been developed specifically for those with mild to moderate dementia who are likely to be able to self-assess their QoL or participate in the process along with an informant. Some measures have been designed to determine QoL in people with late-stage dementia, often relying on formal caregivers as proxy raters since so many of these individuals are cared for in nursing homes.

M. Powell Lawton, one of the most influential forces in how QoL is conceptualized and how instruments have been developed (Ready and Ott, 2003), has stated, 'I reject the idea that there can be one scale of QoL because "life" is composed of many facets' (Lawton, 1997, p. 91). Lawton argued that for clinical and research purposes it is important to know the separate content and salience values for each of the domains that compose QoL. Beyond the subjective measure of QoL involving self-report, he has described objective measures of QoL as those that deal with observable phenomena (Lawton, 1997). Lawton delineated two types of objective measures. First are attribute ratings, which are characteristics rated based on the rater's familiarity with or observation of the person's typical behaviour over a period of time. Instruments examining attributes (e.g. functional health, behavioural symptoms, social interaction and affect) are typically rated by a family member or a healthcare provider. The second type of objective measure is direct observation and coding of ongoing behaviour, which can include behaviours of the person with dementia, their displays of affect and interactions with care providers, or it can include aspects of the environment. Trained researchers typically complete observational measures.

18.4 MEASURES OF QUALITY OF LIFE IN DEMENTIA

The 12 instruments described below and summarized in Table 18.1 are examples of disease-specific measures for assessing QoL in people with dementia. This is not an exhaustive list,

Table 18.1 *Dementia-related measures of quality of life*

Instrument	Content/domains	Respondent	Patient population	Items
Activity and Affect Indicators of QoL	Positive affect Negative affect Activity	Proxy – formal and informal caregivers	Mild to severe	21
Alzheimer Disease Related Quality of Life (ADRQL)	Social Interaction Awareness of self Enjoyment of activities Feelings and mood Response to surroundings	Proxy – formal and informal caregivers	Mild to severe	47
Cognitively Impaired Life Quality Scale (CILQ)	Social interaction Basic physical care Appearance to others Nutrition/hydration Pain/comfort	Proxy – nursing caregivers	Severe	14
Cornell–Brown Scale for Quality of Life In Dementia (CBS)	Negative affectivity Physical complaints Positive affectivity Satisfaction	Clinician with patient's and caregiver's input	Mild to moderate	19
Dementia Care Mapping (DCM)	Well- or illbeing Personal detractions	Trained rater	Moderate to severe	24
Dementia QoL Instrument (DQoL)	Self-esteem Positive affect/humour Negative affect Feelings of belonging Sense of aesthetics	Patient	Mild to moderate	29
Pleasant Events Schedule-AD (PES-AD)	Passive–active Social–non-social	Proxy with patient's input	Mild	20
Progressive Deterioration Scale (PDS)	Extent patient can leave neighbourhood Ability to safely travel distances alone Confusion in familiar settings Use of familiar household implements Participation/enjoyment of leisure/cultural activities Extent patient does household chores Involvement in family finances, budgeting, etc. Interest in doing household tasks Travel on public transportation Self-care and routine tasks Social function/behaviour in social settings	Proxy	Mild to severe	27
Psychological Well-Being in Cognitively Impaired Persons (PWB-CIP)	Engagement behaviours Positive affect Negative affect	Proxy	Severe	16
Quality Of Life-AD (QoLAD)	Physical condition Mood Interpersonal relationships Ability to participate in meaningful activities Financial situation Overall assessment of self Life quality as a whole	Patient, proxy or both	Mild to moderate	13

(Continued)

Table 18.1 (Continued)

Instrument	Content/domains	Respondent	Patient population	Items
Quality of Life Assessment Schedule (QoLAS)	Physical Psychological Social/family Daily activities Cognitive	Patient and proxy	Mild to moderate	10
Quality of Life in Late Stage Dementia Scale (QUALID)	Activity Affect	Proxy	Severe	11

but it includes many of the instruments represented in the current literature on QoL in dementia. Investigators, including many who conduct clinical trials, have often chosen to use generic measures to examine QoL in people with dementia. For additional reviews of generic and disease-specific instruments, see Walker *et al.* (1998), Demers *et al.* (2000), Salek *et al.* (1998), Selai and Trimble (1999) and Ready and Ott (2003).

18.4.1 Activity and Affect Indicators of QoL

Albert and colleagues (1996, 1999) adapted two existing measures to assess QoL related to the domains of activity and affect in the previous 2 weeks as rated by caregivers. The 53-item Pleasant Events Schedule-AD (Teri and Logsdon, 1991; Logsdon and Teri, 1997) was reduced to 15 items, which are used to determine the frequency of, opportunity for and enjoyment of activities that take place either outside the home (5 items) or indoors (10 items). Affect is measured using Lawton's Affect Rating scale (Lawton, 1994, 1997), which consists of three positive affects (pleasure, interest, contentment) and three negative affects (anger, anxiety, depression). The frequency of each affect in the previous 2 weeks is determined based on a 5-point scale. A composite QoL indicator is then constructed by combining the affect and activity indicators.

The psychometric properties of this measure have been reported based on a sample of 130 outpatients diagnosed with AD. Test-retest reliability of the affect indicators ranged from correlations of 0.53 for pleasure to 0.92 for anger. Kappas were reported to be > 0.40 for 13 of the 15 activity items and > 0.60 for 12 of the 15 items, with low values for 'entertainment' (0.14) and 'radio/TV' (0.34) items. Reliability for the enjoyment of activities was reported to be excellent, with kappas > 0.70 for 14 items and a low value of 0.25 for the 'radio/TV' item. Validity was first assessed by comparing QoL ratings for patients who had family caregivers with those who had institutional caregivers. Data from the entire sample showed that QoL was rated significantly higher for patients with family caregivers than for those with institutional caregivers based on activities, but there were no differences in levels of positive or negative affect. For patients residing in nursing homes, family caregivers rated only the opportunity for activity as significantly higher than did the institutional

caregivers. Validity was also assessed based on the relationship of QoL ratings and cognitive status as measured by the modified Mini-Mental State Examination (MMSE) (Stern *et al.*, 1987). Lower cognitive status was significantly related to less opportunity, frequency and enjoyment of the 15 activities. Severity of dementia was significantly correlated with only one of the six affect items, with less frequent interest in the world among those with more advanced dementia. Data from both a clinic sample ($n = 145$), including few minority elders, and a population-based sample ($n = 196$), most of whom were either African American or Hispanic, showed that frequency of activity was significantly related to positive affect but not to negative affect in both samples and activity was significantly associated with three measures of disease severity in both samples (Albert *et al.*, 1999). The authors conclude that the affect measure, which is less clearly linked to observed behaviours, may be a less reliable indicator of QoL when reported by proxies.

18.4.2 Alzheimer Disease-Related Quality of Life (ADRQL)

Rabins and colleagues (1999) developed a proxy rated measure of QoL of people who have AD and other types of dementia across levels of severity. The content of the ADRQL was developed using an iterative process involving input from formal healthcare providers, informal care providers and a national panel of experts in the field of dementia research and treatment. The instrument contains 47 items with five domains (social interaction, awareness of self, enjoyment of activities, feelings and mood, response to surroundings) that describe primarily observable behaviours and actions. The ADRQL is administered using a structured interview format to either a formal or informal care provider who has extensive knowledge of the person with dementia in the previous 2 weeks. One assumption underlying the development of the ADRQL was that the included items and domains vary in their contribution to the concept of QoL. By developing preference weights for the items, these differences were incorporated into the measurement of health-related QoL. These preference weights were used to assign a scale value to each ADRQL item for scoring purposes. Scores ranging from 0 to 100 can be calculated for each domain and for an overall QoL score, with higher scores reflecting a higher QoL.

Psychometric properties of the ADRQL have been reported in the *User's Manual* (Black *et al.*, 2000) for the instrument. Internal consistency of the instrument has been examined based on data for residents in nursing homes and an assisted living facility. Both formal and informal caregivers were interviewed for a small sample ($n = 17$) of nursing home residents with AD. Cronbach's alphas were 0.77 using data from the formal caregivers and 0.84 based on the informal caregivers' data.

Gonzalez-Salvador and colleagues (2000) examined internal consistency of the ADRQL based on data for residents in an assisted living (AL) facility ($n = 56$) and in a skilled nursing facility (SNF) ($n = 64$). Their data resulted in Cronbach's alphas of 0.85 for data on the SNF residents, 0.91 for the AL residents and 0.89 for both groups combined. Their study also provided evidence of the instrument's validity. Based on data from the residents' formal caregivers ($n = 120$), the ADRQL was significantly correlated with MMSE (Folstein *et al.*, 1975) scores ($r = 0.41$; $P < 0.001$) and scores on the Severe Impairment Rating Scale (SIRS) (Rabins and Steele, 1996) ($r = 0.44$; $P < 0.001$), which is a cognitive measure for subjects with MMSE scores < 6 . Their data also showed that QoL was negatively associated with subscales of the Psychogeriatric Dependency Rating Scale (PGDRS) (Wilkinson and Graham-White, 1980) for orientation ($r = -0.51$; $P < 0.001$), behavioural disturbance ($r = -0.37$; $P < 0.001$) and physical dependency ($r = -0.49$; $P < 0.001$). Likewise, ADRQL scores were negatively correlated with the Cornell scale for Depression in Dementia (Alexopoulos *et al.*, 1988) ($r = -0.42$; $P < 0.001$), showing that fewer depressive symptoms were associated with a better QoL.

18.4.3 Cognitively Impaired Life Quality (CILQ) Scale

DeLetter and colleagues (1995) developed the CILQ scale to quantify differences in QoL of the severely cognitively impaired by nursing caregivers. Initially a 29-item version of the CILQ was developed based on focus groups with nursing staff members on rehabilitative, hospice and long-term care units. Factor analysis and clinical judgement were used to reduce the instrument to 14 items with five categories (social interactions, basic physical care, appearance to others, nutrition/hydration, comfort). Discriminate validity was established based on a sample of 12 cognitively impaired patients, who were categorized as either lower functioning or higher functioning. Scale scores based on ratings by 67 nursing caregivers were significantly different for the lower and higher functioning patients.

18.4.4 Cornell–Brown Scale (CBS) for Quality of Life in Dementia

Ready and colleagues (2002) developed the CBS by modifying the Cornell Scale for Depression (Alexopoulos *et al.*, 1988). The

CBS was developed based on the conceptualization that high QoL is indicated by the presence of positive affect, satisfactions, self-esteem and the relative absence of negative affect. This instrument is composed of 19 bipolar items in four categories (negative affectivity, physical complaints, positive affectivity and satisfaction) that yield a single QoL score. The CBS is completed by a clinician after the latter has conducted a joint semistructured interview with the patient and caregiver. Based on information obtained regarding the previous month, each item is rated on a 5-point scale from -2 to $+2$.

Psychometric data on the CBS are based on a sample of 50 patients from a hospital-based outpatient dementia clinic who were diagnosed as having either dementia or mild cognitive impairment (Ready *et al.*, 2002). The data for the entire sample showed good internal consistency based on a Cronbach alpha of 0.81 and very good interrater reliability as measured by intraclass correlation ($r = 0.90$). Validity data showed that the CBS was significantly correlated with a patients' self-rated mood using a visual analogue dysphoria scale (Spearman $\rho = 0.63$). The data also showed a significant negative correlation ($\rho = -0.35$) between CBS scores and Clinical Dementia Rating (Hughes *et al.*, 1982) scores but no significant relationship between CBS scores and MMSE scores. Reliability and validity findings were similar for the more mildly and more severely impaired halves of the sample.

18.4.5 Dementia Care Mapping (DCM)

Kitwood and Bredin (1994) devised the Dementia Care Mapping (DCM) method for evaluating the quality of care and wellbeing of people with dementia in residential care settings. The DCM methodology is based on the social-psychological theory of dementia care (Kitwood and Bredin, 1992), which holds that much of the decline among those with dementia is a consequence of social and environmental factors. DCM is a structured, observational method in which the wellbeing or illbeing (WIB) of patients is rated based on signs from the patient and the behaviour of staff towards the patient. Trained observers also record any personal detractors (PDs), which are any episodes that could lead to a reduction in self-esteem for the person with dementia (e.g. objectification, infantilization, disempowerment, etc.). Typically, five to ten patients are rated every 5 minutes over a 6-hour time period using 24 activity categories and indicators of social withdrawal. WIB values, which range from -5 (illbeing) to $+5$ (wellbeing), can be aggregated to determine an overall WIB score for the group and for each individual. Fossey and colleagues (2002) have shown that ratings for an abbreviated observation period during the hour 'before lunch' are significantly correlated with total scores for activities ($r = 0.68$; $P = 0.001$) and WIB ($r = 0.50$; $P = 0.02$) rated over the 6-hour assessment period.

The psychometric properties of the DCM method were evaluated by Fossey *et al.* (2002) using data from two cohorts of subjects ($n = 123$; $n = 54$). Internal consistency was

established based on significant intercorrelations of the three main measures of the DCM method (activities, well/illbeing, social withdrawal), ranging from $r = -0.27$ to $r = -0.63$. In one cohort, however, the relationship between activities and social withdrawal ($r = -0.16$) was not statistically significant. Test–retest reliability was determined to be good for WIB scores ($r = 0.55$) and moderate for ratings of activities ($r = 0.40$) and social withdrawal ($r = 0.43$). Concurrent validity was determined based on data from a subset of 19 subjects from one cohort. The WIB score was strongly correlated ($r = 0.73$; $P < 0.0001$) with a pencil and paper generic measure of QoL, but the activities rating was not significantly associated with the generic QoL measure.

In a review of literature in which the DCM method was used, Beavis *et al.* (2002) found that interrater reliability was established in three of nine studies, with concordance ranging from 0.70 to 0.95. Criterion validity was established by Brooker *et al.* (1998) from data for a sample of 10 patients in which DCM scores were strongly correlated with levels of engagement ($+0.81$; $P = 0.01$). In their use of DCM for a large scale Quality Assurance Program, they demonstrated improvements in quality of care practice over a 3-year period based on changes in group WIB scores and declines in the numbers of PDs (Brooker *et al.*, 1998). There is also limited evidence that DCM estimates of wellbeing correlate with other indicators of quality of care (e.g. pressure ulcer care, care planning and carer satisfaction) (Brooker *et al.*, 1998; Beavis *et al.*, 2002). Limitations of the DCM method as noted by Beavis and colleagues (2002) include sampling bias, small sample size, short evaluation periods, lack of consideration of the confounding variables commonly associated with dementia (e.g. psychiatric behavioural features, severity of impairment) and the required investments of time and nursing resources.

18.4.6 Dementia QoL Instrument (DQoL)

Brod and colleagues (1999) developed the DQoL, which was designed to be administered to people with dementia of mild to moderate severity. The DQoL is a 29-item instrument developed through an iterative process involving a literature review, focus groups, pilot testing and statistical examination of its psychometric properties. Screening questions are used to assess the individual's comprehension of the response format. The instrument consists of items rated on a 5-point visual scale that form five domain scales (self-esteem, positive affect/humour, negative affect, feelings of belonging, sense of aesthetics).

The psychometric properties of the DQoL were determined based on a sample of 99 people with mild to moderate dementia, 4 per cent of whom were unable to complete the instrument. Measures of internal consistency for the five scales ranged from 0.67 for feelings of belonging to 0.89 for negative affect. Two-week test–retest coefficients on a subsample of 18 subjects ranged from 0.64 for negative affect to 0.90 for positive affect/humour. There were no significant differences in scale reliabilities between those with mild

dementia and those with moderate dementia. Convergent validity was established by correlations of four DQoL scales with the Geriatric Depression Scale (GDS) (Yesavage *et al.*, 1983) (self-esteem $r = -0.48$; positive affect/sense of humour $r = -0.61$; absence of negative affect $r = -0.64$; feelings of belonging $r = -0.42$). Those with lower GDS scores had significantly higher scores on the sense of belonging, absence of negative affect, positive affect and self-esteem scales than those with high GDS scores.

18.4.7 Pleasant Events Schedule–Alzheimer's Disease (PES–AD)

PES-AD is a checklist of events and activities for patients with AD that was derived from two earlier Pleasant Events Schedules, one for a general adult population (PES) and another version for older adults (PES-Elderly) (Logsdon and Teri, 1997). The 53-item PES-AD was developed by eliminating items from the PES-Elderly that were inappropriate for people with AD. This instrument has two domains (passive–active, social–non-social) and is designed for use with people who have mild dementia. Caregivers complete the PES-AD and involve the person with dementia as much as possible by asking questions and discussing each item with the patient. Items are rated according to their frequency and availability in the past month on a 3-point scale and are rated on whether the person enjoys the activity now and whether the activity was enjoyed in the past. A shorter 20-item version of the PES-AD (Short PES-AD) was devised by eliminating items difficult to rate, items not available to many people and items with item-to-total correlations below 0.35.

Logsdon and Teri (1997) provide psychometric properties of both the 53-item and 20-item PES-AD. Because the Short PES-AD is highly correlated with the PES-AD ($r = 0.91$ to $r = 0.95$), reliability and validity data will be presented here for only the Short PES-AD. Regarding the instrument's reliability, internal consistency was demonstrated by coefficient alphas ranging from 0.76 to 0.94 and split-half reliabilities ranged from 0.74 to 0.94 for the Short PES-AD. To assess the instrument's validity, correlations between the Short PES-AD and the MMSE and Hamilton Depression Rating Scale (HDRS) (Hamilton, 1960) were calculated. Both symptoms of depression and decreased cognitive function were associated with reduced frequency of enjoyable activity.

18.4.8 Progressive Deterioration Scale (PDS)

DeJong and colleagues (1989) developed the Progressive Deterioration Scale (PDS) to assess QoL in people with AD across levels of severity and to measure changes in QoL as the disease progresses. They used an iterative process of in-depth interviews with caregivers to determine how QoL was affected by the disease, preparation and testing of questionnaires to determine which factors would discriminate between levels of AD, based on the GDS (Reisberg, *et al.*, 1982), and validation

of the instrument. The final version of the PDS contains 27 items with 11 content areas that focus primarily on activities. The instrument is self-administered by the caregiver who scores each item using a bipolar visual analogue scale anchored with statements that describe the patient's characteristics. A composite score is calculated by averaging across the items, with higher scores reflecting a better QoL.

The reliability and validity of the PDS were reported by DeJong *et al.* (1989). Internal consistency of the PDS was established by Kuder–Richardson split-half reliability coefficients, which ranged from 0.92 to 0.95 for a sample of 151 subjects with AD. Test–retest reliability coefficients based on a sample of 123 subjects ranged from 0.775 for those with late stage AD to 0.889 for those with early AD, with an overall coefficient of 0.898. Preliminary versions of the PDS were shown to discriminate with 95 per cent accuracy between non-AD elders and AD patients, and to have 80 per cent overall accuracy in discriminating between four categories of subjects (controls, early AD, middle AD, late AD). For the final version of the PDS, construct validity was established based on significantly different mean scores across groups of patients ($n = 151$) categorized by the GDS as having early, middle and late stage AD.

Data on responsiveness to change were presented by Knopman and Gracon (1994). In a sample of 62 AD subjects in the placebo arm of a 12-week clinical trial, the mean change in PDS scores was -2.8 to $+11.3$. Their study showed large between-subject and within-subject variability, and they concluded that a reliable change score would be approximately four times larger than the mean change score. The review article by Salek *et al.* (1998) notes that the PDS has been used to measure QoL in some double-blind, placebo-controlled trials of tacrine that showed significant changes in PDS scores, but the significant results were not obtained for all treatment groups and only with certain doses of tacrine in each trial.

18.4.9 Psychological Wellbeing in Cognitively Impaired Persons (PWB-CIP)

PWB-CIP was developed by Burgener (Burgener and Twigg, 2002) to measure one aspect of QoL. Initially, the PWB-CIP was a 16-item observer-rated instrument that measures affective states and engagement behaviours. The instrument consisted of eight items reflecting positive affect and engaging behaviours and eight items that reflect negative affect and withdrawing behaviours. The internal consistency of the 16-item PWB-CIP was established based on a Cronbach alpha of 0.74 for the total scale. Validity of the instrument was supported by a moderate correlation of -0.59 with a measure of depression in the appropriate direction.

Longitudinal data from a sample of 96 outpatients with dementia ($n = 73$ at 18 months) were used to further refine the PWB-CIP and provide additional psychometric data (Burgener *et al.*, 2002, in press). Based on factor analysis, five items were eliminated from the PWB-CIP, leaving 11 items

representing two factors (negative affect/interaction, positive affect/interaction). Item to total correlations ranged from 0.30 to 0.57 at baseline and 0.38 to 0.64 at 18 months. Internal consistency of the 11-item instrument was established based on Cronbach alphas of 0.79 at baseline and 0.82 at 18 months. The PWB-CIP was significantly associated (0.65 at baseline, 0.49 at 18 months) with a single item 'face' scale rated from sad to happy. Construct validity was also supported by significant correlations at baseline and at 18 months between the PWB-CIP and measures of personality, cognitive function, depression and productive behaviours, and at 18 months between the PWB-CIP and measures of interaction in the environment, including total social contacts and the PES-AD.

18.4.10 Quality of Life–AD (QoLAD)

Logsdon and colleagues (1999) developed the QoLAD to assess QoL as perceived by both the patient and the patient's caregiver. The content of the QoLAD was derived based on a review of relevant literature on QoL of older adults and other chronically ill populations and the input of patients, caregivers and experts in the fields of geriatrics and gerontology. This instrument consists of 13 items used to assess seven aspects of the patient's QoL (physical condition, mood, interpersonal relationships, participation in activities, financial situation, overall assessment of self, life quality as a whole). An interviewer administers the QoLAD to patients with mild to moderate severity of illness, and caregivers complete the measure in the form of a questionnaire. Each item is rated by the patient and by the caregiver on a 4-point scale, with 1 being 'poor' and 4 being 'excellent'. Total scores as rated by each range from 13 to 52. A weighted composite score is calculated by giving greater weight to the patient's rating than the caregiver's rating.

The psychometric properties of the QoLAD have been reported based on a sample of 77 community-dwelling AD patients and their caregivers (Logsdon *et al.*, 1999). Measures of internal consistency included coefficient alphas of 0.88 and 0.87 for ratings by the patients and caregivers, respectively. Item-to-total correlations ranged from 0.41 to 0.67 for patient ratings and from 0.34 to 0.63 for the caregiver ratings. Ratings of items by the patients and by the caregivers were significantly correlated for 8 of the 13 items and for their total scores. Agreement was poorest on items related to ability to do chores and memory. Based on a subsample of 30 patient–caregiver pairs, 1-week test–retest reliability was established by intraclass correlation coefficients of 0.76 for patients and 0.92 for caregivers. Validity data showed that the patients' ratings on the QoLAD correlated significantly with the MMSE score, activities of daily living, measures of depression and the Pleasant Event Scale-AD. Higher scores on the QoLAD were associated with lower levels of depression, better day-to-day functioning and higher activity level. The caregivers' ratings on the QoLAD were not associated with the patient's MMSE or the patients' self-reported GDS measure. Measures of reliability and validity were examined separately for patients with lower cognitive

status and those with higher cognitive status, and the authors concluded that moderate levels of cognitive impairment did not have a negative impact on either reliability or validity. However, QoLAD scores for those with mild cognitive impairment was significantly associated only with their GDS scores.

Logsdon *et al.* (2002) have also reported on the psychometric characteristics of the QoLAD based on a sample of 177 AD patient and caregiver pairs. The QoLAD was completed by 155 of the patients. Again, internal consistency for both patients (0.84) and caregivers (0.86) was good based on alpha coefficients. Agreement between patients and caregivers based on intraclass correlation coefficient was 0.28 and absolute agreement was 0.19. Validity was demonstrated by significantly higher QoL associated with less impairment in behavioural competence, better psychological status, less impaired physical function and a better interpersonal environment. QoLAD scores were examined across three levels of cognitive functioning. Patient rated scores were significantly different, with lower QoL reported among the lowest cognitive group, but there were no significant differences in caregiver-rated QoLAD scores across patients' cognitive functioning groups. The authors concluded that it was possible for individuals with mild to moderate dementia to reliably and validly rate their own QoL.

18.4.11 Quality of Life Assessment Schedule (QoLAS)

The QoLAS is an instrument derived from a technique called Quality of Life Assessment by Construct Analysis (QoLASCA) by Selai and colleagues (2001) for use with patients who have dementia. The QoLASCA method was a generic technique to assess QoL in patients with neurological disorders such as epilepsy. The QoLAS is an instrument tailored to individual patients and relies on both qualitative and quantitative approaches to measurement. This instrument is administered by interviewing the patient and the patient's caregiver regarding what is important for QoL and ways in which QoL is affected by one's current health condition. A total of 10 'constructs' are elicited, two each for five domains (physical, psychological, social/family, daily activities, cognitive functioning/wellbeing). The patient is asked to rate each construct on how much of a problem each item is on a scale of 0 to 5 from 'no problem' to 'it could not be worse.' The scores are totalled to give an overall QoLAS score out of 50.

The psychometric properties of the QoLAS were reported based on a sample of patient-caregiver dyads. Thirteen of the 37 patients, all of whom had MMSE scores less than 11, could not engage in the interview, and caregivers were not found for two other patients. In this sample of 22 dyads who were interviewed, the caregivers rated the patients as having a worse QoL than the patient had for each of the five domains. Correlations between patient and caregiver ratings for the five domains were higher for patients with mild dementia ($r = 0.29$ to $r = 0.79$) than for those with mild-to-moderate dementia ($r = -0.05$ to $r = 0.43$). Internal consistency was based on item-to-total correlations ranging from 0.59 to 0.86 for patient

ratings on the five domains and correlations for the caregiver ratings ranging from 0.64 to 0.81. Criterion validity was assessed based on ratings by both the patient and the caregiver. Patient ratings correlated with measures of affect, social life and activities, while caregiver ratings of the patients' QoL were associated with measures of mobility, activities of daily living and neuropsychiatric symptoms. Construct validity was established by demonstrating a significantly worse QoL among those with greater deterioration in daily activity skills.

18.4.12 Quality of Life in Late Stage Dementia Scale (QUALID)

Weiner and colleagues (2000) developed the QUALID for use in assessing QoL in persons with late-stage dementia residing in institutional settings. The items for this instrument were selected from the affect and activity measure devised by Albert *et al.* (1996). A group of clinicians experienced in assessing persons with AD selected the items by consensus to measure QoL in persons with late-stage dementia in long-term care facilities. The QUALID, which is administered as a structured interview, contains 11 items reflecting observable behaviours that are rated by frequency on a 5-point Likert scale by a nursing home technician who has at least 30 hours of exposure to the resident in the previous week. Scores range from 11 to 55, with lower scores reflecting a better QoL.

Reliability and validity of the QUALID have been reported based on a sample of 42 residents of a dementia special care unit (Weiner *et al.*, 2000). Internal consistency of the instrument, using data from 31 assessments, was established by a Cronbach's alpha of 0.77. Item-to-total correlations ranged from 0.17 to 0.70. Test-retest reliability based on a subsample of 19 residents was determined by intraclass correlation ($ICC = 0.807$; $SEM = 0.080$). Interrater reliability was established using data on 23 residents provided by two reporters interviewed by two recorders ($ICC = 0.826$; $SEM = 0.07$). To validate this instrument, QUALID scores were compared with those for measures of cognitive function, functional ability, depression and emotional/behavioural symptoms. The QUALID was not associated significantly with either the MMSE or the Physical Self-Maintenance Scale (Lawton and Brody, 1969) but was related to the GDS ($r = 0.36$; $P = 0.04$) and the Neuropsychological Inventory (Cummings *et al.*, 1994) ($r = 0.40$; $P = 0.01$).

18.5 CORRELATES OF QUALITY OF LIFE IN DEMENTIA

As researcher have developed disease-specific measures of QoL and attempted to establish their validity and as investigators have examined predictors of wellbeing for people with dementia, their findings reveal several fairly consistent correlates of QoL. First, studies often show that scores on QoL measures are associated with severity of illness (DeJong, 1989; Albert *et al.*, 1996, 1999, 2001; Gonzalez-Salvador *et al.*, 2000;

Ready *et al.*, 2002). Those with less cognitive and functional impairments are better able to engage in activities and their QoL is often reflected by less negative affect and more positive affect (Albert *et al.*, 1996, 1999; Logsdon and Teri, 1997). Having more impairments in activities of daily living (ADL) and greater physical dependency is associated with diminished QoL (Albert *et al.*, 1996; Logsdon *et al.*, 1999; Gonzalez-Salvador *et al.*, 2000; Ballard *et al.*, 2001; Logsdon *et al.*, 2002). However, some investigators have found no significant relationship between QoL and cognitive function as measured by the MMSE (Weiner *et al.*, 2000; Logsdon *et al.*, 2002; Ready *et al.*, 2002). These findings may be due to a limited range in the cognitive abilities of study participants. For example, Weiner and colleagues (2000) hypothesized that there would be no relationship between MMSE scores and the QUALID in their sample of nursing home residents with late-stage dementia.

QoL is also frequently associated with symptoms of depression among people with dementia (Logsdon and Teri, 1997; Brod *et al.*, 1999; Logsdon *et al.*, 1999; Gonzalez-Salvador *et al.*, 2000; Weiner *et al.*, 2000; Logsdon *et al.*, 2002; Burgener *et al.*, in press). Depression has a strong negative impact on QoL even when cognitive status is controlled for (Logsdon *et al.*, 2002). It is estimated that 15–30 per cent of people with AD experience clinically significant levels of depressive symptoms (Teri and Wagner, 1992). The strong relationships among dementia, depression and QoL highlight the importance of diagnosis and treatment, especially among residents of long-term care facilities where the risk of depression is high.

Some investigators have found significant relationships between the use of psychotropic medications and QoL among people with dementia. Albert and colleagues (1996) found that participants with low QoL in the Predictors Cohort were significantly more likely to use antipsychotic medications. In a sample of people with dementia living in either assisted living facilities or skilled nursing homes, residents taking anxiolytics had significantly lower scores on the ADRQL, while those on a cholinesterase inhibitor had higher QoL scores (Gonzalez-Salvador, 2000). Ballard *et al.* (2001) also found that people with dementia in residential facilities who used psychotropic medications had reduced QoL as assessed using DCM. Neuroleptic agents were most associated with wellbeing, social withdrawal and restriction of activities. It is important to note, however, that in cross-sectional studies it is not clear whether a medication diminishes QoL or whether a lower QoL is due to the psychiatric and behavioural problems being treated.

QoL instruments can be important tools for assessing quality of care. Several investigators have used the DCM method to examine residential care facilities with the goal of improving care practices (Williams and Rees, 1997; Younger and Martin, 2000; Innes and Surr, 2001; Kuhn *et al.*, 2002). For example, the Elderly Mentally Ill unit of a National Health Service trust in south Wales used DCM to assess quality of care in three types of facilities (continuing care/respite, assessment/day care and day centres) (Williams and Rees, 1997).

They determined that environmental/extraordinary circumstances (e.g. deaths, discharges, admissions) affect care by taking away qualified nurses, that staff to patient ratio is not as important as skill mix and role function and that a main theme was the need for more structure and continuity of care.

Younger and Martin (2000) reported findings from a DCM study conducted in two health districts of the UK that included six units (day units, assessment units, continuing care). They found more activity and less dependency in day units, but they determined that high dependency does not lead automatically to a lower quality of person-centred care. Innes and Surr (2001) used DCM to examine care practices in six residential and nursing homes in the UK. Overall, these facilities were meeting the physical care needs of residents but not the broader psychosocial care needs. The investigators found that activities requiring staff intervention generated higher wellbeing of residents and higher wellbeing was associated with fewer personal detractors.

In the USA, Kuhn and colleagues (2002) examined QoL in 10 assisted living facilities in a mid-western state using DCM. They found that residents in larger non-dementia specific sites fared better overall than those in small dementia-specific sites, with greater diversity of interactions and activities. These investigators also determined that these facilities were meeting basic care needs, but the psychological and social needs of residents were generally not given high priority. Woods (1999) suggests that the DCM method of assessing QoL and quality of care may be most valuable as part of the process of change, with feedback sensitively provided to staff and action plans developed to improve quality of care.

18.6 QoL AS AN OUTCOME MEASURE

Increasingly, efficacy studies are including QoL as an outcome measure of pharmacological and non-pharmacological interventions for people with dementia. In a review article, Howard and Rockwood (1995) identified 36 reports of anti-dementia drug trials for AD in which five mentioned and four measured QoL. They noted that only two of the QoL instruments used in those trials had been formally cross-validated in samples of patients with dementia, the PDS and the Italian QoL Scale (IQLS). A few years later, Salek and colleagues (1998) reviewed the use of QoL measures in assessing drug effects and identified six generic and three disease-specific measures used to assess QoL in clinical trials. They observed, however, that some studies referred to instruments such as the Physical Self-Maintenance Scale (PSMS) and the Instrumental Activities of Daily Living (IADL) scale as QoL measures, while other studies referred to these same instruments as measures of activities of daily living (ADL). This inconsistency illustrates an unresolved issue related to the multidimensionality of QoL, i.e. which constructs are aspects of QoL and which are correlates or determinants of QoL? Salek *et al.* (1998) espoused that an instrument classified as a

QoL measure must comprehensively assess all the components that constitute QoL. They concluded that efforts to develop and use QoL instruments for clinical trials had not yet produced a measure with satisfactory validity, reliability, sensitivity and feasibility.

In a review of outcome measures for drug trials, Demers and colleagues (2000) made a distinction between instruments used to measure function and those to assess QoL. They also noted the limited evidence of reliability and validity of the instruments they reviewed and the lack of data on responsiveness to change. In the absence of a 'gold standard' for measuring function and QoL in AD, they provide a step-wise set of guidelines to help investigators select and use the most appropriate scale for drug treatment trials. Their guidelines include:

- considering the objective of the scale and how it matches the goals of the study;
- making sure that the concept is clearly defined and has a sound theoretical base;
- considering the match between the population with whom the scale was developed and tested and the disability level of the study subjects;
- considering the instrument's test–retest reliability, especially if it is to be used repeatedly;
- considering the interrater reliability if multiple raters are involved;
- making sure that the unidimensionality of the scale has been established before relying on a summed score; and
- considering the expected magnitude of change with respect to the scale's responsiveness to change (Demers *et al.*, 2000).

Woods (1999) reviewed the evidence from research studies of non-pharmacological interventions to increase independence and wellbeing in people with dementia. He noted that few of the studies he reviewed focused specifically on wellbeing. However, Woods included interventions designed to increase participation in activities among the studies that he categorized as promoting independence, such as those targeted at self-care, mobility, continence, orientation and environmental change, rather than with those promoting wellbeing. He suggested that often there is an implicit assumption that increased independence and increased interaction must be associated with a better QoL. The studies that he characterized as promoting wellbeing included interventions such as changes in the physical and social environment, reminiscence sessions, validation therapy, multisensory stimulation, dynamic psychotherapy and cognitive behaviour therapy. The outcomes of those studies included improved mood, improved life satisfaction and contentment or happiness rather than the more global concept of QoL.

To illustrate this, one non-pharmacological intervention that used QoL as a secondary outcome measure was conducted by Spector and colleagues (2003). They examined the efficacy of a cognitive stimulation therapy (CST) programme

for people with dementia using a single-blind, multicentre randomized controlled trial that included participants from 18 residential homes and five day centres. They used strict inclusion criteria to identify suitable subjects (e.g. ability to communicate, no major physical illness or disability, MMSE between 10–24, etc.); 115 subjects participated in the intervention group and 86 were in the control group. Following the 14-session programme over 7 weeks, the intervention group had significant improvements on the MMSE, which was the primary outcome, and on the ADAS-cog (Rosen *et al.*, 1984) and the QoLAD scale, which were two of the secondary outcome measures. They concluded that their results compare favourably with trials of drugs for dementia.

18.7 QUESTIONS AND ISSUES FOR THE FUTURE

We believe that the case has been made for the value of examining QoL as an important means of understanding the experience of people with dementia, evaluating and improving care practices and examining the efficacy of pharmacological and non-pharmacological therapies. However, the study of QoL in dementia is in the early stage of its development. Many questions and issues must be addressed in the future regarding how QoL is defined and measured in dementia and what the ethical and policy implications are of quantifying a fundamentally subjective, qualitative state of being for a group of vulnerable individuals.

While progress has been made over the past 15 years in the study of QoL and in the development of dementia-specific QoL instruments, there is no consensus on what domains comprise QoL in dementia. The selection of domains and items is sometimes guided by theory, sometimes seems arbitrary and often is based on judgements of professionals rather than the lay perspective (Bond, 1999). Among the instruments listed in Table 18.1, the most commonly included domains focus on mood or affect, involvement in activities and social interactions. However, as Whitehouse (2000) notes, there is less agreement on whether to incorporate functional status into QoL models or what beyond function should be included as components of QoL. Categories such as self-esteem, awareness of self, aesthetics or appearance to others are seen less often as components of QoL measures. Agreement is also lacking on whether spiritual wellbeing should be included as a component of QoL, especially for those in the early stages of dementia.

Equally important to achieving advancements in the study of QoL in dementia is the need to address the psychometric characteristics of our instruments. Salek and colleagues (1998) argue that future research should focus on using the available instruments cross-sectionally and longitudinally to identify their strengths and weaknesses rather than developing new instruments. They contend that such an effort would produce instruments that are sensitive to change and provide valid and

reliable results. Most lacking for instruments currently in use are data on sensitivity to change, which is critical information for the selection of an appropriate outcome measure for practice and programme evaluation and treatment efficacy.

One of the limitations faced by measures that rely on proxies or on trained observers is that the QoL of the person with dementia is filtered by the experience, wellbeing and values of the rater. This is an unavoidable weakness when examining QoL of those in the latter stages of dementia when individuals lack the capacities needed to self-assess and/or communicate about their own QoL. However, research is needed to determine the most effective methods for enabling those with mild and moderate dementia to participate to the extent possible in the process of determining QoL. Whitehouse (2000) suggests that studies should examine how the varying patterns of neuropsychological disabilities affect patients' ability to engage in assessing their own QoL.

Currently, the primary outcome of interest for interventions directed towards dementia is improving or maintaining cognitive function or slowing its decline. When QoL is examined in either pharmacological or non-pharmacological trials, it is most often considered a secondary outcome, as the CST study by Spector *et al.* (2003) illustrates. Discussions are needed on whether QoL should be regarded as a primary outcome measure, especially for those in the advanced stages of dementia. QoL increasingly becomes an important factor when decisions are made near the end of life about the aggressiveness of care, the use of life-sustaining treatments or reliance on palliative care.

The assessment of QoL and its use in decision-making for people with dementia raise several ethical questions. Some may question the legitimacy of someone else making judgements about an individual's QoL. Faden and German (1994) contend that such judgements are made all the time in every arena of social policy and in private contexts. They suggest that the key moral questions turn on the legitimate uses of those judgements as justifications for consequential actions and policies. One controversy stems from '... whether, under what circumstances, and according to whose judgment diminished life quality is an appropriate indication for reduction or cessation of medical intervention' (Faden and German, 1994, p. 547). One concern is that the term QoL is sometimes used to refer to the moral worth or value of a person and that person's life (Jennings, 2000). Some may conclude that an assessment of QoL resulting in the lowest measure reflects a life not worth living. Such a conclusion is a misinterpretation of an instrument with a floor effect, not a reflection of the absence of quality (Rabins and Kasper, 1997). Jennings (2000) offers an alternative view of quality as marking 'the gap between actual circumstances and the possible circumstances of an intrinsically valuable life' (p. 169). He argues that QoL may tell us something about the experience of an individual but not the value of being human. As Selai and Trimble (1999) state, 'Given the important existential, moral and legal ramifications, the development of tools to assess QoL in patients with dementia must be scrupulously considered' (p. 103).

In a discussion of what counts as a 'good life' for people with dementia, Schermer (2003) concludes that differences in the philosophical theories about the good life manifest themselves in a number of controversies that may provide guidance for future research. First, he raises the issue of whether or not something can be good for people if they do not endorse it themselves. For example, how much value should be attached to the opinions of the person with dementia in order to determine what is good for them and which opinions should be relied on, those in the present or those that predate the dementia? Second is the controversy of whether or not things need to be experienced by a person in order to improve or diminish their wellbeing. For instance, is loss of decorum bad for an individual if the person does not experience it as such? Finally, there is the question of whether experiences should be rooted in reality. Can feelings such as happiness or belonging add to wellbeing if they are the product of some sort of illusion or delusion? Schermer suggests that research should focus more on the process of dementia and the effects of that process on patients' identities, self-conceptions, capacities, preferences and values. He also believes that a narrative perspective, in which life is conceived of as developing over time, including both the past and the present, can help in developing a more comprehensive account of what is a good life for the person with dementia.

Ethical issues

STEPHEN J LOUW AND JULIAN C HUGHES

19.1 Moral reasoning and casuistry	230	19.4 Summing up: hermeneutics and virtues	233
19.2 Practice: persons and context	231	References	234
19.3 Towards the virtues	232		

In the broad sweep of medical ethics, the issues affecting patients with dementia are sometimes amongst the most daunting for the clinician. They concern life and death and the very nature of personhood. Philosophical thought about the moral issues raised by clinical practice aims, at a meta-level, to show us the structure of our thoughts and decision-making processes; and, at a practical level, it aims to help us make up our minds. Thus, philosophy helps us to make practical decisions on a rational basis. We shall combine these two aims. First, we shall uncover the casuistic (case-by-case) basis to moral reasoning in clinical practice, using wandering as an example. Second, we shall discuss a characterization of personhood that stresses the importance of context and culture and shows the relevance of this way of thinking for issues (e.g. ethical issues around genetics) affecting families. Third, we shall show how virtue theory deepens our understanding of the several issues in connection with dementia that involve truth-telling. We believe it is virtue ethics that provides the most useful way to understand day-to-day ethical decision-making (see Chapter 19c).

In this chapter we cannot hope to mention all the ethical issues relating to dementia (for further discussion see Oppenheimer, 1999; Hughes, 2002). The literature is vast (Baldwin *et al.*, 2003). We hope, nevertheless, to indicate ways of thinking that might be broadly applicable.

19.1 MORAL REASONING AND CASUISTRY

It might be assumed that ethical reasoning is a linear, hierarchical process. So, in making ethical decisions we move from moral theories, such as consequentialism (which asserts that an action is right to the extent to which it promotes the best consequences) or deontology (which asserts that an action is

right to the extent to which it reflects a correct moral rule or principle), to decisions regarding what to do in individual cases.

This approach had its origin in Hellenic times, when the successful method of Euclidian geometry was thought to be equally applicable to philosophy and ethics. Contrariwise, Aristotle (1925) suggested that we should argue from the details of an individual case towards the general principle, rather than the other way round. That is, induction, rather than deduction. Indeed, the rigorous demands of deductive thinking (e.g. that there should be an unbroken, logical chain of reasoning) are too susceptible to mistakes. As an alternative, casuistic reasoning is a practical, more familiar and reliable mode of ethical reasoning (Jonsen and Toulmin, 1988). It is not a new approach in ethics and it forms the basis of legal systems that incorporate case law.

In both the UK and the USA the establishment of and reference to *precedent cases* (case law) is fundamental to the progress of practical juristic reasoning. Judges immerse themselves in the details of a case, compare the facts of the present case with different precedents and decide the case accordingly. Rarely does a case undergo a formal deductive analysis based entirely on jurisprudential principles.

So, too, in clinical medicine many conditions are simply recognized and form the 'precedent cases' that help to establish the diagnosis of new cases. Occasionally general biological principles help to inform our clinical judgements by a sort of *nested deductivism*. For example, we know that anticholinergic medication can cause symptoms of delirium. So we can deduce that starting procyclidine might explain why this particular patient now has hallucinations. However, this deductive reasoning is *nested* in the broader recognition, which is more generally a process of induction, that the patient has a delirium.

In moral reasoning the process of casuistry similarly implies reference to a lexicon of generally accepted precedent cases. Developing such a lexicon of ethical cases itself requires a rigorous process, with cases being included from different perspectives. There must be *immersion in the particularities of the case* (the physical diagnoses, treatment options and prognosis in each instance, the wishes of the patient, the pros and cons of interventions, etc.), and into the *realities for a particular clinic* (what policies are in place, what is the norm of practice, what are the constraints on those norms, etc.); thereafter a process of *interpretation* should be very carefully conducted as to the moral relevance and meaning of theories being applied to the particular case in the light of previous cases. This process of *immersion* and *interpretation* typifies casuistry and, as will always be the case, can be undertaken well or badly (Murray, 1994).

Another important element of casuistry is that it accepts conclusions as being *presumptive* and emphasizes that they are revisable in the light of new experience; there is thus a resistance to dogma. This is also the case in Law, where a judge, having given a verdict, may give leave to appeal.

The justification of casuistic reasoning resides in the presumption that morality lies in the realm of practice, not of theory. Thus:

- arguments move from the particular to the general;
- ethical decisions are not presumed to be ‘universal’;
- the particularities of the case are given great weight, as are the circumstances of the clinical environment;
- the perspectives of different interested parties are important;
- moral theories and principles are informative, but not compelling, in the process of moral reasoning;
- whilst high value is necessarily placed on the precedent cases, these are in themselves open to revision.

19.1.1 An example of casuistic reasoning: wandering

There is increasing interest in using new technology to detect or prevent risky behaviour in dementia. Electronic tagging is seen as a way to prevent wandering, but it raises ethical issues (Hughes and Louw, 2002a). Approaching this problem using the principles of beneficence and non-maleficence would tend to lead to the conclusion that electronic tagging is a good thing, because it will reduce the risk of harm. Using the principle of autonomy, however, the libertarian will counter that tagging is an infringement of the person’s freedom. Both sides start from ethical principles (Beauchamp and Childress, 1994), but they start from different principles, so there is a clash.

Casuistry would start from the details of the particular case: details about the protagonists, the available professional help, the psychological and social environment. The different perspectives of those involved would be considered as important. The principles of autonomy, beneficence and non-maleficence would not be ignored, but the particularities of the case would

be the main focus for discussion. A comparison with other cases might yield the conclusion, as so often in moderate to severe dementia, that it would be too unsafe to allow this person to wander. Casuistic reasoning, however, leaves open the possibility that there might be a case where the importance of getting out, where the person’s deeply ingrained habits of walking a particular route, should not be restricted even if there were elements of risk. At the margin, in a case of very mild cognitive impairment, tagging would be an infringement of liberty. Making estimations about what to do at the margin – and (importantly) recognizing that there is a margin – is a feature of casuistic thought. Approaching decisions about tagging with openness (rather than with dogmatic principles) is appropriate and, we would argue, virtuous. By this means we accord individual people respect.

19.2 PRACTICE: PERSONS AND CONTEXT

We are suggesting, therefore, that just as in the ordinary course of our clinical development we rely on theoretical frameworks as well as practical experience, so too we should in ethical decision-making. The ethical lexicon we thus construct might be private or public, but to carry normative weight (i.e. to have the authority to direct the actions of others) it will have to be shareable in principle.

Thus, there is a background to which our lexicon must conform. Against this background, the lexicon must have some basic level of cogency and comprehensibility. The background will include our shared moral sentiments and reasoning, which will largely be inductive (but may include nested deductivism). However, the background to our decisions (clinical or ethical) will contain much more besides: it is multilayered and multifaceted. Indeed, it is the background of practice, the context in which clinical and ethical decisions must be made.

19.2.1 The situated–embodied–agent and cultural embedding

One way of putting this is to say that we are, as people, situated. We are situated as the bodily beings that we are, with our aims and intentions in a personal story, in a family and social context, in a particular culture and history (which includes a legal framework), in a space of moral and spiritual concerns (Hughes, 2001). Regarding the person against this multilayered background, as situated-embodied agents, is instructive when it comes to considering a whole raft of difficult clinical and ethical decisions (Hughes, 2002).

In keeping with the casuist approach, the clinician will need to be open to the background context. This might mean ‘immersion’ in (involving sensitivity to and respect for) a culture that could be quite different to his or her own. Some cultures involve views and taboos that have far-reaching clinical and ethical implications. The Chinese believe, for example,

that it is bad luck to talk about death or serious, fatal diagnoses. The traditional Navajo American Indians believe that thought and language shape reality and influence events; thus, positive language may have a healing effect and negative language may be harmful (Braun *et al.*, 2000).

The point, however, is not just about cultural politeness. Looking at different cultures also challenges our own predominant view that self-rule (autonomy) is paramount. Consider, for example, the African notion of *ubuntu*, which encapsulates the idea that an individual can exist only in the context of relationships. Similarly, while the Navajo American Indians include autonomy as part of their belief system, this is necessarily in the context of the principle of cooperation or consensus. There is a blurring of the boundaries between the individual and his or her community. Consequently the emphasis shifts from individual autonomy towards communal justice or fairness. In relation to a patient who is developing dementia, the family circle and the community traditionally draw in closer and sustain the individual's identity, by continued respect for his or her personality and traditional roles as an elder.

Cultures might learn from one another. For instance, in these 'non-Western' cultures it is assumed that the community will share the cause of an individual's distress. Hence, issues relating to confidentiality require to be seen from the family and community perspective. But this should be no different in 'Western' societies (Hughes and Louw, 2002b). Indeed, there are several strands of ethical thought that stress the extent to which the person cannot be regarded as a detached atom, but must be seen as embedded in a multi-layered context.

Feminine ethics, for instance, move away from the (masculine) emphasis on rights and autonomy to consider the intrinsic importance of our caring interrelationships (Noddings, 1984). Similarly, narrative ethics suggests that we will understand a person by understanding his or her story. It is in the context of narrative, therefore, that judgements about right and wrong for people must be made. However, our stories interconnect: we do not make them up alone (Jones, 1999).

19.2.2 Interrelationships: from genetics to families

The pace of genetic research in dementia means that ethical issues in this area become ever more pressing (Farmer and McGuffin, 1999). One of the main complexities here highlights the problem of our embeddedness. We each have a unique genetic make-up. Yet genetics link us to the rest of the human species (as well as to the animal kingdom and the living world generally). In particular, knowing about an individual's genetics might give us sensitive information about the person's family. The issue is to do with privacy in a world that interconnects. The interconnections are ultimately, in this case, to those who have to pay higher premiums on their health insurance because of the burden placed on insurers by high-risk individuals and families.

The genetics of dementia has not yet afforded us the ethical experience that would allow the construction of the sort of lexicon to which we have referred above. This is not, however, a problem for casuistry. It simply means we have to look at other cases to make our comparisons (e.g. Huntington's disease). Moreover, it stresses that casuistry provides a process, but not the basis, for our ethical decisions. At root our suggestion is that we should follow the example of the virtuous clinician (see Chapter 19c). How would he or she approach an individual asking for information that might affect the whole family? It would surely be by carefully, empathically negotiating that the person should consider the impact of any decision on others. More broadly, how would the virtuous clinician deal generally with confidential information? This would surely be by maintaining confidence whilst recognizing the limits of this duty with respect to those others who are intimately involved.

Cultural comparisons, as we have seen, demonstrate different perspectives. The ethicist-clinician, in developing the skills of understanding and reasoning, must be aware of the subtle nature and implications of these different perspectives. However, as the issues relating to genetics demonstrate, the different perspectives are not just cross-cultural. The perspective of family carers has long been largely overlooked in the professional literature relating to ethics (Hughes *et al.*, 2002a). The ethical issues for family carers are, however, different from those facing professionals precisely because they arise in a personal context and reflect long-term relationships (Hughes *et al.*, 2002b).

If, however, we should take the views of family carers seriously, how much more seriously should we take the views of people with dementia themselves? The tendency to ignore their perspectives undoubtedly reflects the supposition that they are, in one sense or another, incompetent. There is evidence, however, that even in the moderate to severe stages of the disease people with dementia continue to convey meaning (Sabat and Harré, 1994). Hence, there has been increasing interest in and concern to express the views of people with dementia (Bond and Corner, 2001). It seems important that ethical research should take the same path of involving people with dementia, typically through qualitative research, backed up by rigorous philosophical thought and analysis (Hughes, 2003).

19.3 TOWARDS THE VIRTUES

So, recognizing ourselves as situated-embodied agents means that we see people, including people with dementia, as interconnecting and interrelating in a context. The shared nature of this context is the background against which our interpretive judgements concerning the goodness or badness of particular actions are made. It is the context in which we must immerse ourselves, in keeping with the casuistic approach, in order to understand the particularities of the case. It is the context

against which our interpretations, with reference to our lexicon of ordinary and salient cases, must be made.

All of this involves a building up of experience through practice. It should be the epitome of what Aristotle termed *phronesis*, or practical wisdom. This is the virtue that allows us to make practical judgements about what is good or bad for human beings. It cannot be taken for granted that we shall all acquire this type of wisdom. Some of us will be temperamentally better at it than others, but it is inescapable that we shall have to make decisions and we shall naturally wish to make good decisions, by which we mean decisions that will be good for us generally. To quote Aristotle (1925: pp 138–9):

... since moral virtue is a state of character concerned with choice, and choice is deliberate desire, therefore both the reasoning must be true and the desire right, if the choice is to be good, and the latter must pursue just what the former asserts.

What the virtues, including *phronesis*, require is some sense of what we should be as human beings. Well, whatever this might entail, it is likely to be arrived at by a careful application of the casuistic process against the background of our shared, interconnecting, interrelationships and experience.

19.3.1 Deepening analysis: the virtue of fidelity in dementia

Many of the ethical issues that arise in connection with dementia are to do with truthfulness. Here are examples:

- Should Mrs A be told that she has Alzheimer's disease?
- Should Mr B's son be told that his father has dementia?
- Should Ms C, who has mild cognitive impairment, be told that this might progress to dementia?
- Should Mrs D, with a moderately severe dementia, be told that correspondence is being copied to her daughter, the social worker and the local Alzheimer's Society?
- Should Mr E's medication be hidden in his drinks?
- Should Mrs F's husband tell her he is taking her for respite care, or should he pretend it is just a drive in the country?
- Should Miss G's nephew and niece agree to an admission to long-term care, having promised they would keep her at home?

When such ethical issues are discussed in the literature, appeal is usually made to the principles of medical ethics, or to consequentialist or deontological considerations. Despite the concern that telling the diagnosis might cause depression (and so be maleficent), being truthful is a way of respecting the person's autonomy (Pinner and Bouman, 2002). Covert drug administration may be the best way of relieving a person's agitation and of satisfying the duty of care but is, nevertheless, a breach of trust (Treloar *et al.*, 2001). Interestingly, in a study that consulted people with dementia, although the discussion still centred on conflicting principles (autonomy versus paternalistic beneficence and non-maleficence), 'veracity' was recognized as the underlying 'difficult virtue' (Marzanski, 2000).

Virtue theory offers a deeper analysis of the need to be truthful (May, 1994). First, virtues underlie the principles we have mentioned above. Arguments about telling the truth may reveal a concern for the person's *welfare*. Maybe the truth will have good consequences or bad consequences. Either way, the underlying virtue is that of benevolence. Alternatively, it might be argued that the person has a *right* to know the truth (whatever the consequences) and an appeal can be made to the virtues of honesty and respect. Respect for the person's autonomy is also supported by the virtue of candour. However, there is a deeper link between telling the truth and the virtue of fidelity. As May (1994) suggests:

The virtues with which the professional dispenses the truth may condition the very reality he or she offers the patient ... The professional relationship, though less comprehensive and intimate than marriage, is similarly promissory and fiduciary ... The moral question for the professional becomes not simply a question of telling truths, but of *being true to his promises*. Conversely, the total situation for the patient includes not only his disease but also whether others ditch him or stand by him in extremity ... The fidelity of the professional *per se* will not eliminate the disease ... but it can affect mightily the context in which the trouble runs its course.

Writing from the perspective of professionals, we should not overlook how this sort of analysis also helps to explain the profound sense of guilt family carers feel when, for instance, they have to place the person with dementia in a residential or nursing home. The intimacy of family or similar relationships makes it all the more difficult to break faith: guilt then becomes a manifestation of not being true.

19.4 SUMMING UP: HERMENEUTICS AND VIRTUES

The care of people with dementia requires great understanding. This may in part be instinctive, but it is also certainly acquired and can be improved by careful, critical reflection. Hermeneutic philosophers talk of a pre-understanding, the common background perhaps, that allows meanings to be interpreted. They seek out the common ground in different positions as a way of understanding shared and disputed values. This desire to find a way forward, by attention to what all parties are conveying (through words and actions), requires that a practical solution should be found. Hence, hermeneutics also involves *phronesis*:

... this type of wisdom includes a certain attitude, a certain condition, obtained by practice. Virtues are based on education and training; they are acquired in the process of acting and living. Virtues grow from experience. Only those who have had to deal with numerous ethical questions ... may possess practical wisdom. Understanding dementia is in the end a practical matter, a matter of being experienced (Widdershoven and Widdershoven-Heerdig, 2003).

In this chapter we have sketched an ethical meta-landscape and pointed towards the practical usefulness of theories that stress the importance of experience, that recognize our interrelationships and encourage careful and empathic negotiation. We have suggested how our decisions in ethical and clinical matters require the building up, case by case, of a lexicon against which our judgements can be made. However, the judgements that inform the lexicon are embedded in a background of interrelationships and interconnections, where people are situated in multilayered contexts of shared and disputed valued. Openness to the corrective that this background might impose is itself a sign of the sort of virtue that allows us to negotiate the moral landscape in a practical way.

19.6 Advance medical directives	237	Further reading	238
19.7 Involuntary detention and choice of residence	237		

19.5 CAPACITY

Underlying most legal issues raised by patients' dementia is the question of capacity. Comprehensive legal criteria of capacity are elusive. Specific determinations are often governed more by processes of assessment than by tests that produce uniformly replicable conclusions. Courts pay attention to persons' classifications for instance as moderately or severely demented, and to the cognitive deficits associated with each status. Judicial proceedings achieve legally compelling assessments of individuals' capacities for particular functions, but are frequently prohibitively costly and inaccessible. Physicians' assessments, particularly but not only by psychiatrists, are usually convincing, especially when confirmed by a second, independent opinion. Clinical psychologists' assessments of patients' cognitive capacities are often valuable. However, for testamentary capacity, a lawyer's finding that a client can give adequate instructions, answer standard questions about property and family composition, and make reasonable choices, is usually sufficient to show capacity to make an effective will.

A tendency until recent times, that occasionally persists, was to consider a finding of capacity or incapacity as 'global', or all or nothing. A finding made for one purpose, whatever it was and by whomsoever made, governed all other purposes. Now, however, capacity is considered specific to separate functions, so that a patient who is competent for one purpose, such as to consent to medical care, may not be competent for another, such as making contracts or other financial arrangements.

Competent persons can make decisions on the basis of their wishes, even when these are against their best interests as physicians and others assess them. Patients do not lose the right to be governed by their wishes simply because they become incapable of expressing them, or of confirming them. Incapable persons should therefore be treated according to their wishes

as shown when competent, unless they indicate otherwise when treatment is imminent or they would be seriously endangered. It is not legally justifiable to discount people's wishes just because others, such as their family members, can make better decisions for them.

19.5.1 Medical care capacity

The law sets a fairly low threshold of capacity to consent to medical care recommended by a patient's physician. Patients must be able to understand what the care entails, its alternatives, the risks of each and consequences of forgoing all care. Some legal systems and enacted laws set capacity to refuse consent at the same level as capacity to accept it, on the principle that a person with contractual capacity may accept or reject a contract. A more refined approach where services are available without direct charge to patients, is that higher competency is required to refuse indicated medical care, because that choice may expose individuals to higher risks of harm (see Chapter 19c). Physicians may appear manipulative if they accept competence of patients who accept their recommendations and question that of patients who decline, but since courts respect clinicians' disinterested professional judgment, this is analytically sound.

When patients are incompetent to consent to medical care, others may decide on their behalf. If patients' wishes made when competent are known, they may be legally binding (above). If their wishes are unknown, or would be seriously harmful, care decisions may be made by guardians appointed according to locally prevailing laws. Where these are uncertain, closest family members may decide, such as patients' spouses, children or parents. It is a misnomer to describe this as 'substituted consent'; the patient is treated non-consensually, on the *de jure* or a *de facto* guardian's authorization. A limit may be

that *de facto* guardians have no power to authorize payments for care from the patients' assets, where payment is required.

19.5.2 Medical research capacity

When research is not intended for their personal benefit, patients' capacity to consent requires higher levels of competency. The risks and non-beneficial purpose of treatment must be clearly comprehended. Guardians' powers are limited to therapy, and they cannot authorize invasive research on incompetent patients. They may approve medical record inspections and, for instance, monitoring of patients' therapy as control subjects, however, if confidentiality is protected, and allow the drawing of a few extra drops of blood for research when venepuncture is lawfully undertaken for therapeutic, diagnostic or monitoring purposes.

19.5.3 Contractual capacity

It is commonly supposed that cognitively impaired adults lack contractual capacity, in the same way as legal minors. In many circumstances this is true, because the law recognizes, and aims to protect impaired persons against, their vulnerability to exploitation and undue influence. The contractual principle *caveat emptor*, let the purchaser beware, relies on purchasers possessing ordinary capacity to exercise common prudence, and not be misled by delusions, confusion or defective perception. When cognitively impaired persons lack the ability to be wary or cautious on their own behalf, the law may afford them the protection of contractual incapacity.

However, the law does not discriminate against demented persons by precluding them from acting on their own behalf to acquire items, supplies and services they need for their sustenance, protection and comfort. Accordingly, they enjoy contractual capacity to make binding agreements for the food, shelter, clothing, medical care and other goods and services that will maintain them in a manner appropriate to their accustomed circumstances, known in law as 'necessaries'. Impaired purchasers are protected against exploitation in bargaining for necessities by the courts requiring that they pay not necessarily the contractually agreed price, but only as much as is merited (*quantum meruit*) for a necessary supplied. In case of dispute, the courts will determine the payment due, on the basis of parties' equal bargaining power. When payments are so determined or are set, for instance, as standard rates that parties cannot vary by bargaining, such as for public services like domestic heating or electricity, impaired persons are liable, and legally able, to pay for them from their assets.

A demented person can avoid a contract for non-necessaries if the contractual partner is aware of the disability, and if the disabled person did not take any advantage under the contract. The partner cannot avoid the contract, however, and is entitled to only a *quantum meruit* payment if the disabled person leaves the contract binding.

19.5.4 Testamentary capacity

In many countries, laws on distribution of estates without wills are patterned on distribution with wills, reducing disadvantages of testamentary incapacity. Nevertheless, legal property transactions, including by will, usually require relatively high levels of capacity. Testators must have a reasonable awareness of their assets and how they can be determined, of their family structures and moral obligations, and of liabilities their estates may have to settle. Lawyers uncertain of clients' capacity cannot proceed without reliable, independent assurance. Witnesses to wills observe only that they were signed without coercion, not testators' mental capacity.

A legal concern is the influence of cognitive and affective disorders on testamentary capacity, and their interaction. Provided that prospective testators know how to determine their general assets, although not necessarily their current market value, and key participants in family structures, they have capacity. This is so even if they hold particularly strong and even irrational sentiments about individuals and institutions, whether positive or negative. Capacity should be questioned, however, when evidence arises that an individual's attitude may be based on a demented or serious delusion. It is a matter of professional judgement, of physicians, lawyers and, for instance, accountants, how far to go in probing the convictions that have conditioned what appears an irrational attitude toward a close family member who is a potential beneficiary, or a person or institution named by an intending testator. A legal duty of care may exist to protect a patient or client against the undue influence of those deliberately seeking testamentary advantages. No duty exists to protect potential beneficiaries against irrational exclusion from benefits, although they may contest testators' capacity after provisions of wills become known.

Wills are 'ambulatory', meaning that they are to be understood in the context of the testator's circumstances as at the time of death, or earlier loss of capacity to vary the will, for instance by an added codicil. A common practice is to propose residual provisions to accommodate accidental oversights. For instance, when monetary gifts are made to named grandchildren, any who may have been inadvertently overlooked, and any not anticipated to be born when the will is drafted, may be included by language such as 'and the same to other offspring of my children's unions'.

Wills can usually be revoked more easily than they are made. Testators may tear or deface them or throw them away, without witnesses or requirements of clear capacity. Capacity to repudiate a will is less exacting than capacity to make one, involving only rejection of what was previously arranged.

19.5.5 Matrimonial capacity

Historically, marriages united families, and family property, rather than just individuals. Today, however, matrimonial capacity requires only the affectionate intention to spend

one's life faithfully with another. Incapacity to rear future children is not necessarily a barrier, particularly when partners are beyond childbearing age, such as in second marriages. Because marriage introduces new family and moral obligations, its legal effect in many countries is automatically to revoke existing wills. A dysfunction of this law is that when elderly couples have capacity to enter second marriages, agreeing that both will leave their property not to each other but to their own children of earlier marriages, their existing wills are revoked but they may lack capacity to make new wills giving effect to their agreement. On death with no will, the survivor of them will usually inherit the other's estate, contrary to their intentions. This may be overcome only by complex legal property arrangements, for which again their competence may be suspect, unless they have only modest means and obvious intentions.

19.5.6 Child care capacity

Even mild dementia, in contrast to mild mental retardation, may disqualify individuals from eligibility to adopt children, since courts usually apply relatively high standards of suitability for placement of babies and young children. This is not a barrier, however, to capacity to marry a partner with a dependent child. A more common issue is suitability of patients as caregivers to their grandchildren. The legal approach is less to assess potential caregivers than to consider the best interests of each child. A decision balances its competing interests in physical and, for instance, nutritional protection against the value of maintenance of familiar relationships. Decisive factors are patients' degrees of cognitive impairment and children's ages and degrees of dependency. Mildly or moderately demented patients may be more suitable for short-term placements of children, such as when a single parent is confined to give birth to another child.

19.6 ADVANCE MEDICAL DIRECTIVES

Laws increasingly permit, and encourage, competent people to anticipate times to come when they are no longer competent, and to take the earlier opportunity to arrange how they then want to be treated. Advance directives have been called 'living wills' and often focus on terminal care. As more is learned, however, of genetic predictors of future dementia, and, for instance, AIDS-related dementia, directives will come to focus more on future life than on future death. The value of advance directives is that they can address future residential and healthcare arrangements, medical treatment related and unrelated to advance of dementia, and for instance, acceptance and limits of involvement in research. When people make advance directives while they are undoubtedly competent, the directives are of legal significance whether or not they conform to legally-set formulae. Mildly or moderately demented patients may also create credible directives

concerning matters within their cognitive grasp. Even at advanced stages of dementia, however, spoken directives can be given that effectively deny consent to interventions that cause distress or discomfort. Further, no advance directive can be enforced so as to apply invasive treatment that the patient resists at the time of attempted administration, except perhaps to avoid premature death.

19.7 INVOLUNTARY DETENTION AND CHOICE OF RESIDENCE

Perhaps the most difficult area of legal policy concerning persons with more advanced dementia is their involuntary detention in psychiatric facilities. Beyond determination of correct policy, difficulty arises from the law itself when legislation permits but does not compel such persons' involuntary detention, and when involuntary detention not authorized by legislation may be held excusable on grounds of necessity to protect demented persons against their risk of suffering serious bodily harm.

There is an historical record of severe legal oppression of demented people, related to a conviction that those with cognitive impairments are unpredictable, and therefore dangerous. There is also a more benign record of belief that they merit care, and that needs may be met that they cannot themselves supply, in the safety of suitable residential care. Their detention was therefore justified on grounds both of protecting the public, and of protecting them against those who would abuse and exploit them, and against themselves. The issue of correct policy remains unresolved, and legislation often reacts to publicized tragedies, such as demented people living at home who die from starvation or cold, or people involuntarily detained for years who, on release, prove capable of living safe and fulfilling lives.

The recent, liberal trend has been towards deinstitutionalization. Human rights principles support demented persons' rights to live where and how they wish, unless they can be proven, by legal process, to be significantly dangerous to others, or to risk suffering serious impairment. Danger to others may take the form of physical violence, but may also include non-violent sexual molestation of others, perhaps owing to disinhibition of instinctive behaviour. Danger to self may take the form of failing to eat or to keep warm, with risk of malnutrition or hypothermia, forgetting to watch cooking food, with risk of causing fires, or lapses in personal hygiene that risk infections. Involuntary long-term detention in psychiatric facilities is increasingly legally based only on dangerousness, to others or self. It is legally justified only on proof that no less invasive alternative is available. Short-term detention may be excusable, but only until an episode of dangerousness to self or others has ended. Less invasive for those dangerous to themselves are regular home visits to ensure nutrition and adequacy of heat and, for instance, fitting automatic time switches to turn off cooking appliances.

There is concern, however, associated with reduced budgets for public health and social welfare services, that so-called community care of the mentally impaired is liable to become community neglect. So-called open door policies applied by psychiatric institutions, by which mental health patients may freely enter institutions that offer care, as voluntary or informal patients, and may freely leave when they wish, operate in fact as revolving door facilities through which impaired patients circulate. Demented people do not always achieve the dignity, comfort or protection in the community intended by deinstitutionalization, but often live wretched, abbreviated lives of chaos, neglect, dependency, and sometimes, as an ironic alternative to psychiatric detention, imprisonment.

Although, in many countries, demented patients may be involuntarily detained only on grounds of their dangerousness, family members such as patients' children may achieve the same effect by removing them from their residences of choice, the patients' homes, and taking them into their own care or delivering them to care facilities. By legal action taken on their behalf, patients may insist on remaining in, or being reinstated in, their own homes. However, such action is often hard to initiate through public guardians, and private action may be barred by patients' incapacity to act by themselves or to contract for legal services. Family members may legally defend removal of demented patients from their own homes by showing that, even though they are not dangerous owing to violence or risk of severe self-injury, they cannot live securely without constant care and supervision.

19.8 CRIMINAL LIABILITY

Serious crimes consist not simply in doing prohibited acts, but in doing them with a prohibited intention or state of mind, i.e. like much else in law, the issue turns on capacity. When demented persons lack capacity to form the mental element that makes an act criminal, they may be found not guilty by reason of mental disorder, which in some jurisdictions is called insanity. In some countries, this 'not guilty' verdict has no penal consequences, but the facts may trigger a hearing under mental health legislation to see if the person meets dangerousness criteria and, like any other non-criminal but dangerous person, is liable to involuntary detention in a psychiatric facility.

In many countries, those found not guilty by reason of mental disorder are liable to detention in secure psychiatric facilities, from which they will not be released until considered to be no threat to the public. They are often detained for longer than they would have been imprisoned had they been found mentally capable and guilty. The justification is that they receive necessary treatment in detention, although demented patients may not be amenable to treatment. Under some legal procedures, a criminal court cannot hear a prosecutor's evidence of a defendant's mental disability until the prosecutor has shown that the likely trial outcome, if there is no such disability, would be a guilty verdict. This is to reduce the risk of detaining an innocent person in a secure psychiatric facility on grounds of

mental disability. However, a defendant who wishes to plead not guilty on grounds of mental disorder may do so earlier.

A special problem in facilities where demented patients reside, both involuntarily and voluntarily, comes from sexual behaviour. Molestation of staff members may not be violent, but is conduct against which they are entitled to legal protection. Sexual behaviour with other residents may be consensual, but those with whom such behaviour is initiated may lack legal capacity to consent. Legal models of capacity may be based on adolescents, whose consent to or initiation of consensual sexual behaviour may be legally ineffective, leaving their partners convictable. Further, facility staff may involve police, for fear of their own legal liability for negligence in protection of residents, particularly when a participant in such behaviour has a spouse, or has children who complain of the parent's sexual abuse. Staff members' or police officers' disapproval of or discomfort with demented patients' expressed sexuality may underlie their reactions of invoking criminal law.

A particular problem in criminal proceedings arises when a defendant of borderline competence charged with a serious crime insists on pleading guilty. The problem is aggravated in those jurisdictions, such as in the USA and Caribbean, where the death sentence is retained, and a defendant refuses to appeal against its imposition. The problem involves not only defence counsel, who may be court-appointed, but also prosecuting counsel who, as officers of the court, often acting in a quasi-judicial capacity, cannot knowingly be party to a risk of injustice. Prosecuting authorities may accordingly engage psychiatrists to conduct inquiries into criminal defendants' fitness to plead and fitness to stand trial, and to help them to decide on launching any appeal proceedings.

End-of-life decisions

JULIAN C HUGHES AND STEPHEN J LOUW

19.9 Advance directives and practical wisdom	240	19.11 Artificial nutrition and hydration	242
19.10 Withholding and withdrawing life-supportive treatment	241	19.12 Conclusion	243
		References	243

The end of life, speaking literally, is awful. Our attitude towards death will colour our attitude towards life. Being light-hearted about death is a perfectly reasonable attitude, but death is also a matter of profound seriousness, partly because of the shape it gives to our lives. Whether or not we believe in an after-life, death is a matter of great awe.

In this chapter, which is concerned with end-of-life issues, we shall focus on virtue ethics. In a sense, what virtue ethics does – to good purpose – is to change the questions that arise. In the remainder of this introduction we shall flesh out some of our earlier discussion of *virtue ethics* (see Chapter 19a). Our aim is not to provide a full account of virtue ethics (see Hursthouse, 1999), but simply to indicate its usefulness.

Virtue ethics suggest that an action is right inasmuch as it is the act that a virtuous person (one who has the virtues and uses them) would perform, where a virtue is understood as a disposition required for people to flourish or live well. Thus, virtue ethics does not just tell us about what human beings are like, nor does it simply give us rules or principles to follow. Rather, the virtues gesture at that which we should *become* as human beings. They point us in the direction of what it is to do well humanly. The virtues tell us how to act.

People will question how we can *know* what is virtuous? One easy answer is that we should ask a virtuous person. As Hursthouse (1999) comments:

This is far from being a trivial point, for it gives a straightforward explanation of an important aspect of our moral life, namely the fact that we do not always act as 'autonomous', utterly self-determining agents, but quite often seek moral guidance from people we think are morally better than ourselves (p. 35).

Doctors might note how this mirrors clinical experience: we talk to senior colleagues about difficult clinical decisions.

Hursthouse has a second response to the question about knowing what is virtuous. She points out that, even if we know that we are not fully virtuous, it does not follow that we know *nothing* of the virtues. Our knowledge of the virtues is part of the background context in which our practical decisions are embedded (see Chapter 19a). We know about honesty, truthfulness, prudence etc. Moreover, in the clinical arena, when we want expert advice, we do not choose just anyone. We can pick out clinical expertise judiciously.

Furthermore, it does not seem too unreasonable to notice that such difficult clinical cases often involve a value judgement, or something akin to an ethical dimension. If it were simply a factual question about the next step in therapy, any colleague might do. Where, however, the question is about the real value of pursuing treatment for this individual, we need someone who is streetwise, who shows practical wisdom. So we can recognize virtuous people even as we are aware of our own deficiencies.

Virtue ethicists are sensitive to the accusation that they concentrate more on the agent than on the act. As we have already seen, this is not the case. What is *done* is virtuous or vicious, and right or wrong accordingly. Nevertheless, the dispositions of the agent seem far from irrelevant to the goodness or badness of the act. Our final point in this introduction is that this, too, is a reason for doctors to take the virtues seriously.

What people often complain about is not whatever decision the doctors made, but the manner in which they delivered it or acted on it ... A dose of virtue ethics might make [doctors] concentrate more on how they should respond, rather than resting content with the thought that they have made the right decision (Hursthouse, 1999, p. 48).

In the remainder of this chapter we shall start by discussing the philosophical issues raised by advance directives

in dementia and show the difference that virtue ethics makes. The same approach will then be used to discuss, first, artificial nutrition and hydration and the ethical distinction between ordinary and extraordinary means; second, withdrawing and withholding treatment and the principle of futility. We shall also discuss the palliative care approach to dementia and the case against resuscitation.

We shall, however, pass over the topics of assisted suicide and euthanasia (but see Keown, 1995). Virtue theory makes us take seriously what is important in our lives, what makes a life worth living, what makes it good or bad. In this way it has more in keeping with the palliative care approach than with an attitude that aims at death. The question in virtue ethics is: What do we become by aiming at the death of the person with dementia? And the related question is: What do we become if we aim to keep the life of the person with dementia as good as it can be on its natural trajectory towards death? These are difficult questions, which we cannot do justice to, but it is worth recalling that Aristotle said, in relation to courage, that the exercise of the virtues is not always pleasant.

19.9 ADVANCE DIRECTIVES AND PRACTICAL WISDOM

Advance directives are underpinned by the ethical principle of autonomy. The aim is to extend the patient's autonomy into the future, even in the face of incompetence. There is growing recognition that the liberal idea of autonomy does not take account of the importance of personal relationships and mutual dependency (Agich, 2003). Advance directives raise other philosophical concerns too. These have now been rehearsed many times. We shall give a summary account:

- One way to think of personal identity is to regard it as tied to consciousness and, in particular, to memory (Locke, 1690).
- Personal identity becomes a matter of psychological continuity and connectedness (Parfit, 1984).
- In dementia, memory loss means that there is not sufficient psychological continuity or connectedness to say that personal identity has been maintained.
- So the person with dementia cannot be regarded as the same person as the previous person who did not have dementia.
- But then, if they are different persons, the advance directive made earlier by the non-demented person cannot now be applicable to the demented person (Hope, 1995).

It has even been argued that the demented individual will eventually not satisfy the requirements for personhood and cannot then be called a person at all (Buchanan, 1988). This line of thought is disrupted by the broader notion of the person as a situated embodied agent, which importantly allows that the person's memories are significant, but shows that being a person is to be embedded in a social structure, involving

family and friends, legal advisers, spiritual leaders and advocates (Hughes, 2001). It follows that the individual's personhood may, in a moral and philosophical sense, continue to be expressed through established social connections. In which case, we remain persons even when we have dementia; thus, our advance directives retain their validity.

Another valuable perspective, which squares with the situated-embodied agent view, is to be found in narrative ethics.

From a narrative perspective, a person's identity is formed in stories, which both express and create the unity of a person's life. As stories, advance directives presuppose the unity of the patient's life, and try to contribute to that unity, not by making the different phases identical, but by trying to create a meaningful whole which covers all of them (Widdershoven and Berghmans, 2001).

The idea of taking the person's life as a whole has been used by Dworkin (1993) to develop his notion of 'critical interests', which are those interests that help to shape a person's life. These are contrasted with 'experiential interests', which are the interests we have in current experiences. Critical interests are deemed more central to our lives and, therefore, 'precedent autonomy', as expressed by an advance directive, should rule the day when the person is deemed 'incompetent'. The opposing view has been put by Dresser (1995). She argues that it is an affront to disregard the needs and wishes of the person *now*. To this debate Jaworska (1999) has added that the person with dementia is still a 'valuer', so should still be taken seriously. This chimes with the suggestion that advance directives should be accompanied by a 'values history', to help determine with greater confidence the true wishes of the person who now lacks capacity.

So, at a philosophical level, advance directives in dementia raise questions about personal identity and, in the Dworkin–Dresser debate, raise the issue as to whether the wishes of the 'then-self' or the 'now-self' should take precedence.

These questions and issues, however, seem less important from the perspective of virtue ethics. Confronted by this individual with severe dementia, whose current wishes are difficult to ascertain, but whose advance directive states that he or she would not wish to receive life-sustaining treatment in the event of dementia, what would the virtuous clinician do? Well, any doctor of 'good sense' would, if practicable, talk to as many people involved as possible. It would certainly do no harm to talk with the person with dementia. This might not be easy, but it is wrong to position the person with dementia as 'incompetent' when this might not be the case. From the perspective of the individual with dementia, good communication and empathic understanding will enhance his or her standing as a person (Sabat, 2001).

There are three points to make:

- 'Good sense' is another translation of Aristotle's notion of *phronesis* (see Chapter 19a). It is good sense to talk with people. Weighing up their views in the particular

circumstances of the case, against a background of experience and moral judgements, requires practical wisdom.

- What we are describing is exactly the process commended (e.g. in recent draft UK legislation) as necessary to determine a person's best interests, which is what we should be doing when the person lacks capacity to make a decision (Hughes, 2000).
- The virtuous doctor will wish to do what is best for the patient. This is not because the principle of beneficence dictates that we must do such and such, it is because taking people seriously is the mark of someone who has the virtues of charity, justice and *phronesis*.

The issue is not, then, about whether or not this is a person, nor is it about which self to take seriously (the then-self or the now-self), it is about a right attitude in the face of a tragic and difficult situation. It is about what we do in these particular circumstances; but it is also about how we do it. Paying attention to the person, with all that this entails, is the first step. Practical wisdom is required to determine what decisions will be best in these particular circumstances. This will depend on some concept of what is humanly best. These decisions must be made with the right attitude of concern towards the patient, which is a mark of charity. Finally, the weighing up implied in the adjudication of what is best for this particular person will reflect the virtues of fairness and friendship.

Hence, virtue ethics changes the subject. We move from rarefied debates about whether or not the individual is a person, to a more straightforward discussion about how we respond to, how we help, this fellow human being now in this dreadful predicament. And suddenly it seems outlandish to ignore his current state in favour of something he might have said in the past; yet churlish to ignore what he so clearly wrote previously. However difficult it might seem, we have to weigh things up in the light of the concrete circumstances that now obtain. The advance directive, therefore, sits in a context and serves a useful purpose, but only insofar as it contributes to the good and allows human flourishing, albeit flourishing circumscribed by worldly realities.

19.10 WITHHOLDING AND WITHDRAWING LIFE-SUPPORTIVE TREATMENT

The question whether it is in the patient's best interests to withhold or withdraw life-prolonging treatment arises in a variety of contexts for the person with dementia. The woman with a moderate dementia falls and fractures her hip, but there are postoperative complications. At what stage are supportive therapies withdrawn? The man with severe dementia develops a chest infection that does not clear with a variety of antibiotics. Should intravenous antibiotics be withheld? (Should oral antibiotics ever have been commenced?)

19.10.1 Ordinary and extraordinary means

One way of approaching the general issue of withholding or withdrawing life-prolonging therapy is to consider whether there is proportionality between the complexity of the intervention and the apparent benefit that the patient might derive. The distinction between 'ordinary' and 'extraordinary means' allows that 'ordinary means' can differ from person to person and may be 'extraordinary' in other circumstances.

Clearly this moral approach is essentially casuistic: whether something is ordinary or extraordinary must be assessed on a case-by-case basis. It also involves virtues: it is a matter of practical wisdom that such and such a treatment would be disproportionate in terms of the benefits it might bring. Let us presume that the decision involves whether or not to treat the infection of the person with dementia. It is a difficult decision precisely because it involves both factual and evaluative judgements. The virtue of *practical* wisdom suggests precisely that the wisdom is rooted in the doing: it is the experience of clinical practice, supported by a relevant evidence base, that will count. Hence, a study that showed aggressive treatment of infections did not affect the underlying disease and, in fact, was associated with an acceleration in the severity of the disease (Hurley *et al.*, 1996) would be very relevant to the decision.

19.10.2 Palliative care in severe dementia

This brings to mind the suggestion that, in considering end-of-life ethical issues in dementia, we have much to learn from hospices (Volicer and Hurley, 1998). Palliative care involves:

- an affirmation of life, but one in which dying is regarded as a normal process, so that death should neither be hastened nor postponed;
- providing relief from distressing symptoms;
- integrating the psychological, social and spiritual aspects of care;
- offering support to dying people so that they might live as actively as possible until death;
- offering support to families coping with the person's illness and their bereavement (World Health Organization, 1990).

These principles can equally well be applied to people with dementia as they are to people with cancer. Indeed, there are grounds for arguing that palliative care in dementia can be regarded in the same light as person-centred care, since both are motivated by a concern for the person, where what it is to be a person is understood broadly (Hughes *et al.*, 2004). It will at some stage be the case that people with dementia require terminal care. Our suggestion is that seeing end-stage dementia in this light demonstrates an appropriate attitude – one in keeping with notions of what it is to live well humanly – to the final stages of a terminal disease. Such an attitude is hardly likely to be oblivious to quality of life and

certainly would not involve a commitment to a lingering death (Post and Whitehouse, 1998).

In this regard, Coetzee *et al.* (2003) considered the attitudes of carers and old age psychiatrists towards the treatment of potentially fatal events in end-stage dementia. Clinicians appeared to be less keen on active treatment; but the carers set greater store by 'patient-centred' issues, such as dying with dignity. One of the interesting things here is the possibility that the disagreement between clinicians and carers might disappear in the face of a uniting concern for some humanly important values to do with what can, in the circumstances, constitute a good life. The virtues required, then, are to do with understanding and discernment. The professional virtues of respect and humility towards the families of people with severe dementia may allow the right sort of mutual understanding and, in a way, also suggest respect for the person with dementia. This is not to say that we must simply do whatever the family wishes. Taking their concerns seriously, however, and showing how we share them and how we shall attend to them is a matter of practical wisdom, charity and compassion.

One defining characteristic of hospice care is that cardiopulmonary resuscitation is normally excluded as an option in terminal conditions. Such treatment would be disproportionate in terms of its likely effects on someone with metastatic cancer. The same sort of reasoning (strangely) is not applied to dementia. Practical wisdom would caution against the wholesale adoption of policies that make the resuscitation of people with dementia in the event of cardiopulmonary arrest the norm. Not only might there be harm to the patients (e.g. rib fractures), transgressing the principle of non-maleficence, but also attempts to resuscitate people with severe dementia could be regarded as obscene.

To make this charge is to point towards an incompatibility between the motivation behind such attempts at resuscitation and the thought that death at some point is both natural and can rightly be regarded as a relief. This latter thought says more about how to live well as a human being than the former motivation, which is more concerned with the avoidance of litigation. As such, it is the balanced acceptance of death that is likely to be the stance taken by the virtuous person.

19.10.3 Futility

There has been an increasing trend to think of these issues in terms of futility. At first sight this approach appears deceptively devoid of complex conflicts of values – an intervention is adjudged futile on entirely empirical grounds (e.g. Awoke *et al.*, 1992). Nevertheless, the objective criteria for what may or may not count as 'futile' do not take into account the full details of the individual case, bringing to bear the perspectives of all those involved.

Once again, virtue theory changes things. Resuscitation in severe dementia is wrong, not simply because it is estimated to be futile, but because it suggests an inappropriate attitude towards the human condition when faced by the inevitability

of death. To have the appropriate attitude is to have some notion of what it is to live fully and well, even in circumscribed circumstances. It is also to demonstrate the virtue of courage in the face of a terminal state.

19.11 ARTIFICIAL NUTRITION AND HYDRATION

Recent evidence points to the likelihood that percutaneous endoscopic gastrostomy (PEG) or nasogastric tube (NGT) feeding does not materially affect survival in severely demented patients (e.g. Finucane *et al.*, 1999). These procedures carry a significant morbidity and even the risk of death. Hence, the moral case for using these 'extraordinary' means of support becomes less persuasive (e.g. Gillick, 2000).

The uneasy feeling, however, is that by not using these treatments the patient is effectively being deliberately dehydrated or starved to death. Some would claim, indeed, that this is not a matter of medical treatment; it is a matter of basic human care that people should receive food and drink. It would be a failure in charity, on this view, not to pursue treatment by NGT or PEG. Again, we would need to immerse ourselves in the details of a case in order to make a decision, based on our interpretation in the light of the underlying moral principles. But these should reflect a variety of virtues. So an alternative view would be that it shows a lack of charity not to take seriously the risks and a failure of empathy not to seek some other way of attending to the person with dementia.

It might then be better to accept that giving food and drink constitutes basic human care, whilst at the same time accepting that NGTs and PEGs are a disproportionate response. Hence, feeding could still take place using thickened foods and the correct posture, in the knowledge that the person's life might be shortened if aspiration were to occur. The intimate contact of careful feeding continues, therefore, as a matter of charity and practical wisdom. This will achieve for the person the best quality of life within the confines of the difficult situation. The risk that is taken, which is serious, nevertheless can still be viewed as a matter of honouring the person's ability to interact and interconnect humanly.

The artificial means of treatment provide a technical solution but one that lacks meaningful content, which comes from the embedded nature of food and drink in our lives. Recognition of this broader picture is a matter of practical wisdom, for it keeps in view the overall purpose of our lives in a practical sort of way. We are made to interrelate (think of feminine ethics) and interconnect (think of narrative ethics) through our giving and taking of food and drink. But PEG tubes and NGT feeding do not inherently involve interrelationship or interconnectivity. In other cases, where they will restore the person's ability to interrelate and interconnect, they would seem to be the right choice, but not in severe dementia. To see this is to show virtue, by showing a grasp of the real purposes that make our lives good.

19.12 CONCLUSION

The end of life comes in dementia in a variety of ways. What is required is often a practical matter. We have contended that clinical practice at the end of life in dementia will be enhanced by attention to what might constitute living (and dying) humanly well.

At the core of the syndrome of dementia is the loss of social or occupational function. In the early days of specialist medicine and psychiatry of old age, assessment of function centred on activities of daily living, concentrating on a relatively basic set of skills. An increase in the sophistication of the disciplines, as well as the need to probe relatively high-level loss of function in early dementia has led to an increased attention to instrumental activities of daily living, such as managing financial affairs. Driving is an instrumental activity that has attracted particular attention because of a false perception of hazard to other people as well as increasing numbers who drive at all ages (Wang and Carr, 2004). The United States Transportation Research Board, the Organization for Economic Cooperation and Development and the European Conference of Ministers for Transport have all prepared reports on ageing and transport within the last 3 years (CEMT, 2001; OECD, 2001; US Department of Transportation, 2003). It is a definite health issue: drivers in Finland, the UK, Ireland and the US report health as primary cause of driving cessation, usually without a formal consultation to ensure maximal remediation (Persson, 1993; Rabbitt *et al.*, 1996; Hakamies-Blomqvist and Wahlstrom, 1998; O'Neill *et al.*, 2000). It is a fascinating topic and, while the knowledge base is still relatively slender, the issues involved have major practical, ethical and societal implications for patients, their family carers and healthcare professionals. There are widely differing agendas on the part of those involved: the patient, the carers, the physician, the statutory licensing authority and the insurance companies, both motoring and health.

As dementia is a largely (but not exclusively) age-related disease, it is of note that the developed world is experiencing an exponential rise in the proportion of older drivers among

the driving population. In the USA only 5.9 per cent of drivers were over 60 in 1940: this had increased to 7.4 per cent by 1952 and to 11.4 per cent by 1960 (McFarland *et al.*, 1964). Elderly drivers should comprise 28 per cent of the driving population in the USA by the year, 2000 and 39 per cent by 2050 (Malfetti, 1985). Over a third of those aged over 80 in 1990 drove at least once a year in Ontario, Canada (Chipman *et al.*, 1998). In the UK there has been an increase of 600 per cent in the number of women drivers over the age of 65 between 1965 and 1985 (Department of Transport, 1991). Although most will drive personal automobiles, this is not exclusively the case. On the one hand, licensing regulations for drivers of public service vehicles and heavy transport vehicles is nearly always more restricted and uses a more algorithmic approach than for drivers of personal automobiles. On the other hand, those who develop dementia at a younger age are more likely to be driving heavy goods or public service vehicles, and the abolition of mandatory retirement age in the USA has resulted in school bus drivers being able to continue into their mid-80s, and there has been litigation concerning this group.

19.13 WHAT PUBLIC HEALTH ISSUES ARISE WITH OLDER DRIVERS?

One of the most important, and underrecognized, public health hazards arising from dementia is the consequences of loss of mobility for those with dementia who stop driving (Taylor and Tripodes, 2001). One of the other key questions

about the ageing of the driving population is whether they add significantly to hazard on the roads. This question is in itself symptomatic of an ageist approach to older driver issues: it is likely that the predominant problem is that older people give up driving without sufficient remediation (White and O'Neill, 2000). The crash rate for older drivers for a given period of time is considerably lower than that for the driving population as a whole (Gebers *et al.*, 1993). Many safety experts defend older drivers as a relatively safe group (Evans, 1988) and in some road tests healthy older drivers perform better than younger controls (Gebers *et al.*, 1993). The increased crash rate per miles driven noted in elderly populations in comparison to middle-aged controls is not only academic while older people continue to drive a lower mileage: it also is a product of driving a low mileage, which is in itself intrinsically risky. If younger and older people who drive a low mileage are compared, this apparent increase disappears (Hakamies-Blomqvist *et al.*, 2002).

Low mileage exposes them to more dangers per mile than high-mileage drivers as they encounter disproportionately more intersections, congestion, confusing visual environments, signs and signals (Janke, 1991), yet older drivers cope at least as well with this.

Crashes involving the elderly are also more likely to be fatal, by a factor of 3.5 in two-car accidents (Klamm, 1985), reflecting the increased frailty and reduced reserve of older adults, while raising suspicions that automobile design may not be tailored for maximum safety of this group (Schieber, 1994; Li *et al.*, 2003). Opposing these trends is the fact that the accident rates for young adults often arise from behaviour that leads to high-risk situations; accident rates in older drivers occur despite a trend to avoid high-risk situations (Planek *et al.*, 1968) and the lowest proportion of crashes while under the influence of alcohol (National Center for Statistics and Analysis, 1995).

Janke (1994) has suggested a reasonable interpretation of these apparently contradictory findings. A group's average crash rate per year may be considered as an indicator of the degree of risk posed to society by that group, whereas average accident rate per mile indicates the degree of risk posed to individual drivers in the group when they drive, as well as to their passengers. The increased risk to individual drivers is most likely due to age-related illnesses, particularly neurodegenerative and vascular diseases (O'Neill, 1992; Johansson *et al.*, 1997).

19.14 IS DRIVING WITH DEMENTIA A PUBLIC HEALTH HAZARD?

The precise contribution of the dementias to overall crash hazard is uncertain. Although Johansson suggested a major role for dementia as cause of crashes among older drivers on neuropathological grounds (Johansson *et al.*, 1997), subsequent interview with families did not reveal significant problems with memory or activities of daily living (Lundberg *et al.*,

1999). The Stockholm group also showed that older drivers who had a high level of traffic violations had a high prevalence of cognitive deficits (Lundberg *et al.*, 1998). Retrospective studies of dementia and driving from specialist dementia clinics tend to show a high risk (Friedland *et al.*, 1988; Lucas-Blaustein *et al.*, 1988; O'Neill, 1993b), whereas those which are prospective and look at the early stages of dementia show a less pronounced pattern of risk. In the first 2 years of dementia the risk approximates that of the general population (Drachman and Swearer, 1993; Carr *et al.*, 2000). The most carefully controlled study yet of crashes and dementia showed no increase in crash rates for drivers with dementia (Trobe *et al.*, 1996). Likely causes for this counter-intuitive finding include a lower annual mileage and restriction of driving by the patient, family and physicians.

Extrapolating from special populations may skew predictions of risk. For example, epilepsy, for which there are relatively clear-cut guidelines in most countries, would seem to pose a clear threat to driving ability as viewed from a clinic setting. Recent population-based studies seem to suggest that the increased risk is relatively low (Hansotia and Broste, 1991; Drazkowski *et al.*, 2003). In a population renewing their licences in North Carolina, the lowest decile had a relative crash risk of 1.5 in the 3 years previous to the cognitive testing (Stutts *et al.*, 1998). A somewhat reassuring finding from this cohort is that those with the poorest scores for visual and cognitive function also drove less and avoided high-risk situations (Stutts, 1998). A reasonable conclusion from these studies is that dementia among drivers is not yet a public health problem. Although increasing numbers of older drivers may change this situation, it is also possible that 'Smeed's law' will operate, whereby increasing numbers of drivers among a defined population are associated with a drop in fatality rates per car (Smeed, 1968).

19.15 IS THERE A ROLE FOR SCREENING OLDER POPULATIONS OF DRIVERS?

Despite the lack of convincing evidence for an older driver 'problem', ageist policies in many jurisdictions has led to screening programmes for older drivers. In the absence of reliable and sensitive assessment tools, this approach is flawed, as illustrated by data from Scandinavia (Hakamies-Blomqvist *et al.*, 1996). In Finland there is regular age-related medical certification of fitness to drive, whereas Sweden has no routine medical involvement in licence renewal. There is no reduction in the number of older people dying in car crashes in Finland but an increase in the number of those dying as pedestrians and cyclists, possibly in part by unnecessarily removing drivers from their cars. A more minimalist and less medical approach using very simple measures, such as a vision test and a written skill examination, may be more helpful (Levy *et al.*, 1995); unfortunately this approach is also associated with a reduction in the number of older drivers, a

possible negative health impact (Levy, 1995). Another approach is opportunistic health screening, perhaps of those older drivers with traffic violations (Johansson *et al.*, 1996). It remains to be seen whether these and other screening policies reduce mobility among older people, a practical and civil rights issue of great importance. Another problem is the uncertainty about the outcome of screening, as there is currently a limited repertoire.

19.16 PHYSICIANS AND DRIVING ASSESSMENT

Another problem is the relative ignorance of physicians about the effects of illness on driving. Some of this relates to the predominantly negative tone of much of the medical regulations for driving (White and O'Neill, 2000), and it is likely that doctors are insufficiently aware of healthcare interventions that have been shown to improve driving comfort and safety: examples exist for arthritis, stroke and cataract (van Zomeren *et al.*, 1987; Jones *et al.*, 1991; Monestam and Wachtmeister, 1997). Doctors are unaware of the driving habits of their patients when prescribing drugs that may affect driving (Cartwright, 1990) and also have a patchy knowledge of medical regulations for driving (Strickberger *et al.*, 1991; O'Neill *et al.*, 1994). As the regulations are rarely based on evidence-based criteria and are negatively presented, this 'failure' by doctors to acquaint themselves with the regulations may in fact reflect a healthy cynicism about the current official medical fitness criteria. There may also be an element of ageism by which doctors may assume that older patients do not drive: a review of dementia from the UK seemed to take this attitude (Almeida and Fottrell, 1991), whereas US reviewers have been aware of the high number of older drivers for over a decade (Winograd and Jarvik, 1986).

Drivers may not only be unaware, but also may willfully ignore medical advice and regulations. In many countries they continue to drive despite failing to comply with regulations for diabetes, visual disease and automatic implantable cardioverter defibrillators (Frier *et al.*, 1980; Eadington and Frier, 1988; McConnell *et al.*, 1991; Finch *et al.*, 1993). It must be stated that there is no evidence that this under reporting results in any increased crash risk!

We have little information on advice given to drivers with dementia by family physicians or physicians at specialist clinics for the evaluation of dementia. This would be of interest because of the wide range of answers given for patients with life-threatening arrhythmias (Strickberger *et al.*, 1991). In any event, a major shift of emphasis is required by healthcare professionals to consider driving ability in the functional assessment of older people.

The procedures for intervention after the opportunistic detection of illnesses relevant to driving also vary widely. In the UK the doctor's duty is to inform the patient that he/she must contact the Driver and Vehicle Licensing Authority (DVLA); direct contact by the doctor with the DVLA is only

allowed if there is evidence of continued driving that constitutes a hazard to others, and if persuasion through other family members and carers has been unsuccessful. This contrasts with the position in several states in the US and provinces in Canada where the doctor is bound by law to report patients with certain illnesses to the licensing authorities. The disparity between these practices is confusing, but cross-national comparisons may prove a boon to researchers who wish to establish the most appropriate methods for screening and reporting of age-related diseases.

19.17 ASSESSMENT PROCEDURES

The placing of driving issues in an appropriate therapeutic context is the most important task. Rather than focusing on the difficult case of patients who present late with impaired driving ability and insight, we need to recognize that the assessment of dementia provides the potential for a range of interventions, one of the most important of which is the establishment of a framework for advance planning in a progressive disease. Just as this is commonly recognized for such practical matters as enduring power of attorney in many jurisdictions, so too we need to start a process that encompasses an assessment, a commitment to maximizing mobility and also an awareness-raising process for the patient and carers that the progression of the disease will inevitably result in a loss of driving capacity. This latter component has been termed a Ulysses contract, after the hero made his crew tie him to the mast on the condition that they did not heed his entreaties to be released when seduced by the song of the sirens (Howe, 2000). Developing this process incorporates some new stances in dementia care, in particular of the diagnosis disclosure in at least general terms – the patient who drives needs to be told that he/she has a memory problem that is likely to progress and hamper driving abilities. In general, carers are fearful of diagnosis disclosure but older people seem to want to be told if they have this illness. There is also evidence such a process may facilitate driver cessation, by enhancing a therapeutic dimension to disease diagnosis and advance planning (Bahro *et al.*, 1995). It forms the basis of a useful patient and carer brochure from the Hartford Foundation which is also available online (Hartford Foundation, 2000). This type of approach also seems to have worked with older, visually-impaired drivers (Owsley *et al.*, 2003). The most useful model of assessment is that of an assessment cascade (Figure 19.1).

Not all levels will be required by all patients: a patient with a homonymous hemianopia is barred from driving throughout the European Union, and referral to the social worker to plan alternative transportation is appropriate. Equally, a mild cognitive defect may only require a review by the physician and occupational therapist. The overall interdisciplinary assessment should attempt to provide solutions to both maintaining activities and exploring transport needs. The on-road test may be helpful as it may demonstrate deficits to

Figure 19.1 Assessment cascade.

a patient or carer who is ambiguous about the patient stopping driving. At a therapeutic level, members of the team may be able to help the patients come to terms with the losses associated with stopping driving. The occupational therapist may be able to maximize activities and function and help focus on preserved areas of achievement, whereas the social worker can advise on alternative methods of transport.

The assessment of fitness to drive should only take place after a thorough evaluation of the underlying medical condition(s). The evaluation of dementia, both clinically and investigative, is well covered in other chapters but dementing illnesses may coexist with other conditions that affect driving ease and ability. Important components of the history and examination of theoretical relevance to the driving task are medication and alcohol use (Doege and Engelburg, 1986), perception, cognitive status and psychomotor ability. Perception is probably more important than vision. Cognition may be usefully measured by the physician using one of the many brief mental status schedules (O'Neill, 1993a), and the elements of general clinical assessment of older drivers for medical fitness to drive are now described on both sides of the Atlantic (Carr, 1993; O'Neill, 1993a, b). Although the Mini-Mental State Examination (MMSE; Folstein and Folstein, 1975) correlates with driving performance (Odenheimer *et al.*, 1994; Fitten *et al.*, 1995; Fox *et al.*, 1997), it is not sufficiently sensitive or specific to be used as a determinant of driving ability (Lundberg *et al.*, 1997).

The basic thrust of the assessment is to catalogue and remedy all pathologies that may be relevant to driving: vision, cognitive function, neurological and musculoskeletal disorders, as well as conditions that may give rise to transient loss of consciousness such as diabetes and syncope. In any one illness there may be multiple facets that affect driving: in Parkinson's disease, this includes motor, cognitive and affective aspects. Each component needs to be maximally remedied before a final decision is made. A collateral history of driving behaviour is very important, although one small study has shown a poor correlation between carer rating of driver behaviour and on-road testing (Hunt *et al.*, 1993).

Medications should be minimized; although the data are preliminary, long-acting benzodiazepines (Hemmelgarn *et al.*, 1997), tricyclic antidepressants (Ray *et al.*, 1993) and neuroleptics should be targeted.

19.18 FURTHER ASSESSMENT

In cases of very mild cognitive impairment or very severe cognitive impairment, the judgement may be relatively easy and require little by way of supplementary testing. For those falling in between, the precise nature of the further evaluation is not yet standardized, just as the neuropsychological evaluation of dementia is not yet standardized; and just as not all chest pains arise from pulmonary emboli, clinicians need to have access to appropriate specialist expertise and technology to exclude it in such cases. So too, old age psychiatrists may need to invoke the assistance of a driving specialist centre, the components of which are medical, occupational therapy, sometimes neuropsychology, and specialist driving assessors. A first effort may be made with a suitably trained occupational therapist (Raney and Hunt, 1997): this profession is notable for upskilling in driving assessment in Australia, Canada and the USA.

The choice of tests will be relatively arbitrary and, as in any memory clinic where geriatricians or psychiatrists of old age will familiarize themselves with the battery of tests carried out by the occupational therapist or psychologist in the local area, it is likely that good communication between professionals and familiarity with the chosen tests is as important as the precise tests chosen.

While a number of screening and evaluation test batteries have been proposed, it makes more sense to choose some core areas of interest, and to allow some room for clinical judgements on areas such as patient judgement and impulsiveness. The task is rendered more complex by the sophistication of models of driving, which do not conform easily to traditional cognitive test batteries. At least five main types of model have been explored: psychometric, motivational, hierarchical controls, information processing and error theory (O'Neill, 1996). At a minimum, a test battery should contain a general measure of overall cognitive function, a dementia grading and include tests of attention, particularly visual attention, information processing and perception. Some matching to dementia type will be appropriate: perception in visual dementia, attention in subcortical dementias, judgement in frontotemporal dementia.

Neuropsychology test in themselves show a relatively modest correlation with driving skills in dementia and are unlikely to ever completely replace on-road driving tests (Reger *et al.*, 2004). The British Psychological Society has stated that at present no single test or test battery can be recommended as clearly predictive of fitness to drive (British Psychological Society Multidisciplinary Working Party on Acquired Neuropsychological Deficits and Fitness to Drive, 1999). Specific tests that show correlation with driving ability in more than one study include the MMSE (above), the Trail Making Test (Maag, 1976; Janke and Eberhard, 1998; Mazer *et al.*, 1998; Stutts *et al.*, 1998), and a range of tests of visual attention (Klavara *et al.*, 1995; Marottoli *et al.*, 1998; Owsley *et al.*, 1998; Trobe, 1998; Duchek *et al.*, 2003), including the 'Useful Field of View', a composite measure of preattentive

processing, incorporating speed of visual information processing, ability to ignore distractors (selective attention) and ability to divide attention (Owsley *et al.*, 1991). A range of other tests have been assessed in single studies (an interesting one is traffic sign recognition; Carr *et al.*, 1998) and a comprehensive review is available from the US National Highway Traffic Safety Administration (Staplin *et al.*, 1999). In conjunction with the clinical assessment and collateral history, these tests will help to decide which patients require on-road testing, as well as those who are likely to be dangerous to test!

A more promising approach may be by way of using a hierarchical/behavioural model. This divides the driving task in strategic, tactical and operational levels. The assessment tool examines questions of driving behaviour at strategic and tactical levels. In a preliminary study using this instrument, drivers who select driving tasks below their capacities and compensate by adapting their driving style cause fewer accidents than those who do not apply these strategies (de Raedt and Ponjaert-Kristoffersen, 2000).

Simulator testing is in its infancy: although sophisticated simulator techniques are sensitive (and safe!) (Rizzo *et al.*, 1997), the cost and complexity of an adequate simulator render the technique experimental rather than practical.

19.19 ON-ROAD TESTING

If this assessment is inconclusive, an on-road assessment is advisable. In the UK, such assessments are available from the Forum group of driver assessment centres. In the US, the Association of Driver Rehabilitation Specialists (ADED, www.aded.net) can provide the list of suitably qualified driving assessors. It is important to emphasize to the patient that this test is not the driving test used for learner drivers. Rather, this is an assessment to gain insight into both the capabilities and difficulties of the driver. A good relationship with a specialist driving assessor is an important part of the assessment process. The assessor will require a full clinical report, and may choose to use one of the recently developed scoring systems for on-road testing of patients with dementia. These include the Washington University Road Test (Hunt *et al.*, 1997) or the Alberta Road Test (Dobbs *et al.*, 1998). The latter is of interest as the authors have classified the errors made by drivers with dementia into categories of increasing significance, providing a basis for future studies.

19.20 DECISION-MAKING AND INTERVENTIONS

If the assessment points to safe driving practice, the decision to continue driving entails several components. These are:

- duration before review
- possible restriction
- driving accompanied

- licensing authority reporting relationship
- insurance reporting responsibility.

As dementia is a progressive illness, it is prudent to make any declaration of fitness to drive subject to regular review: a recent study suggests that a review period of 6 months is probably reasonable (Duchek *et al.*, 2003), or sooner if any deterioration is reported by the carer. Following evidence that the crash rate is reduced if the driver is accompanied (Bédard *et al.*, 1996), it could be considered sensible to restrict driving to exclusively when there is someone else in the car, using the co-pilot syndrome (Shua-Haim and Gross, 1996). There is also preliminary evidence from the state of Utah that those drivers with restricted driving licences have lower crash rates (Vernon *et al.*, 2002): patients should be advised to avoid traffic congestion as well as driving at night and in bad weather. The patient and carers should be advised to acquaint themselves with local driver licensing authority requirements as well as the policy of their motor insurance company. All the above should be clearly recorded in the medical notes. Except for jurisdictions where there is mandatory reporting of drivers with dementia (e.g. California and some Canadian provinces), there is no obligation on the doctor to break medical confidentiality in these cases.

19.21 WHEN DRIVING IS NO LONGER POSSIBLE

If the assessment supports driving cessation, patients and carers should be advised of this, and a social worker consulted to help maximize transportation options. Giving up driving can have a considerable effect on lifestyle. Driving is probably both a right and a privilege; however, 42 per cent of the elderly think that driving is a right as opposed to 27 per cent who think that it is a privilege (AA Foundation for Road Safety Research, 1988). However, normal elderly drivers accept that their physician's advice would be very influential in deciding to give up driving (AA Foundation for Road Safety Research, 1988) and many patients with dementia will respond to advice from families or physicians (Adler and Kuskowski, 2003).

For the probable minority who are still resistant to persuasion, removal of a driving licence represents a potential breach of civil rights (Reuben *et al.*, 1988). The way we deal with driving reflects how we help the patient to deal with the reality of the deficits caused by dementia. A more positive approach has been suggested whereby the issue of driving is treated as a part of a therapeutic programme. A case was described whereby the patient's feelings and fears about giving up driving were explored with him (Bahro *et al.*, 1995). The intervention was designed with the patient as collaborator rather than patient and by dealing with the events at an emotional rather than at an intellectual level. The patient was able to grieve about the disease and in particular about the loss of his car. This in turn enabled him to redirect his attention

to other meaningful activities that did not involve driving. Although this approach may be hampered by the deficits of dementia, it reflects a more widespread trend towards sharing the diagnosis of dementia with the patient.

If this positive approach is not successful, confidentiality may have to be broken for a small minority of cases. Most professional associations for physicians accept that the principle of confidentiality is covered to a degree by a 'common good' principle of protecting third parties when direct advice to the patient is ignored (General Medical Council, 1985; Retchin and Anapolle, 1993). Removal of the driving licence is not likely to have much effect on these patients, and the vehicle may need to be disabled (Donnelly and Karlinsky, 1990) and all local repair services warned not to respond to calls from the patient!

In the event of a decision to advise cessation of driving, advice from a medical social worker helpful in planning strategies for using alternative modes of travel. This may be difficult in a rural setting: one estimate of community transport exclusively for older people in the USA was \$US5.14 for a one-way trip in 1983 (Rosenbloom, 1993) and the political system has not woken up to the need for adequate paratransit, i.e. tailored, affordable and reliable assisted transport acceptable to older adults with physical and/or mental disability (Freund, 1991). Tailored transport (paratransit) is expensive, but may have benefits in reducing institutionalization and in improving quality of life. Psychiatrists of old age and geriatricians have an advocacy role to ensure that public policy on transportation is developed to take account of the deficiencies of transit and paratransit systems.

19.22 THE FUTURE

Several developments may attenuate the problems of the older driver with dementia. At a population level, preventive strategies for dementia may lessen the burden of cognitive disability, and strictures on the prescribing of agents such as long-acting benzodiazepines may have a positive impact on reducing crash susceptibility. Improvements in highway design, signage and Intelligent Transportation Systems may make travel safer for all.

For the individual, we still do not know whether anti-cholinesterase-inhibitor therapy can help driving skills in early Alzheimer's disease. There is also a suggestion that cognitive training with useful field of view can help driving skills in non-demented older adults (Ball and Owsley, 1994); this form of cognitive rehabilitation may be useful. Finally, older drivers can benefit from environmental and technological cueing (Dingus *et al.*, 1997); developments in this form of technology may also benefit drivers with cognitive impairment.

Africa

OLUSEGUN BAIYEWU AND ADESOLA O OGUNNIYI

20.1 Care arrangements	254	References	255
20.2 Conclusion	255		

Africa is a multiracial, multicultural society, inhabited predominantly by people of the Arabian stock in the north, while in west, east and southern Africa Negroid people predominate. There is, however, a substantial number of white settlers in southern Africa. The population of people aged 65 years and over in Nigeria is about 3 per cent (National Population Census, 1994). The figures for most countries in sub-Saharan Africa are similar. In 1997 life expectancy at birth in most African countries ranged between 38 and 59 years except for South Africa, Mauritius, Egypt, Morocco, Libya and Algeria where the figure was over 65 years. Life expectancy will increase to between 51 and 70 years in these countries by the year 2025 (World Health Organization [WHO], 1998). Many elderly in Africa are impoverished with little education and low occupational pursuit.

Epidemiological data on dementia are available from few countries in Africa; notably Nigeria, South Africa, Egypt and Ethiopia. The first report available was by Ben-Aire *et al.* (1986) who reported a prevalence of 8.6 per cent for dementia among the coloured older persons in South Africa. The Ibadan–Indianapolis study, a comparative study involving elderly African Americans in Indianapolis and elderly Nigerians in Ibadan, reported a dementia prevalence rate 4.8 per cent for community residents of Indianapolis, compared with 2.29 per cent for residents of Ibadan (Hendrie *et al.*, 1995). In the incidence study the figures were 3.24 per cent and 1.35 per cent for Indianapolis and Ibadan respectively (Hendrie *et al.*, 2001). The rates in Ibadan were much lower than the rates from Western societies.

Farrag *et al.* (1998) reported a dementia prevalence rate of 4.5 per cent, among community dwellers in Egypt, a rate which is close to the reports from Western societies. In a small study of two nursing homes in Lagos, Nigeria, 48 per cent of destitute occupants had dementia (Baiyewu *et al.*, 1997). It would therefore appear that dementia is commoner

in nursing homes even in Africa as found in Western societies. Behavioural symptoms of dementia have been reported in Nigerians (Hendrie *et al.*, 1995; Baiyewu *et al.*, 2003). Generally, the reports point to the fact that caregivers see both dementia and behavioural disorders as symptoms of ageing, so little effort is made to seek orthodox medical treatment. However, there are incontrovertible evidences that behavioural symptoms are distressful (Baiyewu *et al.*, 2003).

20.1 CARE ARRANGEMENTS

Very few facilities are available for caring for demented persons in Africa, in fact most African countries have no policies on ageing. Services available vary from country to country depending on resources. In this chapter, Nigeria and South Africa will be used as representative countries for the continent.

In Nigeria, the family provides care for the demented elderly, with little or no public assistance. Baiyewu *et al.* (2003) observed that caregivers are mostly daughters of the elderly. In a community survey in Ibadan, Nigeria 15 per cent of the elderly lived alone, while 62 per cent lived in multigenerational living arrangements (Ogunniyi *et al.*, 2001), which reinforces the role of family care. Despite the belief that dementia is part of ageing, substantial amounts of money are spent by family members seeking alternative care for dementia in the form of sacrifices with herbalists and prayers and fasting in syncretic churches (Uwakwe, 2001). Medical treatment for the elderly in Nigeria is provided through the network of primary, secondary and tertiary care facilities (Akanji *et al.*, 2002). There are psychiatric units in teaching hospitals, there are also specialist psychiatric hospitals spread all over the country. These hospitals provide treatment for all forms of mental disorders including dementia. There are about

10 nursing homes dotted all over southern Nigeria, most of which are run by churches and voluntary agencies for destitute elderly. In all they hold less than 1000 beds; this is obviously not in agreement with the recommendation of WHO that advises adequate nursing home beds for those who need them (Wertheimer, 1997).

In 2001 a geriatric psychiatry clinic was set up in the University College Hospital, Ibadan; at the same time there are emerging programmes on psycho-education for caregivers of demented individuals, pilot studies based in the community in the eastern part of Nigeria (Uwakwe, 2001). Assessment of services like these are necessary in order to determine their relevance, acceptability and effectiveness.

In South Africa there appear to be more structured programmes. There are six outpatient psychiatric facilities for the elderly and two psychogeriatric inpatient units as well as a number of nursing homes (Baiyewu and Potocnick, in press).

20.2 CONCLUSION

There is a need for more psychogeriatric assessment centres in many African countries. Establishment of such centres by both government agencies and non-governmental organizations will give elderly persons with dementia access to required help and caregivers will be assisted to look after demented individuals in the community for as long as possible.

20.6 Care and treatment of people with dementia	258	References	259

Australia is the oldest continent in geological terms and has been inhabited by modern humans for much longer than North America or northern Europe (Flannery, 1995), but until relatively recently its population was rather young because of high immigration rates. The country is now experiencing very rapid growth in its aged population with a consequent steep rise in the number of people with dementia (Access Economics, 2003).

Most of Australia's 20 million inhabitants live in cities (60 per cent of the population lives in the five state capitals of Sydney, Melbourne, Brisbane, Perth and Adelaide). The country is a federation of six states and two territories. The state governments are responsible for hospital care, but the national government provides the states with much of their revenue and administers the universal health insurance scheme, Medicare. The economy is heavily reliant upon exports of agricultural and mining products and has been in relative decline compared to other developed countries since the late 1950s. Per capita foreign debt levels are among the highest in the world (Australian Institute of Health and Welfare, 2003). In March 2005 one Australian Dollar (A\$) was worth \$US0.78, £0.41 and €0.60.

20.3 DEMOGRAPHY

There are three distinct groups of older people: the Anglo-Celtic majority, the descendants of the original indigenous Australians, and post-war migrants from Europe. One quarter of Australians aged above 60 years are migrants and 25 per cent of them come from a non-English speaking background. Aboriginals and Torres Strait Islanders account for barely 1 per cent of the elderly (Access Economics, 2003).

The number of people with diagnosed dementia in Australia in 2002 was estimated to be 162 300 or 0.8 per cent of the country's total population (Access Economics, 2003). This represents an increase from 0.6 per cent in 1993, but this rise will be dwarfed over the half century to 2051, during which time the number of people with diagnosed dementia is projected to increase to 581 300, while the country's total population rises by only 36 per cent. This rate of anticipated increase is one of the highest for any OECD country (Henderson and Jorm, 1998). The numbers would be much higher if individuals with undiagnosed mild to moderate dementia were included.

20.4 HEALTH AND WELFARE SERVICES

The Australian health and welfare system is pluralistic and complex. Services are provided by national, state and local governments and various private organizations. Medicare, a universal health insurance system financed through taxation and a compulsory income levy, reimburses part or all of the costs incurred by patients for primary medical care, diagnostic and ambulatory specialist medical care. The Pharmaceutical Benefits Scheme (PBS) pays most of the cost of approved drugs for ambulatory patients. The national government also subsidises the cost of residential aged care for eligible people. The total expenditure on health and residential care for the year 1996–97 was \$A43 billion, which represented 8.5 per cent of Gross Domestic Product. For 1993–94 the average health cost per person over 65 was \$A4919 and \$A1301 for persons under 65 (Australian Institute of Health and Welfare, 2003).

Dementia costs in 2002 were estimated at \$A6.6 billion of which \$A5.6 billion were 'real' and \$A1 billion 'transfer' costs.

The costs include residential care (\$A2.9 billion p.a. in 2002), indirect carer costs (\$A1.7 billion p.a. in 2002) and A\$592 million of tax foregone, carer payments of A\$324 million and additional welfare payments of A\$52 million. These costs are expected to double by 2010 (Access Economics, 2003). The hospital sums were determined from principal diagnoses alone and would therefore be a gross underestimate as there is no indication of hidden costs. Many individuals with dementia who enter hospitals for other conditions stay there longer than those who are free of cognitive impairment (Ames and Tuckwell, 1994). By comparison, \$A831 million was spent on hypertension, \$A894 on ischaemic heart disease and \$A630 million on cerebrovascular disease in the same year.

In the Australian health system patients see their general practitioner (GP) for initial consultations. Most GPs work in group practices and bill their older and pensioner patients only for the amount that they will be reimbursed by Medicare. Patients' visits to specialists are reimbursed by Medicare only if the patient has been referred by a GP and many specialists charge fees that exceed the Medicare reimbursement. Patients choose their own GP, may visit more than one GP, and often do, which can lead to imperfect hospital discharge planning.

The six state and two territory governments provide free hospital care, primarily to inpatients but also for some ambulatory care visits. The increasing number of people requiring hospital care and constraints on hospital funding have led to significant delays for admission for 'non-urgent' treatment (e.g. joint replacements). Funding for public hospitals comes from the national government by way of grants to the states from funds raised by income tax. Private health insurance covers hospital and some non-hospital care, but premiums have risen faster than inflation in recent years. Until the end of the last century and introduction of a subsidy scheme financed by the national government, there had been a marked decrease in the number of people in private health insurance, though the fall was least in those on the old age pension. This trend has reversed and over one-third of Australians have private health insurance now. Extra health and welfare benefits are provided for war veterans, most of whom are elderly.

Community services, such as home care and delivered meals, used to be provided by local government, with funding from both state and national governments. Although the funding sources remain unchanged, these days the services are often delivered by private or not-for-profit organizations, which have tendered to provide them.

The disparate nature of the funding and service provision means that organizations providing services for older people are often required to contract with several levels of government and various programmes of the same government to obtain funds. Trials of pooling funding and coordinating care are underway, but the impediments to change are enormous and include the Australian Medical Association, who see this as the 'thin edge of the managed care wedge' (Messenger, 1999).

20.5 ASSESSMENT OF PEOPLE WITH DEMENTIA

20.5.1 General practitioners (GPs)

Reviews show that most GPs have difficulties diagnosing and managing dementia, and that assessment protocols could prove useful (Brodaty *et al.*, 1994), especially those that indicate when to use cognitive instruments; this need is being addressed (Brodaty *et al.*, 1998, 2002). The GP is often the first point of contact for a patient or carer seeking help, yet there is a perceived need for increased coordination between the GP and local services, and better understanding by the GP of the possibilities of 'shared care' for those affected by dementia (Pond *et al.*, 1994; Shah and Harris, 1997). The assessment and management of a person with dementia and their carer is time consuming; however, the reimbursement structure has been adjusted to pay GPs for time spent meeting families or contacting other services.

20.5.2 Aged persons' psychiatry services

The state governments provide psychiatric services. Services for the old in the state of Victoria comprise a regional network of community aged psychiatry assessment and treatment teams (APATTs), linked to specialist aged psychiatry inpatient units with 15–30 beds in modern hospitals, co-located with aged care and adult psychiatry services. The teams are multidisciplinary and cover the entire state. Patients are assessed in their usual abode at the request of a GP, another health worker, family member or other carer. The APATTs provide a continuing care and support service to help patients to remain at home or to return there after discharge from an acute ward.

Limitations on these services relate to a relative lack of psychiatrists willing to undertake salaried public practice and to modest funding for other staff, which limits the community services to office hours, but service provision has expanded in recent years. Old age psychiatry services in other states are variable, but less well developed than in Victoria. The best of the rest are in New South Wales and South Australia.

20.5.3 Geriatric services and Aged Care Assessment Services (ACASs)

The ACASs were set up in 1984 and cover all of Australia (Howe, 1997). They may be co-located with regional geriatric hospital services or with specialist mental health services for the aged, or other health or welfare services. ACASs are funded by the national government to ensure that all people referred to residential care actually need it. Referrals are taken from patients, carers and health workers, including GPs and hospitals. Those referred are assessed at home or in hospital. The teams are multidisciplinary. Occupational therapists, physiotherapists, community nurses and geriatricians

often see patients whose needs can be met at home with supports, which the ACAS will arrange. Other allied health staff (e.g. pharmacists and dietitians) are attached to some teams. ACASs provide assessment but do not offer continuing care. The majority of people assessed by an ACAS have evidence of dementia or other cognitive impairment (LoGiudice *et al.*, 1995).

20.5.4 Memory clinics

In 1998 the Victorian government, acting on the report of a Ministerial Task Force (Ministerial Task Force on Dementia Services in Victoria, 1997) established 14 regional Cognitive, Dementia and Memory Services (CDAMSs) across the state to provide multidisciplinary assessment of people with dementia, and their carers. CDAMSs aim to provide integrated services throughout the 'pathway of dementia' at all levels of the healthcare system. A number of clinical indicators are used to evaluate the services. They include: prompt response to and assessment of referrals, adequate counselling of carers and the development of links with GPs and other care services. Patients have the option of being assessed at home.

Specialized memory clinics operate in major cities outside Victoria but have no distinct pattern or specific government funding, each being the brainchild of a particular specialist. Some are privately operated. Attendance by people with dementia at a memory clinic, which provides education, counselling and referral to services, seems to improve the quality of life of family carers (LoGiudice *et al.*, 1999).

20.5.5 Private specialists

Many patients with dementia see psychiatrists, neurologists or general physicians for initial assessment. There are no complete data on these referrals but younger and wealthier dementia patients are more likely to be referred to a private specialist. The patient may then be referred on to an assessment service for further assistance.

20.6 CARE AND TREATMENT OF PEOPLE WITH DEMENTIA

20.6.1 Community and non-residential services

Family and other informal carers provide most care to those with dementia. They experience high levels of stress (Brodsky and Hadzi-Pavlovic, 1990) and the carer's own GP is often unaware that they are looking after an older person (Payda *et al.*, 1999). A range of community options is provided to help people with dementia to continue living in the community, especially straight after discharge from a hospital. Many of these services are provided by brokerage from a case manager

and are part of broader schemes to replace residential care with community care.

20.6.2 Alzheimer's Australia

An Alzheimer's Disease and Related Disorders Society was set up in 1985. It has undergone two changes of name and is now known as Alzheimer's Australia. Branches operate in each state and territory. Its goals include national dementia policy development, sharing of resources and expertise, and liaison with Alzheimer's Disease International. State branches provide education and counselling for those with dementia, their families, other carers and paid care workers. Alzheimer's Australia provides a national telephone advisory service ('Dementia Helpline').

20.6.3 Residential care

Residential care is provided by a variety of organizations including state governments, private operators and charitable organizations. People with dementia are heavy users of residential care. The national government subsidises and regulates residential care facilities. Two levels of care are provided. Low care facilities (previously called hostels) provide meals and assistance with activities of daily living including the administration of medication. High level care facilities (formerly called nursing homes) offer 24-hour nursing care and the majority of residents in these facilities have dementia (Henderson and Jorm, 1998). Some patients in low level care can have additional help funded to enable them to remain where they are instead of moving to high level care ('Ageing in Place').

20.6.4 Access to drug treatments for dementia

Since February 2001 it has been possible for patients to have most of the cost of treatment with a cholinesterase inhibitor paid for by the PBS if they have been assessed by a physician or psychiatrist who has certified that they have Alzheimer's disease of mild to moderate severity and that they meet other cognitive score-based criteria. The complexity of, and frequent changes to, these rules, and a relative lack of specialists interested in dementia probably cause cholinesterase inhibitors to be underprescribed and commenced at a later stage of the illness than would be ideal. Memantine is available but unsubsidized so few patients take it. Many patients with behavioural and psychological symptoms of dementia receive drug treatments. The prescription of subsidized novel antipsychotics via the PBS as limited to individuals whose doctors would state that they have a diagnosis of schizophrenia, until 2005 when low-dose risperidone was approved for subsidy when prescribed to patients with behavioural disturbance in the context of dementia.

20.7 RESEARCH AND REVIEWS OF SERVICES

20.7.1 Research

Australian researchers have made major contributions to knowledge about dementia, especially in epidemiology, neuropathology, new drug evaluation and carer support (Ames, 1997) and despite modest government research funding, this effort continues.

20.7.2 Reviews

There have been multiple reviews of existing services and of pilot schemes to provide new or integrated services for patients and carers. The national government released a National Action Plan for Dementia Care (NAPDC) in 1992, a mid-term report of the Plan in 1996 (Howe, 1997) and two national mental health plans in 1992 and 1998. An evaluation of the NAPDC indicated a need for further integration and development of demonstration programmes, resources and education strategies. Populations who were highlighted as requiring special attention included Aboriginal and Torres Strait islanders, immigrants of non-English-speaking background, and younger people with dementia. The desirability of managing dementia in the acute healthcare and primary care settings was emphasized. A Ministerial Working Party Report to the Victorian government led to the funding of regionalized CDAMS (Ministerial Task Force on Dementia Services in Victoria, 1997) and a recent review supported the ongoing role and funding of these clinics (Department of Human Services, 2003).

20.8 EDUCATION AND TRAINING

Australian medical education has undergone great change since 1990. Of the 10 established and three new medical schools, five offer graduate-only programmes and all are implementing new curricula. Nearly all of these curricula are integrated, combining basic science with clinical teaching and use problem-based learning. These curricula are too new for their outcomes to be judged. There are five professors of old age psychiatry and most medical schools have an old age psychiatrist at senior lecturer level or above. Departments of geriatric medicine are well developed and are usually led by a professor.

All nursing education is university based. There are chairs of gerontic and psychiatric nursing with postgraduate training available in these and other fields. Allied health training is via an undergraduate degree with additional postgraduate study for some disciplines such as psychologists.

The medical colleges all expect their fellows to undertake continuing medical education and for some, such as the

Royal Australian College of General Practice, there is a financial incentive to do so. Academics provide some courses for GPs on the basics of assessment and management of dementia. Since cholinesterase inhibitors started to be reimbursed through the PBS some pharmaceutical companies have paid for GPs to receive education about aspects of dementia.

20.9 THE FUTURE

Changes in education for health professionals, both at undergraduate and continuing medical education level, provide opportunities for educators to develop and implement modules that teach the basics of dementia assessment and care to a majority of health professionals in Australia.

There is hope that the steady improvements in services for people with dementia that have occurred since the mid-1980s will continue. All levels of government acknowledge the rapid ageing of Australia's population and that this phenomenon will be associated with a huge rise in the number of people affected by dementia (Howe, 1997). The costs of providing services to a rapidly growing elderly population in the context of relative economic decline may constrain further improvements and even the maintenance of services in the end, but this has not happened yet.

20.12 Caregivers and care-settings for people with dementia	262	References	264
20.13 Key factors in service delivery for people with dementia	263		

20.10 AGEING IN CHINA

The proportion and absolute number of elderly people in the total population of China has increased in recent years as the rate of ageing has accelerated. Chinese life expectancy reached 70 years in 1993. In 2000, elderly people comprised 10.2 per cent of the population, 129 million elderly (Lu Zhishan, 1994) (Table 20.1). In Shanghai, the largest city in China, people over 60 form 18.2 per cent of the city's 14 million population.

China became an elderly nation by the end of last century, but professional and social infrastructures have not been organized to meet the challenge of ageing. The 1 per cent sampling survey showed that the average family size in 1995 was 3.7, a 0.3 reduction compared to the 1990 national population survey (Chinese National Statistical Bureau, 1995). Thus in China, the traditionally valued extended family in which three or even four generations live together has weakened. Although the one child per family policy (which was first initiated in the 1980s) has been implemented mainly in urban areas, rural families are getting smaller in the same way. There are several reasons for this change.

- People have the freedom to choose where they live since housing has become a commodity. Young people prefer to move out from old dormitories which were allocated by the government to new apartments, leaving their elderly parents at home.
- People have more freedom of migration. Because of the disparity of economic development and a continuous decrease of arable land in the countryside, labourers tend to move from western and central parts of China to the east and coastal areas. More importantly, living and working in cities is no longer a crime for country boys and girls but the right of a citizen. Thus villages are more and more forgotten places full of elderly people and children.
- In the final quarter of last century, many unpredicted changes occurred in China. For the first time in thousands of years, the authority of the elderly is being questioned, especially when they are living on limited pensions while their children are enjoying the fruits of the market economy. 'Reverence to elderly' is repeatedly emphasized in the media, not because the Chinese are still proud of it but because it is felt that this virtue is threatened by social reform.

Table 20.1 Prediction of the ageing population in China

	1985	1990	1995	2000	2025	2050
Total population in China (millions)	1049.00	1143.33	1197.00	1270.00	1498.00	1547.00
Aged population (millions)	86.00	98.21	116.00	129.00	264.00	331.00
Aged/total population(%)	8.2	8.6	9.7	10.2	17.6	21.4

20.11 EPIDEMIOLOGY OF DEMENTIA IN CHINA

Dementia used to be an unusual condition even for psychiatrists. Not only were the elderly a small portion of the total population two decades ago, but people with dementia were rarely seen in clinical practice.

In 1986 the first epidemiological study of age-related dementia on a population aged 60 and over in China was conducted in an urban area of Beijing (Li Ge *et al.*, 1989). In this study, 1090 elderly people were screened using the Mini-Mental State Examination (MMSE), the suspected cases were interviewed by psychiatrists, DSM-III was adopted for diagnostic criteria, and Dementia Differential Diagnostic Schedule (DDDS) for differential diagnosis. Fourteen cases of moderate and severe dementia were identified, with a prevalence rate of 1.3 (≥ 60) and 1.9 per cent (≥ 65), respectively.

Table 20.2 lists important epidemiological studies on dementia in the past 10 years. Lai Shixiong and colleagues (2000) did a survey in a group of people older than 75 and showed that the prevalence rate of dementia especially Alzheimer's disease (AD) was much higher in this age group. Zhang Mingyuan and his colleagues (1990) indicated that loss of spouse and lower economic status were more common in dementia patients.

A nationwide survey on the epidemiology of dementia included 42 890 people aged 55 and over in six rural and six urban areas of China (Twelve Areas Epidemiological Investigation on Mental Disorders Coordinating Group, 1986). Although the final paper has not yet appeared some reports have been published and some of the results are listed in

Table 20.2. The survey suggests that AD is the major type of dementia in old age and more prevalent in men. Vascular dementia seems more common in rural areas.

20.12 CAREGIVERS AND CARE-SETTINGS FOR PEOPLE WITH DEMENTIA

20.12.1 Where are the aged living?

Most of the Chinese elderly age at home. A survey by the ministry of social welfare demonstrated that 11 per cent of the elderly intended to live in nursing homes, i.e. 14 million people felt difficulty in living alone. However, there are only 1.04 million beds in a total of 51 000 residential institutions for the elderly. Furthermore, among these 1.04 million beds, the occupancy rate is only 70 per cent.

What makes these residential institutions unpopular with elderly people? First, these institutions are usually located in the countryside, far away from families, necessary facilities, and medical services. Second, these institutions are under-resourced, understaffed, and poorly equipped. They have no qualifications to take care of elderly people with medical conditions, much less of dementia.

20.12.2 Psychiatric services for people with dementia

With the astonishing recent changes in society and public health, Chinese psychiatrists also face a great challenge never

Table 20.2 Prevalence rates* of dementias in China

Author	Location	Population	Diagnostic Criteria	Results
Zhang Mingyuan <i>et al.</i> (1990)	Shanghai, urban area	5055 (≥ 55)	DSM-III-R	>55:2.57%; >65:4.61%
Chen Changhui <i>et al.</i> (1992)	Beijing, urban community	5172 (≥ 65)	DSM-III	1.03%
Gao Zhixu <i>et al.</i> (1993)	Shanghai, both rural and urban areas 3779 rural/urban:	2560/1219	DSM-III-R	4.21%
Tang Muni <i>et al.</i> (1999)	Si Chuan, rural areas	5987	DSM-III-R NINCDS-ADRDA	1.74%
Lai Shixiong <i>et al.</i> (2000)	Guangzhou, urban area	3825 (≥ 75)	DSM-III-R, NINCDS-ADRDA	8.90%
Qu Qiumin <i>et al.</i> (2000)	Xian, both rural and urban areas	4850 (≥ 55)	DSM-IV, NINCDS-ADRDA	3.53%
Zhou Bin <i>et al.</i> (2001)	Shanghai, both rural and urban areas	17018 (≥ 55)	DSM-IV, NINCDS-ADRDA	2.03%
Zhang Zhenxin <i>et al.</i> (2001)	Beijing, both rural and urban areas	5743 (≥ 55)	DSM-IV, NINCDS-ADRDA	4.2%
Tang Zhe <i>et al.</i> (2002)	Beijing, both rural and urban areas	2788 (≥ 60)	DSM-III-R, NINCDS-ADRDA	5.1%

* Except for two prevalence rate studies on vascular dementia (VaD) conducted in Beijing in the early 1990s, all studies indicate that the prevalence rate of VaD is lower than that of AD

seen before. In 1997 there were 485 psychiatric hospitals in China, which could offer 107 362 beds; 13 912 doctors were working in psychiatric hospitals. Unfortunately, facilities for elderly patients are very limited. Accurate figures are not available, but it is estimated that fewer than 10 per cent of beds in each psychiatric hospital serve the elderly. Qualified geriatric psychiatrists are even fewer, proportionally.

20.12.3 Living in communities

Two studies in Beijing and Shanghai indicated that demented people were mainly looked after by their families at home (96.3 per cent vs 87.3 per cent) (Li Yongtong *et al.*, 1990; He Yanling *et al.*, 1995). Wu Wenyuan *et al.* (1995) evaluated the total burden of dementia caregivers compared with normal controls. The study suggested that dementia caregivers had more care burden, especially when the caregivers were female, and those with dementia were male. He Yanling *et al.* (1995) also indicated that dementia caregivers had more depressive and somatic symptoms than normal controls. Taking care of people with dementia is distressing work. The work is harder if the family is living in a community in which few resources are available.

20.13 KEY FACTORS IN SERVICE DELIVERY FOR PEOPLE WITH DEMENTIA

20.13.1 Government

The government plays a leading role in each aspect of social activities in China. Medical services are regarded as one part of the social welfare system. The government plans to build up the tertiary medical service delivery system in which the focus is on community health care. However, in China, there was no such thing as a community until a decade ago. The Chinese used to live in government dormitories assigned by work units (known in Chinese as *danwei*). A professor's next door neighbour could be a cleaner who worked in the same unit. Only when housing became merchandise and free mobility was allowed, could people live together according to their income, taste, and other social characteristics. The modern community is just developing in China. 'The Dormitory form' community was closely linked to where people worked, thus administration and supervision were easy and simple. The old primary care service was based on this system. With the collapse of old communities and rise of new ones, the primary healthcare system needs to be reformed. The pathway from community-based care to tertiary care is not well structured. The deficiency was completely exposed during the outbreak of the severe acute respiratory syndrome (SARS): the primary healthcare system did not work as a doorkeeper to keep suspected cases in communities, thus more and more people rushed into tertiary hospitals and got infected or infected others. The government has been aware

of the importance of community health care, but feels perplexed when putting it into practice. No referral system between primary, secondary and tertiary health care is established yet. Primary healthcare workers are usually poorly trained. Medical insurance companies are not willing to cover primary health care since they are not confident in the quality of service provided. The government encourages neighbourhood committees to set up nearby residential institutions for local elderly people, but medical services, administrative arrangements and personnel resources are not ready for these institutions to admit people with dementia.

20.13.2 Non-governmental organizations (NGOs)

Many NGOs, both academic and non-academic, can help in building up care systems for people with dementia. The Chinese Society of Psychiatry is drafting treatment guidelines for dementia in the elderly. The Chinese Society of Neurology conducted a nationwide survey on the prevalence of dementia in the elderly in four areas in China. Alzheimer's Disease of China has organized public education campaigns on World Alzheimer's Disease Day for three years. The Chinese Federation for the disabled and handicapped has helped to establish nursing homes for poorly functioning elderly people.

20.14 FUTURE PROSPECTS

When Japan became an elderly nation in 1970, its GDP per capita was \$US1689. China transformed to an elderly nation with a GDP per capita of less than \$US800 in the year 2000. Moreover, the government has no accumulated monies for the current generation of elderly since their working years were in the period of the 'planned economy', when there were no such things as insurance, or savings for pensions. Institutional care for people with dementia is completely unaffordable for most families. An optional solution for providing a decent service for dementia patients is to develop home care. In order to keep people with dementia at home as long as possible, the following considerations should be taken into account:

- The community should be empowered for self-administration in order to make the welfare of its members its first priority.
- Facilities and resources in the community can be available for families who are taking care of people with dementia at home.
- Primary health care should be qualified to provide necessary services for those with dementia.
- Tertiary, secondary, and primary healthcare systems should be organically integrated so that people with dementia can be shifted freely if needed.
- Social welfare agencies, and medical insurance organizations should adopt more flexible policies

to cover part of the expenses of caring for people with dementia at home and to compensate family caregivers.

- Finally, nursing homes, which are specific to dementia care, should be established. Some of the 5 million people with dementia will always need decent places for the final phase of their lives.

20.15 CONCLUSIONS

China is becoming an ageing society with surprising speed, while dementia becomes a challenge as prominent as it is in Western countries. Social and economic development is at a relatively low level that cannot meet the needs of people with dementia in any existing models. A unique service delivery system for dementia care should be developed which takes account of Chinese realities.

The Former Soviet Union

ROBIN JACOBY

20.16 Demography and epidemiology	265	20.18 Future developments	266
20.17 Old age psychiatry services	265	References	266

In the previous edition of this book, Poznyak and Solodkaya (2000) described very clearly the services available, or rather the lack of them, for older people living in the former USSR. In summary, they depicted countries with large populations in which overall life expectancy was decreasing, especially for males, but the proportion of older people was increasing. Rates of mental illness were high; levels of service provision were low; the focus of care was essentially institutional; and professional training was only just beginning to develop. What, therefore, has changed since then?

20.16 DEMOGRAPHY AND EPIDEMIOLOGY

United Nations data and projections continue to demonstrate a marked divide between declining overall populations in former Soviet countries and a growth in the proportion of those aged 65 and over. This is shown in Table 20.3 using the same countries as in Poznyak's and Solodkaya's table (2000, p. 349). The divide is greatest in the two most populous countries, Russia and Ukraine, which contain about 190 million people. Put crudely, but accurately, Russians and Ukrainians eat diets high in saturated fats, smoke tobacco excessively, and have high rates of alcoholism, tuberculosis (TB) and HIV/AIDS. Together with poorer standards of public health provision than were offered by the USSR, these facts conspire to reduce survival in adults of working age, especially males. As in Western countries, although for different reasons, there are fewer economically active persons to provide resources for more old people.

Poznyak and Solodkaya (2000) indicated that ICD-10 was beginning to make an impact in former Soviet countries. There is no doubt that this is increasingly true, helped by dissemination of relevant literature in Russian (Cooper, 2000; Goldberg, 2000). However, given the geographical vastness of the USSR, modern epidemiological literature is extremely

sparse. In a survey of 1109 people of 60 and over in part of the Moscow area, Gavrilova and Kalyn (2002) found that 36.6 per cent suffered from some form of disorder definable by ICD-10. Furthermore, when they compared the results of one study conducted 10 years before with another 10 years after the collapse of the USSR, they found an increase in mental disorders that they attributed to the stress caused by the immense social disruption and poverty of the immediate post-Soviet period.

20.17 OLD AGE PSYCHIATRY SERVICES

The basic structure of services, insofar as they exist, has not changed since Poznyak and Solodkaya (2000) described them in the last edition. There are very few psychiatrists whose practice is only with older patients. The focus remains institutional. At primary care level there are polyclinics in which psychiatrists sometimes work. Mostly, however, polyclinics are staffed by primary care physicians (PCPs), so-called *terapevty* (терапевты). Boundary disputes between PCPs and psychiatrists are common, with psychiatrists claiming that only they are qualified to treat mental disorders. Given that there are not nearly enough psychiatrists and secondary resources in rich Western countries to treat all patients with mental disorders, and that the majority have to be treated in primary care, it is clearly nonsensical for psychiatrists in former Soviet countries to claim such restrictive practices. In some places, however, encouraged by Western non-governmental organizations (NGOs) who provide teaching and written material in Russian, PCPs are being taught to diagnose and treat suitable cases of depression and other disorders.

Specialist psychiatric resources include:

- outpatient clinics at so-called dispensaries (диспансеры);

Table 20.3 Population data and projections from four former Soviet Republics (Source: United Nations Population Division)

Country	Year	Total population (millions)	Age 65+ (%)
Belarus	2000	10 034	13.7
	2005	9 809	14.9
	2010	9 612	14.4
	2020	9 208	16.3
Kazakhstan	2000	15 640	6.9
	2005	15 354	8.6
	2010	15 130	8.4
	2020	15 422	10.1
Russia	2000	145 612	12.5
	2005	141 553	14.1
	2010	137 501	13.3
	2020	129 018	16.7
Ukraine	2000	49 688	13.8
	2005	47 782	15.9
	2010	46 038	15.9
	2020	42 605	17.5

- inpatient wards at large mental hospitals;
- and beds in institutions for the chronic mentally ill (*internaty*/интернаты).

Both hospitals and *internaty* do have some wards specifically for older patients, but many of the latter are treated in standard general adult psychiatry wards, not unusually containing around 70 patients, with two or three nurses per shift. Whether housed on specialist old age psychiatry or general adult wards, older patients have to put up with facilities that would be considered scandalous in richer Western countries (see Plates 6 and 7), reflecting not only the low status of the mentally ill, but also the lack of resources that the authorities wish or feel able to put into psychiatric services.

Many old persons with mental disorders, including dementia, live at home, some, but not all, known to psychiatric services. Apartments are small and often house three generations of one family. The younger adults have to work hard, frequently doing two or three jobs to maintain a reasonable standard of living. If a grandparent suffers from dementia, enormous strain is placed on the shoulders of younger members. Since it is known how bad the alternative to home care is, efforts are made to keep elderly relatives at home beyond a stage that would be considered tenable in Western countries. On the other hand, families are forced frequently to institutionalize a demented relative simply in order to maintain a reasonable income.

In most former Soviet countries the Ministry of Social Protection provides some home-care services, but with untrained staff who are generally reluctant to be involved with mentally ill clients, the latter being regarded as problems

for the health services. Thus, community services are poorly coordinated between healthcare and social welfare, exacerbated by an unwillingness for the two relevant ministries to collaborate.

20.18 FUTURE DEVELOPMENTS

Although it is difficult to avoid the conclusion that too little has been done to improve services for the elderly mentally ill in former Soviet countries and that a huge injection of resources is needed to bring them up to acceptable levels, it would be wrong to assume that the future is entirely bleak. There is no shortage of manpower and no lack of enthusiasm in younger professionals to see change. Resistance to change comes from the old Soviet *nomenklatura* (establishment) who remain in positions of power but are not, of course, immortal. Western NGOs, such as the Geneva Initiative on Psychiatry*, raise money to print material in Russian (e.g. Jacoby and Oppenheimer, 2003), and organize courses in old age psychiatry given by Russian-speaking Western psychiatrists. The demand for the written material and the courses outstrips the ability to provide them. A great deal of time and money are required to repair the harm done by Soviet power to all aspects of life in the countries it dominated for 70 years, but the peoples of these countries want change and are certainly intelligent and resourceful enough to achieve it.

20.19 Alzheimer's disease clinical and research centres	267	20.23 Nursing homes	268
20.20 Local memory centres	267	20.24 Home care	268
20.21 Inpatient units	267	20.25 Family association	268
20.22 Day hospitals	268	Further reading	268

Alzheimer's disease (AD) is a common disease in France, with more than 700 000 patients and approximately 140 000 new cases each year. Owing to the burden related to this disease many initiatives has been realized in the past few years to care those patients.

20.19 ALZHEIMER'S DISEASE CLINICAL AND RESEARCH CENTRES

The French government developed recently an Alzheimer Plan. Part of this plan was the accreditation of 16 CMRRs (Centres Memoire de Recherche et de Ressources – Memory Research and Resource Centres). These centres of excellence comprise clinics, research and education in the field of AD at the top levels. They are formed from Neurology, Psychiatry or Geriatric departments.

The four CMRRs from the South of France (Bordeaux [Pr Dartigues], Toulouse [Pr Vellas], Montpellier [Pr Touchon], Nice [Pr Robert]) decided to create the F-CMRR-SF (Federation of the Alzheimer's Centres from the South of France). The advantage of this federation is to associate four CMRR from different specialities (neurology, psychiatry, geriatric and public health). Medical directors have a weekly telephone conference.

A national federation of the CMRR is in process. Some projects of the F-CMRR-SF and the national federation are:

- a common computerized patient medical chart;
- common educational projects;
- jointly research projects.

20.20 LOCAL MEMORY CENTRES

Moreover, approximately 200 local memory centres (CMPs, Centres Memoire de Proximite) have been identified. To be selected each centre must have a multidisciplinary team including neurologist, geriatrician, psychiatrist and neuropsychologist.

Some other initiatives are also being developed such as a standardized neuropsychological and geriatric assessment for each of these memory centres, as well as a standardized form to follow the patients.

The PHRC (Programme Hospitalier de Recherche Clinique), financed by the French ministry of health, decided to fund some large collaborative programmes. One is the ReAl.Fr project (Reseau Français sur la Maladie d'Alzheimer). The aim of this project is to follow for 4 years a cohort of 700 elderly patients with AD living at home, with a monthly assessment follow up (Principal Investigator: Pr Vellas).

One other programme aims to develop and validate a 'Care Plan Project' for the AD patients, with a standardized follow up every 6 months; 1200 AD patients over France will be part of this programme, involving 80 CMPs, half in the control group and half in the care plan intervention group.

There is also one other PHRC again financed by the French Ministry of Health – Focus on MCI Patients (Principal Investigator: Pr Dubois).

20.21 INPATIENT UNITS

The first acute care unit for AD patients was created over 10 years ago in the Toulouse Alzheimer's Centre, Toulouse

University Hospital. Since that date, acute care units for AD patients have been created in several university hospitals in France. These acute care units, usually part of a department of internal medicine and geriatrics, are able to receive patients with AD 24 hours a day, all year round. Usually 30 per cent of the patients come for difficult diagnosis, 40 per cent for complications related to the disease, mostly behaviour disorders, and 30 per cent for associated disease like pneumonia, weight loss or anorexia. These units play a major role in the care of the patients, linking together with home care and nursing home care. They work also closely with the emergency department of hospitals.

20.22 DAY HOSPITALS

We have two kinds of day hospital in France: those related to CMRR or CMP are involved in the diagnosis and patient follow up; and respite day care for AD patients. These respite day care centres are mostly in the community.

20.23 NURSING HOMES

They are approximately 10 000 nursing homes in France, around 30 per cent of which have special care units for severely demented patients. The criteria for special care are:

- to receive demented patients;
- to have a special care plan for dementia;
- to have special environmental design;
- to keep the family involved;
- to have a special training programme.

Every 2 years a national congress on SCU is organized, with more than 1000 participants attending.

20.24 HOME CARE

Home care for AD patients is largely developed in France, with special funding to care for the elderly with loss of autonomy, giving them money to receive help to perform basic activities of daily living at home. Nurses and physicians are likely to visit their elderly patients at home. More than 25 per cent of AD patients from the REAL-FR study are living at home alone with help.

20.25 FAMILY ASSOCIATION

Family associations like France Alzheimer are very much involved and active in France at the both national and regional levels. There are also many other initiatives presently being developed in France in the field of AD care, including aspects of ethics. However, there is more to be done in France: as in many other countries, only 50 per cent of AD patients are diagnosed, 30 per cent are undertreated, and still fewer have a really long-term and well-evaluated healthcare plan programme.

20.26 LONG-TERM CARE INSURANCE AND MEDICAL TREATMENT OF INDIVIDUALS WITH DEMENTIA

Among the population in Germany who are over the age of 65 years, about 1 million individuals suffer from moderately severe to severe dementia (Bickel, 2001). About 40 per cent of them are institutionalized in residential and nursing homes, while 60 per cent live in private households and are generally cared for by family members.

In Germany statutory health insurance generally covers the costs of medical services. However, the provision of long-term care for elderly patients suffering from chronic disorders such as dementia places an enormous emotional and financial burden on both patients and their families. To alleviate this situation, legislation establishing a system of statutory long-term care insurance came into effect on 1 January 1995, with automatic coverage for people who are covered by statutory health insurance. The system of statutory long-term care insurance offers financial aid ranging from 205 € (Euros) to 1688 € per month depending on the nature and extent of the demand for basic nursing care and household help. However, the need for general care and supervision of persons with mental disorders (which accounts for a major portion of the costs for care of those with dementia) is not taken into consideration when long-term care insurance benefits are assessed. In order to better meet their needs, since 2002 those in need of care who are residing in private households and who can justifiably claim for substantial general care and supervision can claim additional financial aid up to a total of 460 € per year. However, no current figures are available as to the number of claims filed or the sum of benefits paid on behalf of dementia patients.

Over 90 per cent of the adult population visit a primary care physician at least once a year. The percentage among the elderly is even higher and their annual consultation rate is well above average. Most patients with dementia first consult a primary care physician, many of whom are not well enough informed about or trained to deal with gerontopsychiatric disorders. They rarely refer patients with dementia to mental healthcare institutions. Results of various studies show that the use of psychiatric institutions and services drops sharply from roughly 25 per cent by the 65–74-year-olds in need of care to less than 10 per cent by those over the age of 75 years (Bickel, 2003). This seems due in part to a sense of nihilism with regard to dementia patients. This attitude is also reflected by the relatively low number of prescriptions for antidementia drugs. From 1992 to 2000 the number of prescribed daily doses of antidementia drugs in Germany dropped by 60 per cent, from 516 million to 215 million. This indicates a marked and increasing undersupply of the affected population with these medications. Two regional studies showed that on average only 10 per cent of Alzheimer patients are treated with acetylcholine esterase inhibitors (Demling and Kornhuber, 2002).

Over the past 20 years, more than 70 memory clinics have been established. These outpatient services specialize in the early recognition of cognitive problems, the diagnosis of dementia, pharmacological treatment and clinical trials, the development of non-pharmacological treatment strategies, the support and counselling of patients and their relatives and the support and advanced training of primary care physicians and psychiatrists (Kurz *et al.*, 2003). Memory clinics are usually integrated into university hospitals and are heavily committed to research. Their services are generally not covered by statutory health insurance. Owing to the limited number of memory clinics and the particularities of their

funding, they are not a standard component of the system of ambulatory dementia care (Stoppe, 2002).

Facilities and services that play an important role in the care of dementia patients in Germany will now be discussed.

20.27 CARE FOR COMMUNITY-DWELLING PATIENTS

20.27.1 In-home services

In-home services provide mainly medical treatment measures (dressing of wounds, administration of injections, etc.), basic nursing care (personal hygiene, etc.), and – to a lesser extent – household help for patients living at home. Upon the introduction of long-term care insurance, which prioritizes ambulatory care over inpatient care, it was expected that there would be a regular rush by claimants on such ambulatory care providers. Indeed, their number has increased markedly since then: from roughly 3000 in 1993 to 12 596 licensed services in October 2000. Nonetheless, only about 27 per cent of those eligible for benefits of long-term care insurance and who reside in private households file claims for the care or household help available from the ambulatory services (Bundesministerium für Familie, Senioren, Frauen und Jugend, 2002). Claims solely for financial benefits were filed on behalf of 73 per cent of eligible patients, meaning that their care will be provided exclusively by private caregivers, usually family members. At present, no estimate of the current demand by dementia patients for in-home services is available. Results of an earlier study indicate that approximately 1 out of 10 dementia patients living at home in the southern Germany city of Mannheim made use of an ambulatory care service (Schäufele *et al.*, 1995). The study also revealed that the services in themselves cannot provide the necessary complete support. In particular, weekend service, in-home supervision, or activating care, all of which are essential in dementia care, are available on a limited basis, if at all. Moreover, the costs for these services are not covered by the long-term care insurance but must be borne by the patients themselves.

20.27.2 Geriatric day and night care

Semi-inpatient services constitute the link between in-home and institutional long-term care. They are an important component of the system of geriatric care, providing elderly individuals in need of aid with qualified assistance on work-days from the morning throughout the afternoon (day care) or from the evening throughout the night (night care).

The first geriatric day care centres in Germany were established in 1973 with the aim of preventing or at least prolonging the often unwanted and expensive referral to a nursing home. Despite the strong increase in the number of day care centres within the past 25 years, they remain less important than institutional long-term care. A study carried out in

17 centres providing geriatric day care revealed that slightly more than half (58.6 per cent) of their clients suffered from dementia (Weyerer and Schäufele, 1999). Dementia patients who regularly wander off or who exhibit a high potential for aggression cannot be cared for in geriatric day care centres (Kurz *et al.*, 2003).

Disorders of circadian rhythm particularly complicate the in-home care of dementia patients. For this reason, night care has been available in Germany for a number of years. Approximately 1400 night-care beds were created; however, at 13 per cent the demand lags far behind the supply (Schneekloth and Müller, 2000).

20.28 CARE FOR RESIDENTS OF OLD-AGE HOMES

The type of care provided by old-age homes has changed greatly in Germany over the last 20 years: the original focus on residential care has since given way to nursing care. In 1999 the number of old-age homes in Germany totalled 8859, most of them nursing homes, with altogether 645 456 beds (Bundesministerium für Familie, Senioren, Frauen und Jugend, 2002). In Germany, as in most other industrialized nations, nursing-care facilities are key providers of dementia care. Cost estimates for dementia indicate that long-term institutional care in nursing homes accounts for 50–75 per cent of the total direct costs (Bickel, 2001).

A move into institutional care is all the more probable in cases of advanced dementia. Recent results indicate that up to 80 per cent of the affected population will enter a nursing home during the course of dementia, remaining there until their death, because in-home care can no longer be guaranteed. Residential nursing-care facilities in Germany were unprepared for the shift in the numbers of demented patients, who now constitute the majority of residents: currently approximately 60 per cent (Weyerer *et al.*, 2001). The work load and stress upon nursing staff have increased accordingly. This development is a major challenge to the principle of integrated care. Lately political efforts have been made to improve the institutional care of dementia patients. Special types of augmented care, such as partially integrated approaches (special day care for dementia patients) or segregated approaches (for example, special care units) have been introduced, accompanied by architectural and conceptual changes and advanced training for the nursing staff.

The forerunner of this development in Germany was the city of Hamburg, which in 1991 made 750 beds available in 30 nursing-care facilities as part of the so-called ‘Hamburg Model’. These beds were designated specifically for the special institutional care of dementia patients. The Hamburg Model encompasses both domus units, in which solely dementia patients are cared for, as well as integrated units. In the latter, dementia patients reside on the same ward as those without dementia, but are cared for separately, either all day or for a

few hours every day. Like the domus unit arrangement, segregated daytime care also includes group play, music, physical activities and certain therapy measures oriented to the capabilities and deficits of the residents. The care beds in the Hamburg Model are more expensive than those in traditional nursing homes since the staff is larger and better qualified. Admission to the Hamburg Model is governed by specific requirements: the presence of a medically diagnosed advanced dementia in conjunction with marked behaviour disturbances and the capacity to participate in group activities (patients cannot be bed-ridden). A recent study carried out in traditional nursing homes in Mannheim revealed that one out of six nursing-home residents with dementia fulfils these criteria.

As an alternative to hospital-like care in nursing homes, sheltered households for dementia patients have been established by various social welfare institutions in recent years that feature a normal daily routine and a family-like environment. The success and effects of this type of living arrangement are not yet known.

No official figures are available on the number of facilities in Germany that offer special dementia care programmes. However, they are still outweighed by the number of traditional nursing homes. Partially integrated care (i.e. segregated daytime care) seems to be the most popular specialized concept, offered by approximately 10–15 per cent of the German nursing homes.

20.29 SUMMARY AND CONCLUSIONS

Dementia patients are the most frequent users of long-term care facilities. However, several studies have shown that many care-providers, as well as physicians, hospitals, and nursing homes are inadequately prepared and lack adequate training. Training opportunities and quality of service are in dire need of improvement. Dementia care is still strongly characterized by the dichotomy between the in-home care provided by family members, augmented by ambulatory care services, and the residential care provided by nursing homes. Contrary to expectation, ambulatory care services or semi-inpatient services such as day or night care have been used less frequently than was originally anticipated (Bundesministerium für Familie, Senioren, Frauen und Jugend, 2002). This is most likely due to the fact that the supply and the operation of these services do not sufficiently match the needs of the dementia patients and their families.

Moreover, statutory long-term care insurance does not cover the costs generated by the specific needs of the severely mentally ill elderly: supervision, instruction, activation, occupational therapy. Although it is a step in the right direction, the recently passed Act Supplementing Domiciliary Care

Services (Pflegeleistungs-Ergänzungsgesetz) fails to meet the needs of demented patients and their caregivers.

The number of dementia patients in Germany is expected to double within the next 40 years, while at the same time the number of family caregivers will continue to decrease, giving rise to an enormous demand for professional geriatric care (Bickel, 2001). Nursing homes will see the number of dementia patients among their residents soar to at least 75 per cent. In view of these demographic data, the development of specialized types of institutional care for dementia patients, which began later in Germany than in other countries, is an urgent matter.

Hong Kong is situated on the South China coast. It returned to Chinese sovereignty in 1997 and is now a Special Administrative Region of China with a high degree of autonomy under the policy of 'one country two systems'. As Hong Kong was a British colony for over 100 years, it is more westernized than the rest of China, and the development of dementia services is also different. The current population is 6.8 million and the percentage of population aged 65 or above is 11 per cent. Service development for dementia care has only started in the last few years under the pressure of a rapidly ageing population. Long-term care of people with dementia is a great problem because of the breakdown of traditional family care in Hong Kong in recent years. This may be related to growing westernization and attrition of filial respect, combined with a decreasing trend of extended families.

20.30 PREVALENCE OF DEMENTIA

A local study involving 1034 older people has found that the prevalence of dementia was 4 per cent for people aged 65 or above (Chiu *et al.*, 1998). Alzheimer's disease and vascular dementia accounted for 65 per cent and 29 per cent of cases respectively; 45 per cent of the subjects with dementia were living in residential homes, which is a high figure compared with the rest of China and Taiwan.

20.31 MEDICAL SERVICES

Most medical services for dementia are provided by psychogeriatric teams whereas geriatricians treat many elderly

with vascular dementia, as well as those with physical problems. At present, there are seven multidisciplinary psychogeriatric teams serving different catchment areas in Hong Kong. These teams provide services to patients with dementia and functional psychiatric illness, including inpatient, outpatient, consultation and limited day hospital services. These teams also run an outreach programme to assess and treat elderly people living in subvented old-age and care-and-attention homes. Five memory clinics have been set up for early diagnosis of and intervention for dementia.

Protocols for assessment and clinical management of dementia have been developed by the Psychogeriatric Working Group, which consists of leaders of all the psychogeriatric teams. Guidelines for use of cholinesterase inhibitors are very similar to the NICE guidelines in the UK. However, the drug budget in the public health sector is very tight, and there are financial constraints on prescription of these drugs even if patients fulfil the criteria to receive antidementia drugs. Traditional Chinese medicine is rarely used for dementia. Besides medication, input from other members of the multidisciplinary team, including nurses, occupational therapists, physiotherapists, social workers and clinical psychologists, is an important part of management.

20.32 COMMUNITY SUPPORT SERVICES

Elderly health centres run by the Department of Health offer health education and screening for a number of disorders including dementia. In addition, general practitioners play an important role in screening for patients with dementia. Financial support to the elderly is available in the form of old-age allowance and disability allowance.

Community support services include home help, home-delivered meals (meals-on-wheels) and day care centres for the elderly. The Alzheimer's Association was established in Hong Kong in 1995. In 1998, the Hong Kong Psychogeriatric Association was founded and one of its targets has been to promote public awareness and facilitate training as well as research on dementia.

Residential services for the elderly are provided by care-and-attention homes and nursing homes. Care-and-attention homes provide accommodation, general personal care and limited nursing care. Nursing homes serve those who require a higher level of nursing care. In general, the subvented facilities are of better quality than the private ones but some of them do not like to accept patients with dementia and behavioural problems. Many of these elderly are thus admitted to privately run care-and-attention homes, some of which are not up to standard, and physical restraints are frequently used.

20.33 LEGAL ISSUES

A major gap in dementia care concerns legal provision. The Mental Health (Amendment) Ordinance 1997 set up a Guardianship Board to appoint guardians to make decisions on behalf of people who are mentally incapacitated. In addition, enduring power of attorney is now available, but it does not cover healthcare issues. Development on the issue of advance directives remains very slow.

20.34 SPECIAL DEMENTIA SERVICES

Extra funding to subvented care-and-attention homes to look after the elderly with dementia was given in the form of dementia care supplement. In 1999, the government funded a pilot project to set up several dementia residential units and dementia day care centres. However, because of lack of funding, these special dementia services were not supported after 4 years.

A major advance in dementia care recently is the establishment of a specially designed dementia centre, the Jockey Club Centre for Positive Ageing in 2000. This centre is funded by the Hong Kong Jockey Club with the objective to promote dementia care in Hong Kong. The service arm comprises of day care and respite residential service. The training and public education arm provides training to professionals,

front-line workers and informal carers, as well as education to the public. In addition, there is a resource centre and a website (www.jccpahk.com). The research arm conducts studies on dementia care as well as opinion surveys on human rights issues in dementia care, including physical restraints, advance directives, etc.

20.35 RESEARCH

The Department of Psychiatry at the Chinese University of Hong Kong has a dementia research unit, which is linked with the Jockey Club Centre for Positive Ageing. Studies conducted in the last few years include development of neuropsychological tests for use in the Chinese elderly, epidemiological surveys on dementia, genetic investigations of Alzheimer's disease and vascular dementia, neurobiological correlates of behavioural and psychological symptoms in dementia, as well as studies on dementia care.

20.36 THE FUTURE

Hong Kong has made significant progress in the development of dementia care over the last 5 years. For instance, the Jockey Club Centre for Positive Ageing is evolving into a centre of excellence in the region of South-east Asia. However, there is still no clear or consistent policy on dementia care by the government. In addition, after the outbreak of the severe acute respiratory syndrome (SARS), a lot of funding and resources in the health sector will be channelled to the prevention and control of infectious diseases. The economic downturn in the recent few years, as well as the shift of priority in health care after SARS outbreak (Chiu *et al.*, 2003) are two major challenges in the further development of dementia care in Hong Kong.

20.39 Issues concerning people with dementia	274	References	275

Projections indicate that by the year 2020, there will be 470 million people aged 65 and older in developing countries, more than double the number in developed countries. Three countries projected to have the largest number of old people in the year 2025 are China, India and Indonesia (Siegel and Hoover, 1982). India's elderly population, which was 57 million in 1990, is expected to cross 100 million in 2013. From a mere 5.1 per cent of the population in 1901, the elderly will become 21 per cent of the population by the year 2050. The elderly constituted 7.7 per cent of the total population in the India census 2001, and this figure is expected to rise to 11 per cent by the year 2020. With the country's population exceeding a billion, India ranks second in the entire world in the number of 'aged' citizens.

20.37 AGEING SCENARIO IN INDIA

As most elderly people live at home, family members should caregiving responsibilities. The existing healthcare facilities are not geared to meet these challenges posed. In India life expectancy has gone up from 20 years in the beginning of the twentieth century to 62 years today. The erstwhile joint family, the natural support system, has crumbled. The fast-changing pace of life has added to the woes of the older person: 30 per cent of older persons live below the poverty line, and another 33 per cent just marginally over it; 80 per cent live in rural areas; 73 per cent are illiterate, and can only be engaged in physical labour; 55 per cent of women over 60 are widows, many of them with no support whatsoever. There are nearly 200 000 centenarians in India.

20.38 CARE ARRANGEMENTS

Old age was never seen as a social problem in ancient India. Respect towards elders and the concept of obligation towards parents (*pitra rina*) forms part of the cultural value system (Venkoba Rao, 1993). In contemporary Indian society, however, the position and status of the elderly and the care and protection that they have traditionally enjoyed have been undermined by several factors. Urbanization, migration, the break-up of the joint family system, growing individualism, the change in the role of women from being full-time caregivers, and increased dependency status of the elderly are some of the prominent factors.

20.39 ISSUES CONCERNING PEOPLE WITH DEMENTIA

Studies by the 10/66 Dementia Research Network in Goa and Chennai examined the impact of care giving for elders (Dias *et al.*, 2004). Carers of people with dementia spent significantly longer time providing care than did carers and co-residents of depressed persons and controls. The highest proportion of time was spent in communicating, supervising, and helping with eating and toileting. Levels of carer strain were notably higher among carers of people with dementia. They were 16 times more likely to have a common mental disorder than other carers. Economic strain was indicated by high proportion of caregivers of people with dementia who had given up work to provide care, coupled with the increased likelihood that the family had to meet relatively high healthcare costs.

20.40 SERVICES IN INDIA

20.40.1 Hospital-based services

Most of the hospitals in India see persons with old age problems. However, most physicians do not recognize dementia as a medical problem. Also, other than the routine coverage in the psychiatry training curriculum, there are no specific training courses in geriatric (or old age) psychiatry. At present only a handful of hospitals offer special outpatient psychiatric services for the old age population.

20.40.2 Non-governmental agencies

There are two well-known non-governmental agencies, which have been operating in India in the care of the elderly. These are the Alzheimer's and Related Disorders Society of India (ARDSI) and Helpage India.

20.40.2.1 THE ALZHEIMER'S AND RELATED DISORDERS SOCIETY OF INDIA (ARDSI) (WWW.ALZHEIMERINDIA.ORG)

ARDSI was founded in June 1992. At present ARDSI has 14 Chapters in various cities across the country, with another 9 Chapters proposed. The Registered Office is in Cochin, Kerala. ARDSI also offers a range of community-based services such as:

- community care
- domiciliary care
- day care
- community geriatric nursing training
- dementia care fund
- memory clinic
- research.

Their website is WWW.ALZHEIMERINDIA.ORG

20.40.2.2 HELPAGE INDIA (WWW.HELPAGEINDIA.ORG)

HelpAge India is a national level voluntary organization that was formed in 1978. It has 37 offices all over India with its headquarters in New Delhi. It aims to foster the welfare of the aged in India especially the needy aged. It also helps to raise funds and increase social awareness about the problems of the elderly. HelpAge India has implemented 3084 projects and made a difference to the lives of over 7 million persons. Its programmes focus on improved access to health and eye care facilities, community-based services, livelihood support,

and training. In addition, the organization also supports welfare programmes like old-age homes, day care centres and the Adopt-A-Grandparent scheme.

20.41 DISCUSSION

Mental disorders in the elderly in India are a major public health issue for four major reasons:

- Because of increased population of elders, the number of people with mental disorders is rising rapidly.
- There is very poor awareness about these disorders.
- Traditional family and social support systems for elders are rapidly changing.
- There are virtually no health services geared for the special needs of elders in India.

Caregiver strain has not been acknowledged; instead, a near mythical strength is attributed to the abilities of families to cope. This distracts from the need for a rational debate regarding the future balance between informal family support and formal care services, and hinders evidence-based policymaking. Prioritizing home-based support for elderly persons with serious mental disorders and their carers should be given serious consideration. Removing stigma may require integrating the subject of mental disorders of elders into community and general health programmes. Collaboration is required with non-governmental organizations (such as the Alzheimer's and Related Disorders Society of India) that are pioneering programmes to empower the elderly and support families. Working with the existing manpower and health and social service infrastructure is likely to be more successful in meeting the mental health needs of elders in India than developing specialized psychogeriatric services throughout the country.

Italy

ANGELO BIANCHETTI AND MARCO TRABUCCHI

20.42 Health services for dementia patients in Italy	276	20.45 Conclusion	280
20.43 Burden of care associated with Alzheimer's disease	278	References	280
20.44 The costs of Alzheimer's disease in Italy	279		

Dementias, and Alzheimer's disease (AD) in particular, affect an increasing number of people in the developed countries and also in less developed regions of the world (Wimo *et al.*, 2003). Worldwide there lacks a homogeneous approach to neurodegenerative disorders, and various health services follow different lines of development, not always supported by scientific evidence (Bianchetti and Trabucchi, 2003).

Italy has only a short history in this field. The regional organization of its health system causes variability both in the number and in the quality of interventions for people affected by dementia (Dello Buono *et al.*, 1999).

In Italy interest in dementia started in the early 1980s mostly from the commitment of Luigi Amaducci. In the early 1990s Trabucchi, Bianchetti and Zanetti started the first National Research and Clinical Center for AD and related disorders (IRRCS San Giovanni di Dio Fatebenefratelli) in Brescia (Lussignoli *et al.*, 1998). In 1997 the Italian Association of Psychogeriatrics was founded, involving neurologists, psychiatrists and geriatricians.

In this short review the most important steps of the Italian organization of care for demented patients are summarized.

AD is the most common dementing disorder. Once considered rare AD is now recognized as a major cause of death and a growing public health challenge (Bianchetti and Trabucchi, 2001). On the basis of a multicentre longitudinal survey carried out in Italy (Italian Longitudinal Study on Ageing – ILSA), started in 1992/1993, it has been estimated that approximately 6.4 per cent of the population over 64 years of age is afflicted by dementia (2.5 per cent for AD and 1.4 per cent for vascular dementia), with a higher prevalence in women (7.2 per cent) than in men (5.3 per cent) (ILSA, 2002). The prevalence of dementia increases with age, both for AD and vascular dementia (VaD) (Figure 20.1). The incidence rates are 12.47 per 1000 person-years and 6.55 for AD (Di Carlo *et al.*, 2002). On

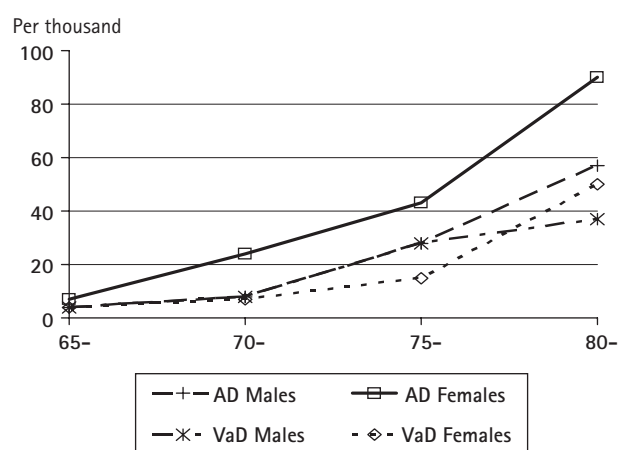

Figure 20.1 Prevalence rates of dementia in Italy for different age groups (based on ILSA study).

these bases about 150 000 new cases of dementia per year are expected. The ILSA study demonstrated that dementia is a major causes of mortality and disability in individuals aged 65 to 84 years; the 2-year mortality risk ratio (MRR) was 3.61 for the demented elderly, higher than for neoplasm (MRR = 2.01), heart failure (MRR = 1.87), and diabetes (MRR = 1.62) (Baldereschi *et al.*, 1999).

20.42 HEALTH SERVICES FOR DEMENTIA PATIENTS IN ITALY

Despite progress in the development of new treatment strategies for AD, many patients and caregivers receive inadequate care (Bianchetti and Trabucchi, 2001). Health service organizations do not satisfy the complex needs of demented patients. In

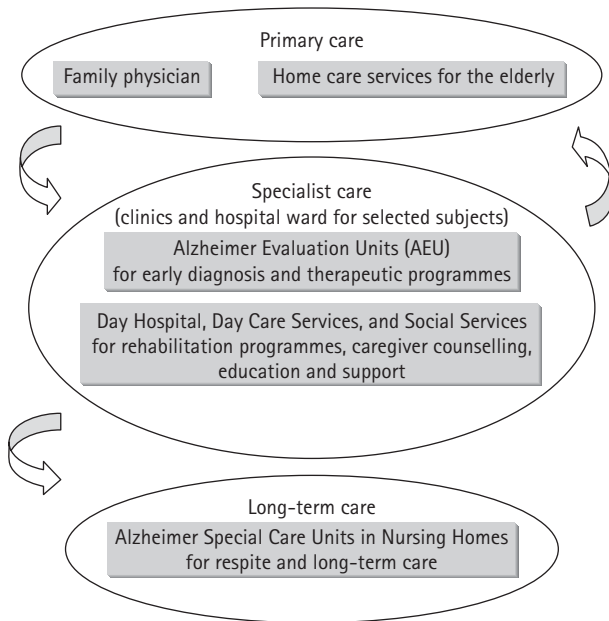

Figure 20.2 Comprehensive care network for demented patients.

recent years different health services were designed to diagnose dementia more accurately and to improve the care of patients (Bianchetti and Trabucchi, 2003). The aims of these services (diagnostic evaluation, treatment/referral, case management, research, training and continuing education, rehabilitation programmes, special care programmes), their target subjects (outpatients, inpatients, nursing home residents), organization and costs are substantially different, but still not thoroughly studied (Dello Buono *et al.*, 1999; Doody *et al.*, 2001).

In 1994 the regional government of Lombardy (northern Italy, 8.5 million inhabitants) started a comprehensive care network of services called 'Piano Alzheimer', aimed at the care of patients in different dementia phases (Trabucchi *et al.*, 1995). The care network delineated by Piano Alzheimer is summarized in Figure 20.2. On the basis of the results of a pilot study, 20-bed Special Care Units (SCUs) in 70 nursing homes (corresponding to 4.5 per cent of the total nursing home beds in the Region) were opened and dedicated to demented patients with high levels of behavioural disturbance (Bianchetti *et al.*, 1997; Frisoni *et al.*, 2000).

To assess the efficacy of SCU in comparison to traditional nursing home models of care, a study (SCUD project) has been performed (Frisoni *et al.*, 1998). Ambulating patients with moderate to severe dementia and severe behavioural disturbances on the modified Neuropsychiatric Inventory were enrolled in 18 SCUs and 25 traditional nursing homes. Patients were assessed at baseline and after 6 months. Baseline behavioural disturbances significantly improved at follow up in both groups (38 and 41 per cent change, respectively), with no increase in the percentage of patients taking neuroleptic and non-neuroleptic drugs (ranging from 46 to 56 per cent for both groups at baseline and follow up). Indicators of adverse effects of psychotropic medications (cognitive performance and falls) remained unchanged. In the case group the reduction of

behavioural disturbances was achieved with lower use of physical restraints: 10 per cent of cases and 32 per cent of controls ($P = 0.02$) at follow up respectively (Frisoni *et al.*, 1999).

The mean daily cost for patients in the SCUs is approximately 100 €. In Italy, 50 per cent of nursing home costs are paid for by the National Health System, which contributes a further 11 per cent of the cost of patients in SCUs. The cost/effectiveness analysis demonstrated that, with a cost increase of only 11 per cent, a considerable improvement in quality of life may be attained, with a reduction in physical and pharmacological restraints (Trabucchi, 1999). The role of SCUs in the care of demented patients is widely debated, and the importance of the quality of life as outcomes of these type of services has been emphasized recently (Albert, 2004).

The Piano Alzheimer also planned a number of day centres specifically devoted to demented subjects. They follow patients during day time (from 8 am to 6 pm), 6 or 7 days a week, and work in collaboration with family doctors in providing disease evolution, performing non-pharmacological interventions and a general surveillance of therapy. However, their costs are very high (about 70 € a day) almost completely charged to the families; for this reason day centres have not developed successfully.

Piano Alzheimer of the Lombardy region also provides an acute hospital ward offering medical care to the demented elderly, with the aim of studying specific guidelines for all hospitals of the region that have a high prevalence of patients affected by dementia (about 50 per cent of over 65 admitted to acute medical wards have a Mini-Mental State Examination (MMSE) score <24).

Others Italian Regions (i.e. Emilia, Tuscany, Marche, Liguria) organized specific projects for demented patients, on the assumption that their care needs a devoted organization, with employees (physicians, nurses, social workers) expressly devoted and skilled. Most of these projects are based on geriatric services. The projects include a number of Alzheimer Centres for coordination, research, education, and second or third level diagnosis (the allocation and the number of these centres differs between regions), SCUs in nursing homes, and a great effort for the education of personnel. In all projects the role of the primary physician is central, but it is well known that family doctors often do not comply with the psychological and time-consuming involvement needed by the care of persons affected by dementia. Caregivers and patients' families are considered not only targets of treatment, but also partners in care. In general, great differences are observable in the different regions in the dissemination of services, emphasis on home care in comparison with residential care, economic interventions in favour of persons affected by dementia and their families.

The most recent and important step in service organization in Italy has been the implementation of 'Progetto Cronos', born with the aim to standardize prescriptions of cholinesterase inhibitors (AChE-I) and to assess their effects on defined outcomes (cognition, functional status, behaviour) in non-selected subjects (Bianchetti *et al.*, 2003). This national project

Table 20.4 Clinical characteristics at baseline of 1362 patients enrolled in Piano Alzheimer in the Cremona area

	Total (n = 1362)	Females (n = 1007)	Males (n = 355)

started in October 2000 and involved about 500 Alzheimer Evaluation Units (AEUs), embracing all health districts. Besides helping to adopt a definite attitude towards the reimbursement of AchE-I, the project aimed to build up a nationwide network of centres with a homogeneous level of diagnostic and therapeutic competence. It has been a great effort with good results, since it stimulated the *ex novo* organization of centres, with standardized protocols and a database collected by the Ministry of Health. At the end of the project (March 2003) about 40 000 mild to moderate AD patients had been recruited. This pattern of prescription is lower than expected, revealing insufficient attention to the early detection of the disease. Data collected from AEUs of a northern Italian area (Cremona) on 1362 AD patients in the mild-moderate stage of the disease are presented in Table 20.4. Mean MMSE values in patients starting treatment were 19.2 ± 3.9 , 19.8 ± 4.5 after 3 months ($P < 0.05$, t-test for paired samples), and 18.9 ± 4.9 after 9 months (not significant by t-test for paired samples versus baseline). Data replicate in the real world those obtained in controlled clinical trials. This fact further confirms that non-selected AD patients with a mild to moderate cognitive decline seldom enrolled in randomized controlled trials may benefit from AchE-I treatment. The specific role of drugs compared with the positive effect exerted by the care given at AEUs remains to be clarified. In the near future the AEUs system will be in charge of data monitoring regarding the efficacy and the risk ratio of atypical antipsychotic drugs in dementia. The availability of data on thousands of patients will be of great value for the definition of guidelines regarding the prescription of these drugs for behavioural and psychological symptoms of dementia.

In all Italian regions one of the main unresolved problems is the education of professionals at various levels. Historically, universities demonstrated only moderate interest in chronic diseases of the elderly, neglecting teaching both during undergraduate and postgraduate curricula. Today, education-information in the field of dementias is almost completely in the hands of the pharmaceutical industry, with the risk that

Box 20.1 Characteristics of AD caregivers in Italy: results of a national survey*

- 73.8% of principal caregivers were females (72.1% in mild AD, 81.2% in severe AD)
- 69.1% were <60 years old (71.1% in mild AD, 63.1% in severe AD)
- 49.6% were children, 34.1% spouse
- 65.0% lived with the patient (59.1% in mild AD, 75.5% in severe AD)
- 58.6% of caregivers received help from other family members (73.6% in mild AD, 50.9% in severe AD), and 37.3% from paid personnel (21.6% in mild AD, 40.0% in severe AD)
- 26.3% of caregivers reported a direct impact on working activity (17.5% stopped working activity)
- 60.4% reported a worsening of quality of life
- 33.6% used drugs after the beginning of caregiver activity (72.2% psychotropic drugs; 15.7% somatic drugs and 12.1% unconventional drugs)

the quality and quantity of messages are modulated by the needs of the drug market.

20.43 BURDEN OF CARE ASSOCIATED WITH ALZHEIMER'S DISEASE

The care of a demented patient induces high levels of psychological, physical and economic burden on individuals, their caregivers, families and society as a whole. Caregivers play a key role in the management of dementia and are the main social buffer against the early institutionalization of patients (Prince, 2004).

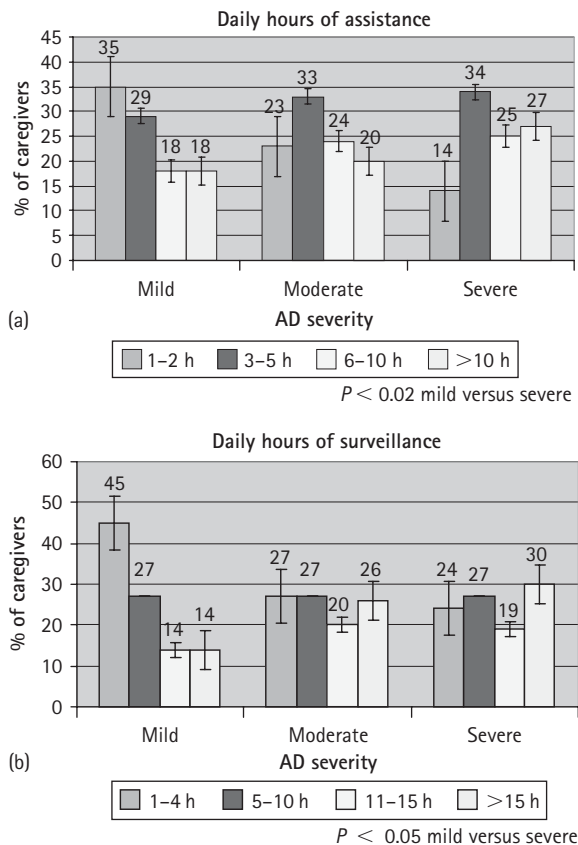

Figure 20.3 Caregivers' time spent for the assistance (a) and surveillance (b) of AD patients in Italy: results of a national survey. (Adapted from CENSIS, 1999.)

In 1999 the Geriatric Research Group collaborated with the Italian Association for Alzheimer Disease (AIMA) and the Centre for Social Studies (CENSIS) in the conduct of a national survey on 802 AD principal caregivers equally distributed between Italian Regions (CENSIS, 1999). The AD patients were females in 68.1 per cent of cases, and 80.0 per cent were aged 65 years or older. The characteristics of caregivers are summarized in Box 20.1. The data confirm that caregivers experienced a substantial burden in the assistance and surveillance of patients (Figure 20.3).

The use of supportive and educational programmes has been regarded as the most reliable way to reduce distress and decrease the risk of institutional placement of demented patients (Schulz *et al.*, 2004). In Italy many interventions were conducted using different strategies, the elements of which can be categorized into three broad aspects: psychological, educational, and social. It has been possible to demonstrate that caregiver interventions (psychological and educational programme) significantly reduce burden in carers and improves their quality of life (Zanetti *et al.*, 1998).

In the field of caregiving, in Italy a new phenomenon has occurred in the last 5 years, i.e. the presence of a large number of paid caregivers, mostly coming from Eastern European countries (Poland, Moldavia, Ukraine), who demonstrate a high level of humane attitudes, and have good ability both to

learn the Italian language and to perform basic home care. These persons, mostly females (80 per cent), with a mean age of about 50 years, plan a stay in Italy to collect sufficient money for specific purposes (building a house in their original country, funding a university degree for their children, etc.). Their mean wage is about 800 € per month plus housing and food. In the area of Brescia (1 million inhabitants) the number of these workers has been estimated at 10 000–12 000.

20.44 THE COSTS OF ALZHEIMER'S DISEASE IN ITALY

Recent funding changes in many developed countries have left AD patients and their families responsible for many costs that were previously reimbursed, such as those for medication, hospitalization or nursing care. Indeed, it has been estimated that a major component of the total cost of the care of an AD patient falls upon the family caregiver who is caring for the patient at home.

In Italy economic pressures stimulated a large debate on the need for a new tax specifically devoted to the support of the chronically ill elderly. Although no decisions have so far been taken by the Parliament, a yearly amount of about 10 million € is considered necessary to maintain the present level of care in the northern part of the country and to build even a rudimentary network in the southern regions.

One study conducted in Italy calculated that the family's expenditure for the non-medical care of the patient at home was \$US8218 annually (about 9000 €) (Cavallo and Fattore, 1997).

The Geriatric Research group conducted a cost-of-illness study (CoDem – Cost of Dementia), designed to give a profile of the total economic costs of AD in Italy, based upon measurement of the direct and indirect costs associated with the care of community-dwelling AD patients (Trabucchi *et al.*, 1996). As a result of the onset of dementia, 35.4 per cent of patients were forced to stop work, while 20.4 per cent of caregivers either reduced their working hours or stopped work altogether. Thirty-five per cent of all caregivers made some modifications to their house to make it more suitable for the patient (mean cost \$US7900). Total mean weekly costs for a patient's care were estimated to be \$US585, including paid providers (housekeeping, cooking, transportation, medication and drug administration) and an estimate of the indirect costs associated with family caregiving. The estimated cost of direct and indirect home care increases with disease severity (from \$US852 to \$US1062 per annum, as calculated using the cost replacement method) (Bianchetti *et al.*, 1998).

In the CoDem study, the principal predictor of the weekly costs for home care (direct and indirect) was the number of instrumental activities of daily living functions (IADLs) lost, with an increase in weekly costs of \$US72 per function (Bianchetti *et al.*, 1998). Total annual nursing home costs increased from \$US1200 to \$US4000 from mild (1) to severe

(3) dementia ratio with the Clinical Dementia Rating (CDR) scale, and the ability to perform IADLs was the single best predictor of nursing home placement (Trabucchi, 1999).

20.45 CONCLUSION

The management of AD is multimodal, guided by the stage of illness and focused on the specific symptoms of the patient. While no current therapy can reverse the progressive cognitive and functional decline of AD, several pharmacological and psychosocial techniques have been proven to be effective to control behavioural symptoms, to slow cognitive and functional decline and to improve the quality of life of patients and caregivers (Cummings, 2004). They have special needs; programmes, environments and care approaches must reflect this uniqueness, and the organization of health services must make the different possible effective interventions available. Whatever the cost–benefit outcome of a particular treatment option, it is the responsibility of physicians to determine the optimal quality of care for their patients. However, physicians also have a responsibility to ensure that scarce resources are not squandered. To do so outcomes must be shown such as those involving drug treatment, rehabilitation procedures or the organization of services.

In the near future Italy will be challenged by historical events: an economic crisis as in many other developed countries, ageing of the population with an increased number of chronic patients owing also to their prolonged survival, and uncontrolled immigration from Africa and Eastern Europe where the outcomes are unpredictable. Only strong political control of this scenario will allow us to assist the most frail citizens, such as demented subjects in an appropriate way in future.

MASAHIRO SHIGETA AND AKIRA HOMMA

20.46 The new public Long-Term Care Insurance (LTCI) programme	281	20.47 The new Adult Guardianship system	282
		References	282

The circumstances that surround the elderly drastically changed in 2000. One reason was the public Long-Term Care Insurance (LTCI) programme which started in 1 April 2000 (Maeda, 2003; Shimizu, 2003). Many Japanese people think that daughters and their sons' wives should take care of their aged parents. Even women who work feel a strong sense of responsibility to take care of their own and their husband's aged parents. However, social care for the elderly has started after the implementation of LTCI and it is likely that many people will change their attitude towards care with this new programme in the future. It will become easier to use various services for the elderly and the burden on relatives will be reduced. Another dramatic change has been the review of the Adult Guardianship System (Maeda, 2003). Previously adult guardianship in Japan had several drawbacks, because its simplicity and strictness (Arai, 1999). When a person was judged as incompetent by a psychiatrist, the Japanese legal term of incompetent was a significant discriminator – for example, this is documented in the census registration (family register). Moreover, a relative nominated as a guardian might not always do things in the best interest of the demented older person. For instance, a child nominated as a guardian for the child's mother or father might have used his or her property only for child's advantage. However, the most important drawback was that there was no legal system for a person to nominate a guardian voluntarily while the person was still mentally intact. A new Japanese Guardianship System was legislated for in order to solve these problems.

20.46 THE NEW PUBLIC LONG-TERM CARE INSURANCE (LTCI) PROGRAMME

The LTCI system covers Japanese citizens aged 40 and over. There are two types of insuree: Type I insuree and Type II

insuree. Type I insurees are aged 65 or over and in need of long-term institutional or domiciliary services. Type II insurees are aged between 40 and 65, have age-related diseases such as Alzheimer's disease and stroke, and are in need of institutional or domiciliary services because of the disease. When the insuree wants to use the services of the LTCI (see Box 20.2), he or she should apply to the insurer, which is the local government where he/she lives, for the assessment of needs for care and services. A designated care service agency can act as proxy for the insuree. Once the assessment committee of the local government determines that the applicant is in need of the services, the cost of services used after the date of application is covered by the Insurance. As the application is

Box 20.2 *Services to be covered by Long-term Care Insurance*

Community care services

- Home care service (including domiciliary services)
- Visiting bathing service
- Visiting nurse service
- Visiting rehabilitation service
- Use of the services in a rehabilitation centre
- Physician's or dentist's call on
- Use of the services in a day care centre
- Short-term stay service
- Group home service for the demented
- Care services at the retirement home
- Rental service or purchase of technical aids
- Costs for improvement of housing

Institutional care service

- Care service in a nursing home
- Care service in a healthcare facilities for the elderly
- Care services in a long-term care geriatric hospital

approved, a care plan is made either by the insuree or by a licensed care-manager, although the insurer pays for a care plan made by a care manager. The care plan is made in accordance with the approved degree of care needs and there are six degrees of care needs. The care plan made by the insuree or a licensed care-manager is then presented to the insurer. The insurer pays the cost of services to the designated home care service agency according to these care plans presented prior to the start of services. In the case of community services, the insuree is required to pay the cost of meals and 10 per cent of the total cost of services.

20.47 THE NEW ADULT GUARDIANSHIP SYSTEM

The new Adult Guardianship system consists of the Guardianship, Curatorship and Help system. Previously, when someone was declared by the Family Court to be incompetent in the management of the property, he or she lost all legal capacity and a guardian was mandated to take over all the legal authority to make decisions on their behalf. Under the new Adult Guardianship system, even an incompetent person may keep the capacity to decide acts related to daily living for themselves.

Previously when someone was declared as quasi-incompetent, he or she partially lost all legal capacity. Under the new Curatorship System, he or she loses only the capacity for specified acts written in the Civil Code. The newly legislated Help System is for those who suffer from intellectual deterioration such as dementia as well as mental disability, and thereby lack a sufficient level of mental ability as a normal adult, but the level of incompetence is less than that of quasi-incompetence. For these persons, the Family Court may

nominate a Helper in accordance with the application of a client, a spouse, a close relative or a public prosecutor, with the informed consent of the client. The Court may nominate more than one person including a legal person. A Guardian, a Curator or a Helper is obliged to give as much attention as possible so that the client can receive appropriate health and medical care, live in a decent dwelling, use a welfare institution and have adequate rehabilitation, although the Helper is only responsible for the management of the client's property and for the arrangements of and care service needed.

The most important innovation in the Adult Guardianship system is that anyone can nominate a guardian for oneself voluntarily while still mentally intact. 'The Law for Voluntary Nomination of Adult Guardian' was enacted by the Diet along with the revision of the Civil Code. Voluntary nomination is made in the form of a notarial deed and registered according to the 'Adult Guardianship Registration Act'. However, despite these improvements one serious drawback remains. Consent to medical examination and treatment can be done by neither Guardian nor Curator. A system that clarifies who legally consents regarding medical decisions for an incompetent subject needs to be developed.

Latin America is a vast and heterogeneous region, approximately 10 times the size of Europe. It can be divided into four regions: North America, Central America, South America and the Caribbean. Languages spoken in Latin America are predominantly Spanish and Portuguese. Almost 512 million people live in Latin American countries, including Mexico, Central America, the Latin Caribbean and the Latin population of the USA (Encyclopaedia Britannica, 2003).

20.48 MEXICAN POPULATION

Mexico comprises 31 states and a federal district, which is the national seat of government (Alba, 1982). The 2000 census showed that 7.1 per cent of the population speak one of 68 indigenous languages (INEGI, 2000). In the case of the elderly it is often their only language. These languages are unrelated to each other and are widespread across the country.

Mexico is undergoing a demographic transition that will be complete by the year 2050. During this transition, changes in life expectancy, fecundity rate and migration will impact on the demographic structure resulting in progressive ageing of the population. Ageing is one of the most important risk factors for dementia. In industrialized countries it has been estimated that the prevalence of dementia of about 3 per cent for the 60–65-year-old population doubles every 5 years to reach about 50 per cent for the population older than 80 years. In Mexico from the year 2000 to 2050 the life expectancy of 74 years will increase up to 81.3 years (men 79, women 83.6). The probability of dying in the first year of life will decrease from 23/1000 to 5/1000 in the same time period. The fecundity rate will also fall from 2.11 children/woman in 2000 to 1.85 children/woman in 2050 and there is also an expected rise in the age of marriage and the age at the

time of first childbirth. All these changes, including also migration factors, will result in an increase of the Mexican population from 100.6 million to 129 million inhabitants by the year 2050. In this same period the median age of the population will increase from 26.6 years to 42.7 years and the percentage of people of 60+ years old will also increase from 6.8 per cent to 28 per cent. On the other hand the economically productive population (15–59.8-year-olds) will remain relatively constant from 59.8 per cent in 2000 to 62.2 per cent in 2030 and 55.3 per cent in 2050 (INEGI, 2000). According to the analysed data in Mexico there were 6.8 million people 60 years old or older in 2000 and there will be 36 million people of this age group in 2050. The estimated number of people with dementia is likely to increase from approximately 980 000 people to 6.7 million in the same period; in other words in 2050 there will be as many demented people as adults older than 59 years are today. This numbers may be conservative considering that the estimated prevalence of dementia is taken from industrialized countries. Lower level of education, decreased access to health services and other factors that accompany poverty in the elderly might make these estimates larger in Mexico.

The health of the Mexican population is well below the minimum World Health Organization's (WHO) standards and more than 30 per cent of the population is malnourished (Campos Ortega, 1992); 10.6 million Mexicans are marginated from the rest of the population (CONAPO, 2003). The enormous population increase has been caused partly by a drop in the mortality rate, owing to both massive vaccination programmes and acute treatment for dehydration related to gastrointestinal infections, and partly by a very high birth rate. Although standards of health are gradually improving, central government has found it almost impossible to offer adequate health education and other social services (SSA, 1992).

Official unemployment figures are around 7.5 per cent (INEGI, 2000) but 40 per cent of the population work outside the formal employment sector in occupations such as windscreen washers at traffic lights and illegal street vendors. Since the 1994 economic crisis, there has also been a large increase in a well organized and still growing delinquency industry (gang robberies, automobile theft, kidnapping and drug trafficking). The majority of the population live between a state of survival and tremendous poverty. The extreme poor constitute 15 per cent of the population, 47 per cent live under the minimum level of decent living, and 36 per cent have no access to good medical services (SSA, 2000).

The majority of health-related problems have their origin in poverty, ignorance, malnutrition and a deficient health-care infrastructure; in the 2000 general census it was estimated that 9.5 per cent of the population >15 years could not read and write (INEGI, 2000). In Mexico City this is aggravated by land, water and air pollution. Bearing in mind the pressure on public spending, government spending on programmes for the elderly have had a low priority. However, the elderly are high consumers of health resources. Up to 30 per cent of the beds in the public sector were occupied by the old in 1992 (Ruiz and Salvador, 1994) – an increasing tendency that places insurmountable pressure on the healthcare system. Recent figures show that in recent years the elderly occupancy of beds in the public sector has increased by 12 per cent in the last 8 years (SSA, 2000).

20.49 GENERAL STRUCTURE OF HEALTHCARE SERVICES

The Mexican healthcare system is a complicated network of different institutions, which offer service in all areas of care. Government-provided health care is organized into three levels as follows:

- *Primary care.* These services aim to solve 70–85 per cent of health problems. Their main objectives are the promotion of health, prevention of disease and detection of initial treatable or chronic conditions. They mainly constitute unsophisticated and low-budget health clinics, attended by family and general practitioners. Since the collapse of the Mexican economy in 1995, the government is redirecting resources to this level of care.
- *Secondary level.* The purpose of this level is to solve between 10 and 15 per cent of healthcare demands. It constitutes an organized network of hospitals and outpatient clinics with low-level trained doctors in different specialties. This level of care has been crippled owing to the budget deficits of overspending governments.
- *Tertiary care.* At this level, highly specialized centres treat the 3–5 per cent of the problems previously unresolved. Scientific investigation, research and education are major objectives (Resnikoff *et al.*, 1991).

The type of population served and supporting finance also define Mexico's healthcare institutions. Various groups of workers are catered for by occupational health schemes including those who work for the nationalized petroleum industry, and civil servants. There is a private sector, which accounts for 12 per cent of the medical facilities in the country and caters for 17 per cent of the population (SSA, 2003).

20.50 PSYCHIATRY

Historically, Mexico was a pioneer, ahead of other American countries in providing care for those who, during colonial times, were malnourished and wandered the streets. In 1566 the first psychiatric hospital of the Americas was founded in Mexico City. In the recent past, dependent mainly on charitable donations, these sorts of institutions have decayed and many have disappeared (Campillo and De la Fuente, 1976). In 1910 President Díaz inaugurated the building of a new national general asylum called 'La Castañeda'. During the next few decades several private institutions for the care of the mentally ill were built, and along with La Castañeda contributed to the development of psychiatry as a medical specialty. Between 1950 and 1960 the Health Ministry (Secretaría de Salubridad y Asistencia; SSA) established a network of 11 psychiatric institutions to substitute for the failing general asylum. Unfortunately, appropriate technical and economic resources were not made available for their maintenance and, over a period of several years of poverty and neglect, they suffered severe deterioration. Other institutions to emerge from the Mexico City Council (DDF) and hospitals belonging to the workers unions (IMSS) have suffered the same fate. Only two hospitals in the public sector have been able to overcome some of these problems and they have played an important role in the teaching of psychiatry (De la Fuente, 1982). In one of these institutions, the Fray Bernardino Hospital in Mexico City, the country's first psychogeriatric unit was created 4 years ago with 20 short-term beds for the assessment and initial treatment of psychiatric disorders (including dementia) in the elderly.

In 1991 the SSA mental health services comprised 17 hospital units with a total of 5200 beds and 24 mental health clinics. Other public and private institutions provide 3300 more beds. Of the total number of psychiatric beds, 57 per cent are in SSA hospitals, 24 per cent are in other government hospitals and 19 per cent are run privately (Resnikoff *et al.*, 1991); 60 per cent of the psychiatric beds (1 for every 5453 inhabitants) are located in the Mexico City area, while in central and south-eastern regions the figure is 1 bed for every 55 315 and 44 115 inhabitants respectively (Pucheu, 1984).

Unfortunately, recent data are unavailable; however, many public institutions catering for the mentally ill have disappeared owing to the economical pressures on the governmental budget.

Personnel specializing in the field of mental health (doctors, psychologists, nurses, occupational therapists and social

workers) are scarce and badly distributed. The WHO recommends a minimum of five psychiatrists for every 100 000 inhabitants. In Mexico we calculate 3.1 psychiatrists for every 100 000. Recent figures from the national psychiatric Council state that there are 2800 trained psychiatrists, but only 200 are certified. In 1985 there were 1108 practising psychiatrists in Mexico; 85 practised child psychiatry and 170 were psychoanalysts. The rest were a mixed bag of general psychiatrists. Of these 7 per cent dedicated the whole of their time working in public institutions, 23 per cent solely to private practice and 63 per cent combined both activities. Only 10 per cent of all psychiatrists have carried out any documented scientific investigation and 20 per cent participate in teaching activities (De la Fuente *et al.*, 1988). With regard to other workers in the mental health field, the deficit is even more acute. Notwithstanding an intensive programme of training, there are only 126 social workers in the field of mental health and 35 nurses with formal training in the management of psychiatric patients.

20.51 PSYCHOGERIATRICS AND GERIATRICS

In Mexico as a whole there are only eight trained psychogeriatricians and a handful of psychiatrists and neurologists committed to treating the aged. In other words less than 1 per cent of trained psychiatrist dedicate their practice to old age. In Mexico City there is the aforementioned psychogeriatric inpatient unit at the Fray Bernardino Hospital, with 20 beds, and three informal units at private hospitals amounting to a total of 550 beds for a population of 20 million. Teaching of psychogeriatrics is poor and limited to three main programmes, and there has not been an improvement in this area in the last 5 years:

- Diploma in Psychogeriatrics – training in mental health of the aged for mental health workers;
- psychogeriatrics as a subject for general psychiatrists in training in two city hospitals comprising 10 sessions of 2 hours each and no practical placement;
- a 2-year course in psychogeriatrics run by the national university, that also falls down on clinical training and experience.

In the central state of Jalisco there is a small psychogeriatric unit run privately by one of the few trained psychogeriatricians, which involves some teaching of trainees.

Most of the specific knowledge acquired by psychiatrists in the treatment of the elderly therefore comes from experience gathered during general psychiatric training – there is little formal training. Very recently the Ministry of Health has acknowledged the lack of resources for old age psychiatry and for the first time there is to be serious planning concerning the future of mental health caring for the elderly.

The field of geriatric medicine is better organized with a long-standing tradition in teaching and training. The 400

geriatricians distributed throughout the main cities have traditionally covered the shortfall in services for the elderly mentally ill.

20.52 SERVICES FOR DEMENTIA

It is clear that services for dementia are scarce in Mexico, and are mainly located at the tertiary level of the healthcare system, which caters for the unresolved problems or those who have slipped through the previous levels of care. Only a minority of patients with dementia are seen and treated by health professionals. At this level, diagnosis and outpatient care are priorities, with most patients being cared for at home or in unregulated nursing homes. There are eight specialized centres in Mexico City for assessment, diagnosis and follow up of patients with dementia. Each centre works individually with few guidelines for diagnosis and treatment strategies. Five of these centres are part of the IMSS system and three are private centres; four are within geriatric areas of general hospitals and one belongs to a neurological institute. In the private sector three memory clinics cater for patients with dementia. All centres lack both medical and nursing care at community level and there is little input from social services. Respite care and crisis intervention services are virtually non-existent. The rest of the country has no specialized care except for simple small units for assessment of patients in the private sector.

In real terms private family doctors treat patients diagnosed with dementia at home or in private nursing homes by professionals with little training or understanding of the problem.

20.53 DEMENTIA AND THE COMMUNITY

There are two national non-profit organizations for patients with dementia and their families. the Asociación Médica de Alzheimer y enfermedades similares (AMAES) was founded by relatives of patients with dementia in 1988, affiliated to Alzheimer's Disease International (ADI) and hosted the ADI international conference in 1989. The objectives of AMAES are:

- family counselling and support;
- promotion of and assistance of support groups around the country (20 exist);
- education of the public;
- training for primary and secondary carers;
- promotion of clinical and epidemiological investigation;
- leadership in public policy (AMAES, 1988).

Fondo de Apoyo para la Enfermedad de Alzheimer (FAEA) was initially part of AMAES. Subsequently it has concentrated on the specific objective of creating respite through day care centres around the country. At present it manages two day care centres for patients with dementia capable of handling 20 patients each. One is located in Mexico City and

the other in the city of Queretaro. The centres are privately administered and non-profit making (FAEA, 1992).

20.53.1 The Mexican national plan for dementias

The demographic explosion has many implications both for today and the future, creating a huge demand on education, employment and health services, especially for the underprivileged and particularly for our ageing population.

The Mexican family has survived as a powerful and conservative institution, and it is very important for political stability. Traditions and moral and religious values are passed on through the family. The extended family gives a supportive structure to the young and to the old. Nevertheless, a number of factors have greatly affected the familial structure in recent years. These include:

- demographic changes;
- migration to urban areas;
- illegal migration to the USA;
- westernization;
- diminished religious influence.

Taking all these factors into account, and with the recent changes in the political structure, with a new ruling party after 70 years without any political change, the scenario is changing towards a more humane and politically sound system that will take into account the needs and future demands of Mexican society.

In the year 2001, the Ministry of Health started to develop a National Plan of Health. Within its core, the mental health of the citizens was contemplated and it became clear that as a national priority the health of the elderly, and particularly the need to develop public policy related to the dementing illnesses, was urgently needed.

A National Advisory team that could promote a plan for tackling this problem was created. I (first author) was asked to develop the team structure and within 6 months produced with my six-member team a National Plan for Alzheimer Disease and Related Disorders that could be working within the next year.

This is not the time or place to state our plan; however, let me put forward the four main objectives that we are trying to achieve.

20.53.1.1 SERVICE DELIVERY

This refers to all the measures needed to promote quality and presence in our services, especially at primary care level promoting integral management of patients with intellectual decline and for their families.

We need to create services for each community for prevention, early diagnosis, treatment, rehabilitation and respite, basically at primary care level with support of secondary units for more precise diagnosis and cases with special needs. At the same time, there is an urgent need to

promote social services to assist the families in need, with help and feedback from non-governmental agencies like Alzheimer support groups and associations.

20.53.1.2 HEALTH EDUCATION

Health education within the programme includes all aspects related to the improvement of health preventative measures when applicable to the dementing illnesses. They include means to tackle poverty, social inequality and education. In the specific area of education *per se* the following are clear objectives of the plan:

- to promote changes in the curriculum in the educational programmes, which would include dementias in the Medical Faculties and postgraduate training programmes in Medicine, plus programme changes in the psychology, nursing and social workers training programmes;
- to promote the development of a Diploma in Intellectual Decline and Dementias as a formal 2-year course for medical and paramedical personnel;
- to provide behavioural and psychological signs and symptoms of dementia (BPSD) training packages for nurses, primary care physicians and families;
- to initiate public awareness programmes.

For the educational programmes we are attempting to use novel educational systems via the internet and educational packages to promote service delivery in remote areas of Mexico.

20.53.1.3 RESEARCH

Our programme is aware that without formal research no public policy can be established. With very limited resources in our country, we must find the means to optimize the economic resources and establish guidelines for those specific areas urgently needed to support policy changes in the area of the dementing disorders.

20.53.1.4 LEGISLATION

To be able to consolidate the National Plan for Dementias, we should take into consideration the changes needed to promote both patients' and health providers' rights.

We are aware that the plan we have produced has to have short- and long-term objectives and we know that results will not be seen for some years. One major problem is clouding the whole success of this enterprise: lack of resources and bureaucracy can limit success.

20.54 THE INTERNATIONAL PSYCHOGERIATRIC ASSOCIATION'S (IPA) LATIN AMERICAN INITIATIVE

The elderly population of Latin America is projected to increase dramatically over the next 20 years (Liviv-Bacci, 1995), and with this in mind the IPA has launched an initiative

to promote the development of psychogeriatric services in this area (Resnikoff, 1997). Of a worldwide IPA membership of 1112 in 1998 only 6.11 per cent were Latin American professionals even though the total population of Latin America is greater than that of Europe and the USA combined.

Latin American countries are beginning to recognize the impact of an ageing population on their cultures and societies. This in turn will dramatically affect policy-making and general health service delivery in countries where old age has traditionally been the responsibility of extended family networks. Owing to rapid changes in the economy of the region and resultant social restructuring, traditional family values and support systems are collapsing and extended families are often no longer capable of caring for elderly relatives, leading to a demand for social intervention policies.

The IPA'S Latin American Initiative has three primary concerns:

- *Policy.* The IPA is concerned with giving assistance to healthcare professionals in the area of education of policy-makers, with the aim of a healthy approach to an ageing population. The IPA has active members who have tackled similar problems in their respective countries and who are willing to share their experiences with Latin American countries.
- *Education.* Education in geriatric and psychogeriatrics is still underdeveloped in this part of the world. The IPA will advise and assist on general principles of developing educational programmes.
- *Communication.* The flow of information in and out of Latin American countries, between them and with other nations is developing at a very slow rate. The IPA intends to promote a better system of information sharing (Resnikoff, 1997).

Netherlands

THEA J HEEREN

20.55 Diagnosis and treatment	288	20.57 Cooperation and coordination	289
20.56 Care	288	References	289

In the Netherlands the development of specific services for people with dementia started in the 1950s with the setting up of Psychogeriatric Nursing Homes. There were both quantitative and qualitative reasons: the shortage of beds in the general psychiatric hospitals and the feeling that people suffering from dementia needed specialized care (Robben, 2002).

In the 50 years that followed, the number of beds for people with dementia in nursing homes has grown to 30 813 in 2003. The nursing homes take care of patients with severe dementia for whom care at home or other residential care facilities is no longer possible. However, only 18 per cent of people with dementia reside in a nursing home (Health Council, 2002) and therefore services have been established to meet the needs of those living on their own with mild or moderate dementia. The estimated growth of the number of elderly with dementia underlines the necessity of adequate services. Whereas in the year 2000 it was estimated that 1 in 93 people in the Netherlands was demented, this figure will be 1 in 81 in 2010, 1 in 71 in 2020 and 1 in 44 in 2050 (Health Council, 2002)

In this chapter an overview of services available in the Netherlands will be given. At the moment not all services exist in every healthcare region; the Dutch Government has asked the Netherlands Institute for Care and Welfare to develop a National Dementia Care Programme giving guidelines with regard to services that should minimally be available in each healthcare region.

20.55 DIAGNOSIS AND TREATMENT

20.55.1 General practitioners

In the Netherlands the general practitioner (GP) diagnoses the majority of people with dementia. The main reasons for

referral to a specialist service are (The Dutch College of General Practitioners [NHG], 1998):

- dementia with an indication for neuroimaging (suspicion of tumour, infarcts etc.)
- rapid progressive dementia
- young age (<65)
- uncharacteristic features or course, and doubt about diagnosis
- non-cognitive symptoms that need specialist treatment
- indication for treatment with cholinesterase-inhibitors.

20.55.2 Memory clinics; multidisciplinary dementia team

Specialist services for diagnosis and treatment of dementia have in common that they work with a multidisciplinary team consisting of medical specialists, (neuro)psychologists and specialized nurses. Regional differences exist in the location of the service and the medical department from which it originates. Memory clinics usually are part of the general (or university) hospital, organized either by the department of neurology, geriatrics or psychiatry. Multidisciplinary dementia teams generally are based in community mental healthcare centres or in the general psychiatric hospital. The memory clinics usually focus more on a disease-related diagnostic work-up, whereas the mental healthcare-based teams lay more emphasis on needs assessment, case management and treatment of non-cognitive and behavioural disturbances.

20.56 CARE

20.56.1 Ambulatory

The GP can ask for support from home care (for both nursing and household tasks). When more support is needed, day

care, usually in either a residential home or a nursing home, can be obtained, including transportation to and from the day care facility. Also night care and care during a holiday by the caregiver can be arranged. Support for the family caregiver is available through meetings with other caregivers organized by either the regional community mental health-care centres or by the Dutch Alzheimer Foundation. Forms of integrated support (in which both patient and relative participate) are 'the Alzheimer cafe' (available in more than 50 cities in the Netherlands) (Miesen, 2002) and support programmes where healthcare professionals attend to both the needs of the patients and their caregivers (called 'meeting centres') (Droes, 2000).

20.56.2 Residential

When it is no longer feasible to take care of a patient with dementia in the home, the GP and/or the family will request long-term care. As mentioned before, long-term care is organized in psychogeriatric nursing homes, where a specialized Nursing Physician is responsible for the care of the patients. A recent development is the establishment of small-scale housing for people with dementia. Small-scale housing consists of separate units and of small units within a larger context (nursing home, residential care home or other type of residential care) where 8–12 persons live together. Small-scale units give a better overview, which is important for patients with dementia, allowing them to retain some degree of control over their environment. Furthermore, if a limited number of permanent carers are linked to small groups of patients, this has the benefit of promoting the individualization of care. The small-scale approach also offers the opportunity of forming groups of people who are better suited to one another in terms of background, interests or disease stage. The main problem at the moment, however, is a shortage of places both in large and small scale nursing homes.

20.57 COOPERATION AND COORDINATION

The basic principle of the current policy in the Netherlands is 'tailored care': care on the basis of a sound personal needs assessment. Dementia patients often require various types of care, treatment and counselling, delivered either simultaneously or in sequence. Many informal and professional carers, as well as various organizations, are involved in this. Integration and coherence are needed for a good quality of care. The above mentioned National Dementia Care Programme will have to provide a framework for coordination of the care delivered by many different organizations, institutions and disciplines, including GPs. High expectations are placed upon the concept of case management, in order to promote the cohesion of care.

Engā iwi, e ngā reo, e ngā karangatanga maha o ngā hau e whā – tenei te mihi atu ki a koutou kātoa. Tēnā koutou, tēnā koutou, tēnā koutou kātoa. [To all people, all voices, all the many relations from the four winds, greetings to you all] (Māori Greeting)

20.58 EPIDEMIOLOGY

New Zealand is an independent bicultural nation of 4 million people living in a group of South Pacific Islands covering an area of 268 000 square kilometres, slightly greater than the United Kingdom. Much of New Zealand is rural and the majority of the population is concentrated in the cities of Auckland, Hamilton, and Wellington in the North, Christchurch, and Dunedin in the South. One-third of New Zealanders live in the Auckland region alone. Currently, about 11 per cent of the population is over 65 years but in common with the worldwide trend of population ageing this figure is expected to rise to over 18 per cent by 2030. In New Zealand, about 3500 people die annually of various forms of dementia. The only survey on dementia to date (Campbell *et al.*, 1983) estimated 7.7 per cent of people over 65 years had dementia. In present day terms this suggests about 30 000–35 000 older New Zealanders have dementia and require services and care.

20.59 ASSESSMENT FOR DEMENTIA

For the majority of people with dementia, access to services is through geriatric or geriatric psychiatry teams via primary care. Most base hospitals have geriatric services, but geriatric psychiatry services are confined to the more populated centres. While both specialties accept patients with dementia, the

geriatric psychiatry teams assess and manage patients with the more difficult or complex behavioural, psychological symptoms of dementia (BPSD), patients for whom the diagnosis is indeterminate, need neuropsychiatric evaluation, or their dementia is complicated by a pre-existing psychiatric disorder. About 25–50 per cent of a geriatric psychiatry team's workload is with cognitively impaired or demented older people. Most of these demented patients have complications of BPSD, delirium or comorbid depression (Melding and Osman, 2000). In most major centres, geriatric and geriatric psychiatry teams work closely together either as jointed or co-located services with cross-referral systems.

Geriatric and geriatric psychiatry services use a community/outreach-based model of assessment and treatment. Multidisciplinary community teams are the norm for geriatric psychiatry and are becoming more common in geriatrics also. One or more members of a geriatric or geriatric psychiatry multidisciplinary team will usually assess a patient with possible dementia in their place of residence and if necessary, cross-refer for further assessment or admit to inpatient assessment treatment and rehabilitation (ATR) services (the term ATR is used for both disciplines). Home assessment is preferred as this gives the opportunity to assess the home situation and family burden of care. Day clinic services are in short supply with one-third of geriatric and over one-half of geriatric psychiatry services lacking such facilities. Only a few larger geriatric psychiatry services can offer a memory clinic. In the hinterland of the major cities and towns are many small rural towns and a higher proportion of older people live in these outlying areas (20 per cent as opposed to urban 15 per cent). Service delivery and provision of facilities for people with dementia in these areas are limited and provision is often by outreach clinics to these areas (national range 2–6 clinics per service) from the base hospital.

20.60 CARE FOR PEOPLE WITH DEMENTIA

20.60.1 Care in the home

The majority of people with early stages of dementia and less significant functional impairment (70–80 per cent) usually are cared for in their own homes, by family caregivers (National Health Committee, ADARDS, 1997; Richards 2001). Current health policy advocates ‘ageing in place’ (Howden-Chapman *et al.*, 1999) as the preferred option. Certainly, the majority of patients prefer to continue in their own homes for as long as possible and this option is cheaper than providing government-subsidized residential care. To enable this policy, New Zealand has a system of Need Assessment Service Coordinators (NASC), attached to all older people’s services, who design packages of home support for patients with early dementia (meals on wheels, home assistance, district nursing, etc.) When applicable, they arrange placement in a rest home or private hospital. A patient can be admitted to a rest home, state funded, for up to 28 days annually for respite. The care may be taken flexibly, a day, a week or *en bloc* to allow the hardworking family caregivers a break or perhaps a holiday. At the present time, the total number and range of services available through NASC varies throughout the country, but the recent adoption of the *Best Practice, Evidenced Based Guideline: Assessment Process for Older People* (New Zealand Guidelines Group, 2003) and the proposed use of a common assessment tool should, in the next few years, make access to home care services more equitable, nationwide.

As dementia progresses, patients will often need more specialist or greater levels of care than NASC can provide in the home environment. The most common reasons for relatives to relinquish care to institutions are: mental confusion, particularly where agitated or disruptive behaviour occurs, or frequent nocturnal disturbance, together with urinary incontinence (Richmond *et al.*, 1995).

20.60.2 Hospital care

Traditionally, older people with advanced dementia were cared for in geriatric wards in public hospitals. In the 1960s and 1970s, government policy of that time provided means-tested subsidies for patients requiring rest home or private hospital care, who were occupying public hospital beds. This policy encouraged mushrooming development of rest homes and private hospitals by the ‘not for profit religious and welfare’ sector and ‘for profit’ private operators. Over the next 25 years, the policy had the effect of devolving geriatric patients from public hospital wards to the private sector. Currently, very few long-stay beds exist within the public hospital system, and the few that remain are only on the West Coast and Northland, large rural areas with few facilities other than the base hospital. At the present time, contracted to the Ministry of Health (subsidised beds) are 21 411 rest home plus 9509 private

hospital beds (Ministry of Health, 2002). These establishments are graded into levels of care with the highest levels being for those most disabled. Eighty per cent of residents are over 75 years (MOH, 2002), of whom well over half have dementia (NZ Department of Statistics) as their main disability. In addition, there are 2315 specific beds for people with behavioural disturbance and dementia, taking about 7–8 per cent of patients with dementia who need care that is more specialized. These special dementia units attract a higher subsidy and patient entry to them is only through the geriatric psychiatry teams, who also provide consultation and liaison services to these units and indeed to the residential sector.

20.60.3 Non-Governmental Organizations (NGOs)

NGOs provide many services for people with dementia. A major contributor of services is the Alzheimer Association, which has branches in most areas of the country. The local Alzheimer societies provide help and support to family members and particularly to those caring for relatives at home. They often provide short educational courses for caregivers on managing a demented relative at home and their field workers provide caregiver support. Age Concern is another major NGO that provides advocacy and support services. Age Concern also plays a key role in health promotion (Age Concern, 1999), organizing ‘elder abuse’ local teams and providing welfare guardianship services for people without kin. Quite a few rest homes also provide day care services as well as respite care for people with dementia, services not usually available in the public sector.

20.61 MĀORI ISSUES

The constitutional basis, legislature and ethos of New Zealand is the country’s founding document, *The Treaty of Waitangi*, which in 1840 protected the ‘rights’ of the *tangata whenua* (lit. ‘The people of the land’), the indigenous Māori, while granting sovereignty of the Islands to the British Crown. Today, 15 per cent of New Zealand’s population is Māori. The Treaty is a living document and an important current ‘right’ to be protected is health. Another is the special status of Māori elders amongst their communities. *Kaumāmua* (male elder) status is associated with the cultural practices of older age, wisdom, experience and knowledge of the culture, and they are the traditional leaders of the Māori people.

Despite improvements over the last few decades, there are still marked disparities between Māori health and life expectancy when compared with the European population of New Zealand. Māori have been prone to vascular disease, stroke, renal disease, cancer, respiratory disease and diabetes, which result in untimely deaths, early onset ageing and premature dementia, particularly cerebrovascular dementia.

Ill health commences approximately 5 years earlier than in other New Zealanders and life expectancy of Māori males is 10 years less and for females 8 years less than for New Zealanders as a whole (NZ Department of Statistics). Debate is ongoing as to whether the legal definition of 'elderly' for Māori on which eligibility for national superannuation is determined should be a lower age than for other New Zealanders (Māaka, 1993). Māori ill health, poor life expectancy and the diminishing number of *kaumātua* as a result are major health priorities for New Zealand.

Ability to provide assessment, treatment and placement options for older Māori with dementia that are also culturally appropriate is a major challenge for all services. Many teams have limited access to cultural advisors and there is a major shortage of Māori professional staff within the teams. Māori concepts of health are more holistic than those espoused by their European treaty partners. For Māori, and particularly older Māori, health has a framework of *taha tinana* (physical health), *taha hinengaro* (emotional and psychological), *taha whānau* (health family), and *taha wairua* (spiritual health) (Durie, 1998). This latter dimension involves concepts of interconnectedness with their *papatūānuku* (lit. 'Mother Earth', i.e. traditional lands and landscape). Older Māori are much more likely to be living close to their ancestral *Maraes* (traditional meeting places) in provincial or rural areas that often lack geriatric services. Traditionally, Māori culture is rooted in the *whānau* (extended family) in contrast to the Western ethos of personal autonomy; their individualism is subsumed within the *whānau* so that, for Māori, all matters relating to a patient's health need discussing with the family. The *whānau* and not the individual make the key decisions.

Not only are Māori prone to dementia at an earlier age, but services for Māori older people and elders are lacking in traditional Māori areas, and attempts at residential placement of patients with dementia far away from the *whānau* contradicts the Māori framework of health and cause more distress. In common with most other ethnic groups, the older Māori population is increasing and these issues are increasing in significance for a New Zealand health service delivery.

The New Zealand Government has recently begun to take considerable interest in older people's health. The ageing of the population, the 'baby boom' generation reaching retirement in the next 10 or 20 years, and the increases in cost of disability support for older people have pressed the urgent need for a national *Strategy for the Health of Older People* (Minister for Disability Issues, 2002). The guiding principles are person- (and their family) centred care, personal choice in options for care, together with provision of a range of inpatient, community geriatric and geriatric psychiatry services, residential assessment, treatment and rehabilitation, and residential care to be available for patients in each District Health Area, nationwide. Other requirements include administrative processes that enable integrated services, are needs based, are responsive and flexible to changing patient needs, are based on best practice, supported by research and, of course, affordable to the individual and state. It remains to

be seen if the individual District Health Boards can achieve this utopian vision by the due date of 2010.

New Zealand has one of the highest rates of subsidized institutionalization for older people in the world with over 6 per cent of total public health expenditure and 25 per cent of all health expenditure for the over-65s funding residential care subsidies for older people, the majority of whom have dementia. To control burgeoning expenditure, residential services have to contract with the Ministry of Health through their local District Health Authorities, who require measurable quality criteria, including provisions for training of staff, staffing levels, medication practices and restraint minimization, all of which are subject to auditing and monitoring of facilities.

A particularly thorny issue is lack of provision of medications for the treatment of dementia. The anticholinesterase inhibitor drugs are licensed for use and therefore available but not subsidized, as the funding body believes that there is insufficient evidence of their efficacy to make them freely available. Therefore, patients have to pay the full cost of these drugs. This is seen by older persons' advocacy groups as inequitable and unfair, as many elderly patients are not able to afford them. For clinicians, inability to provide these drugs at reasonable cost for those who might benefit is extremely frustrating.

Whilst there will always be challenges to overcome, one strength of dementia care in New Zealand are that there is good cooperation between geriatrics and geriatric psychiatry. There is a clear national strategy and the policy direction is towards conjoined services nationwide by 2010 to ensure the 'continuum of care'. The strength is that there is a well-developed residential sector when patients need higher levels of care and generally, the residential, community, advocacy organizations and public arms of care are happy to work with each other for the betterment of the patients. There is political will to improve dementia care for elderly people and there is clinical will to develop the flexible community support programmes desired by patients and their families.

20.62 Local culture and demographic data	294	20.65 Conclusion	295
20.63 Laws	295	References	295
20.64 Education	295		

'Services are based on local culture, politics, skills and education of the staff who provide the service.' This was one of the main conclusions of a symposium on Service Delivery at the 11th IPA (International Psychogeriatric Association) Chicago Congress 2003 (IPA, www.IPA-online.org).

20.62 LOCAL CULTURE AND DEMOGRAPHIC DATA

The Nordic countries Iceland, Finland, Sweden, Norway and Denmark to some extent have a common Scandinavian model of the service delivered to older people. The Scandinavian model means that nearly all education, hospital treatment, social support and services to the elderly are free and paid through taxation. In Finland 25 per cent of the social costs are paid privately. The social expenditure in the Nordic countries ranges from 5.0–11.3 per cent of Gross Domestic Product (GDP, Nordic Council of Ministers, 2003) (Table 20.5). It is striking that Denmark has the lowest life expectancy for men (74.6 years) and women (79.2 years) and has the highest expenses per elderly, while Iceland has the lowest expenses and the highest life expectancy for both men (78.5 years) and women (82.1 years). However, this might in part reflect differences in statistical estimates between the countries.

The burden of the elderly differs between countries. The demographic data in Table 20.6 shows that the percentage of

the population who are over 65 varies from 11.6 (Iceland) to 17.2 (Sweden). In some counties in Sweden, more than 35 per cent of the population is over 65 (www.nordregio.se/ population). Norway has the highest rate of nursing home facilities, Finland has the lowest. It is difficult to compare the resources for the elderly in the five countries as different admission criteria are used for nursing home places, sheltered nursing facilities and special apartments etc. Only Norway and Denmark have special statistics (*Statistical Yearbook*, 2003).

In Denmark, no new nursing homes have been established for the last 15 years and 15 000 nursing home places have been replaced with two-room flats, which may be unsuitable for people with dementia.

All Nordic countries have psychogeriatric services, but not in all counties within those countries.

The Municipals are responsible for the services for older people, and as nursing home places are reduced, home service in the Municipals has increased. In the middle of the 1980s a saying became popular among the local authorities: 'Stay as long as possible in your own home'. Nursing home places were reduced and a new development began in a communal nursing system.

All countries have day facilities and different ways of providing help in the patients' own homes. Personal care, meals on wheels, administration of medication in special boxes daily and weekly, cleaning help and help in the garden are some of the possibilities. There are also day care centres.

Table 20.5 *Social expenditure in the Nordic countries*

Social expenditure	Iceland	Finland	Sweden	Norway	Denmark
Per cent of GDP	5.5	8.1	11.3	7.4	10.9
Euro (millions, 2001)	412.8	10 156.7	23 885.1	11 108	15 578.5

Table 20.7 Acts that govern the following situations

	Social service	Public health	Patients rights	Old age housing	Legal guardianship	Psychiatry
Denmark	+	+	+	+	+	+
Norway	+	+	+		+	+
Finland	+	+	+		+	+
Sweden	+	+	+	+		+
Iceland	+	+	+	+	+	

Most of the Nordic countries provide reduced fares for transportation on buses and trains, and one municipal has provided a free holiday tour to southern Europe.

Sweden has, from late in the 1970s established 'housing and living' facilities, a house for 6–8 people with dementia and full-time staff, who try to make the day as natural as possible instead of an ordinary nursing home placement. This has become more fashionable in recent years in the Nordic countries.

In 2002, the municipal staff in Denmark had risen to 129 930, and the number of people over 65 receiving help from the community nursing system stood at 324 661. Forty-one per cent of 65+ -year-old Danish people get help in their own home, some of these for 24 hours (*Statistical Yearbook*, 2003).

20.63 LAWS

The laws in Finland point out that the client must be treated so that the dignity of the elderly is preserved and that his or her convictions and privacy are respected (Vaarama *et al.*, 2001). The Danish laws, especially the Social Services Act (www.sm.dk/english/Legislation/Act) emphasize patients' integrity and autonomy. The conflict between autonomy and helplessness may lead to loss of dignity, care desertion and, in the extreme situation, senile squalor. After the first Social Services Act (2000), this conflict has left nursing staff with an ethical dilemma – tension between respect for the elderly person's autonomy and need of care.

The second Social Service Act (2003) has reduced some of the negative effects, but it still highlights the autonomy of the patient and care is still perceived, in some way, as paternalistic.

All the Nordic countries have laws concerning mental health and social service, all have a policy of patients' rights and most have legal guardianship regulations (Table 20.7).

20.64 EDUCATION

The staff in the municipal home nursing system are 'Health and Social' helpers with 14 months of basic training, 'Health and Social' assistants with 3 years (www.sosu.dk – English version not available) in basic training and nurses have 3 1/2 years training. (www.sygeplejerskeuddannelsen.dk – English version available).

20.65 CONCLUSION

Services for the care of older people in the Nordic Countries is, in most cases, functioning well, but legislation does not cover but complicates the lives of 5–10 per cent of the most disabled demented elderly.

20.66 What do we expect from old age psychiatry?	296	20.69 Conclusions	298
20.67 Old age psychiatry in Romania	296	References	298
20.68 Mental health services for the elderly in Romania	296		

In Romania, around 12 per cent of the population are over the age of 65 years. The increased prevalence of mental health problems in the elderly requires different approaches to the development of the old age psychiatry.

20.66 WHAT DO WE EXPECT FROM OLD AGE PSYCHIATRY?

The most developed countries have policies, programmes and facilities to address mental health problems associated with the ageing of their populations. Because developing countries lack such specific organization, the World Health Organization promotes such developments and has collaborated with the World Psychiatric Association and other European and international psychiatry associations to elaborate on consensus statements and technical documents. These assist the development of the care for old people with mental disorders. (World Health Organization, 1996, 1997, 1998, 2002).

20.67 OLD AGE PSYCHIATRY IN ROMANIA

Old age psychiatry is recognized as a specialty in only a few countries. It requires a grounding in general psychiatry, general medicine and gerontology. In Romania, old age psychiatry has been a recognized subspecialty of psychiatry since 2001. There is a training postgraduate course organized in Bucharest leading to a diploma in psychogeriatrics for psychiatrists, geriatricians and medical residents (World Health Organization, 1998; Camus *et al.*, 2003).

20.68 MENTAL HEALTH SERVICES FOR THE ELDERLY IN ROMANIA

In the last few years, in most countries the psychiatric services have been more and more orientated towards the community (Jolley and Arie, 1992; Arie, 1994; Wattis, 1994; Philpot and Banerjee, 1996; Wertheimer, 1997). The special needs of older people were not always recognized and respected by generic services (Wattis, 1994). Any new mental health service strategy must take the following into consideration: integration of mental health care, creation of services adequate to specific needs of patients, continuity of care by cooperation among various services providers, multidisciplinary team work, community involvement and geographic catchment areas (Cooper, 1997; Tătaru, 1997).

Stigma remains an obstacle in ensuring access to good care for the elderly. Stigma against the elderly mentally ill leads to the development of negative attitudes, including the attitudes of professionals and services, and consequent poor quality treatment and care, and inadequate funding at both national and local levels (World Health Organization, 2002). In most developing countries, including Romania, no national programme for care of the elderly exists or has been financed.

Only recently have we started to add community health-care services to the traditional system of hospital care. The Mental Health Law appeared in Romania in August 2002. In Chapter 4 of the law the forms of specific mental health services existing in Romania are listed, along with the care standards for people with mental disorders (Mental Health Law, 2002).

20.68.1 Inpatient services

The elderly with acute or chronic mental disorders are treated in:

- *psychiatric hospitals* for acute mental disorders – in most districts
- *long-stay accommodation/continuing hospital care*
- *geropsychiatric wards in psychiatric hospitals* (Nucet only; in Iași the department is only for dementia patients)
- *psychiatric wards in general hospitals* (in areas where psychiatric hospitals do not exist)
- *Liaison Psychiatry Department* in University General Hospital Bucharest
- *psychiatric department in geriatric hospitals.*

In developed countries some mentally ill people are treated in general hospitals in consultation-liaison psychiatry departments as a new way of integrating care for patients with physical and psychiatric comorbidity (Lipsitt, 2003). In Romania and other developing countries, traditionally the mentally ill were treated for financial reasons in general or geriatric hospitals as there were insufficient psychiatric hospitals.

Older people with dementia and no behavioural disorders or significant physical disabilities are also admitted to *nursing homes* and other *social service long-stay* units organized by the state, non-governmental organizations (NGOs) or churches.

20.68.2 Outpatient units

- *Outpatient or community assessment units – day care centres* (Bucharest, Brasov, Cluj, Iași, Oradea, Sibiu, Timișoara)
- *Primary care/Residential care*
- *Hostel respite care* (Oradea)
- *Community mental health centre for older people.* Organized in Oradea in 1996 by the Foundation 'Worrying about Grandparents'. The centre is a link between the patients and their families, general practitioners and hospitals for acutely or chronically mentally ill people (Tătaru, 1997; Tătaru *et al.*, 2002; Tătaru, 2003)
- *Memory Centre Bucharest.* Opened in 2000 within the 'Professor Doctor Alexandru Obregia' University Hospital in Bucharest by the Rumanian Alzheimer Society. The Memory Centre is a modern ambulatory facility for diagnosis and intervention (Tătaru *et al.*, 2002; Tătaru, 2003)
- *Community and social support services* (organized by NGOs and churches in almost all districts)
- *Clubs for elderly.*

In Romania the above services operate only in few districts and there is still a severe lack of resources.

Day programmes contribute to reducing stigma and discrimination by reducing isolation and furthering the ability

to face to daily life. (Tătaru *et al.*, 2002; De Mendonca Lima *et al.*, 2002; Tătaru, 2003).

20.68.3 Residential care

In 2003 a programme was started for residential care and follow up for patients of all ages. The elderly with mental disorders including dementia are also cared for by this programme (Health Department, 2003).

Medical treatment and also the domiciliary services, including meals-on-wheels, home helps and mobile laundry help handicapped elderly to remain at home. The latter are now only provided by NGOs and churches.

There is also some financial support from the Labour and Social Protection departments as compensation for families or caregivers of the chronically ill with handicap (including those with dementia), who are treated at home.

In Romania there is no intermediate stage between home care support and the nursing home, which provides sheltered accommodation for elderly people, or those with less severe dementia and behavioural disorders (Lovestone and Gauthier, 2001).

Most Romanians with dementia who have a family are treated at home. It is difficult for families to place them in a long-stay unit, not only because of attitudes, shame and feelings of guilt, but also because patients who have families or relatives are not admitted to state nursing homes.

Patients with dementia who have behavioural disturbances, psychotic symptoms or agitation require admission to a psychiatric hospital for acute or chronic illness, both those who live in nursing homes and the ones who live in their own homes.

Cooperation between social and medical services is difficult, because they are separately organized. The role of NGOs and of churches in the system of community care for the elderly is increasing in Romania, but is still very limited.

The extension of outreach services of nursing homes and residential homes in conjunction with day care centres, day hospitals and residential care could be a valuable alternative to the high degree of institutionalization of Romanian elderly people with or without mental disorders (Tudose, 2001; Tătaru *et al.*, 2002, 2003).

General practitioners and community nurses are also involved in the care of the elderly and it would be opportune for them to participate in domiciliary visits by psychiatrists (Jolley and Arie, 1992; Wattis, 1994). To this end we have initiated an educational programme that includes courses for family doctors who are involved in the primary care of dementia. The objectives of the training are to promote development at every level for all those concerned and indicate the groups to whom education should be offered, what to teach them and which teaching methods to use (World Health Organization, 1998; Cazmus *et al.*, 2003).

One of the key theoretical issues for the future development of community services is likely to be the distinction

between care and treatment. Psychogeriatric services will need to retain a proportion of their long-stay beds for rehabilitation and treatment of elderly people with functional illnesses and demented people with behavioural problems (Wattis, 1994).

20.69 CONCLUSIONS

Today in Romania, in the care of mentally ill people we are trying to reorientate the mental health services from old-fashioned psychiatric hospitals towards community care services. We started by reducing the number of beds, but without ensuring care programmes and community services for these patients. A great number of long-stay psychiatric wards were transferred to the social services. The elderly with chronic mental disorders as well as those with dementia are looked after both in psychiatric long-stay hospitals and in social services facilities whose staff are inadequately trained to care for these patients. However, most dementia patients are still in the care of their families, if they have one. It is a pity, but we do not have either a clear picture of all services for elderly care or local epidemiological studies in this field.

In spite of the professionals' endeavours specializing in teaching and educational programmes, there are only a few psychogeriatric services and even fewer special care services for dementia patients. The national programme for elderly care is only a project that, for the time being, lacks financial support.

20.70 AGEING IN LATIN AMERICA AND THE CARIBBEAN

Population ageing usually has been associated with the more industrialized countries of Europe and North America, where a fifth or more of the entire population typically is aged 60 or over. What is less known is the fact that population ageing has occurred and is occurring in less industrialized countries and is growing much more rapidly than the ageing population in more-developed nations. Uruguay, for example, currently has a higher percentage of older (60+) population than does Canada and the USA. Outside of Europe and North America, the Caribbean is the 'oldest' region of the world, with 10 per cent of its aggregate population aged 60 years and over.

According to the Pan American Health Association (PAHO), Latin America and the Caribbean region can be divided in four subregions for the socioeconomic profiles of older persons: Andean Countries; Central America with the Spanish-speaking Caribbean and Haiti; English-speaking Caribbean and Netherlands Antilles, and Southern Cone and Mexico, which together have two-thirds of the total older population in Latin America and the Caribbean. Brazil and Mexico alone have 50 per cent of all older people in the region.

During the first quarter of the new century, the ageing population of Latin America and the Caribbean will grow by more than 138 per cent, increasing from 42 million in 2000 to 100 million by 2025, according to a report on *The State of Ageing and Health in Latin America and the Caribbean* (PAHO and the Merck Institute of Aging and Health, 2004) (Figure 20.4).

By 2025, in every country of the region at least 10 per cent of all those aged 60 or older today will then be aged 80 or older. In Argentina, Brazil, Chile and Uruguay this proportion will be even higher. The region's oldest old percentage is projected to grow significantly during the coming decades, more than

doubling between 1990 and 2020. Brazil will likely see more than a tripling of its oldest old during this period, from 1.9 million to 7.1 million. After 2020, the growth of the oldest old will further accelerate as the large baby-boom cohorts born after World War II begin to reach age 75 (CEPAL, 2002).

Latin American and the Caribbean have a heterogeneous ethnic and racial origin population with different socioeconomic and cultural profiles. It is estimated that 60 per cent of the region's older population are women. The majority of older people have only a primary level of education. With the exception of Argentina and Cuba, the illiteracy rate among the elderly is above 10 per cent all over Latin America and the Caribbean, being over 20 per cent in most of the countries, including Brazil, Colombia and Mexico (PAHO and the Merck Institute of Aging and Health, 2004). Around two-thirds of this population lives in urban areas and there are

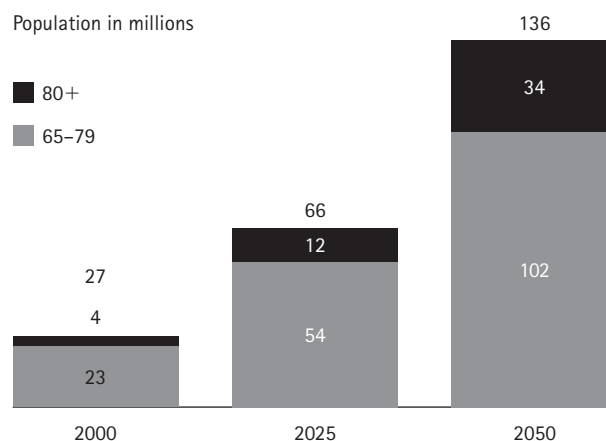

Figure 20.4 Projection of the population aged 65 or older, Latin America, 2000, 2025 and 2050. (CEPAL 2002, reprinted with permission)

51 cities with more than 1 million inhabitants. Some cities, such as Buenos Aires, Lima, Mexico City, Rio de Janeiro and São Paulo, are among the 30 largest cities in the world (United Nations, 2003).

In contrast to industrialized societies which have witnessed a steady increase in overall standards of living, in Latin America and the Caribbean access to sources of income by the elderly is usually far below what is required to secure self-sufficiency. The difference persists between the most and the least equitable societies in terms of the distribution of income. Forty per cent of men 60 years and older are still working while only 8 per cent of women have any paid employment. A higher proportion of women than men do not live with a spouse or partner, but with a child or another relative, with a decline in traditional family support.

Government efforts and resources have been insufficient to guarantee adequate healthcare and social support systems and the policy-makers do not prioritize ageing issues. Not surprisingly therefore information and research programmes are lacking and the issues of long-term care, institutionalization and pension reform have not yet been addressed.

The ageing process of the population has coincided with an increase in chronic and degenerative diseases and disabilities. As a result of these demographic changes there also have been changes in the pattern of diseases at the regional level. Two mortality patterns currently coexist: one typical of poor societal living conditions (infectious and parasitic communicable diseases) and the other of more developed societies (chronic and degenerative non-communicable diseases) are combined with high mortality from accidents and violence. The resulting 'epidemiological polarization' magnifies the persistence of significant health gaps between different social groups and geographical areas within countries (PAHO, 1997, 2002).

20.71 EPIDEMIOLOGY: DEMENTIA PREVALENCE

Despite the scarcity of available epidemiological data it is reasonable to consider the dementias as a major public health problem in Latin America and the Caribbean, although it is not recognized as such at either governmental or community levels (Arizaga *et al.*, 1999).

A MEDLINE-based search to assess the epidemiology of dementia in Latin America and the Caribbean by Caramelli (2003) found a total of 16 studies of which only seven were population-based studies carried out in Brazil (The Catanduva Study) (Herrera *et al.*, 2002), Colombia (The Aratoca Study) (Rosselli *et al.*, 2000; Pradilla *et al.*, 2002), Cuba (The La Habana Study) (Llibre *et al.*, 1999) and Uruguay (The Villa del Cerro Study) (Ketzoian *et al.*, 1997). In addition there are two other ongoing studies being conducted in Mexico (C Zunica, personal communication) and Venezuela (The Maracaibo Aging Study) (Maestre *et al.*, 2002).

Methodology for dementia screening, as well as criteria and tools used for dementia diagnosis varied widely in the different

studies. In Uruguay, Ketzoian *et al.* (1997) estimate a prevalence of 4.03/1000 when the entire population of Villa del Cerro is considered. Herrera *et al.* (2002) found a prevalence of dementia of 7.1 per cent among 1156 randomly selected subjects (25 per cent of the total elderly population) aged more than 65 years in Catanduva, Brazil. Llibre *et al.* (1999) found a prevalence of dementia of 8.2 per cent among subjects aged more than 60 years in Havana, Cuba. Pradilla *et al.* (2002) estimate a prevalence of dementia of 10.5/1000 subjects (all ages) in a rural area in Aratoca, Colombia. The differential diagnosis of dementia subtypes is not available in all studies, but when it is described, Alzheimer's disease (AD) or degenerative dementia is the leading cause, ranging from 47.4 per cent to 62.5 per cent of all dementia cases. Mixed dementia or AD with cerebrovascular disease is the second most common diagnosis in three out of five studies and vascular dementia is the second leading cause in the remaining two population studies.

20.72 ORGANIZATION OF SERVICES FOR PEOPLE WITH DEMENTIA

Although overall improvements in dementia care can be seen in this region, improvements are not uniform for all countries or for all social groups within a single country (Mangone *et al.*, 2000). However, some similarities are still present. Patients and their families have misconceptions about normal ageing and dementia. Resignation and lack of expectations are very common.

In a study conducted in 24 centres in developing countries including Latin America and the Caribbean, 706 persons with dementia and their caregivers were interviewed. It was found that older people are indivisible from their younger family members. Most caregivers were women, living with the person with dementia in extended family households. Nonetheless, despite the traditional apparatus of family care, levels of caregiver strain were at least as high as in the developed world. Many had to curtail employment in order to provide care and also faced the additional expense of paid carers and health services. Families from the poorest countries were particularly likely to have used expensive private medical services, and to be spending more than 10 per cent of the per capita GNP on health care. It is suggested that the high levels of family strain feed into the cycle of disadvantage and thus should be a concern for policy-makers (The 10/66 Dementia Research Group, 2004).

An overview of the healthcare system in the region shows that it is a mixed public-private system in both insurance and provision, with most elderly persons being forced into the public system (Marin and Wallace, 2002). The dominance of the public system in the care of the elderly has the potential to improve the organization and delivery of needed services, but up to now health care for older persons has not been a top priority compared to broader macrosystem issues.

Specialized services for the elderly are fairly scarce across Latin America and the Caribbean. Most are based in big cities

at large teaching hospitals with few psychogeriatric hospital wards, day hospitals, dementia reference centres and memory clinics or day centres. In recent years there has been a rising awareness by the health and social services acknowledging the lack of resources available for the elderly and the need for a change.

In Brazil, after the approval of the National Policy Act for the Health of the Aged by the Ministry of Health in 1999, 13 reference centres out of 78 planned are now open for the care of demented patients and their families. These centres offer free distribution of cholinesterase inhibitors and atypical antipsychotics under rigid medical control. In 2003, the Elderly Act was approved by the national parliament with the intention to ensure social, health, citizenship and human rights for the Brazilian elderly population.

In Mexico, the Ministry of Health began the development of a National Plan for Alzheimer's Disease and Related Disorders, now considered a national priority with the following components: service delivery, health education, research and legislation (Resnikoff, 2001).

The healthcare services usually are divided into primary, secondary and tertiary care. In most primary care settings, the professionals have inadequate working conditions combined with time constraints. General practitioners (GPs) often consider memory problems as part of the normal ageing process. Most professionals have scarce knowledge of dementia recognition and management with poor understanding and training in the use of diagnostic tools (Sarasola *et al.*, 2003). To illustrate this fact a study was conducted in Brazil (Bertolucci and Ferretti, 2002), which surveyed 1500 medical practitioners with regard to time of graduation, specialty, study habits, work setting and basic questions about dementia. Lack of knowledge was noticed in 942 doctors from different specialties who participated in the survey, especially among those who had graduated 7 years and over, as well as GPs. Not surprisingly, patients are not adequately investigated and, as a result, if they are referred to the reference centres, it is often late in the course of their dementias.

Specialists are concentrated in big cities working mainly on their own in private practice. At the universities, services are not prepared to see the number of patients in need and in general there are few properly trained specialists in dementia care. Specialist doctors are usually geriatricians, neurologists or psychiatrists and a multidisciplinary team is rarely available (Machado, 2003).

Most countries in the region have the availability of diagnostic studies, genetic testing, neuroimaging (cranial computed tomography, magnetic resonance imaging and single-photon emission tomography) as well as neuropsychological testing, although they are available mainly in reference centres, which are considered expensive and not always readily accessible to the population (Mangone and Arizaga, 1999).

Support groups for patients and their carers have sprung up in the region over the past 10 years. Alzheimer's Disease International (ADI) as well as private groups offer a range of activities for the aged, and support family members and

carers; these are appreciated, but are of insufficient number to cover the needs of the population, little publicized and difficult to access.

20.73 EDUCATION, TRAINING AND RESEARCH

Despite the growing interest of the professionals in the field there are a small number of specialists. Most countries (if not all of them) lack a national framework for postgraduate education in dementia. There is no unique specialty or society for the care of demented patients. In most countries national geriatric, psychiatric and neurological societies usually have special interest groups on dementia. By valuing the importance of an interdisciplinary approach to dementia and other neuropsychiatric disorders in old age, Argentina, Brazil and Chile have successfully founded interdisciplinary associations of geriatric neuropsychiatry, although the medical councils do not recognize geriatric neuropsychiatry as a medical subspecialty (Machado, 2003; Sarasola *et al.*, 2003).

In the years to come, the development of public health strategies to cope with dementia will be very challenging for Latin America and the Caribbean. Therefore, efforts should be made for a permanent collaboration among academics, clinicians, national medical societies, governmental and national/international non-governmental organizations. Initiatives in that direction will be crucial for raising awareness of the dementias, which should influence political action, policy-making and general health service delivery in the region.

With this purpose, Latin American members of the International Psychogeriatric Association (IPA) have established an interest group named the Latin American Initiative (IPA LAI) (Resnikoff, 1997). Of the worldwide IPA membership in 2004 only 5 per cent were Latin American professionals, even though the total population of Latin America is greater than that of Europe and the USA combined.

IPA LAI aims to help in the development and implementation of educational programmes in Latin America as well as to support collaborative multinational epidemiological studies. The IPA LAI Educational Program Group is directed to primary care physicians and the healthcare team working in primary care (Machado, 2001).

The programme includes the design of educational strategies to allow the transfer of new knowledge to the daily practice of professionals dealing with dementia, as well as to provide direct training to healthcare professionals giving them the necessary tools to train the caregivers. Moreover, aims are:

- to assess the impact of sociodemographic variables on dementia diagnosis such as education and illiteracy;
- to develop or adapt assessments for sociodemographic factors relevant to the diagnosis;
- to adapt screening and diagnostic instruments that are reliable, practical, easy to implement and interpret; and

- to develop diagnostic decision trees for expensive diagnostic studies in dementia considering the local financial situation and other health priorities.

Another example of a partnership reported to have been very effective in helping to direct and support advocacy was between The 10/66 Dementia Research Group with ADI and its national Alzheimer's Associations (Prince *et al.*, 2004).

20.74 CONCLUSIONS

The care of persons with dementia has shown considerable and steady improvement in Latin America and the Caribbean. In spite of this progress, governmental funds are not enough to provide all the needs, societal awareness is low, socio-economic problems are great and the number of specialists in the public and private sector is very low.

According to Gutierrez-Robledo (2002), the fast epidemiological transition faced by Latin America countries has created an enormous opportunity to develop systems that differ from those in more developed countries by capitalizing on the lack of infrastructure to produce more home-based rather than institution-based long-term care systems. Since dementia treatment is a dynamic process, it should be approached through programmes that range from health promotion strategies to the establishment of support networks for long-term care in the community. These programmes should be part of a public policy that involves all sectors of society to provide adequate care for patients with or without family support, family members and carers. Involvement of the elderly in the planning of their own futures will be also of paramount importance.

Considering the important cultural and historical links present between Latin American and the Caribbean countries, a joint effort to determine and share common solutions for the significant challenges in providing better care and in promoting a higher quality of life for dementia patients in the region should be mandatory.

20.75 Sociopolitical framework	303	20.78 Conclusion	304
20.76 The assets of health and social resources	304	References	305
20.77 Liabilities of health and social resources	304		

20.75 SOCIOPOLITICAL FRAMEWORK

20.75.1 Unity versus diversity among autonomies

It is not possible to understand the organization of the Spanish health system services without knowing the key points of the sociopolitical context. Spain is a highly aged state of around 43 million inhabitants (17 per cent are more than 65 years old, and this percentage reaches up to 25 per cent in some provinces). A crucible of languages and cultures, it is politically organized into 17 autonomous governments, very different in their extension, number of inhabitants, degree of urban development, economic growth and cultural heritage. Although the general principles are guaranteed by some national laws, for instance, the Health General Law (Ley General de Sanidad, 1986) or the Gerontology National Plan (Ministerio de Asuntos Sociales, 1992), each autonomous government is concerned with the development of some specific laws, standards of performance and budgetary endowments. Therefore, there are remarkable territorial differences in practice.

20.75.2 Service systems

In this context, dementia care is mainly exercised by the three main public systems (Health System, Social Services and so called 'Welfare-Health Service') complemented by a private system of irregular implementation.

The National Health System guarantees the right to complete, free health care for almost all the population. It is

complemented by the Social Service System, which manages retirement pensions and all kinds of social welfare (for illness, unemployment, poverty, etc.). In the last few decades, the capabilities of both systems (and their economic expenses) have increased in an exponential way, with serious coordination failures between both. This is especially noticeable when diligence is needed for groups with many health and welfare needs (a situation for which dementia patients and their families are a typical example).

With the purpose of palliating the aforementioned deficiency, the Catalanian autonomous government started a decade ago the programme 'Vida als Anys', addressed to chronic patients (80 per cent were elderly). This integrated model of resources, which was accompanied by a specific budget, has succeeded in showing its judicious points and has become a referential point for other autonomies (e.g. Galicia).

Finally, with regard to the private sector of Health and/or Social Services, two facts must be pointed out:

- it has an unequal representation in the different autonomies of the state;
- given the wide basis of public health and social services, it aspires to 'sell' its product to the public system rather than 'competing' with it.

20.75.3 Public opinion

The mass media quickly showed great interest on the subject. The degree of social alert has increased remarkably during over the last years. The Spanish situation will be outlined by

considering the assets and the liabilities of Spanish systems of care for dementia patients and their carers.

20.76 THE ASSETS OF HEALTH AND SOCIAL RESOURCES

There is some epidemiological information available, regarding the magnitude of the problem (Lobo *et al.*, 1992; López-Pousa *et al.*, 1995) and the relationship between cognitive impairment and other pathologies (Mateos *et al.*, 1997, 2000).

The family is still the main source of social support in Spain. Consistently, the diminution of its members, the increasing involvement of women in the professional world and a decrease of the birth rate has turned the situation into an untenable one. Some devices to measure carer burden and needs have recently started to be introduced into clinical (Martín-Carrasco *et al.*, 1996) and epidemiological (Mateos *et al.*, 1998; Ybarzábal *et al.*, 2002) studies.

Public health coordination was successfully achieved some time ago in some provinces such as Alava, by reason of its unusual administrative autonomy, its high socioeconomic level and prevailing urban organization, as well as its small territory.

At some health centres there are psychogeriatric teams with full-time interdisciplinary staff, a community philosophy and team work (Martín-Carrasco *et al.*, 1991; Mateos *et al.*, 1994; Martín-Carrasco and Artaso, 1996; Sánchez-Pérez, 1997, 2002; Sánchez-Pérez *et al.*, 1997).

Social centres include modern residences/nursing homes with a community projection (SEGG, 1995) and home help respite care (SEGG, 1997).

Carers' self-help movements rely on two big state associations and an increasing number of regional offices.

Several universities give postgraduate courses on gerontology and the autonomous University of Barcelona still offers, in its sixth edition, the unique postgraduate Diploma and Master of Psychogeriatrics held in Spain (Sánchez-Pérez, 2003).

The autonomous governments of first Cataluña and then Galicia, Cantabria and Asturias, have created advisory commissions for psychogeriatrics. Their task is to set up the philosophy and to reach an agreement on protocols for performance and coordination of resources needed for dementia care, including modalities of treatment for those disorders (Servei Català de la Salut, 1988a, b; Comisión Asesora en materia de Psicogeriatría, 1999).

We are witnessing an increase in the number of psychiatrists interested in taking care of dementia patients and carers as a result of the improvement of the young psychiatrists' training not only in dementia, but in geriatric psychiatry in general. This is due to a conjunction of interests and opportunities. On the one hand, those professionals working within the limited welfare points are enthusiastic and available for teaching and training residents. On the other hand, some scientific societies, like the Sociedad Española de Gerontopsiquiatría y Psicogeriatría

(SEGP), have played a stimulating role by means of congresses and monographic courses.

20.77 LIABILITIES OF HEALTH AND SOCIAL RESOURCES

The coordination between the different departments is still deficient, not only between Health and Social Services, but also within both areas:

- between primary and specialized health care;
- between the three specialties mostly involved – psychiatry, neurology and geriatrics; and
- between basic and specialized social services.

The success of the first Alzheimer conference, under the leadership of neurology, created the hope that the rest of the involved medical specialties (psychiatry and geriatrics, as well as primary health care) would join forces with other professional sectors and patients' informal carers. After the fourth conference, the feeling is that such an effective and supportive coordination in daily welfare activities will take much longer than relatives and many professionals had imagined and still hope for.

There is a lack of basic resources including places in nursing homes, day hospitals and home care, and there are few specialized services with specific programmes for dementia care. If residential facilities for elderly people develop too quickly, a disconcerting diversity is created, in such a way that besides centres equipped with modern technologies and medical staff *in situ*, suitable for housing dementia patients, there persists the out-of-date asylum model where philanthropic organizations assume care for patients without enough professional support. The current regulations in this sector need to be improved.

There is an increasing debate over the proliferation of clinics exclusively focused on the diagnosis of dementia and that are not always equipped with interdisciplinary teams. This model contrasts the principle of welfare continuity emphasized by the World Health Organization (WHO) and the World Psychiatric Association (WHO, 1997).

Geriatric and psychogeriatric teaching is not yet consolidated in the undergraduate courses of the medical faculties in most of the universities of the country. Many professionals lack awareness and training, especially within primary health care and community social services (Mateos, 2000).

The plight of carers has still not been recognized by society. We lack legal regulation to lighten their economic burden and to help them continue their job.

20.78 CONCLUSION

At present the balance is negative (Mateos, 2003). The Spanish House of Commons decided in 1997 to urge the Government to develop a National Plan on Alzheimer's disease. It seems that

the National Health Ministry wants to revitalize this unfinished project, which should outline concrete actions to improve the deficiencies discussed above. It is a way for hope, not only for carers but also for those professionals entrusted with the task of delivering and improving dementia care in Spain.

20.80 Organization of services in Britain	307	20.84 Opportunities for the future	310
20.81 Community support	307	References	310
20.82 Specialist services	308		

Since the last edition of this book a number of major events have influenced the practice of old age psychiatry in Britain. Five years ago we were optimistic about the impending Royal Commission report on long-term care, yet disappointingly the Government did not fully accept their recommendations, which has led to divisiveness between the different countries within Britain. The National Health Service had been organized for a while through acute trusts, which were mostly concerned with running the general hospitals, and community trusts providing the rest of the services, which contained most of the psychogeriatric services. Community trusts have now been abandoned in favour of primary care trusts (PCTs) who purchase care from the acute and mental health trusts. In some cases the old age services have been incorporated into the new mental health trusts, whereas elsewhere they are provided directly by PCTs. Other changes include the publication of a *National Service Framework for Older People* (Department of Health, 2001) and the appointment of an older persons' 'tsar'. Whilst these initiatives are welcome they have largely focused on physical health issues and have not been accompanied by extra readily visible monies, and the impact of their development appears at best neutral.

On a more positive note the last 5 years have seen a huge expansion in the use of cholinesterase inhibitors in the management of mild to moderate Alzheimer's disease endorsed by the recommendations of the National Institute for Clinical Excellence (NICE, 2001). The emergence of these drugs has led to differing patterns of referral from primary care with a tendency for patients to be seen and diagnosed at a much earlier stage of their illness than would have been the case 10 years ago. However, there are still up to four-fold differences in uptake between different strategic health authorities within the UK (T Gosden and C Baker, personal communication).

20.79 THE CLIENTELE

20.79.1 People with dementia

The prevalence of dementia in the UK has increased by at least 50 per cent in the last 30 years and is estimated to increase by the same proportion between 1991 and 2021; by this time over 900 000 people are likely to be affected (Challis *et al.*, 2002).

A small proportion of those with dementia have illnesses starting before the age of 65 (early onset dementia). These patients usually present first to adult psychiatric services or neurologists, but, whereas the latter may have a particular role with initial diagnosis and assessment, the overall management often falls to old age psychiatry services who tend to exhibit a more holistic approach. The development of memory clinics has increased the role of old age psychiatry in the initial diagnosis and treatment of these early onset cases. However, only a minority of districts have services specifically geared to their support in the community or indeed their longer-term care.

20.79.2 Informal carers

The bulk of care in the UK is provided by informal carers and it has been estimated that the replacement cost of the care provided by friends and family for chronic disorders such as dementia exceeds £20 billion. There is a great recognition of the need to provide services that not only help patients but also support and offer respite to their carers. Most services offer carers support groups, both educational and supportive, sitting services and respite care. Voluntary services like MIND and the Alzheimer's Society work with carers to provide continuing support including helplines and advocacy. Most carers wish

to keep the patient at home but features such as aggression, agitation, insomnia and incontinence make this difficult and are correlated with the need for residential care. One study has shown that whilst only 10 per cent of carers wished their relatives could be taken into residential care, this was shown to be the only intervention that had a positive impact on the mental health of carers.

20.80 ORGANIZATION OF SERVICES IN BRITAIN

20.80.1 Health care

The bulk of health care in Britain is provided by the National Health Service (NHS) funded through taxation and predominantly free at the point of delivery. The NHS has struggled to keep up with the pressures of technological and demographic change and has only managed by the encouragement of growth in private health insurance and a narrowing of the definition of health care. The latter has been achieved by moving much of the responsibility of care for chronic disability and illness, such as dementia, onto social services, people with dementia and their families.

General practice remains the cornerstone of the NHS and manages the vast majority of mental disorder without referral to secondary care. However, the last 40 years have seen the emergence of Geriatric Medicine and Old Age Psychiatry as specialties. Although geriatric medicine has become increasingly engrossed in the acute hospital care of older people, old age psychiatry has focused much more on community-based assessment, treatment and support of carers. This, together with an active approach to the treatment of functional illness and close work with primary and social care has made it an attractive branch of psychiatry expanding 15-fold since the mid 1970s. Whilst the specialty continues to grow, some areas of the country fail to attract or retain consultants. Psychiatry has failed to attract more than 4 per cent of the medical graduates who are necessary to fuel consultant expansion. Most services in Britain manage the mental health needs of all the population over 65, i.e. depression, alcohol misuse, paranoid states, as well as dementia, though a few old age psychiatrists will work with dementia alone. Treatments for depression have improved greatly in the last 10 years and this, combined with the emergence of cholinesterase inhibitors, the continuing closure of hospital-based long-stay beds and demographic changes, have all led to a higher proportion of community-based referrals relating to dementia care.

20.80.2 Housing, social and voluntary services

A major problem in coordinating care for people with chronic disability in Britain has been the lack of co-terminosity, different management and funding arrangements between health

and social services and again between the latter and local authority environmental services, e.g. housing, transport and leisure. Initiatives to ensure closer working between health and social services have been slow to materialize for the over 65s and have lagged behind a closer working between the same agencies dealing with mental illness in younger people, a process accelerated by the *National Service Framework (NSF)* for mental illness (which specifically excluded any coverage of mental disorder in those over the age of 65). In many areas old age psychiatrists now work more closely with geriatricians than with their colleagues practising general adult psychiatry.

The last decade has seen a continued expansion in the care, both in the community and within institutional settings, provided by the commercial sector. However, the voluntary sector provides a significant proportion of day care and specialized domiciliary support. Organizations such as Age Concern, the Alzheimer's Society and MIND continue to play key roles as pressure groups, as sponsors of research and pilot developments, and as instigators of a wide range of information, self-help and relative support groups.

20.80.3 Financial support

Care provided by the NHS is free and people with at least moderate disability are eligible for non-means-tested allowances, e.g. attendance allowance, subject to independent medical assessment. These grants are designed to allow the individual to purchase care to cater for the disability but the attendance allowance would, for example, purchase about 10 per cent of the weekly cost of nursing home care.

The Royal Commission on Long-Term Care of the Elderly (1999) recommended that all personal care should be provided free regardless of assets, and that residents of homes should be responsible only for the hotel charges. The Government in England rejected this recommendation as too costly and instead introduced free nursing care. In reality most care provided in nursing homes was again deemed to be personal care with the Government restricting the NHS contribution to the funding of care provided by registered nurses alone. This free nursing care is assessed as falling into one of three bands attracting payments of between £40 and £135, each a fraction of the total care costs. The Scottish Parliament, however, accepted the recommendations of the Royal Commission. These different practices have helped fuel a lively debate about long-term care and have attracted considerable media attention.

20.81 COMMUNITY SUPPORT

20.81.1 Primary health care

Nearly all patients with dementia live in the community and hence the bulk of their medical care comes from GPs. Although their skills and confidence in diagnosis and management appear to be improving, there are still wide variations as a

result of inconsistencies in training with little exposure to old age psychiatry at undergraduate or GP training level. In primary care many district nurses have been seconded as care managers, which has improved liaison between health and social services, as has the development of older persons' health-care coordinators. These initiatives have probably brought some cases of dementia, where carers are under considerable stress, to secondary care at an earlier stage than otherwise would have been the case. These initiatives have had more impact on dementia care than GPs' contractual needs to screen all patients over 75 annually or through specific inputs of health visitors who are predominantly involved with families and young children.

20.81.2 Domiciliary support and day care

For the demented person living with a resident carer, social care aims to provide support in the form of domestic tasks, shopping, aspects of personal care and respite to allow the carer to go out. For the demented person living alone, such care is targeted at aspects of personal and domestic care, in which skills have been lost, e.g. maintenance of adequate diet and compliance with medication. The limiting factor to the successful introduction of home-based care will often be the degree of insight of the patient. Unwillingness to accept help will lead to increased risks through self-neglect and wandering. Here the community psychiatric nurse (CPN) visiting the home and developing a rapport with the patient is crucial and, where paranoid symptoms exist, the judicious use of an antipsychotic may be vital.

Day centres, as opposed to day hospitals, are run by social services departments or voluntary agencies and may form an important part of a package of care that allows a demented person to continue living at home. They cater for a wide range of clients with varying degrees of confusion and physical disabilities, with some day centres setting up separate days for those patients with more advanced dementia often associated with mild behavioural problems such as wandering.

Day care has been shown to form part of the package of support in up to two-thirds of patients with dementia. Studies have emphasized the positive effects on both the carers and those with the dementia themselves, particularly for the latter at the relatively early stages of the illness.

20.82 SPECIALIST SERVICES

In the UK with its ageing population, people with dementia are seen in all areas of medicine but the specialist management and assessment *per se* is largely the province of old age psychiatry. Very few neurologists provide dementia services, with most only being involved in the diagnosis of younger and atypical cases. Geriatricians have always managed dementia in the physically frail, and as they become more proactive in the

management of risk in stroke patients, running clinics for falls and 'funny turns', they are much more likely to be involved in the diagnosis and management of vascular dementia.

20.82.1 Assessment

Although most dementia referrals are still assessed in the home setting by an old age psychiatrist, increasingly this is delegated to one of the members of the multidisciplinary community mental health team. The aim of any assessment is to establish a diagnosis, identify any treatable disorders, ascertain the suitability of current living environment, and make some estimation of care requirements and future prognosis.

Some centres have always used day hospitals to undertake these initial assessments rather than home visits, and the trend to outpatient assessment is increasing with the advent of symptomatic treatments and the consequent development of memory clinics. Patients tend to be seen much earlier in the disease process and outpatient attendance is quite appropriate.

Old age psychiatry services have tended to devote most of their energies to developing community assessment and treatment programmes with a great emphasis on caregiver support, though increasingly attention is turning to the multitude of patients admitted to general hospitals with physical illness complicated by dementia. A few experiments with joint psychiatric and geriatric assessment units aimed at treating both physical and behavioural problems have not been widely adopted. Most services now favour 'inreach' or liaison services to the general hospital wards often employing specialist nurses to great effect.

20.82.2 Treatment

The rapid expansion of memory assessment clinics, prompted by the enthusiasm following the licensing of the first cholinesterase inhibitor in 1997, has not been uniform across the UK. This has not only been based on lack of resources, although no additional funding was made available to provider trusts who would bear the costs of prescriptions and monitoring, but also on the traditional conservatism of the UK medical establishment who felt the evidence of efficacy was not sufficiently robust.

Some impetus to prescribe these treatments was given by the NICE guidelines although these have also provided hurdles. Their guidance suggested that treatment with one of the three licensed cholinesterase inhibitors should be made available to patients with mild to moderate Alzheimer's disease with Mini-Mental State Examination (MMSE) scores above 12, provided that the diagnosis had been made in secondary care and that treatment was monitored regularly by the specialist team or as part of a shared care protocol with primary care (NICE, 2001).

This advice has neither been justified scientifically nor implemented fully owing to the debate about whether the budgetary responsibility should fall to primary or secondary

care. Although it was a laudable attempt to promote the rational use of these drugs, it has effectively removed the management of uncomplicated cognitive impairment from primary care where it must belong. The guidance has paradoxically complicated management and escalated costs, with the need to develop numerous specialist clinics to monitor the treatment, and has effectively deskilled GPs who now feel unable to take responsibility for what is quintessentially a primary care problem. Despite the introduction of the NSF for older persons, with its attempt to root out age discrimination, the NICE guidance has introduced a hurdle to the NHS treatment with a licensed drug for a common, disabling and distressing illness in older people unparalleled in any other age group. Its attempt to resolve the marked variations in availability across the country, up to four-fold differences in use, for which the term 'post code prescribing' was coined, has been unsuccessful. Prescription levels have increased overall but the geographical inequities remain. One benefit from the resultant infrastructure is that more patients with early Alzheimer's and younger onset cases are being assessed and the systems are now established to enable the utilization of new treatments as they evolve. It is interesting to note that the use of these treatments is much higher in Northern Ireland, which has combined health and social service boards and may reflect an understanding that the use of these drugs could provide savings in long-term care costs.

20.82.3 Community support

The increasing emphasis on community-based support has led most services towards a model based on community mental health teams (Coles *et al.*, 1991). These multidisciplinary teams usually comprising psychiatrist, CPN, social worker and occupational therapist, take a generic approach to the allocation of assessments at a team meeting, although the person designated as the key worker or care manager can call on the specialist advice of other team members as required. For most services the CPN is the team member most involved with continuing care and carer support for dementia patients. They often take on the role of liaising with primary care, social services and private community care and residential providers as well as accessing secondary care in the form of assessment or respite admissions. They often run carers' groups both as support and education and are usually able to respond quickly to avoid crises. Some services have now developed 24-hour services to allow continuity of care. Increasingly charities are involved in providing community support in terms of helplines, sitting services and advocacy programmes, which add considerably to the quality of the support provided by statutory services.

20.82.4 Day hospital and respite care

While day hospitals have a definite role in the initial assessment of dementia patients, continued attendance has often

been criticized as being synonymous with day centre supportive care, providing social and diversional activities for the patient and respite for the carers. However, they provide skilled ongoing support for the increasing numbers of cases of dementia living in the community with high dependency needs and behavioural disturbance, who can be very disruptive in a day care facility, and they appear to identify and meet the needs of such patients (Rosenvinge, 1994; Howard, 1995; Ashaye *et al.*, 2003). Many patients had been offered planned regular respite admissions in hospital as part of a care package to enable carers to continue looking after their relative at home. However, there is increasing pressure on beds and respite is now limited to those patients whose continuing care needs cannot be met in residential settings. The lack of frequent regular respite has had the effect of increasing the number of patients requiring full-time care as carers give up, and many of these now ironically occupy the same short-term beds as a result of the lack of public funding of nursing home care beds.

20.83 INSTITUTIONAL CARE

20.83.1 Historical perspective

The advent of specialist services such as geriatrics and old age psychiatry shifted the emphasis from long-stay care towards acute care and rehabilitation. In old age psychiatry many long-stay wards were closed to support investments in community care and day hospitals. At that time there were very few nursing homes, and local authorities, then the major providers of residential care, were directing funding to sheltered housing and domiciliary support. The 1980s saw the private sector take on an increasing proportion of the provision of residential and nursing home care, with the financial costs picked up by Social Services, patients and their families with the heavy means testing mentioned earlier. Perverse incentives applied by the Thatcher government led to a massive increase in institutional care and starvation of community developments of the previous decade. It was also used as an opportunity for the NHS to withdraw heavily from its role in continuing care.

20.83.2 NHS and Community Care Act, 1990

Following criticism by the Audit Commission and new models such as the Kent Community Care Scheme, this important legislation (DHSS, 1990) attempted to redress the imbalance of the 1980s. It gave Social Services the responsibility for assessing need and commissioning appropriate care, with the emphasis on supporting people in their own homes where possible. Unfortunately inadequate funding and continued cost shifting by the NHS handicapped the efforts of Social Services' domiciliary provision and was slow to take off; the growth of 'warehousing' in residential care

continued well into the 1990s. The low tariffs offered by Social Services have often resulted in poor quality and inadequate training by the private providers, a situation in which the continuing care of those with dementia tends to suffer most. This with a fall-off of capacity owing to unprofitability in the institutional sector has resulted in increasing resort to hospital admission when social care breaks down and then blocking of beds through delays in the care packages and placements necessary for discharge. The rising tide of blocked beds has caused much consternation to the Government as it contributes to problems in achieving targets on waiting times for elective procedures, such that from 2004 Social Services are being fined for 'bed blocking' that occurs in acute beds. At present such arrangements will not apply to delayed discharges from dementia assessment beds as they are not considered as acute.

20.83.3 Settings for long-term care

Changes described earlier in this section have led to an increasing proportion of people in residential homes suffering from dementia. Those residential care homes specializing in dementia care are often termed Elderly Mentally Infirm (EMI) homes. Most of these homes have responded well to the challenge of managing behavioural problems and fears of overreliance on sedative medication are not borne out by recent research (Lindesay *et al.*, 2003). At least 50 per cent of residents of non-EMI homes nevertheless have dementia. Research suggests that in these homes the recognition and skills in the management of dementia, even by registered general nurses, is often poor (Macdonald and Carpenter, 2003).

Those with the most difficult behaviour may need to receive ongoing care in an Old Age Psychiatry Unit or in an EMI nursing home environment. Since 1996 health and social services have had to produce jointly agreed criteria for those people entitled to receive free NHS continuing care (Department of Health, 1995). This process has accelerated a rapid decline in the number of NHS continuing care beds, though there is widespread variability in the existence of such beds from one health authority to another (Audit Commission, 2000). These often operate as medium stay units for patients with disturbed behaviour, often in the middle stages of their illness.

20.84 OPPORTUNITIES FOR THE FUTURE

A new millennium has continued to bring a frenetic pace of change to health services but, while the health service as a

whole has started to receive real extra investment, little of this as yet has found itself directed towards dementia care. Fortunately old age psychiatry continues to expand as a specialty and appears an increasingly attractive career option for doctors choosing to work in mental health. The expansion in use of cholinesterase inhibitors and other drugs for dementia has changed the practice of old age psychiatry and exciting opportunities exist for further developments in this sphere. These factors, having coincided with increasingly responsible coverage of dementia issues in many areas of the national press, promise to make the next few years challenging but rewarding for all those who work in this important area.

20.85 Care for community-dwelling patients	311	References	315
20.86 Care for non-community-dwelling adults	312		
20.87 Services for both community and non-community-dwelling patients	313		

Dementia is the most common psychiatric disorder of late life. It is characterized by progressive cognitive impairment, behavioural disturbances, and functional decline. Given the range and progression of symptoms over time, healthcare services for demented patients are varied and dynamic in order to respond to patients' changing needs.

An important goal of care is to optimize the time the patient is able to reside in the community while simultaneously minimizing the burden to caregivers and families (American Psychiatric Association, 1997). This is important as caregiver burden can have serious consequences for both the family and the patient. The substantial demands on time and energy, coupled with the reality that a family member will not get better, often lead to depression and/or ill health for caregivers. In extreme cases, this can lead to elder abuse and/or neglect. The following discussion describes various types of services, the population for which they are most appropriate, and the characteristics of ideal clinical programmes.

Regardless of type of service, quality clinical programmes share some common characteristics, the most important of which is the recognition that the management of dementia should address both physical and mental health. As other authors in this book indicate, there is a high rate of psychiatric symptoms among demented patients but many do not receive mental health services. Barriers include:

- a shortage of geriatric mental health professionals;
- a lack of training identifying and treating behavioural problems; and
- a lack of adequate reimbursement rates for mental health services.

A second characteristic of quality programmes is the use of non-pharmacological approaches to manage behavioural

problems when possible, and to recognize the need for pharmacological treatments when appropriate. Both are preferable to restraints, which are not only inhumane but do little to encourage positive social interactions and feelings of wellbeing.

Another characteristic of exemplary programmes is that their physical settings are conducive to the needs of demented people both with and without sensory impairments. Some people with dementia have a tendency to wander; environments in nursing homes, for example, that promote safety (e.g. secure boundaries), while at the same time allow patients freedom of mobility, are optimal. Further, colour coded rooms and hallways may help disorientated patients find their way, and furniture and fixtures in contrasting colours may help them navigate safely.

A final attribute of optimal clinical programmes is the involvement of the family in care planning. Families are an invaluable source of data for the physician as they can provide detailed information about patients' histories and responses to previous interventions. Conversely, information should flow the other way as well; physicians can educate families about the disorder's progressive nature so that they can adequately plan for future care and have reasonable expectancies.

20.85 CARE FOR COMMUNITY-DWELLING PATIENTS

Services for patients living in the community can serve as a bridge between independence and institutionalization. They can give caregivers peace of mind with respect to the care and safety of their demented relatives, while allowing them the freedom to attend to other aspects of their lives. Further, in

many instances, patients are able to continue living in their homes, affording them the comfort of being in familiar surroundings. There are two types of services for community-dwelling patients: in-home services and adult day care (see Zarit *et al.*, 1999 for a review).

20.85.1 In-home services

In-home care is a general term referring to a multitude of services (e.g. housekeeping, companionship) that are provided in the home. Their overall goal is to provide assistance with tasks of daily living or respite care so caregivers can have some relief from care duties. Specific services can consist of home-delivered meals, nursing care, homemaker services, occupational therapy, transportation services and companionship.

There are several problems with in-home services. First, they are underused by minorities, low-income people, those without families, and people living in rural areas (Advisory panel on Alzheimer's Disease, 1996). Ironically, these individuals are often those who have the greatest need for assistance. Accessibility is a major barrier to care since services are simply not available in areas where these individuals are likely to reside (e.g. poverty stricken areas and rural areas). Services are most likely to be solicited by family members since dementia often renders people incapable of seeking care. Thus socially isolated people are not likely to be recipients of in-home services. Clearly, outreach programmes that target demented people who are socially and/or geographically isolated are needed. One such programme, Gatekeepers, relies on referrals from unconventional sources (e.g. utility companies, postal workers) to identify older people living alone who may be in need of services (Florio *et al.*, 1996).

Another problem with in-home services is the employment of unskilled personnel. When an agency is being selected to provide in-home care, it is essential that licensing requirements, intensity and type of training, and background checks be specified. In-home care is also problematic because it can be quite costly. Finally, because it often has poor linkages to other services, appropriate referrals are unlikely to be made. In fact, there is no evidence that in-home services delay or prevent nursing home placement (Cohen, 1991).

In sum, in-home services can provide a useful service for both patients and their families. However, it is important that families thoroughly investigate the qualifications of staff, and do not rely on in-home care as the sole source of information and care. In-home services are probably best viewed as an adjunct to more comprehensive care.

20.85.2 Adult day care

Adult day care is an attractive option for older people who are able to live in the community yet are not capable of functioning

independently. There are two general models of care: medical and social. Medical programmes provide rehabilitation and other medical care, while social programmes focus on social functioning and recreation. In general, day care provides a structured and safe environment where patients receive cognitive and social stimulation. Patients may receive psychological counselling (either individually or in a group) to help them adjust to the dementia, and to provide emotional support. Many centres allow families to arrange for ancillary services such as transportation, personal care, respite care and rehabilitation therapy.

Quality day care programmes employ adequately trained staff with a staff/patient ratio of 1:7. At least some staff members should be qualified to dispense and manage medication. Nursing services should also be available, and there should be special protocols for incontinent patients. The activities should be planned and overseen by an experienced activities coordinator. The activity schedule should include both individual and group level activities. Since some patients, especially those who are depressed, may have little motivation to participate in activities, staff should strongly encourage patient involvement. At least one meal is provided daily at day care centres, so special diets should be available, and staff should be on hand to assist with eating.

For the most part, research evaluating the effects of day care has noted positive outcomes for both patients and their caregivers (see Gaugler and Zarit, 2002 for a thorough review). With respect to patients, while overall day care does not appear to lead to improved functional outcomes, it does have positive effects on subjective well being. Day care can also benefit caregivers. Zarit *et al.* (1998) compared caregivers of patients who used adult day care to caregivers whose family members did not. Caregivers whose family members were enrolled in day care for at least 3 months for at least 2 days per week reported less stress, less depression, and lower feelings of overload compared to control caregivers. It is important to note that the positive effects for caregivers are only apparent when services are used frequently and consistently.

The biggest problem with adult day care is a shortage of services. There are currently 4000 programmes available, but approximately 10 000 are needed. Lack of transportation is another obstacle to care. Finally, adult day care is not funded by Medicare, and all costs are absorbed by the patient or families. Daily costs can range from \$US50 to \$US180.

20.86 CARE FOR NON-COMMUNITY-DWELLING ADULTS

For demented adults with severe cognitive impairment, or co-morbid physical or psychiatric disease, residing in the community may not be feasible. For these patients there are three types of care: adult foster care homes, assisted living, and nursing homes.

20.86.1 Adult foster care homes

Adult foster care homes are state-regulated, small sites that provide supervised housing for demented adults. There are currently 60 000 such homes available. Care at the homes is family oriented, and patients have the opportunity to interact with other people. The major problem with foster care is that most homes are not licensed and personnel are not highly trained, creating a situation where abuse and/or inadequate care can flourish. Further, there is a lack of federal guidelines regulating such homes (Advisory Panel on Alzheimer's Disease, 1996).

20.86.2 Assisted living

Assisted living is any residential programme that is not licensed as a nursing home, yet is equipped to respond to needs for assistance (e.g. tasks of daily living). Patients usually reside in congregate apartment-like settings where they live alone or with a spouse, and they are able to bring their own furnishings. Meals may or may not be eaten in a dining hall-like setting. A great deal of autonomy is available, and only needed services are purchased (e.g. meal preparation, house-keeping, transportation). This can be an ideal arrangement for patients who desire a certain degree of privacy and are capable of some independence. Further, as the dementia progresses, additional services are available so that changing needs for assistance are met.

20.86.3 Nursing homes

Severely demented adults usually reside in nursing homes. In 1995, there were 1.8 million nursing home beds in the United States, and half of all patients were demented. Fifty per cent of the demented residents are over age 85, and 75 per cent are female. Many are incontinent. Greater than one-third have psychiatric symptoms, and over half exhibit behavioural problems.

The major problem with nursing homes is that they are modelled after standard medical hospitals, and are thus unlikely to provide adequate psychiatric care (Rovner *et al.*, 1996). Consequently, dementia and other psychiatric disorders (e.g. depression, delirium) are often undiagnosed. Staff are usually not knowledgeable about dementia and how to manage its associated behavioural problems. According to a report issued by the Office of Technology Assessment (1992), these issues are manifested in a lack of continuity of care, no provision of space to wander, inappropriate levels and type of stimulation, and the encouragement of patient dependency on staff. Nursing home patients are also likely to be over-medicated with psychoactive drugs, which can have profound side effects (Avorn *et al.*, 1992).

A recent trend in nursing home care is the implementation of Special Care Units (SCUs), which are self-contained units housed within nursing homes. While there are no agreed-upon

criteria as to what constitutes an SCU, care is usually specialized and individualized to meet the needs of demented patients. Patients' strengths are identified and elicited, reversible medical and psychiatric disorders are treated, and behavioural disorders are viewed as a product of patient/nurse/environment interactions rather than the disease (Rovner, 1994; Rovner *et al.*, 1996). Patients are usually free to wander and there are fewer patients per staff member than is typically found in a nursing home.

Research regarding the benefits of SCUs are mixed, in part because of a lack of uniformity concerning what constitutes an SCU. Among the more favourable findings were that SCU patients were less likely to experience functional decline after 1 year compared to a control group comprising demented nursing home residents (Rovner *et al.*, 1990). Further, SCU patients were more inclined to participate in activities, and less prone to have behaviour problems, be restrained or receive antipsychotics (Rovner *et al.*, 1996; Bellelli *et al.*, 1998). SCU patients are also less likely to have falls (Rovner *et al.*, 1990). Other research found less favourable results. For example, Phillips *et al.* (1997) found that SCU placement did not lead to slower functional decline.

It should be noted that it is impossible to apply rigorous clinical trial methodology to the study of SCUs (i.e. residents cannot be randomized to an SCU versus a non-SCU), and this could account for discrepant findings. In addition, there is a lack of standardization concerning what constitutes an SCU, and this too could account for conflicting results. In theory, SCUs should possess the following characteristics:

- assessment and diagnosis;
- staff specialization and education;
- minimal restraint use;
- flexible care routines; and
- specialized environmental design.

In an attempt to determine the extent to which SCUs actually possess these ideal characteristics, Chappell and Reid (2000) examined 510 institutionalized Canadian residents. The sample represented 77 care facilities, and 51 per cent of the sample were residing in an SCU. Results indicated that SCUs were no more likely than traditional units to possess these characteristics. In a similar study of long-term care facilities in Arkansas, very few SCUs met all of the requirements for an SCU as mandated by state legislature (Gerdner and Beck, 2001). In theory, SCUs appear to be a viable alternative to nursing home care for the severely demented patient. However, placement should be done with the caveat that many SCUs do not meet the requirements of an exemplary unit.

20.87 SERVICES FOR BOTH COMMUNITY AND NON-COMMUNITY-DWELLING PATIENTS

Three types of services, case management, inpatient geriatric psychiatry units and dementia clinics, are used by patients presenting with a range of cognitive decline.

20.87.1 Case management

Case management attempts to aid clients and families negotiate the fragmented and institutionally based United States long-term care system. The basic components of case management include identifying the target population, screening assessment, care planning, linkage to services, monitoring, advocacy and reassessment. While case management for long-term care became popular in the 1970s to provide chronically ill elderly with adequate access to appropriate and reasonably priced community-based services, its focus has shifted. More recently it has evolved into a gatekeeping mechanism for containing healthcare expenses. Several studies have demonstrated that case management services for the elderly can be cost effective (Eggert and Brodows, 1984). The services can be provided by public agencies, but more recently, private for-profit firms have proliferated.

Various legislative proposals addressing the long-term care system for the elderly have been introduced. For example, the Elder-Care, Long-term Care Assistance Act of 1988 provides assistance for a full range of home care and adult day care services, and expands benefits for nursing home care. While there is considerable variation as to the type of organization that should be providing case management, some common themes emerge. Among them is that case management should be provided for persons who are limited in two to three activities of daily living (ADL) and or need substantial supervision due to mental/cognitive problems. It appears that the evolving case management system will play an increasing important role in the long-term care of individuals with dementia in the future.

20.87.2 Inpatient geriatric psychiatry units

Demented patients often experience comorbid psychiatric illnesses and symptoms. Mental health problems among demented people include agitation (55 per cent), depressive symptoms (42 per cent), hallucinations/delusions (33 per cent), sleep disorder (26 per cent), and weight loss or anorexia (22 per cent). These disorders frequently necessitate admission to an inpatient geriatric psychiatry unit (Rabins and Nicholson, 1991). The primary goals of hospitalization are:

- the assessment and provision of safety;
- treatment of psychiatric symptoms that may be contributing to excess disability; and
- the monitoring of such treatment.

Demented patients may exhibit suicidal and/or violent thoughts or behaviours. A psychiatric unit provides a safe environment where patients can express their thoughts and feelings, while at the same time reducing the risk of harm to self or others. Electroconvulsive therapy (ECT) is occasionally used to treat depression in demented patients. The invasive nature of this procedure requires that it be performed on an inpatient basis. Further, prescribing of several antidepressants

needs to be closely monitored, and this is best accomplished when the patient is an inpatient. Finally, psychiatric illness can worsen or exacerbate existing dementia, so a thorough neurological assessment is often warranted to identify and treat any comorbid psychiatric conditions. For example, among older people, depression can be manifested as a mild dementia, and depression treatment may improve cognitive function. Some easily treatable or manageable diseases (e.g. thyroid disease, syphilis) may cause symptoms of dementia, and a complete diagnostic evaluation can identify these conditions. In fact, a recent study found that 34 per cent of inpatients had a previously unknown illness at admission (Perry *et al.*, 1995). In sum, a geriatric psychiatry unit provides an opportunity for close monitoring and assessment so that psychiatrists and other professionals trained in geriatrics can determine the most appropriate treatment needs.

Few studies have examined the impact of inpatient units for dementia. One recent study examined 15 patients admitted to an inpatient unit for an average of 2 weeks to treat agitation and disruptive behaviours. Results showed that most of the patients exhibited less agitation at discharge (Wiener *et al.*, 2001).

20.87.3 Dementia clinics

Accurate clinical diagnosis of all individuals with suspected dementia is essential given the multiplicity of medical and psychiatric conditions that may mimic dementing syndromes.

Dementia clinics have existed more or less in the United States for about 10–15 years and provide a multidisciplinary assessment of the patient and family. Clinics of this nature can both facilitate entry to the dementia care system and be a resource for optimal long-term management. It appears, however, that they select for patients whose cognitive deficits are complicated by emotional or behavioural problems and whose conditions are of significant duration. Coyne and associates (1990) found that the average age of clients coming to their clinic was 73.16, and that symptoms of cognitive impairment had been displayed for 4.2 years. It appears that less than 10 per cent of referrals are living in health-related facilities at the time of evaluation (Larson *et al.*, 1984; Coyne *et al.*, 1990), with the overwhelming majority living at home or with relatives. Not surprisingly given this data, family members prove to be the most common source of referral (Larson *et al.*, 1984; Coyne *et al.*, 1990).

The majority of patients receive a standard examination battery. Components include patient history, past medical history, complete physical and neurological examination, comprehensive blood work (including measurements of blood counts, electrolytes, thyroid function, blood urea nitrogen, creatinine, B₁₂, folic acid, sedimentation rate, and serological test for syphilis and urinalysis). Additionally, electrocardiography, electroencephalography and neuroimaging studies are routinely done in the United States. Psychometric tests, including the Mini-Mental State Exam (MMSE), and the

Boston Naming Test are frequently used. Additional neuropsychological testing as well as lumbar puncture are performed when clinically indicated. While the National Institute of Aging task force recommends this extensive and expensive evaluative process, a number of investigators have advocated a selective approach to diagnostic testing. Larson and colleagues (1986) found that a careful history and physical exam accompanied by complete blood cell count, chemistry battery and a thyroid function test are effective in diagnosing treatable illness causing cognitive impairment. Larson and associates (1986) likewise found that most patients could be diagnosed with careful bedside evaluations and a few screening tests.

Dementia evaluation centres are of diagnostic value, providing relatives, and where appropriate patients, with clear comprehensive information about diagnosis and prognosis. More often, however, working with families to plan appropriate short-term and long-term management of the demented individual proves to be the clinic's primary responsibility.

21.6 Planning services	320		

According to the Alzheimer's Society (AS) in the United Kingdom (UK), there are approximately 18 500 younger people with dementia (Alzheimer's Society, 2001). For the purpose of this chapter 'young' is defined as less than 65 years of age. The needs of these individuals do not readily fit into existing health and social care systems. As numbers are small, their needs tend to be invisible to planners. Even those who receive care find the services fragmented. Unmet need has led to a 'declaration of rights' for younger people with dementia from one of the pioneering services in Merseyside, UK. This is reproduced in Box 21.1. Although quite old, it has formed the basis for several innovative services and is the basis for the principles of service development to be outlined (Alzheimer's Society, 2001).

21.1 EPIDEMIOLOGY

Table 21.1 illustrates the findings from two epidemiological studies of young-onset Alzheimer's disease (AD) in the UK, one in Scotland (McGonigal *et al.*, 1993) and the other in the North of England (Newens *et al.*, 1993). The latter authors calculated a point-prevalence of 34.6 per 100 000 for AD in the age band 45–64. They also estimated a further 11.7 per 100 000 for vascular dementia (VaD) and 7.0 per 100 000 for other forms of dementia. The latter included alcohol-related dementia, traumatic brain damage, frontotemporal dementia, Creutzfeld–Jakob disease, multisystem failure, cerebral tumour

and normal pressure hydrocephalus. There are other causes not included or not found in these studies:

- Huntington's disease, a genetic disorder with a peak incidence of symptoms between the ages of 30–45, has important diagnostic implications as predictive testing is possible and protocols for this are available (Cetnarskyj and Porteous, 1999). AIDS-related dementia poses special demands for multi-agency working (Murray, 2003).
- Prion disease is a recent highly publicized cause of early-onset dementia (although very uncommon).
- Dementia in Down's syndrome will become more common as patients with learning disability age (Neary and Snowden, 2003). It is estimated that 13 per cent of people with a learning disability develop dementia, rising to 22 per cent in those aged 65 years (Cooper, 1999).
- Alcohol-related dementia remains a controversial entity although undeniably excess alcohol consumption causes multiple handicaps, including cognitive impairment (Crowe, 1999).

It is important to have accurate estimates of non-AD causes of dementia when planning new services. In a study, which did not focus on AD alone (Harvey, 1998), the latter accounted for less than 50 per cent of all cases of young-onset dementia. Of importance, frontotemporal dementia was the third most common form of dementia, after VaD, with a similar prevalence to alcohol-related dementia.

In summary, taking into account all causes of dementia, in an area serviced by an average primary care trust in England

Box 21.1 Declaration of rights for younger people with dementia*

- *Full informed medical assessment.* General practitioners should have the relevant skills to recognize the symptoms of dementia in all age groups and be aware of the need to refer on to appropriate consultants
- *Recognition of the need for specialist services.* Identification of consultants with special responsibilities for this group of people who will make a diagnosis where possible and from whom caregivers are entitled to ongoing medical supervision
- *After diagnosis* people with dementia and their caregivers should have access to the following services organized on at least a subregional basis:
 - *specialist day care services* organized in a flexible way so that caregivers can continue to work. The aim should be for appropriate stimulation with an emphasis on constructive occupational therapy for those who are able to benefit from it and, for those who cannot, diversional activities. Within the service should be properly funded resource centres providing comprehensive and accurate information and counselling, and support for caregivers with a drop-in facility
 - *appropriate residential care* when required – not elderly persons' homes or acute psychiatric establishments
 - *implementation of care management* so that services are assessed at the time of need, enabling a progressive build-up of care as the person's health deteriorates
- *Access to welfare benefits.* Easy access to welfare benefits currently available plus some benefits:
 - *a specialist caregiver's benefit*
 - *a benefit equivalent to Disability Living Allowance* (mobility component) payable to people with dementia irrespective of age
 - *universal acceptance of Alzheimer's as a 'terminal' illness* irrespective of age
 - *money* to provide care for the person in the community on the scale now available to pay for residential care
- *Retrospective reinstatement of rights and benefits* for people who have had to terminate their employment either voluntarily or through dismissal and who have later been diagnosed as having dementia and who have consequently been discriminated against. Employers should be directed to recognize dementia as a reason for early retirement so that pension rights and other benefits are not affected
- *Appropriate training and information* to be made available at all levels for public and professionals alike, including general practitioners

*This declaration was originally prepared for and on behalf of people with dementia under pensionable age in the Mersey Regional Health Authority (February, 1991)

Table 21.1 Estimated age and prevalence of young onset Alzheimer's disease in two studies from the UK

Age range	Prevalence per 100 000	
	Scotland ¹	Northern Region ²
40–44	1.4	0
45–49	8.1	2.4
50–54	27.6	11.8
55–59	39.7	35.6
60–64	37.8	87.3

¹ McGonigal *et al.* (1993)

² Newens *et al.* (1993)

(about 100–150 000 individuals), there will be between 75–100 patients with young-onset (age of onset under 65 years) dementia. In the UK specialist mental health trusts serve populations upward of 1 million, with correspondingly larger predicted numbers. The main diagnoses in young-onset dementia are AD, VaD, frontotemporal dementia and alcohol-related dementia.

21.2 THE NEED FOR A SERVICE

The epidemiological data above demonstrate that the number of younger people with dementia is miniscule in proportion to the 500 000 or so people in all with dementia in the UK, the majority of whom are elderly. Why then should effort be expended developing specialist services? There are three main reasons.

- The diagnosis of young-onset dementia is complex and specialized.
- The needs of people with dementia in younger adult life are largely unmet and differ from older persons with dementia.
- National policy is important. In England and Wales the *National Service Framework for Older People* (Department of Health, 2001) proposes that Old Age Psychiatry take a strategic lead for this patient group, a position supported by the Royal College of Psychiatrists (Royal College of Psychiatrists, 2001).

21.2.1 Diagnosis and assessment

The causes of early-onset senile dementia include diagnoses that psychiatrists rarely encounter, such as prion diseases and multisystem failure. The spectrum of diagnoses of dementia in younger people differs from that in old age. For example, frontotemporal dementia, which often presents with behavioural problems, may account for 20 per cent of young-onset dementias but is rare in later life (Neary *et al.*, 1988). Diagnosing dementia in younger people is complex and requires a team with specialist skills, including neurological, neuroimaging and neuropsychological evaluation. Access to

genetic counselling for conditions such as Huntington's disease, familial Alzheimer's disease (which usually has an onset in mid-life) and frontotemporal dementia are essential. Varma *et al.* (2002) showed that in three dementias occurring in relatively younger patients (Alzheimer's disease, VaD and frontotemporal dementia) diagnostic accuracy using a combination of magnetic resonance imaging (MRI) and single photon emission computed tomography (SPECT) was very high. This is different from late-onset dementias where mixed pathology and medical co-morbidity make diagnostic precision harder.

A major complaint by caregivers is the inordinate time to diagnosis, over 3 years in one study (Luscombe *et al.*, 1998). In research conducted in the 1990s, which compared the diagnostic practices of two teaching hospital departments, one in neurology and the other geriatric psychiatry, it was found that the neurology department, which specialized in the diagnosis of presenile dementia, conducted a much more comprehensive medical assessment than did the old age psychiatry department. Those referred to the neurology service were more than twice as likely to receive detailed neuropsychological testing. The rates for neuroimaging were likewise double those of the geriatric psychiatry service (Allen and Baldwin, 1995). In the study of Luscombe *et al.* (1998), better diagnostic accuracy was achieved by neurologists when compared to that by psychiatrists. The contemporary picture remains far from ideal, with evidence that neurologists are still more complete diagnosticians while old age psychiatrists are better at involving support services, organizing follow up and prescribing antidementia treatment (Cordery *et al.*, 2002). Perhaps the optimum model is for a neurologist and a psychiatrist to work together. There are examples of this in practice (Allen and Baldwin, 1995; Ferran *et al.*, 1996).

The audit of Allen and Baldwin (1995) took place when neuroimaging was hardly available to psychiatrists. Improvements in old age psychiatry services, better training of old age psychiatrists and markedly improved access to brain imaging by psychiatrists means that some psychiatric services are perfectly competent to make a diagnosis of dementia in younger people. Also, the arrival of the antidementia drugs (currently donepezil, rivastigmine, galantamine and memantine) has been an impetus to old age psychiatrists to improve diagnostic accuracy. In a given geographical locality clinicians from the specialties of neurology and psychiatry should develop their own protocols to enable a competent assessment of a younger person presenting with dementia. These should include how to access a range of diagnostic services, including genetic counselling and must be able to offer advice about fitness to drive a motor vehicle.

Another major area of development since the previous edition of this book is the Memory Clinic (Lindesay *et al.*, 2002). Although these have arisen largely in response to the growing demand for cholinesterase inhibitors they are often sufficiently well resourced to undertake the specialist assessment of a range of cognitive disorders including dementia of younger adulthood (Lindesay *et al.*, 2002). They have the

added advantage of reducing the stigma attached to the terms dementia and psychiatry.

Lastly, a common diagnostic error is to overlook an affective disorder in a younger person with memory problems (Nott and Fleminger, 1975; Ferran *et al.*, 1996). This should not be forgotten.

21.2.2 The needs of young people with dementia and their caregivers

In England a person with young-onset Alzheimer's disease may receive outpatient care from a neurologist, a social worker from the social services adult mental health team, psychiatric nursing support from the provider adult mental health team, day care and respite care from the social services elderly team and continuing (long-term) care from an old age psychiatrist. A similar person in his or her 70s will receive a 'package' of care delivered by an old age psychiatry team, with one person named as the care coordinator with responsibility for coordinating services under the Care Programme Approach (Department of Health, 1999). This inconsistency in management underpins the need for a specialist service.

A common myth is that younger people with dementia die quickly thus obviating the need for elaborate 'packages' of community care. In a study by Newens *et al.* (1995), of 109 subjects, the median survival time from onset to death was over 9 years; 57 per cent were still living at home 5 years from the date of survey, which contradicts this view. Moreover, of those who remained at home 20 per cent required some assistance in each of six areas of activity of daily living.

There have been a few surveys specifically of need of patients with young-onset dementia and of their caregivers. Baldwin (1994) in a survey of 44 patients, the majority in the community, found higher morbidity from non-cognitive symptoms (aggression, wandering, delusions and hallucinations) than from cognitive impairment, as assessed by the Clifton Assessment Procedures for the Elderly (CAPE) (Pattie and Gilleard, 1979). Other studies have confirmed this (Sperlinger and Furst, 1994; Delany and Rosenvinge, 1995; Harvey, 1998), the importance being that non-cognitive symptoms have a direct impact on increasing perceived burden in caregivers (Harvey, 1998; Ballard *et al.*, 2001). Stress among caregivers is very high (Baldwin, 1994; Delany and Rosenvinge, 1995; Luscombe *et al.*, 1998). Harvey (1998) found that anxiety and depression were the most typical symptoms of stress and that females were most affected. The type of dementia did not appear to influence the degree of stress.

Financial hardship is very common and often not recognized (Harvey, 1998). In surveys that have asked about employment status (Baldwin, 1994; Sperlinger and Furst, 1994; Delany and Rosenvinge, 1995), nearly all those with dementia were unemployed. In the survey of Sperlinger and Furst (1994), three-quarters had to give up their jobs because of their dementia. Lastly, younger people with dementia tend to be relatively physically fit, unlike patients accessing old age psychiatry services.

21.3 THE ECONOMIC BURDEN

Harvey (1998) conducted an economic analysis of the costs of young-onset dementia. The average community costs were £1560 per patient, whereas for those who were in residential or nursing home care it was £20 924. The costs overall were higher per patient than have been estimated for older people with dementia and this effect was accounted for by the younger patients using more residential or nursing home care. While one cannot read too much into these findings, the implication is that better community care may reduce or delay the need for institutionalization, thereby lowering overall costs.

21.4 PRINCIPLES OF SERVICE DEVELOPMENT

Drawing upon the studies summarized above, when caregivers are asked what they would like, better coordination of services, welfare and benefits advice, day care and respite, including respite in the home are regularly requested. In reality these needs are not met. Baldwin (1994), Delany and Rosenvinge (1995), Newens *et al.* (1995) and Cordery *et al.* (2002) found that the most common support offered was a visit from a community psychiatric nurse (CPN), but only for fewer than half of those surveyed. In these studies availability of and contact with social workers was minimal.

The epidemiological data summarized in Table 21.1 illustrate an important point of relevance in service planning. The majority of people with young-onset Alzheimer's disease are in the age range of 50–64 years. Harvey (1998) has calculated that there are only 2500 individuals with AD in the UK under the age of 50. This poses difficulties for a service that is attempting to meet the needs of such a wide age range. The offspring of the youngest are likely to be teenagers whereas the older patients are likely to have offspring who themselves are approaching middle age.

In the UK the Faculty of Old Age Psychiatry of the Royal College of Psychiatrists has proposed guidelines for planning services for younger people with dementia (Box 21.2). These place a responsibility on purchasers of social care and health to develop specific contracts for the care of younger people with dementia and their caregivers in areas covering upward of half a million. It is important that neurological and psychiatric services collaborate and that relevant caregiver organizations are consulted. One way to start a service is to identify a lead psychiatrist, a community psychiatric nurse and a named person to provide a link with social services. In England the *National Service Framework for Older People* specifies that old age psychiatric services should take the lead (Department of Health, 2001). However, this will require additional funds.

Large numbers of beds in institutions was not a priority for caregivers in the surveys cited earlier. However, Harvey (1998) has calculated that there is a need for 10 residential or

Box 21.2 Summary of recommendations from the Royal College of Psychiatrists*

- Purchasing agencies should have specific contractual arrangements for a specialized service for younger people with dementia, and a named consultant with special responsibility and sessions over and above that available for older patients with dementia.
- In each area there should be one named consultant, often an old age psychiatrist, responsible for the service, drawing from a population base of 500 000.
- Close collaboration with neurology and neuropsychiatry for accurate diagnosis is needed.
- For a population of 500 000 a specialist multidisciplinary team is justified. For smaller populations a named community health nurse is needed, while each local authority should have a named social worker.
- Relevant caregiver and voluntary organizations should be involved in planning.
- Initial service development should focus on diagnostic and community services. Specialist services should only be developed where traditional services are deficient.
- A comprehensive service comprises the above plus day and respite care and long-stay care, with provision separate to that for older people with dementia.

*The Royal College of Psychiatrists, 2001

nursing home places per 100 000 population at risk; enough for a small unit, or for a contracting arrangement between a number of purchasers and a provider with specialist expertise.

The needs of younger people with dementia are best met by a small multidisciplinary team comprising input from a consultant psychiatrist, mental health nurse or nurses, an occupational therapist, psychologist and social worker, with additional services as required by speech and language therapist, podiatrist, physiotherapist, etc. The team should ideally have its own community support workers. Such a team can offer outreach in to the home, day care and access to respite resources, ideally in a special facility and will serve a population of approximately half a million. The roles and tasks of the specialist multidisciplinary team have recently been described by Baldwin and Murray (2003).

21.5 GENERIC VERSUS SPECIALIST SERVICES

The Royal College of Psychiatrists cautions against over-development of specialist services. Wherever possible it is best to make full use of existing age-appropriate services, such as home helps, welfare and benefits advice, etc. The principle should be to optimize cooperation and collaboration across existing statutory and other services. The latter include not only social services and the voluntary sector but also child support agencies, child and adolescent psychiatric services and family therapy services (Garrod, 2003; Murray, 2003).

Box 21.3 *Preliminary data for planning a service*

- Estimate local prevalence
- Estimate diagnostic heterogeneity (e.g. alcoholic and vascular dementia)
- Identify lead consultant
- Identify lead nurse
- Identify local relevant resources (e.g. welfare and benefits advice)

Box 21.4 *Practical issues in planning a service for younger people with dementia*

- Single point of access
- Clear arrangement and protocols about who makes the diagnosis
- Right of access to all existing relevant services
- Care coordination by a key worker
- Access to a reasonable range of specific services
- Clear protocols for respite care
- Clear protocols for emergency psychiatric admission

21.6 PLANNING SERVICES

In the last edition of this book we recommended that each locality conduct a survey to estimate prevalence and need. The advent of good quality epidemiological data means that accurate estimates can be made without doing this (Box 21.3). In the UK the Alzheimer's Society offers web-based information about need in specific localities (Alzheimer's Society, 2001; www.alzheimerers.org.uk). However, diagnoses can vary from area to area; for example in Baldwin's (1994) study there were more cases of VaD and alcohol-related dementia than there were of AD. This is probably because the location was a deprived inner city area. Likewise, local resources, some of which may be relevant to those with young-onset dementia, can vary enormously. If it is thought necessary to garner more detailed estimates of need, this can be crudely ascertained by conducting a survey of local specialists in the fields of psychiatry, neurology, medicine, trauma, rehabilitation and neurosurgery. Local social service offices can also be approached. The neuroimaging department may also have a register with information about diagnoses as well as age. Some specialist organizations such as the Huntington's society and Headway (a head injury charity in the UK) may also be of help. Lastly, it is relatively easy and cheap in the UK to conduct a postal survey of general practitioners.

Box 21.4 summarizes some of the practical issues which must be addressed before setting up a new service. A single point of access must be organized. Agreement must be reached about how a diagnosis is to be made and by whom, with protocols for respite care and acute admission on psychiatric grounds. Given that the patients are quite fit physically, an old age psychiatric ward may not be the best place to

admit a disturbed younger person with dementia and there should be an agreed protocol addressing where such patients should be admitted and under whose care.

21.7 CARE FOR CAREGIVERS

Luscombe *et al.* (1998) conducted a survey of 102 caregivers of patients with young-onset dementia. They describe the plight of the typical caregiver as: 'an harassed person, beset by psychological problems, financial worries, loss of employment and family conflicts.' Those most distressed were young females caring for male patients and children caring for a parent.

CANDID (Counselling and Diagnosis in Dementia) (Harvey *et al.*, 1998) has been established at the National Hospital for Neurology and Neurosurgery, London. The aims of CANDID are to increase accessibility to advice, diagnosis and counselling for the person with a young-onset dementia, their caregivers and other health professionals. CANDID also offers information and education to increase the general awareness of the needs of the younger person with dementia for nurses, doctors, social workers and others working within this specialized area. The service is available on the Internet (http://dementia.ion.ucl.ac.uk/DRG_Website/Candid/welcome_to_the_candid_home_page.htm). Another site offering specialist advice and support is the Pick's Disease Support Group (<http://www.pdsg.org.uk/>).

21.8 EXAMPLE OF A LOCAL SERVICE

Manchester offers a needs-led service which has been provided through the collaboration of health and social services (Baldwin and Murray, 2003). The service works closely with both the local and regional branch of the Alzheimer's Society. It is multidisciplinary with a whole-time specialist nurse, 0.6 whole-time equivalent occupational therapist, half-time social worker and sessional input from a psychologist and speech and language therapist. There is a team manager. The service has a single point of access, but referrals are closely monitored by the lead consultant and specialist nurse, to ensure a thorough diagnosis has been made. It does not offer a diagnostic service.

The Manchester service has expanded to develop day care and outreach care, which often incorporate social activities and special interests. It also offers basic personal care and support. A caregivers' support group and campaigning group help to promote the needs of this group of people and ensure that young-onset dementia is very much on the local agenda. Views of users and caregivers are systematically collected and inform service development (Shlosberg *et al.*, 2003).

A specialist nurse is able to provide support and advice and is able to direct and link people to other appropriate services, for example care management, welfare rights information and advice. He/she can act as care coordinator for a proportion of the clients.

21.9 OTHER INITIATIVES

From 1998 to 2000 there was a national young-onset dementia initiative in the United Kingdom (http://www.alzheimers.org.uk/Younger_People_with_Dementia/index.htm). It was aimed at caregivers, professionals and local branches of the Alzheimer's Society requiring support or advice about service development.

Regional forums have been developed to raise the profile at regional level, provide support for users and caregivers, to encourage service development and to learn from the practice and experience of others. They exist largely as partnerships between statutory services and providers, the independent and voluntary sectors, and usually meet quarterly. For a disorder like younger-onset dementia they provide an invaluable source of support and networking. They may also guide local service commissioners. The above website provides a link to regional forums, the numbers of which are increasing. For example in the north west of England there were two specialist services for younger people in the mid-1990s but by 2002 this had grown to 10.

The Clive Project (<http://www.thecliveproject.demon.co.uk/>) in Oxfordshire, England, has formed a group in collaboration with MHA Care Group (formerly Methodist Homes, an independent sector provider), to develop suitable accommodation for younger people with dementia. MHA hopes to offer the following three options: short breaks, independent supported living and enhanced support. These should offer the person and their family flexible choices and continuity of care and support. Appropriate accommodation is not currently available in most areas of the UK. Where caregiver preferences have been sought, the following have emerged as relevant: small-scale domestic-type houses accommodating around four to six people, which are close to a welcoming and accepting community and accessible to local leisure facilities and social activities. The accommodation should be as 'normal' as possible, with care tailored to the individual and able to promote independence appropriate to the person's abilities. Appropriate accommodation for younger people with dementia may be the next step in the evolution of specialist services.

21.10 SUMMARY

Dementia services have arisen largely to address the needs of older people. The prevalence and needs of younger people with dementia is now much better understood. Services for these people, some of which should be specialized, can be organized around a population base of around half a million. At a minimum there should be clear local protocols for diagnosis and assessment and a named consultant and specialist nurse to take the lead in service development in partnership with other relevant bodies, such as social service departments and the local Alzheimer's Society.

Alzheimer (disease and related disorders) Associations and Societies: supporting family carers

HENRY BRODATY, ALISA GREEN, NORI GRAHAM AND LEE-FAY LOW

22.1 Self-help groups	324	22.4 Conclusion	329
22.2 National Alzheimer Associations	326	References	329
22.3 Alzheimer Disease International	327		

National Alzheimer Disease Associations and Societies have become a powerful force throughout the world, advocating on behalf of people with dementia and their carers. The growth in these voluntary organizations has been brought by the quantum leap of public awareness about Alzheimer's disease (AD) and related dementias, particularly in developed countries. This rise in public awareness has occurred as a result of a number of converging factors.

First was the relabelling of senility and senile dementia following the landmark clinicopathological study of Blessed *et al.* (1968). Suddenly, what had previously been accepted as normal ageing was dignified as a disease, albeit one with a somewhat unusual name. Prior to 1968, AD had been regarded as a relatively rare dementia in younger people.

Second, the demographics of the developed world changed. Average life expectancy in developed countries now extends beyond 75 years for men and 80 years for women. The percentage of older people is the highest ever recorded, with the proportion of those over 65 years in some countries such as Sweden and the United Kingdom exceeding 15% of their population. There were estimated to be 25 million people with dementia worldwide in 2000. This number is projected to increase to 63 million in 2030 (with 41 million in less developed regions) and to 114 million in 2050 (41 million in less developed regions) (Wimo *et al.*, 2003). As age is the major risk factor for dementia, affecting 6% of those 65 or older and 20% of those aged 80 years or more, the greying of the world's population has resulted in a marked rise in the number of people with dementia.

With so many people affected by dementia, the number of people caring for them is even greater. It is therefore a common experience for many in the developed world to know of someone suffering from dementia. It is now people's

expectation to live a long and healthy life as so many physical diseases have been eliminated. AD is one of the few diseases one is likely to develop in old age.

A third factor has been increasing public awareness, as demonstrated in the press and media. This is partially the result of publicized cases, such as those of Rita Hayworth, Ronald Reagan and Charlton Heston in the USA, Iris Murdoch in Great Britain and Hazel Hawke, the ex-wife of a former prime minister, in Australia. Sensational media stories abound, be they medical 'breakthroughs' (e.g. discovery of genes that cause AD, the role of aluminium, the suggestion that red wine protects against AD, and trial of an AD vaccine) or heart-breaking tragedies. This has fuelled the public's fascination with, and fear of, AD.

A fourth factor is the upsurge of research activities on so many fronts: molecular biology, epidemiology, genetic studies, the search for more accurate diagnoses and assessment, and the search for better treatments for both cognitive and non-cognitive symptoms. Effective prevention and treatment may be on the horizon, but meanwhile there are many millions of people affected by dementia, and for every person with dementia there is at least one, and often several, carers under stress. It is therefore important to highlight social research on the impact of AD on carers, and to identify practical ways to reduce the stress and burden of caring.

Certain factors can reduce stress, such as adequate home help to assist with the practical hard work, giving carers the opportunity to go out and have some time for themselves (Levin *et al.*, 1989). The importance of recognition of the disease by the general practitioner and other primary care workers, the need for referral to a specialist for diagnosis, and ongoing follow up and advice have also been stressed. Most

of these will be required for the rest of the life of the person with dementia.

A fifth factor is the breakdown of traditional family structures with the changing roles of women and adult children, and the diminution of the sense of moral obligation to care for the older members of the family. This is putting great pressure on health and social care systems, and governments are being forced to consider how to provide a system to meet the needs of dementia and their carers. In the developed world it is beginning to be recognized, if not acted upon, that there is a limit to what families can tolerate or can be expected to tolerate.

The problem of caring for someone with dementia at home has led carers to seek each other out, to talk together and support one another. This has resulted in the growth of Alzheimer Associations all over the world. In the larger developed countries – USA, UK, Canada, Australia – these Associations have been able to exert a powerful voice about carers' needs.

22.1 SELF-HELP GROUPS

The late twentieth century witnessed the rise of consumer organizations and the self-help group (SHG) movement. SHGs are now available for almost every chronic condition, and should be part of the armamentarium of every clinician.

SHGs may be formed by groups of people who feel themselves to be powerless or stigmatized. They may see themselves as different from the general community or disadvantaged, e.g. 'Alcoholics' Anonymous', or may seek political advantage such as 'Grey Power' or they may consider that their condition is being ignored, as was the case for people with dementia and their families. SHGs may be composed of people who share a similar status or condition, such as the 'Nursing Mothers' Association'. Some SHGs are formed by people connected in some way to a group for whom they are advocating or for whom they have a specific concern, be they friends, for example the 'Association of Relatives and Friends of the Mentally Ill', or professionals dedicated to the same cause.

Many SHGs are linked to medical conditions: 'Arthritis Foundation', 'Autism Association', 'Colostomy and Ileostomy Society', 'Epilepsy Association', 'National Heart Foundation', and the 'Schizophrenia Fellowship'.

The advantages of SHGs, such as the Alzheimer Association, are several:

- support
 - emotional
 - practical
- education for professionals
- universalization – a sense of belonging, a feeling of no longer being alone
- identity – a sense of purpose
- political power – lobbying
- influence and advocacy
- public awareness.

Potential disadvantages are that:

- the SHGs can become a substitute culture;
- charismatic leaders can subvert the primary goals for their own personal objectives;
- governments can abandon provision of care to non-government organizations;
- rival SHGs may squabble for members or influence and internal divisions can beset any organization.

Support groups are distinct from group psychotherapy in that participants in support groups are not viewed as 'patients', but rather as 'normal' people who, as result of their caring role, are at an increased risk of becoming overburdened and developing psychological and physical problems (Cuijpers *et al.*, 1996).

Support groups can be led either by professional support group leaders, or by peer group leaders. In professionally led groups, the leader has professional qualifications and/or training, and the group tends to be more formally structured. By contrast the facilitator of a peer-led group usually is, or has been, a carer himself or herself. Peer-led groups tend to be less structured, and use more of a self-help approach by focusing on sharing common problems and information gained from participants' personal experiences (Toseland *et al.*, 1989). Other methods of support link carers by computer and telephone networks (Gallienne *et al.*, 1993; Smyth and Harris, 1993) and are particularly useful for reaching isolated carers such as those living in rural and remote areas. There are also support groups for people with dementia themselves, particularly in the early stage of the disease (Yale, 1995) including an internet-based virtual support group run by 'Dementia Advocacy Support Network International' (www.dasninternational.com).

22.1.1 Alzheimer SHGs

At a local level, support groups primarily for family carers, meet regularly and frequently, usually monthly. Support groups tend to be led by a health professional, such as a social worker, often in combination with a carer. Some support groups are led by carers alone, and some by professionals alone. Meeting may be structured (see above) so that there is a formal speaker, viewing of a videotape or discussion of a set topic, followed by general discussion; or unstructured in order to allow for more interaction between attendees. Practical arrangements for people with dementia during the support group vary. Some support groups only allow family carers to attend, others allow people with dementia to come too, or provide a separate room for patients' activities. Carers' groups are sometimes held adjacent to day centres. Interested health professionals, students and observers sometimes attend too, although only with the prior permission of the group.

Anecdotal evidence suggests that some carers attend SHGs regularly over many months, even years. Others come for one or two meetings, perhaps feeling that they have achieved all

they need, or may feel that support groups are not suitable for them. Other carers may never come because they have no need, have enough support from their own networks of friends and family, have obtained the support that they need from one-to-one counselling, or, most often, have never been told of the existence of such groups (Thomson *et al.*, 1997).

Telephone and internet education and online support networks are becoming more common and used by caregivers (Harvey *et al.*, 1998; White and Dorman, 2000; Glueckauf and Loomis, 2003). Caregivers express particular interest in using telephone support lines (Colantano *et al.*, 2001).

22.1.2 The efficacy of support groups

Participation in support groups may have a positive impact on the wellbeing of carers. Support group participation, in cross-sectional studies, has been found to be associated with lower levels of objective and subjective burden; the more frequent and the longer the periods of support group participation, the less the subjective burden (Gonyea, 1990). Carers who attend support groups have also been found to have higher levels of morale than carers who do not attend support groups (Gonyea, 1990). Additionally, support group attendees have been found to experience a significant increase in feelings of self-efficacy (Lovett and Gallagher, 1988; Gallagher *et al.*, 1989), and improvements in their psychological functioning.

In the only randomized trial we could locate, the Cleveland Alzheimer's Managed Care Demonstration evaluated the effects of integrating 'Alzheimer Association' care consultation with a not-for-profit managed healthcare organization. Care consultation is a telephone-based information, support and referral service with follow up supplied by professional staff. Care consultation decreased use of some services and caregiver depression but did not alter satisfaction with healthcare services or strain (Bass *et al.*, 2003).

Comparatively, professionally led groups appear to produce greater improvement in carers' psychological functioning, whereas peer-led groups have been found to increase informal support networks and the extent to which carers feel able to handle the caregiving role more (Toseland *et al.*, 1989). Finally, most importantly, carers themselves tend to value support groups, and often report them to be informative, useful and meaningful (Clark and Rakowski, 1983; Gallagher, 1985; Kahan *et al.*, 1985; Mohide *et al.*, 1990; Jansson *et al.*, 1998).

The findings to date regarding the efficacy of support groups are, however, equivocal, since some studies have not found support groups to result in statistically significant gains. In their review of eight studies that examined the effects of support groups, Cuijpers *et al.* (1996) found that only three demonstrated a significant reduction in carers' depression and stress and an improvement in their wellbeing. In one study, while carers who attended support groups were found to have significantly better help-seeking coping efforts compared to carers who did not attend support groups, there

was no significant difference found between the two groups of carers in terms of their wellbeing (Gage and Kinney, 1995). A study published since this review reported that the level of carer distress decreased and quality of life improved (Fung and Chien, 2002).

There is also evidence to suggest that support groups may be more beneficial for some carers than for others. For instance, SHGs have been found to be more effective for carers whose social network lacks contact with others who have similar caring experiences and for caregivers in more stressful situations (Pillemer and Sutor, 1996, 2002). Additionally, Cuijpers *et al.* (1996) found that support groups were more effective for carers who were dissatisfied about their role as a carer or who had a paid job, where the person with dementia was more apathetic and/or lived in a nursing home, and where participation in the support groups incurred a small cost (\$5–\$20).

In spite of the benefits of support group attendance that have been reported, many carers do not attend support groups, either by choice or because of barriers. Cuijpers *et al.* (1996) reported that there were three main reasons that affected carers' decision to attend support groups – for information, for help with dealing with problems, or for help dealing with their feelings of severe burden. Molinari *et al.* (1994) reported that the reason given by 80 per cent of carers who did not attend support groups was that they had not received advice encouraging them to attend a support group. Analysis of data from 608 dementia caregivers found that enabling variables such as knowledge of services, cost and access, explained more variation in service use than predisposing and need variables such as demographics, patient behaviour and caregiver burden (Toseland *et al.*, 2002). Communication problems between caregivers and general practitioners (GPs) may impede timely referrals for appropriate information and support (Bruce and Paterson, 2000; Bruce *et al.*, 2002). These findings suggest that it is incumbent upon relevant health professionals to provide information about local support groups to carers as part of their management plan.

22.1.3 The impact of cultural factors

In Western countries such as the USA and Australia, ethnic minorities often underuse community services such as support groups (Henderson *et al.*, 1993). Researchers have started to examine the factors that prevent ethnic minorities from participating in support groups, and to look at the extent to which the traditional structure of support groups can be modified to meet the needs of ethnic minority populations (Henderson, 1992; Henderson *et al.*, 1993). For instance, Henderson and colleagues (1993) attempted to set up more culturally sensitive support groups, when they noted that despite widespread advertising and promotion, attendees at local AD support groups were exclusively white. After surveying African American and Hispanic communities on issues of late life, health and wellbeing, and dementia, they started up several African American and Hispanic support

groups, and demonstrated that ethnic minority groups responded to AD support groups when they were implemented in a manner that was consistent with the cultural values of their community. In particular, Henderson (Henderson, 1992; Henderson *et al.*, 1993) recommended that in order for support groups to reach ethnic minority populations successfully, it is important:

- to get acquainted with ethnic communities;
- to recruit and train ethnic support group leaders;
- to find a culturally neutral site for the group to meet; and
- to let the participants determine the form of the group.

22.1.4 Special support groups

Young people with dementia, people with unusual forms of dementia and people who are very prominent in their community and their families often find traditional support groups do not suit them. Attempts have been made to meet their needs by setting up special groups for them, e.g. for younger people with dementia, for people with frontotemporal dementia (such as Pick's disease) (Armstrong, 2003; Diehl *et al.*, 2003). There is increasing emphasis on providing support groups for people with early dementia themselves while they retain insight (Chung, 2001; Coaten, 2002).

22.2 NATIONAL ALZHEIMER ASSOCIATIONS

The overarching aim of all Alzheimer Associations is to improve the quality of life for people with dementia and for their carers. (The term 'Alzheimer Association' is used generically hereafter to include the more correctly named 'Alzheimer Disease and Related Disorders Association', as well as similarly named organizations such as the 'Alzheimer Disease Society'; see www.alz.co.uk and follow the links to find Alzheimer Association in your country. They are also listed in the appendix on page 805.) Alzheimer Associations have a number of important aims.

22.2.1 Information

One of the most important aims is the provision of information. It is well recognized that information brings power. It is fundamental that people with dementia, their carers, professionals, members of the general public and government should have easy access to accurate information. National offices of Alzheimer Associations throughout the world meet an ever-increasing number of enquiries about the disease itself, about financial and legal matters, and about nursing homes. They provide a shoulder to cry on, and information on up-to-date research findings, and where to get help and how to manage particularly difficult problems. For these enquiries to be dealt with in an efficient manner, it is necessary to have an office, staffed by one or more people, paid or unpaid, and a telephone line. A regular newsletter sent out to

all members is invaluable. In addition good publications and fact sheets written in response to the most frequent enquiries (written by knowledgeable professionals) are all essential. It is helpful to start building up a library of books, videos and papers to meet the demand. A new national society can take articles from existing publications elsewhere, as there are many topics that come up again and again. The Internet has revolutionized the availability and speed with which information is available to all those who need it.

22.2.2 Membership

Caring for someone with dementia can be a very isolating experience and the knowledge that there are others around who understand the problems and who can be contacted can be very reassuring. In the UK, for example, the membership of the 'Alzheimer's Society' is now over 20 000. This has been achieved by having a single national body to which all members from all over the country belong. The national office ensures that members know where to find a local branch or group so that they can take part in local activities. Having a large membership gives the Association more power and clout and is impressive to politicians and professionals.

22.2.3 Training

Alzheimer Associations often play an important role in the training and education of family members as well as care workers in residential nursing homes, day care and domiciliary services. The situation is similar all over the world. Care workers often have no background in this sort of work and have been given little if any information about the care recipient's illness or behavioural problems, or any sort of guidance as to how to do their work. Better training and information for family and professional carers are key to ensuring better care for people with dementia. Training and counselling programmes conducted by or in conjunction with Alzheimer Associations may reduce carer distress and delay nursing home admission (Mittelman *et al.*, 1996; Brodaty *et al.*, 1997; see Chapter 11a). In Australia, the Commonwealth Government has funded 'Alzheimer's Australia' to conduct the 'Living with Memory Loss Program', anecdotally a highly successful parallel 7-week course for people with early dementia and for their partners. A pilot of this programme demonstrated a decrease in distress in the person with dementia (Brodaty and Low, 2004).

A partnership between the New Jersey police department and their local Alzheimer Association educated police on wandering reduction in AD, increased enrolment of people with AD in a national registration programme, and increased police sponsored AD community outreach programmes (Lachenmayr *et al.*, 2000).

22.2.4 Services

There are several types of services that are used by carers: home care, day care, in-home (sitting) and residential respite

care, and permanent care, although each carer may have a different requirement. Finding the right solution reduces the stress on carers and makes institutionalized care less likely (Mittelman *et al.*, 1996). The 'Alzheimer's Connection Demonstration Program' in the USA was an attempt to link families with needed services and resources using case management (Cox and Albusu, 2001). Individual carers' needs cannot always be met because resources either do not exist or are very patchy. Adequate provision of services for carers is a major problem in most (or all) countries around the world. This problem presents differently in every country and sometimes is the main reason that dementia has reached the top of many political agendas, as care is often needed well beyond the capacity of the family to provide or the government's willingness to pay.

The challenge to all governments in all countries is how to provide cost-effective resources for carers of people with dementia and their families, as well as improving the quality of training of professional carers. Worldwide there is immense pressure by governments on the private and voluntary sectors to deliver these services. Whichever sector provides these services, a national association has an extremely important part to play in defining how to deliver and monitor services with reasonable standards of care and at economic cost.

22.2.5 Research

Whilst well established and wealthy societies such as the US and UK are able to fund research, most Alzheimer Associations are not. Associations can and do act as an advocacy group to pressure other funding bodies and government to provide more money for dementia research and to ensure that such funding is available for investigation of the best way to help people with dementia and their families as well as for basic sciences and drug studies.

Alzheimer Associations can help researchers in various ways. They can provide access to people with dementia and their families. They can advise researchers on their projects, giving the carer perspective, which is immensely valuable. Researchers can help Alzheimer Associations by advising, contributing to newsletters and giving talks. Most Alzheimer Associations have found it important to have a strong supportive medical and scientific committee to provide advice to the Association.

It is important that the relationship between carers and interested professionals is worked out in a sensitive way. Ultimately, support for persons with dementia and their carers must remain the main focus of all Alzheimer Associations.

22.2.6 Public awareness

Good publications, training materials and courses are a fundamental way of increasing public awareness and respect amongst professionals and politicians. As public awareness grows, and more people become involved and interested, so

gradually there is more coverage in radio, television and the press. Time spent lobbying politicians and other professionals is time well spent. Links established with other associations, with politicians and with professionals foster recognition of AD and the other dementias as a priority area of concern, underscored by their increasing prevalence in the community. Alzheimer Associations are in a powerful position to prioritize their concerns on behalf of the family, and these may well vary from country to country.

22.2.7 Fund raising

Inevitably funds have to be raised to pursue the aims of the Association. Government grants are important, not only for the actual amounts of money but also because of the recognition such money offers. In many countries governments give no money. Many countries find that the major amount of funding come from individuals, trusts, industry and legacies. Some countries find having a membership and members paying a fee in exchange for receiving a newsletter and other information is helpful; many members give a donation as well as their membership fee. It must, however, be remembered that, although having sufficient funds is important, equally important is how to use the money as efficiently as possible, with careful budgeting along prepared activity lines. Every Alzheimer Association needs people with financial experience to help guide it, and a fusion of personal, business and professional experience is of primary importance to achieve these aims.

Building a strong national Alzheimer Association is difficult and can be a long process. It is essential that from the start the Association decide on its aims. It will need a good team of staff and volunteers and some good information and training materials. It will also need to put into place parliamentary lobbying. In order to carry this out it is necessary to have an efficient office with up-to-date computerization and a fundraising strategy in order to raise the money to pursue these aims.

22.3 ALZHEIMER DISEASE INTERNATIONAL

The first Alzheimer Disease Association was founded in 1978 in Canada. In 1984 'Alzheimer's Disease International' (ADI), the World Federation of Alzheimer's Disease and Related Disorders Associations and Societies, was formed at a special meeting in Washington. There are now 66 countries with National Associations which are members of ADI and the number is growing every year (see Figure 22.1).

All National Associations face a serious array of tasks which are going to become more important as the years go by. ADI draws on international expertise to support its member societies and encourage new countries to form National Associations.

In the office of ADI, which was originally based in Chicago but is now in London, there are four paid staff who

Figure 22.1 Map of the world with those countries belonging to ADI shown in dark grey. (Source: Alzheimer's disease International, Member Countries map 2004–2005. Reprinted by kind permission of Alzheimer's Disease International.)

are responsible for the administration of the organization. The organizational structure includes an elected Executive Committee and Board and a general Council that meets annually. The organization is run on a tight budget with money from membership fees and donations.

Criteria for ADI membership are that:

- The member must act as the national carer based organization and produce evidence that it is the representative body of families of people with AD and related disorders in that country.
- The organization needs to have national credibility and to have reached organizational maturity with a Board of Directors with adequate representation of family members.
- The Association needs to be able to pay the reasonably modest dues to participate in ADI.
- It should provide services for family carers, e.g. helpline, support groups, public information and education programmes.

The primary aim of ADI is to assist Alzheimer Associations who have already become members and to encourage the formation of Associations in countries where they do not exist. In order to pursue this primary aim, ADI has developed the 'Alzheimer University Course', with the assistance of the Open University in the UK. Since 1998 ADI has conducted an annual 3-day course for members of new and emerging Alzheimer Associations, consisting of workshops aimed at assisting and strengthening new organizations. Alzheimer University Courses on focused issues are also run for more established associations.

ADI disseminates information and acts as a resource point for enquiries and requests for help around the world. A regular newsletter is published which many countries translate for their own purposes. It produces several basic publications including help for carers, how to set up and run an Alzheimer Association, how to influence public policy, and how to set up a support/self help group.

It has also produced a number of important fact sheets dealing with issues of international importance such as demography, prevalence and genetics and drug treatment. All the publications are available on the webpage and can be downloaded from there (www.alz.co.uk). Publications are translated into Spanish. Communication between countries and people has been made greatly easier by email (adi@alz.co.uk). A list of national Alzheimer Association websites providing information on AD and other dementias in different languages is also available from the webpage.

ADI is officially affiliated with the World Health Organization and is closely linked with many international associations with similar interests, such as the International Psychogeriatric Association, World Psychiatric Association, and the World Federation of Neurology. The pharmaceutical industry increasingly looks to ADI for advice about dementia and consumer needs.

Every year ADI hosts an international conference focused on carers and carer issues, which provides a unique opportunity for carers and professionals of all disciplines from many countries to come together and learn from one another.

ADI encourages research and there is a large medical and scientific panel with representatives from many countries around the world. This panel acts as an advisory board and

its members act as ambassadors for ADI when people travel to countries to attend meetings; they also give help with articles and talks at conferences.

ADI's major research commitment is the 10/66 Dementia Research group (<http://www.alz.co.uk/1066>) that brings together a collaboration of researchers from developed and developing countries. 10/66 refers to the less than one-tenth of all population-based research into dementia that is directed towards the two-thirds or more of people with dementia who live in developing countries. 10/66 was formed to redress this imbalance, encouraging active research collaboration between centres in different developing countries and between developed and developing countries. Since its establishment in 1998, 10/66 has published the results of pilot investigations in 26 centres from 16 developing countries. These studies aimed to establish a culture-fair method for diagnosing dementia in older populations characterized by very low levels of education (Prince *et al.*, 2003), and to describe the care arrangements for people with dementia in the developing world (Prince, 2004). The 10/66 group has also highlighted the lack of awareness and understanding of the nature of the dementia syndrome, and the unresponsiveness of healthcare services as currently constituted (Shaji *et al.*, 2002a, Patel and Prince, 2002). The group has developed and described services for people with dementia in developing countries using local health workers, who can be trained to identify cases of dementia with reasonable accuracy (Shaji *et al.*, 2002b).

Stimulating national and international political and public awareness is an important objective of ADI. This is partly being achieved by more countries developing Alzheimer Associations and all of the Associations becoming stronger. However AD is a global problem. World Alzheimer's Day is 21 September and was launched in September 1994 when ADI celebrated its tenth anniversary. ADI supplies its members with a world bulletin with a special focus each year. It produces badges, posters, and ideas for activities which countries can organize themselves according to their different cultures and languages.

22.4 CONCLUSION

Very few governments, even of Western countries are fully aware of the significance of the problem of AD and related disorders and their impact on families. Even if they are aware, the social and economic implications are not fully recognized. Every country, whatever its level of economic development, has a duty to put the dementias and their consequences high on its political agenda. It also represents responsible planning and will be cost effective to work in conjunction with Alzheimer Associations to meet the current and future needs now. The challenge for ADI and all National Associations is to find ways of influencing governments worldwide to take seriously the impact of AD and related disorders on the individual and family, while simultaneously

providing support, information and other services to people with dementia and their families.

23.1 COGNITIVE IMPAIRMENT AS A FEATURE OF NORMAL AGEING

Alterations in cognitive functioning in the absence of dementia have long been considered a normal aspect of ageing-related brain changes. Affecting principally episodic verbal memory, such changes are generally distinguished from neurodegenerative disorders by their far slower progression, their lesser impact on ability to perform activities of daily living, and the relative sparing of linguistic and visuospatial functions. Increased interest in the nature and long-term prognosis of ageing-related modifications in cognitive performance have now led us to question to what extent they may be considered ‘normal’. The past 50 years have seen numerous attempts to define these subclinical alterations in cognitive functioning and to establish their aetiology with greater precision than the general notion of ‘ageing brain changes’ to which they have formerly been attributed.

One of the earliest attempts to characterize subclinical cognitive disorder was Kral’s notion of benign senescent forgetfulness (BSF) (Kral, 1962) which referred to patient complaints of a persistent difficulty in recalling detail, commonly with accompanying depressive symptoms. While Kral initially considered such complaints to characterize a depressive state, which he referred to as depressive pseudodementia, long-term follow up of some of these patients showed that a significant proportion went on to develop vascular dementia. BSF was diagnosed by Kral by an open psychiatric interview and no formal algorithm was proposed. Formal diagnostic criteria for non-dementia cognitive impairment were first proposed by Crook *et al.* in 1986 for the National Institute of Mental Health. Referring to ‘age-associated memory impairment’ (AAMI); they defined these changes as subjective

complaints of memory loss in older (aged > 50) people verified by a decrement of at least one standard deviation on a formal memory test in comparison with means established for young adults. Blackford and La Rue (1989) later suggested suitable tests of non-verbal and verbal secondary memory tests, proposing that AAMI be defined as performance at least one standard deviation below the mean for young adults on one or more of these tests. They also differentiate AAMI from the more severe state of ‘late-life forgetfulness’ (LLF), defined as performance between one and two standard deviations below the mean on at least 50 per cent of a battery of at least four tests.

Levy *et al.* (1994) argued that there is little reason *a priori* that cognitive decline in normal old age should be confined to memory functions exclusively, and in collaboration with the International Psychogeriatric Association and the World Health Organization proposed an alternative concept of ageing-associated cognitive decline (AACD). The criteria for AACD not only admit to the possibility of a wider range of cognitive functions being affected (attention, memory, learning, thinking, language, visuospatial function), but also stipulate that the deficit should be defined in reference to norms for older and not young adults to avoid confounding of decline with age and cohort effects. This refinement takes into account the observations of researchers such as Schaie and Willis (1991) who have demonstrated that much of the difference in cognitive performance observed between young and elderly cohorts is attributable to generation differences (notably in education and health care) rather than to ageing-related brain changes. Studies comparing the performance of AACD and AAMI criteria have concluded that they do not identify the same individuals within general population studies, AACD targeting a more severe state of impairment within a larger AAMI group (Richards *et al.*, 1999).

Recognition by the major international classifications of disease of subclinical cognitive deterioration linked to the normal ageing process began with the appearance in DSM-IV (1994) of the concept of age related cognitive decline (ARCD). Like AACD it refers to an objective decline in cognitive functioning owing to the physiological process of ageing; however, no operational criteria or cognitive testing procedures were specified. It is rather loosely defined as a complaint of difficulties in recalling names, appointments or in problem-solving, which cannot be related to a specific mental problem or a neurological disorder. Subsequent attempts to operationalize ARCD using data from two general population studies in France and the USA have concluded that the concept has little value either in predicting clinical outcomes or in identifying comparable populations for research purposes (N Quizzilbash, personal communication).

23.2 DISEASE MODELS OF SUBCLINICAL COGNITIVE IMPAIRMENT

Early conceptualizations of subclinical cognitive deficit have in common the theoretical assumption that such changes are distinct from dementia and other pathologies, being the consequence of inevitable ageing-related cerebral changes such as cortical atrophy, which may be considered a normal feature of the ageing process. As parallel research into the causes of dementia and cerebrovascular disease has now led to a clearer understanding of their aetiology, it has also been shown that many of the physiological abnormalities seen in these disorders are also present to a lesser extent in subjects identified as AAMI and AACD. Consequently elderly persons with subclinical cognitive deficits have become the subject of neurological as well as psychogeriatric research, the underlying question being whether cognitive deficits of this type may be due to underlying brain pathology, which might be potentially treatable. Alternative concepts have subsequently appeared in the literature linking cognitive disorder to various forms of underlying pathology. For example, the 10th revision of the *International Classification of Diseases* (1993) described 'mild cognitive disorder' (MCD) which refers to disorders of memory, learning and concentration, often accompanied by mental fatigue, which must be demonstrated by formal neuropsychological testing and attributable to cerebral disease or damage, or systemic physical disease known to cause dysfunction. MCD is secondary to physical illness or impairment, excluding dementia, amnesic syndrome, concussion, or postencephalitic syndrome. The concept of MCD, which was principally developed to describe the cognitive consequences of autoimmune deficiency syndrome but then expanded to include other disorders in which cognitive change is secondary to another disease process, is applicable to all ages, not just the elderly. Attempts to apply MCD criteria to population studies of elderly persons suggest it to be of limited value in this context, casting doubt on its validity as a

nosological entity (Christensen *et al.*, 1995) for this age group. DSM-IV (American Psychiatric Association, 1994) has proposed a similar entity, mild neurocognitive disorder (MNCD), which encompasses not only memory and learning difficulties but also perceptual-motor, linguistic and central executive functions. While the concepts proposed by the two international classifications, MCD and MNCD, do not provide sufficient working guidelines for application in a research context, they do provide formal recognition of subclinical cognitive disorder as a pathological state requiring treatment, and as a source of handicap, and are thus likely to be important within a legal context.

A similar concept of cognitive change secondary to multiple underlying disease processes, but in this case referring to elderly populations, is that of CIND (cognitive impairment no dementia). The concept was developed within the context of the Canadian Study of Health and Aging and is defined by reference to neuropsychological testing and clinical examination (Graham *et al.*, 1997). Persons with CIND, like MCD and MNCD, are considered to have cognitive impairment attributable to an underlying physical disorder, but may also have a 'circumscribed memory impairment', which is a modified form of AAMI. CIND encompasses a wider range of underlying pathologies than MCD and MNCD, including disorders such as delirium, substance abuse and psychiatric illness, which are excluded from the ICD and DSM categories.

23.3 MILD COGNITIVE IMPAIRMENT – SUBCLINICAL COGNITIVE CHANGE AS PRODROMAL DEMENTIA

MCD, MNCD and CIND are constructs that have been developed principally for research purposes and consider cognitive disorder in the elderly to be heterogeneous, not necessarily progressive, with treatment being determined by the nature of the underlying primary systemic disease. On the other hand many clinical observations of the long-term outcome of cognitive complaints, particularly those presenting to memory clinics and neurology departments, led to the general conclusion by many neurologists that subclinical cognitive disorder in the elderly is in fact principally, if not exclusively, early-stage dementia. Thus whereas dementia was considered by many in the early 1990s to be an extension of a 'normal' process of progressive ageing-related cognitive deterioration, by the end of the decade subclinical cognitive deficit began to be perceived as an extension of a pathological process. Numerous studies have referred vaguely to mild cognitive disorders in relation to dementia and in 1997 Petersen and colleagues (Petersen *et al.*, 1997) proposed diagnostic criteria for the concept of mild cognitive impairment (MCI), initially defined as complaints of defective memory and demonstration of abnormal memory functioning for age, with normal general cognitive functioning and conserved ability to perform activities of daily living. MCI was considered to be a prodrome of Alzheimer's disease (AD). MCI criteria proved

difficult to apply as it referred to poor cognitive functioning as assessed at one point in time, thus precluding appreciation of decline over time, and difficult to differentiate from cohort effects, low IQ and education. A later definition refined the initial concept by referring to memory impairment beyond that expected for both age and education level (Petersen *et al.*, 1999). An alternative approach has been to define it in terms of early-stage dementia. For example Krasuki *et al.* (1998) refer to cognitive impairment with a score of 20 or more on the MMSE, and Zaudig (1992) defines MCI as a score of more than 22 on MMSE or 34–47 on the SIDAM dementia scale. Others have referred to criteria based on Clinical Dementia Rating Scale or Global Deterioration Scale scores (Flicker *et al.*, 1991; Kluger *et al.*, 1997). The concept of MCI subsequently became the focus of considerable interest as it opened up the possibility of widescale treatment of a subclinical state by the new cholinergic therapies developed for dementia.

23.4 OPERATIONALIZING MILD COGNITIVE IMPAIRMENT CRITERIA

Subsequent studies using MCI criteria have encountered numerous difficulties. These have been principally due to the lack of a working definition based on designated cognitive tests and other clinical measures. The result has been that population prevalence, the clinical features of subjects identified with MCI, and their clinical outcomes, vary widely between studies and even within studies where there has been longitudinal follow up. A consensus conference held in Chicago in 1999 confronted the many difficulties facing the MCI concept (Petersen *et al.*, 2001), notably its two underlying assumptions that it should be confined exclusively to isolated memory impairment and whether it constitutes a prodrome of AD, or alternatively a more clinically heterogeneous group at increased risk of dementia owing to any cause. While there is some limited evidence that a purely amnesic syndrome may exist (Richards *et al.*, 1999), these appear to represent only a very small proportion (6 per cent) of elderly persons with cognitive deficit when the full range of cognitive functions are examined. Higher rates of 'circumscribed memory deficit' (31.7 per cent of CIND cases) are observed within the Canadian Longitudinal Study (Graham *et al.*, 1997), but only subjects with a score below a cut-off on the MMSE are examined, and the test battery itself consists predominantly of memory tasks. Memory tests also involve cognitive capacities other than memory, notably attentional and linguistic capacities, so that it is difficult in the absence of a detailed neuropsychological examination to conclude that an individual has an isolated amnesic impairment. Many of the studies that observe principally memory deficits in MCI have used almost exclusively memory tests in their diagnostic examination.

The Chicago consensus group concluded that subjects with MCI have a condition different from normal ageing and are likely to progress to AD at an accelerated rate; however, they

may also progress to another form of dementia or improve. This group thus proposed subtypes of MCI according to type of cognitive deficit and clinical outcome distinguishing MCI Amnesic (MCI with pronounced memory impairment progressing to AD), MCI Multiple Domain (slight impairment across several cognitive domains leading to AD, vascular dementia or stabilizing in the case of normal brain ageing changes), and MCI Single Non-Memory Domain (significant impairment in a cognitive domain other than memory leading to AD or another form of dementia). It has subsequently been suggested that MCI be further subdivided according to the suspected aetiology of the cognitive impairment, in keeping with international classifications of dementing disorders: for example MCI-AD, MCI-LBD, MCI-FTD and so on.

23.5 THE FUTURE OF MILD COGNITIVE IMPAIRMENT

A number of concepts now exist to describe subclinical cognitive disorder in the elderly. Application of these concepts in general population studies gives quite different prevalence rates both between concepts and even between studies using the same concept (Table 23.1).

Clearly such deficits have multiple causes. A longitudinal study of a general population sample with subclinical cognitive deficits has demonstrated multiple patterns of cognitive change with variable clinical outcomes including dementia, depression, cardiovascular and respiratory disorders (Ritchie *et al.*, 1996). However, it is the identification of those cases likely to evolve towards dementia that have been given priority, especially given the development of treatments that may delay dementia onset. The potential treatment window for dementia is large, with twin studies indicating that insidious changes in cognitive performance may occur up to 20 years before disease onset (La Rue and Jarvik, 1987). For this reason at a conceptual level, MCI has been the principal focus of interest as longitudinal studies confirm the high risk rates of MCI for dementia, with conversion estimates ranging from 10 to 15 per cent per year (Petersen *et al.*, 1997), 40 per cent over 2 years (Johnson *et al.*, 1998), 20 per cent over 3 years (Wolf *et al.*, 1998), 30 per cent over 3 years (Black, 1999), 53 per cent over 3 years (McKelvey *et al.*, 1999), to 100 per cent over 4.5 years (Krasuki *et al.*, 1998). Population studies show, however, lower dementia conversion rates (2–8 per cent per annum; Tierney *et al.*, 1996; Johanssen and Zarit, 1997; Kluger *et al.*, 1999; Hogan and Ebly, 2000; Artero *et al.*, 2001; Morris *et al.*, 2001) than those observed in clinical studies (12–31 per cent; Flicker *et al.*, 1991; Bowen *et al.*, 1997; Devanand *et al.*, 1997; Huang *et al.*, 2000) as they include a wider range of cognitive impairments, which are probably also less severe than those presenting in clinical settings. These studies suggest that alternative cognitive criteria (notably those for ARCD) in conjunction with subtle measures of loss of ability to perform activities of everyday living

Table 23.1 Characteristics and estimated prevalence rates (where available) of nosological entities designating cognitive impairment in elderly persons without dementia

Concept	Reference	Criteria	Population prevalence (%)
BSF	Kral (1962)	Memory complaints, forgetting details. Depression	–
AAMI	Crook <i>et al.</i> (1968)	Memory impairment with decrement on formal cognitive test compared to young adults	7–38
LLF	Blackford and LaRue (1989)	AAMI with greater decrement on 50% of a test battery	–
AACD	Levy <i>et al.</i> (1994)	Impairment on any formal cognitive test compared to peers	21–27
ARCD	DSM IV (APA, 1994)	Objective decline in cognitive functioning due to old age	8
MCD	ICD-10 (WHO, 1993)	Disorders of memory learning and concentration demonstrated by testing. Due to disease	4
MNCD	DSM IV (APA, 1994)	Difficulties in memory, learning, perceptual-motor, linguistic and central executive functioning. Due to disease	–
CIND	Graham <i>et al.</i> (1997)	Circumscribed memory impairment and low MMSE score due to disease or age	30–80
MCI	Petersen <i>et al.</i> (1997)	Complaints of defective memory, demonstrated by deficit on cognitive tests with normal general intellectual functioning compared to peers. Due to dementia	3–15

and anatomical changes on cerebral imaging (volume loss in hippocampal and entorhinal cortex) may ultimately provide better dementia prediction (Tierney *et al.*, 1996; Touchon and Ritchie, 1999; Artero *et al.*, 2001, 2003; Ritchie *et al.*, 2001; Visser *et al.*, 2002; Palmer *et al.*, 2003).

While the recognition of MCI as a potentially pathological entity marks an early step towards the recognition of non-dementia cognitive disorder as an important clinical problem with a potential treatment, it does not now meet the necessary validation criteria for a formal nosological entity (Ritchie *et al.*, 2001). The feasibility of widescale treatment will very much depend on the development of more precise diagnostic criteria. Premature application of MCI criteria for the identification of subjects for clinical trials is likely to lead to either the inclusion of high numbers of non-cases (yielding high failure rates and subsequent discreditation of a treatment that may have been successful on sample subgroups) or alternatively by restriction to subjects in reality already manifesting early dementia, in which case potential preventive/delaying effects will be minimized. The future of MCI development will depend very much on close collaboration between specialist clinical units refining clinical criteria and epidemiologists monitoring screening efficiency within the general population where MCI will principally be detected.

In recent years, increasing attention is being paid to the transitional state between normal ageing and early Alzheimer's disease (AD). As research on ageing and dementia moves toward prevention, and as baby-boomers advance into the age at which they are at risk for AD, it has become important to characterize individuals who are at the earliest stage of a cognitive impairment, and to distinguish them from those experiencing normal ageing. Mild cognitive impairment (MCI) is a term used to describe this transitional zone between normal ageing and very early AD. Mild cognitive impairment represents a condition where individuals show memory impairment greater than expected for their age, but otherwise are functioning well and do not meet the commonly accepted criteria for dementia (Petersen *et al.*, 1999).

Inherent in the definition of MCI and in its differentiation from normal ageing is the question of 'What is normal?'. While there are well-established diagnostic and research criteria for dementia, the picture has been less clear with regards to what constitutes normal ageing. In discussing normal ageing, it is useful to differentiate between what is being referred to as 'successful ageing' and typical normal ageing. Successful ageing represents a state of health that allows individuals to function effectively and successfully as they age (Kaye *et al.*, 1994). In this setting, there is likely very little cognitive decline over one's life span, and cognitive function can be preserved well into the 10th decade or beyond. However, this definition of normal pertains to a very small segment of the population. What characterizes many of the elderly is normal typical ageing, where individuals encounter comorbidities, such as hypertension, coronary artery disease and sensory abnormalities, as part of ageing. In this discussion, the latter definition of normal is used.

Historically, attempts at characterizing cognitive changes at the normal tail-end of the continuum have produced several terms such as, benign senescent forgetfulness (Kral, 1962),

age-associated memory impairment (AAMI) (Crook *et al.*, 1986), and ageing-associated cognitive decline (AACD) (Levy, 1994). These terms are generally meant to reflect the extremes of normal ageing, rather than to describe a precursor of pathologic ageing. Mild cognitive impairment, on the other hand, is recognized as a pathological condition, rather than manifestation of normal ageing, and it has recently received a great deal of attention as a clinically useful entity.

24.1 CLINICAL ASPECTS

Most clinicians recognize patients in their clinical practice who have some cognitive impairment, but are not sufficiently debilitated as to warrant the diagnosis of dementia or AD. These intermediate groups of patients are common in everyday practice, and their characterization is becoming increasingly important. While the diagnosis of probable AD, and its correspondence to definite AD, is well defined, the picture has been less clear concerning this group of patients who are in the boundary between normal ageing and very early AD. As the theoretical model in Figure 24.1 depicts, the current challenge is to move to the left on the function curve to allow clinicians to make the diagnosis of a cognitive impairment prior to reaching the threshold for clinically probable AD. This region on the curve has recently been characterized as 'MCI'. During this phase, individuals experience subtle cognitive deficits, usually forgetfulness, but otherwise have largely intact cognition and activities of daily living.

24.1.1 Criteria

At present, there is no consensus in the field on a single set of criteria for MCI. A great deal of research is moving forward

Figure 24.1 Hypothetical characterization of function by age. As function declines, subjects go through a transitional stage of mild cognitive impairment prior to reaching the threshold for the diagnosis of clinically probable Alzheimer's disease (AD). (With permission from Petersen, 2000.)

Box 24.1 Criteria for amnesic mild cognitive impairment (a-MCI)

- Memory complaint usually corroborated by an informant
- Objective memory impairment for age
- Essentially preserved general cognitive function
- Largely intact functional activities
- Not demented

to characterize certain features of the construct and additional work will likely continue. The most typical and well-studied scenario of MCI pertains to individuals who have impairment in a single domain of memory, and recently, this form of MCI has been termed amnesic MCI (a-MCI) (Petersen, 2003). The criteria for a-MCI are outlined in Box 24.1. It is important to note that these are clinical criteria, and that while neuropsychological testing can be very helpful, the ultimate diagnosis is a clinical judgement. The operationalization of these criteria has generated considerable research, and is currently being examined by a number of investigators worldwide. In general, these criteria are satisfied as follows.

The first criterion concerns the subjective memory complaint, which preferably is corroborated by an informant who knows the subject well. Several studies have indicated that a cognitive impairment substantiated by an informant is more likely to be reliable (Morris *et al.*, 1991; Tierney *et al.*, 1996), as subject's memory complaints are of variable reliability (Ritchie *et al.*, 1996; Smith *et al.*, 1996). As such, this criterion is 'soft' and may be a challenge to implement, but without prior cognitive function testing, it is critical for the purpose of excluding individuals with life-long static cognitive deficits (Graham *et al.*, 1997).

A second criterion concerns an objective memory impairment for age. This criterion can be fulfilled by use of neuropsychological testing, where tasks commonly used for this purpose include the Auditory Verbal Learning Test, the

Wechsler Memory Scale-Revised, Logical Memory II, or Visual Reproductions II (Rey, 1964; Wechsler, 1987). It is important to note here, however, that no particular test or cut-off score is specified for this criterion; rather, this was left to the judgement of the clinician in the appropriate clinical context. In the literature, the cut-off score of 1.5 standard deviations (SD) below age norms has been suggested by some investigators. In the original description of the MCI cohort followed at the Mayo Clinic, subjects with MCI scored approximately 1.5 SD below age- and education-matched controls on measures of learning and delayed recall, and their performance was more similar to patients with AD than to normal controls. However, this level of performance was not used as a cut-off score. Rather, these persons have a mean memory impairment of 1.5 SD; as such, there is a range of performance around the mean, where nearly half of the group had performance score somewhat less than 1.5 SD below the mean. Thus, it is important that this criterion is interpreted in conjunction with the first criterion. The memory complaint is meant to represent a change in function for the person. The clinician may be challenged by persons who are of either high intellect (whose performance is now in the statistically 'normal' range, but this level of performance represents a change for that person), or by persons with low education level (whose lower cognitive performance may not represent a change from baseline). The preferable approach to this challenge is to allow the clinician to use judgement in combining all of these criteria. As such, a precise history from the patient and an informant coupled with neuropsychological testing can be invaluable.

Third, general cognitive function is essentially normal. Subjects with MCI usually show mild impairments in non-memory cognitive domains such as language, attention and visuospatial skills; however, these impairments are not of sufficient magnitude to compromise functional abilities, or to warrant a diagnosis of dementia. It should be noted here again that performance in these domains should be judged relative to age-appropriate standards, but no specific instruments or cut-off scores are predetermined. Ultimately, the judgement of the clinician is required in making these determinations.

The fourth criterion pertains to largely intact activities of daily living (ADL). Subjects with MCI might show slower performance in complex ADL, but they are still able to complete them without difficulty and their slight impairments are of insufficient magnitude to constitute dementia. This criterion, however, can also be a challenge to implement especially in older adults. That is, the criterion requires that the slight functional impairments observed be due to a decline in cognitive function, which can be difficult to delineate in older subjects who may have several medical comorbidities and physical limitations. This once again underscores the necessity of assimilation of all of the data available in making the clinical judgement.

Finally, the last criterion is that subjects are not demented. This criterion hinges on the degree of functional impairment and is also made on the basis of the clinician's best judgement.

Many of these subjects will have a slight degree of general cognitive impairment, but it will not be of sufficient magnitude to meet the standard *Diagnostic and Statistical Manual of Mental Disorders IV* (American Psychiatric Association, 1994) criteria for dementia.

In general, subjects with MCI appear more normal than not. As such, the difficult distinction is between normal ageing and MCI rather than between MCI and AD. In the older subjects, a degree of memory impairment is frequently associated with ageing and consequently, the demarcation between normal ageing and early MCI can be a challenge. Nevertheless, the concept is a reasonable one, and several multicentre studies have now documented that these criteria can be implemented on a reliable basis across institutions (Grundman *et al.*, 2004).

24.1.2 Clinical subtypes

Although most research has focused on a-MCI, as the field of MCI has advanced, it has become apparent that other clinical subtypes exist as well (Petersen *et al.*, 1999; Petersen, 2003). More recently, the concept of MCI has been expanded to include at least three more subtypes.

- *Multiple domain amnesic MCI* pertains to individuals who, in addition to memory deficit, also have impairments in at least one other cognitive domain such as language, executive function or visuospatial skills.
- *Multiple domain non-amnesic MCI*, on the other hand, pertains to individuals who have impairments in multiple cognitive domains, but not including memory.
- *Single domain non-amnesic MCI*, which is the least common subtype, pertains to individuals with impairment in a single non-memory domain such as language, executive function or visuospatial skills. Other cognitive domains, including memory, are essentially normal.

Individuals in the non-amnesic subtypes are likely to have a different outcome from those with memory impairment. It is also imperative that individuals in all of these subtypes of MCI have minimal impairments in functional activities that do not represent a significant change in function from a prior level, and they also do not meet the criteria for dementia.

In addition to the clinical subtypes, there can also be multiple aetiologies or causes for each subtype, as depicted in Figure 24.2. Therefore, if one selected the single domain a-MCI subtype of a presumed degenerative aetiology, this would likely represent a prodromal form of AD. However, one could also add the subtype of the multiple domain a-MCI since this subtype has a high likelihood of progressing to AD as well (Petersen *et al.*, 2004). In contrast, the other subtypes emphasizing impairments in non-memory domains such as executive function and visuospatial skills, may have a higher likelihood of progressing to a non-AD dementia, such as dementia with Lewy bodies (Boeve *et al.*, 2004). Therefore, the combination

		Aetiology				
		Degen- erative	Vascular	Psychiatric	Trauma	
Clinical classification	Amnesic MCI	Single domain	AD		Depr	
		Multiple domain	AD	VaD	Depr	
	Non-amnesic MCI	Single domain	FTD			
		Multiple domain	DLB	VaD		

Figure 24.2 Classification of clinical subtypes of mild cognitive impairment (MCI) with presumed aetiology. (Modified from Petersen and Morris, 2003.)

of clinical subtypes and putative aetiologies can be useful in predicting the ultimate type of dementia to which these diseases will evolve.

24.1.3 Proposed diagnostic scheme

One logical question that can arise from the above, then, is based on these criteria and classifications: How does one generate a diagnosis of MCI in a new patient? Figure 24.3 depicts the scheme proposed to help guide this diagnostic process, and ultimately, this scheme will lead to the classification outlined in Figure 24.2. The diagnostic process usually begins with a person, or an informant who knows the person well, expressing some complaint about the person's cognitive function. For example, the person may note forgetfulness for names, or that they are misplacing objects, such as car keys. When presented with these complaints, the clinician's first task is to make a judgement as to normal cognition or suspected dementia based on the person's history and a mental status exam. For example, a score of 18/30 on the Mini-Mental State Examination along with clear signs of impairments in functional activities may suggest dementia, while a score of 28/30 on this exam added to no signs of impairment in complex ADL may suggest that the person, despite subjective complaints, is likely normal. The clinician at this point should also entertain other explanations, such as depression, for this complaint. In cases, however, where the clinician is uncertain as to the precise cognitive status of the person, the diagnosis of MCI may be entertained, and here, the flow chart depicted in Figure 24.3 can be useful (Petersen, 2004).

Once the diagnosis of MCI is entertained, the next step for the clinician is to assess the decline in cognitive function to determine whether it constitutes a diagnosis of very mild dementia. This can be accomplished through a careful history from the patient and preferably a collateral source. If the clinician determines that the decline in cognition does not constitute a significant impairment in functional activities as to warrant the diagnosis of a very mild dementia, then the

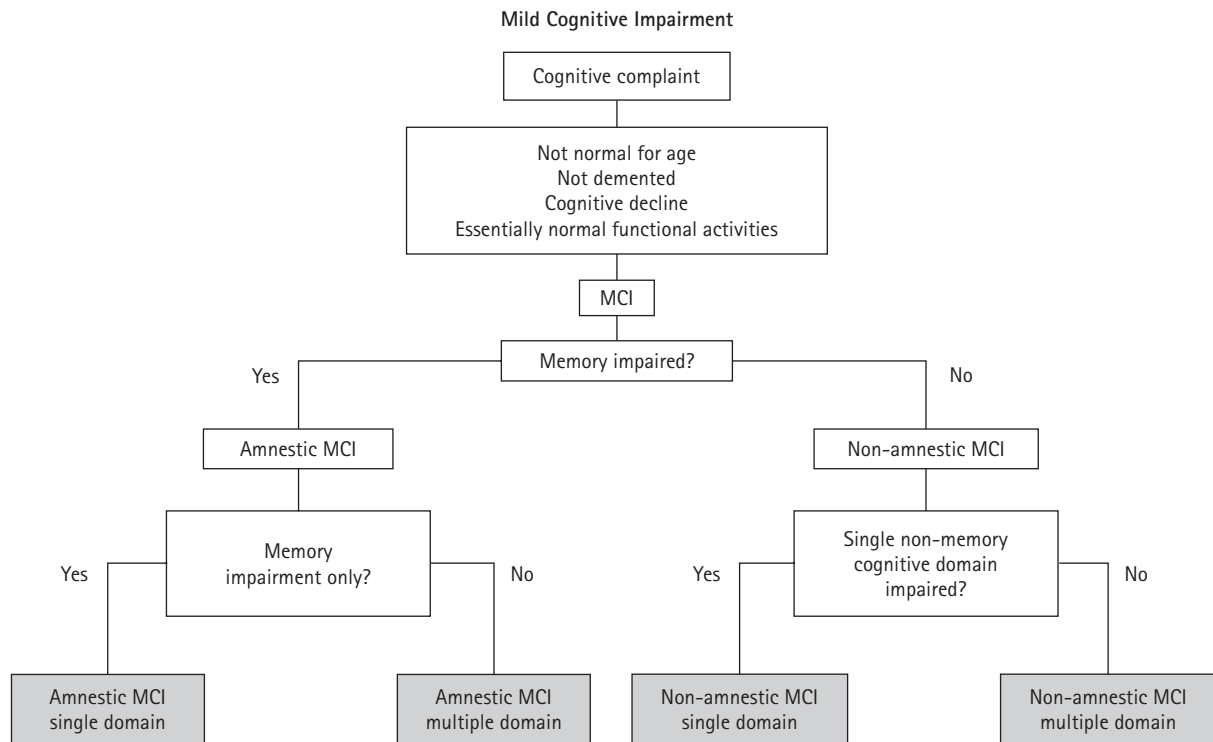

Figure 24.3 Flow chart of decision process for making diagnosis of subtypes of mild cognitive impairment. (With permission from Petersen, 2004.)

diagnosis of MCI is further assumed, and the next step is to identify the clinical subtype. Here, the clinician should first ask, 'Is memory impaired?' and assess memory more carefully. Although there are no generally accepted instruments for this purpose, neuropsychological tests involving word list learning or paragraph recall can be useful. If memory is determined to be impaired for age, the clinician can assume that this is an a-MCI. If, on the other hand, memory is found to be relatively spared, but the person has impairment in other non-memory cognitive domains, such as language, executive function, or visuospatial skills, this constitutes a non-amnesic subtype of MCI.

Once this determination has been made, the next step for the clinician is to ask, 'Are other cognitive domains also impaired?' This can also be addressed using neuropsychological testing or other relatively brief office instruments. If these assessments reveal, for example, that a person with an a-MCI has impairment only in the memory domain, but that other cognitive domains are relatively intact, this constitutes the diagnosis of single domain a-MCI. If, on the other hand, other cognitive domains are also found to be compromised in addition to memory, this constitutes the diagnosis of multiple domain a-MCI. Likewise, if a person with non-amnesic MCI is found to have impairments only in a single non-memory domain, such as language, executive function or visuospatial skills, this constitutes the diagnosis of single domain non-amnesic MCI. However, if multiple non-memory domains are found to be mildly impaired, the diagnosis of multiple domain non-amnesic MCI is warranted.

Although this type of classification of MCI may appear cumbersome, it may be important if one is to gain more insights into the various subtypes of cognitive impairments. It can also have practical utility in so far as the medical treatments for the prodromal forms of dementia are specific to the presumed underlying aetiology of the developing dementing disorder, and are different depending on the presumed outcome of the subtype of MCI.

24.1.4 Outcome

As interest in MCI increases, several studies using the construct are being conducted around the world in a variety of research settings. As indicated above, most of the literature to date pertains to individuals with memory impairment, and it is useful to review these studies to determine the outcome of these individuals. At the Mayo Alzheimer's Disease Research Center/Alzheimer's Disease Patient Registry, a group of approximately 220 individuals with a mean age of 79 years has been followed for 3–6 years using the original Mayo criteria, which focused on amnesic MCI (Petersen *et al.*, 1999). The subjects in these studies have progressed to dementia at a rate of approximately 12 per cent per year, which is in contrast to the normal elderly cohort that developed dementia at the rate of 1–2 per cent per year (Petersen *et al.*, 2003). Further, over the course of 6 years, up to 80 per cent of them will have converted to dementia, suggesting that this group represents a population at risk. In addition, as is shown in Figure 24.4, when individual measures such as mental status are examined,

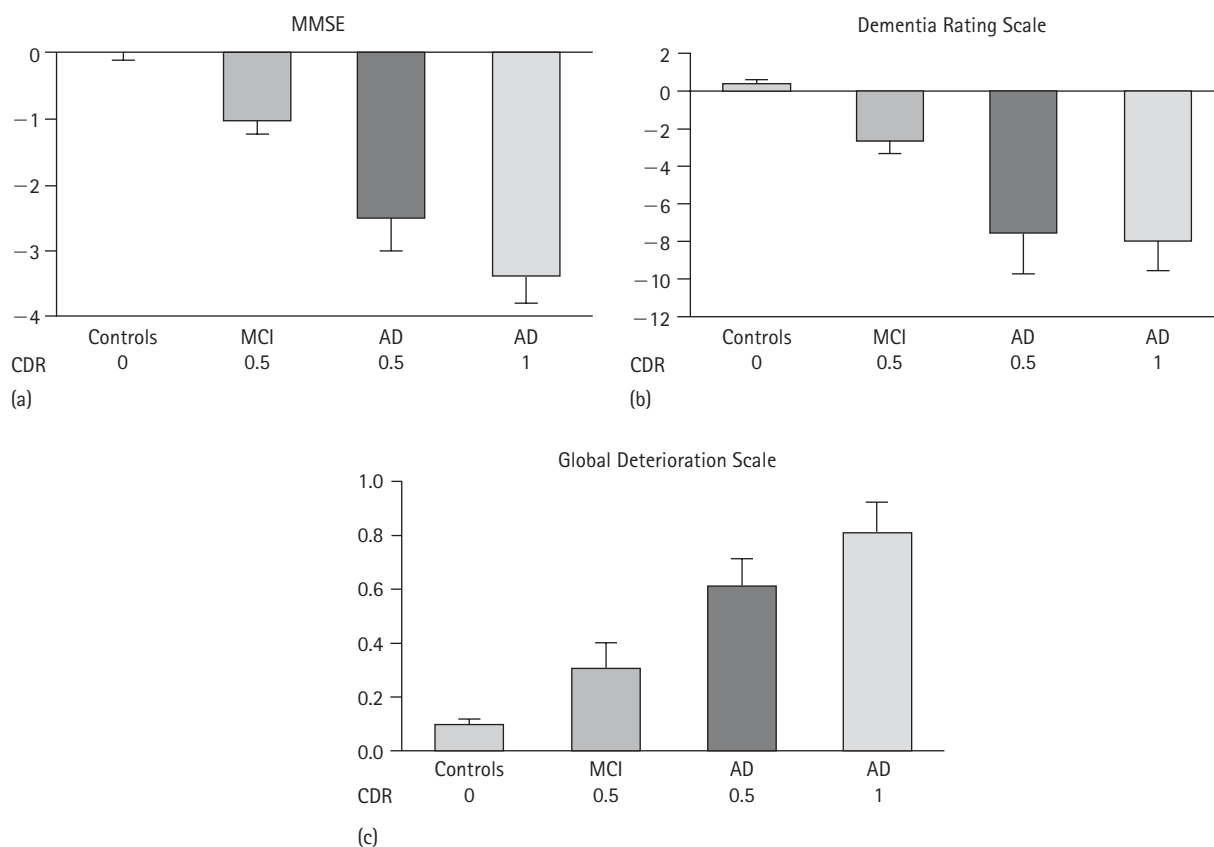

Figure 24.4 (a-c) Annual rates of change on the Mini-Mental State Examination (MMSE), Dementia Rating Scale and Global Deterioration Scale. (With permission from Petersen *et al.*, 1999.)

subjects with MCI tend to fall midway between normal elderly controls and patients with very mild AD, and their progression rate also indicates a similar pattern.

In evaluating the measures that could predict a more rapid progression to dementia, Mayo investigators have also shown apolipoprotein E (ApoE) $\epsilon 4$ allele carrier status to be one of the most prominent variables (Petersen *et al.*, 1995). Performance on a cued memory task and several neuroimaging measures such as volumetric measurements of the hippocampus were also found to be useful predictors (Petersen *et al.*, 1991; Jack *et al.*, 1999).

Similarly, Tierney and colleagues in Toronto followed a group of 123 patients who had been identified by primary care physicians as having memory impairments. Over the course of two years, they found that 29 of these individuals had developed AD (Tierney *et al.*, 1996). Further, in evaluating predictors for the progression, they found delayed recall and an index of mental control to be better indicators, with ApoE $\epsilon 4$ carrier status being a reliable predictor only when combined with memory tests.

Investigators from the Alzheimer's Disease Patient Registry in Seattle followed a cohort of patients with an isolated memory impairment for 5 years and found that 10 of 21 subjects developed dementia over this time period, with the mean duration to dementia of 3.8 years (Bowen *et al.*, 1997). In this

study, no individual memory test was found to be better indicator than any other.

Investigators from New York University identified a group of individuals with a Global Deterioration Scale (GDS) of 3 whom they characterized as representing mildly impaired subjects and followed them for two years (Flicker *et al.*, 1991). They found that 23 of 32 subjects progressed to dementia over this time frame.

Daly and colleagues from Harvard recruited their subjects from media advertisements and identified a cohort of individuals who were mildly impaired but not demented (Daly *et al.*, 2000). These investigators modified the Clinical Dementia Rating to make it more sensitive in detecting individuals with subtle memory impairment and a CDR of 0.5. Of the 123 individuals characterized in this fashion, 23 progressed to AD over 2 years at the rate of 6 per cent per year. This rate is lower than seen in other studies and may reflect the combination of recruitment strategy and use of the CDR as the instrument of evaluation and progression.

In an epidemiological study from France, Ritchie and colleagues evaluated a cohort of 833 subjects they had followed longitudinally (Ritchie *et al.*, 2001). These investigators retrospectively applied neuropsychologically based criteria to create a group of MCI subjects and compared their outcome to a group meeting criteria for AACD. They found that the MCI

criteria when applied retrospectively through the use of neuropsychological instruments were unstable, and that AACD subjects actually demonstrated a higher conversion rate. The instability in this study, however, may have arisen from the literal, neuropsychologically based interpretation of the MCI criteria, rather than the clinical application of the criteria used in other studies.

In the PAQUID study from several south-western regions of France, Larrieu and colleagues followed a population-based sample of 1265 subjects who were at risk of developing cognitive impairment by virtue of age (Larrieu *et al.*, 2002). They found that overall MCI was a good predictor of AD but that the concept was unstable over time. They also found that over 2–3 years, 40 per cent of the sample had reverted to normal, which is quite unusual relative to other studies. It is possible that some of the instability may have been related to their use of the Benton visual retention test as their only memory measure.

Investigators from Rush Alzheimer's Disease Center studied individuals from the Religious Order Study, a research project constituting a volunteer cohort of nuns and priests who are being followed longitudinally (Bennett *et al.*, 2002). They identified a group of 211 nuns and priests with multiple domain MCI including memory, and followed them for a mean of 4.5 years. Their findings showed that persons with MCI developed AD at a rate 3.1 times higher than those who did not meet criteria for MCI.

In the first population-based study to yield prevalence data on MCI subtypes, investigators from the Cardiovascular Health Study assessed prevalence rates from the sample they had applied the criteria for a-MCI and multiple domain MCI (Lopez *et al.*, 2003). They found that the overall MCI prevalence in the Pittsburgh site was 22 per cent, with a-MCI accounting for 6 per cent and multiple domain MCI representing 16 per cent.

The Canadian Study of Health and Ageing used subjects with cognitive impairment, no dementia (CIND) to investigate the relative contributions of each of the features of the criteria for a-MCI. They felt that subjective complaint and impairment in ADL might not be necessary for the definition of MCI. Nonetheless, most people with MCI, regardless of the definition, were found to progress to dementia, usually AD (Fisk and Rockwood, 2003).

Using the Kungsholmen Project, investigators from Stockholm evaluated the outcome of subjects with CIND defined by Mini-Mental State Exam scores (Palmer *et al.*, 2002). They found that the risk of developing dementia in these subjects was associated with the level of severity of CIND, and that those who improved from CIND did not show increased risk of subsequently progressing to dementia.

Dawe and colleagues reviewed the concept of MCI a decade ago and concluded that there was a wide discrepancy in the rates of progression, which ranged from 1–25 per cent (Dawe and Philpot, 1992). These investigators put forth several factors that could account for the variability, including the source of subjects, specific criteria used and methods for implementing

them, and length of follow up. Interestingly, all these factors continue to be relevant today.

More recently, Luis and colleagues at Mount Sinai Medical Center in Miami reported a review of MCI with recommendations for future research (Luis *et al.*, 2003). These included additional research to develop appropriate and sensitive neuropsychological and functional measures, reliable methods to assess progression, and epidemiologically oriented instruments that are sensitive to multiple cultures.

In summary, as is apparent from the literature, considerable variability exists in the characterization of subjects with MCI. This variability is more likely due to lack of consistent criteria and to variable neuropsychological instruments employed to measure progression. As such, these findings emphasize the need for more consistent criteria and instruments that can allow comparability of studies across various subject populations and settings. Nevertheless, it is also apparent from these studies that the concept of MCI, regardless of the definition, is a valid construct and as such, merits further study (Petersen *et al.*, 2001a).

24.2 NEUROIMAGING

Recently, neuroimaging has become an important tool in the diagnosis of MCI and subsequent prediction of its progression. Several neuroimaging studies have indicated that magnetic resonance (MR)-based measurements of hippocampus can differentiate MCI from normal ageing and AD, and predict the rate progression to AD. Jack and colleagues have shown that hippocampal volumes of subjects with MCI falls midway between normal controls and patients with mild AD (Jack *et al.*, 1997). More recently, Jack and colleagues also demonstrated the usefulness of MRI volume measurements in assessing progression to AD by showing that hippocampal volumes in MCI subjects were predictive of conversion to AD, even after controlling for age, oestrogen use, neuropsychological test performance, ApoE status, history of ischaemic heart disease and hypertension (Jack *et al.*, 1999). Kaye and colleagues have demonstrated the predictive ability of hippocampal volume measurements by showing that subjects who progressed to develop dementia had smaller hippocampal volumes at the time of presentation compared with those individuals who did not progress to dementia (Kaye *et al.*, 1997).

Further, based on the theoretical rationale that AD pathology first appears in the transentorhinal cortex, several studies have recently focused their attention on the entorhinal cortex. While some of these studies found the entorhinal cortex to be a better discriminatory measure of early cognitive impairment than hippocampus (Bobinski *et al.*, 1999; Killiany *et al.*, 2000; Du *et al.*, 2004), others have found both structures to be equally useful in differentiating MCI from normal ageing and very mild AD (Xu *et al.*, 2000). Although it is quite likely that the disease initiates in the entorhinal cortex, measurement

of hippocampus may be preferable because MRI depiction of the borders of the entorhinal cortex can be obscured by technical difficulties in imaging this area.

More recently, magnetic resonance spectroscopy (MRS) studies performed to assess MCI have proven useful. Kantarci and colleagues used myoinositol/creatine ratios and *N*-acetylaspartate/creatine ratios to compare MCI subjects to normal controls and to patients with very mild AD (Kantarci *et al.*, 2000). These investigators found increased myoinositol/creatine ratio in MCI subjects relative to normal controls, and in AD patients relative to those with MCI. In contrast, the *N*-acetylaspartate/creatine ratio did not decline until the subjects had reached the stage of AD. Even though this area requires further investigation, the data suggest that myoinositol/creatine ratio, which likely reflects glial activity, may be more useful earlier in the disease than *N*-acetylaspartate/creatine ratio, which may reflect neuronal integrity.

Thus, the existing literature indicates that the field of neuroimaging is well situated to provide a powerful tool for evaluation of MCI. Larger studies with prospective follow up would be needed to establish the reliability of these techniques in routine use.

24.3 NEUROPATHOLOGY

Despite the increased focus on MCI, the neuropathological basis of this condition is unknown. This is mainly because subjects with MCI are unlikely to die of the disease; as such, neuropathological confirmation of the condition is relatively uncommon. Nonetheless, the few data that are available have shed important light on the neuropathological substrates of MCI. A recent report from the Nun Study examined the neuropathological characteristics of individuals whose cognitive function ranged from normal to mild cognitive impairments to dementia (Riley *et al.*, 2002). The findings indicated that the development of Alzheimer's neurofibrillary pathology was one of the neuropathological substrates of mild cognitive impairments.

DeKosky and colleagues (2002) evaluated choline acetyltransferase activity in the hippocampus and frontal cortex using subjects enrolled in the Religious Order Study. Using a classification of MCI that allowed for multiple cognitive domains to be impaired, they found that 44 per cent of their sample of MCI had low likelihood of AD pathology while another 44 per cent showed intermediate likelihood of AD pathology according to NIA-Reagan criteria. Further, a study from Washington University focusing on subjects with very mild AD (CDR 0.5) has shown that 84 per cent of these subjects had neuropathological features of AD upon autopsy. Finally, a study from the Mayo Clinic identified 15 subjects who died while their clinical classification was a-MCI and found that all of the subjects had some form of medial temporal lobe pathology accounting for their memory impairment (Petersen, 2002).

Thus, the findings from these neuropathological studies suggest that MCI patients do not have fully expressed features

Table 24.1 *Clinical trials in MCI*

Sponsor	Duration	End point	Treatments
ADCS*	3 years	AD	Vitamin E Donepezil
Merck	2–3 years	AD	Rofecoxib
Novartis	3 years	AD	Rivastigmine
Janssen	2 years	Symptoms	Galantamine
Pfizer	6 months	Symptoms	Donepezil
UCB	1 year	Symptoms	Piracetam

* Alzheimer's Disease Cooperative Study supported by National Institute on Aging, Pfizer Inc., Eisai Inc. and Roche Vitamins.

of AD. As such, they are an important group to identify for possible intervention.

24.4 CLINICAL TRIALS

As the focus of AD research moves toward prevention, numerous clinical trials on MCI are being undertaken. A recent report from the Memory Impairment Study, which conducts multi-centre trials on MCI, indicates that the operational criteria for MCI are successful in distinguishing MCI from normal ageing and AD (Grundman *et al.*, 2004). Thus, AD prevention trials involving MCI patients appear to be promising in detecting, intervening in and delaying the disease while it is still in a transitional clinical stage. As outlined in Table 24.1 the therapeutic agents currently being tested are cholinesterase inhibitors, antioxidants, anti-inflammatories, nootropics and glutamate receptor modulators. In their recent review, Geda and Petersen (2001) indicate that several clinical trials are undertaken by ADCS (Alzheimer's Disease Cooperative Study) and a number of pharmaceutical research groups. These clinical trials are similar in their design, hence the authors discussed the ADCS study as a prototype of these trials. About 70 institutions in North America participating in this study funded by National Institute on Aging, Pfizer Inc., Eisai Inc. and Roche Vitamins. It is a randomized, double-blind, placebo-controlled trial involving three arms with 240 subjects per arm. The objective is to assess the safety and efficacy of vitamin E (2000 IU/day) and donepezil (10 mg/day), and is powered to bring about a 33 per cent reduction of the conversion of MCI to AD over the 3-year period of the study. Over the course of the study donepezil reduced the risk of progressing to AD for the first 18 months of the trial. Vitamin E had no therapeutic effect. The secondary cognitive measures supported the overall group progression rates. No unexpected adverse events were observed. This was the first therapeutic trial to demonstrate an ability to delay the clinical diagnosis of AD.

24.5 CONCLUSION

MCI is becoming an increasingly popular clinical entity. The American Academy of Neurology has recently reviewed the

literature on this topic and made recommendation that, while the precise outcome of these subjects is uncertain, MCI is a useful clinical concept worthy of attention and further investigation (Grundman *et al.*, 2004). As clinicians draw their attention to the earliest presentation of a cognitive impairment, this could translate into earlier and possibly more effective treatment options.

Treatment

ROGER BULLOCK

25.1 Epidemiological issues	347	25.4 Conclusion	352
25.2 Pathophysiological mechanisms of cognitive impairment	348	References	352
25.3 Treatment strategies	348		

Life expectancy is increasing, with a consequent increase in the cognitive disorders of old age. Treating these as early as identifiable would seem an appropriate course of action. Mild cognitive impairment (MCI) represents a stage where people have the early neuropathology of dementia, particularly Alzheimer's disease (AD), but do not have sufficient symptoms to fulfil current clinical criteria. Transition to dementia is frequent, raising questions as to whether this is a new nosology or the earliest diagnosable point of the more common neurodegenerative disorders.

25.1 EPIDEMIOLOGICAL ISSUES

While the definitive description of MCI is still awaited, there is general agreement that, when it is identified in an outpatient population, it usually represents a preclinical dementia; and that appropriate intervention at this time would be relevant and valuable. MCI represents a trigger for holistic evaluation of a person's physical and mental state, but any treatment considerations need properly defined therapeutic goals. This is important as MCI is positioned in the hinterland between preserving a state of wellness and treating a disease. The Petersen criteria (Petersen *et al.*, 1999) try to define the MCI population with strict definitions, but in a community sample a significant proportion of MCI subjects stay stable over time, or even revert to normal cognitive scores (Ritchie *et al.*, 2001). The Canadian study of Health and Ageing demonstrated a 1 per cent prevalence in over-65-year-olds if strict criteria were applied, rising to 3 per cent if subjective memory loss and intact activities of daily living (ADL) were not used so rigidly. Again, a third of those identified had no cognitive

impairment after follow up at 5 years (Graham *et al.*, 1997). This non-linearity of progression is probably due to the adaptive capacity of the brain, with its continuing plasticity and many compensatory mechanisms. These issues are particularly pertinent when treatment studies are being designed.

The Petersen criteria are strict, but only produce a positive predictive value of 31 per cent, making understanding the clinical context and longitudinal reassessment essential for the individual patient. Any intervention that slows progression of dementia at this stage should lead to delay in the development of AD. In turn, this may reduce the population prevalence of severe AD, even if the benefit for the individual is less predictable. If such outcomes are not achieved, the value of such an intervention becomes less clear. Three possible treatment scenarios exist:

- *More time in MCI and mild AD, less time in moderate to severe disease* – consequently no expansion of the overall disease longevity but a longer phase of relative independence. This may increase the cost of treatment earlier in the disease, but reduce full-time care costs.
- *More time in MCI and mild AD, same time in moderate to severe*. This still leads to a longer phase of relative independence, but does not reduce the full-time care costs.
- *More time at all stages*. Preservation of independence but longer period of dependency. This increases costs at all stages and the time in residential care could actually increase.

Unless the first scenario is achieved, costs for the health and social care community could rise along with additional pharmacological costs – unless death from other causes

intervenes. So, in order to adopt a universal preventative approach to MCI, an intervention needs to reduce the risk of reaching the later stages of dementia, be inexpensive, with a low risk profile, and have few side effects. Ideally, if used early enough, it should also have the potential to prevent further cognitive impairment. Examples of population initiatives include addition of folate to flour in the USA and thiamine enrichment of food in Australia, where Wernicke's encephalopathy is common.

However, the individual with MCI experiences symptoms sufficient to seek advice; and using Peterson criteria (Petersen *et al.*, 1999), may already have significant loss of cognitive ability. The goal in treatment is improvement or maintenance of this already reduced function, which for the amnesic MCI patient, is a situation akin to treating mild AD. Some individuals may improve in some aspects of cognition and function when treated at this stage; and stabilization here looks preferable to stabilization in moderate AD. However, more data are needed to understand and capture longer-term effects of current symptomatic treatments, before they can be used to treat MCI in general clinical settings. Research into what this emerging patient group actually understands and wants has to accompany this, as it is not proven that stability at this stage is any more desirable (Frank *et al.*, 2003), especially as neuropsychiatric inventory (Cummings *et al.*, 1994) scores in MCI are higher than expected – with anxiety and depression being prominent (Lysetkos *et al.*, 2002).

So current knowledge suggests a more selective prevention model is better with MCI. Here more expensive or higher risk treatments can be matched to the most appropriate individuals rather than applied across the board. With such a universal MCI definition, this application may be more difficult in practice until firmer therapeutic milestones are defined. These will remain clinical until the acceptance of robust biomarkers. Some potentially exist. For example, alteration in the ratio of different forms of the amyloid precursor protein has been described in MCI and to a greater extent in AD (Borroni *et al.*, 2003a). Cerebrospinal fluid (CSF) tau, phosphor-tau and β -amyloid are 68 per cent sensitive and 97 per cent specific at predicting MCI conversion to AD (Zetterberg *et al.*, 2003). Electrophysiological tests of olfaction appear consistent from MCI into AD (Peters *et al.*, 2003) and computerized batteries show characteristic profiles in MCI that become worse as AD criteria are reached (Dwolatsky *et al.*, 2003). Finally, volumetric magnetic resonance imaging (MRI) of regional brain areas in MCI, such as the hippocampus (Killiany *et al.*, 2000), are predictive of AD; and positron emission studies can show reduced activity in normal subjects at risk of familial AD years before clinical symptoms (Wahlund *et al.*, 1999). All these findings clearly open opportunities for early diagnosis and intervention, though it could be argued that what is being defined is the early stage of the underlying dementia, rather than a marker for MCI. These techniques are some way from the average clinic.

Cholinesterase inhibitors (ChEIs) are relatively expensive treatments with well-established side effects (Bullock, 2002). These will be prime candidates for the selective prevention model should clinical trials in MCI prove positive. Better clinical criteria may then quickly emerge, but even then, a preventative strategy may be inappropriate where either a third of those identified do not develop full dementia, or the best outcome may be to maintain an impairment, or it does not reduce any years lived free of cognitive impairment, and treatment may both increase longevity and increase costs. Difficult cost benefit decisions will have to be made – for example, by the National Institute of Clinical Excellence in the UK. Current examples of selective prevention in MCI are rare. Two examples are the specific treatment of hypertension in those with cognitive impairments and the practice in some US clinics to use non-steroidal anti-inflammatory drugs (NSAIDs) in people with first degree family histories.

25.2 PATHOPHYSIOLOGICAL MECHANISMS OF COGNITIVE IMPAIRMENT

Many factors seem to contribute to a complex cascade of events at molecular level to cause the degenerative processes that lead to MCI and dementia (Hardy and Higgins, 1992). Ageing is the predominant risk factor for which no intervention is possible, but the ageing process produces free radical damage, oxidative stress and alterations in calcium homeostasis which coincide with reduced efficacy of amyloid clearance and increasing cerebrovascular disease (Heininger, 1999). In turn, this causes synaptic damage, transmitter and receptor loss, microglial activation and inflammation, leading to neuronal death and subsequent clinical symptoms. Many of these processes are partly understood and some have putative therapeutic options, currently in development. While the licensed drugs for AD are predominantly symptomatic, new treatments may confer some protective effects. Such strategies will have the greatest impact during MCI (or perhaps even earlier).

25.3 TREATMENT STRATEGIES

25.3.1 Treating risk factors and comorbidity

The prevalence of vascular risk factors in mid-life, such as raised diastolic blood pressure, white matter hyperintensities on MRI and apolipoprotein (ApoE) ϵ 4 genotype, relates to late-life MCI (Kivipelto *et al.*, 2001a). High systolic blood pressure and raised cholesterol levels are related to developing late-onset AD and vascular dementia (VaD) (Kivipelto *et al.*, 2001b). This contribution of vascular lesions to cognitive impairment is just becoming understood, but may explain some of the heterogeneity in MCI. Identification of these factors, at any stage, may thus impact on the clinical

expression of dementia. A population strategy across primary and secondary care for hypertension detection and treatment, along with cholesterol monitoring and lowering, may not just protect from heart disease and stroke, but MCI and dementia as well.

This has already been demonstrated in normal elderly hypertensive subjects in the Syst-Eur (Forette *et al.*, 2002) and PROGRESS (Scheen, 2001) studies. Similarly, treatment with the angiotensin-converting enzyme (ACE)-inhibitor, ramipril, has improved intellectual functioning in normal elderly hypertensives (Pogosova *et al.*, 2003). If MCI was already present, treating concomitant hypertension produced a 40 per cent reduction in relative risk for dementia in a Swedish cohort (Guo *et al.*, 1999).

Statins raised particular interest when two observational studies showed their use led to large reductions in the risk of developing AD (Jick *et al.*, 2000; Wolozin *et al.*, 2000). Another large observational study in postmenopausal women correlated cognitive impairment with higher levels of low density lipoprotein and total cholesterol (Yaffe *et al.*, 2002). The mechanism of action of statins is not known, but it is independent of cholesterol levels and may be due to reduction in amyloid production, increase in ApoE ϵ 4 and/or effects on the microvasculature (Hartmann, 2001). Also, high levels of high density lipoproteins (HDL) in late life correlate with numbers of neurofibrillary plaques and tangles (Launer *et al.*, 2001). Unfortunately, a recent study looking at statins in older people with heart disease, the PROSPER study (Shepherd *et al.*, 2002), which contained a cognitive battery, reported no effect on cognition over 3 years. However, the battery used was subject to a large learning effect and the design may not properly capture any cognitive protection. Cholesterol may play a part in the treatment equation as high levels appear to reduce the effect of ChEIs in AD (Borroni *et al.*, 2003b). Studies combining statins to ChEIs are ongoing. At present, statins cannot currently be recommended as a primary therapy, but taking them for other clinical indications probably confers additional benefit.

25.3.2 Antioxidants and oxidative stress

Oxidative stress has been proposed as a central process in various neurodegenerative disorders (Delanty and Dichter, 2000). The formation of reactive oxygen species can cause damage to lipids and induce amyloidogenesis and apoptosis, as well as increasing atheroma (Witzum, 1994). High levels of oxidative markers have been shown to be a risk factor for cognitive decline (Berr *et al.*, 2000) and reduced antioxidant activity has been demonstrated in MCI and AD (Rinaldi *et al.*, 2003). Conversely high ascorbic acid and β -carotene levels relate to improved memory performance (Perrig *et al.*, 1997). It may be that diet alone does not provide enough central activity, and that ingestion of specific free radical scavengers, such as *Ginkgo biloba* and vitamins C and E, is required (Rosler *et al.*, 1998).

Vitamin E has been studied in moderate AD (Sano *et al.*, 1997), where a delay in institutionalization was reported, but no advantages were seen in cognition or function. The 2000 IU dose used was much higher than usually given. *In vitro*, vitamin E protects nicotinic receptors from β -amyloid (Guan *et al.*, 2000), which may be relevant given that the loss of these receptors seems to correlate with the memory loss found in AD (Paterson and Nordberg, 2000). Vitamin E is already recommended in the AD practice guideline in the USA (Doody *et al.*, 2001), but perhaps less often used in Europe. It fulfils the requirement for use in a simple intervention at population level, so further studies to demonstrate its utility in MCI are needed. Currently, such a long-term study with both vitamin E and donepezil is underway in the USA (Thal, 2003).

Ginkgo biloba is one of the most used antidementia agents worldwide, from both over the counter and prescriptive routes. It has a free radical scavenging effect among other putative modes of action. Clinical trials vary, but cognition and social function have been shown to improve in MCI in one study (Le Bars *et al.*, 2002). The relative low cost and minimal side effects suggest it may have a population use, but better constructed studies will need to be performed before any recommendation can be made.

High homocysteine levels have been associated with AD (Selley, 2003), VaD (Storey *et al.*, 2003) and cognitive decline in healthy elderly individuals (McCaddon *et al.*, 2001). High levels are recognized as a marker of vitamin B₁₂ and folate deficiency, both of which have also been associated with incident AD (Wang *et al.*, 2001). Oxidative stress seems to impair the metabolism of homocysteine, and it may be that only certain B₁₂ supplements have any preventive effect in this circumstance, for example, glutathionylcobalamin (McCaddon *et al.*, 2002). Folate also reduces homocysteine levels and in the USA folate is already added to flour to reduce neural tube defects. This has led to a consequent reduction in population serum homocysteine levels. However, there is no evidence yet that folate administration, with or without vitamin B₁₂, has any effect on measures of cognition or mood (Malouf *et al.*, 2003). Large scale prospective studies using folate in MCI are underway in the USA.

25.3.3 Anti-inflammatory drugs

It is well established that inflammatory processes are involved in AD (Akityama *et al.*, 2000), and observational studies have shown a reduced risk of AD in long-term users of NSAIDs (Stewart *et al.*, 1997). Consequently, studies have been performed using various anti-inflammatory drugs in AD, but with mixed results (Rogers *et al.*, 1993; Scharf *et al.*, 1999). Studies of celecoxib and rofecoxib have not yet shown efficacy. This may be because one of the proposed actions of the NSAIDs is an amyloid lowering effect that may be cyclo-oxygenase independent and not present in all the NSAIDs (Weggen *et al.*, 2001). The Alzheimer's disease anti-inflammatory prevention

trial (ADAPT) is looking at patients with advanced risk of AD in over 70-year-olds (Zandi and Breitner, 2001). It is using celecoxib and naproxen and is the only long-term study currently running to address how well this class works in MCI. Data suggest that ibuprofen and indomethacin have the better profile for β -amyloid lowering (Lim, 2000), and an enantiomer of flurbiprofen, which may have secretase activity, is in clinical trial for AD (Eriksen *et al.*, 2003).

Clearly no data support the primary use of NSAIDs in MCI and they have potential problems with long-term side effects. Like statins, taking them for other reasons may have additional benefits. No specific data exist for aspirin in MCI, although its action in the secondary prevention of stroke may confer similar benefits in some cases. It is not free from side effects, even at 75 mg, so more definitive work is needed before routine recommendation.

25.3.4 Oestrogen

While observational data (Tang *et al.*, 1996; Henderson *et al.*, 2000) and experimental data (Xu *et al.*, 1998; McEwen and Alves, 1999) suggest a role for oestrogen in cognitive disorders, no clinical studies have demonstrated any significant effect in AD to date (Mulnard *et al.*, 2000; Wang *et al.*, 2000). The Women's Health Initiative hormone therapy study was discontinued in 2002 because of health risks. It measured the Mini-Mental State Examination (Folstein *et al.*, 1975) in 4381 participants over a period of 7 years, finding no cognitive advantage in the oestrogen plus progestin group – and even a suggestion that they may have fared worse than placebo (Rapp *et al.*, 2003). This problem with oestrogen studies may be due to methodological issues (route of administration, length of study, dose) and the need to identify which specific oestrogen modulator will have the most beneficial effect on cognitive disorder. Clearly better studies are required but, until they are available, no data support the use of oestrogen as a primary treatment in MCI – although as with statins and NSAIDs, being on hormone replacement for other reasons may provide some cognitive advantage.

25.3.5 Nootropics

Improving memory has led to the use of drugs with non-specific actions to alter energy metabolism, cholinergic mechanisms, steroid sensitivity and excitatory amino acids (Riedel and Jolles, 1996). Piracetam has shown improvement in attention and memory in non-demented cognitively impaired elderly patients (Fioravanti *et al.*, 1991), with a second study soon to be reported – this time using the current Petersen MCI criteria. A meta-analysis of 19 studies using piracetam for cognitive impairment also showed statistical improvement versus placebo using global measures (Waegemans *et al.*, 2002). These data are not sufficient to justify the routine use of piracetam yet, even though it is commonly used in various

parts of Europe. No systematic data really support the use of any other nootropic in MCI.

25.3.6 Cholinesterase inhibitors

The cholinergic hypothesis of AD has led to the development of ChEIs (Bartus *et al.*, 1982). These are now well established in the treatment of AD. Given that a large proportion of MCI is amnesic, which is generally regarded as a precursor to AD, it is not surprising that these drugs have emerged as the likely choice to use in MCI (Jelic and Winblad, 2003). This rationale is supported by finding similar neuropathological evidence in the basal forebrain in both AD and MCI (Whitehouse *et al.*, 1981), plus radiological evidence measuring hippocampal atrophy that suggests a continuum from MCI to AD (Killiany *et al.*, 2000). However, two recent studies cast some doubt as to whether the cholinergic model holds up in MCI. First, the cholinergic deficit may appear much later in the illness (Davis *et al.*, 1999). Second, regional upregulation of choline acetyltransferase in MCI patients suggests some form of compensatory mechanism (Dekosky *et al.*, 2002). This may explain why the course through MCI is non-linear, and may give optimism that other treatment approaches at this stage may have equal benefit.

Notwithstanding this, all three currently marketed ChEIs are undergoing long-term trials in MCI. A large National Institute of Ageing study comparing donepezil, vitamin E and placebo began first (Doody *et al.*, 2001). Outcome measures include cognitive, functional and global scores. Interim analysis has confirmed the predictive value of conversion to AD using hippocampal volume and ApoE ϵ 4. Rivastigmine is being investigated in the InDDEX study (Sramek *et al.*, 2001), where conversion to AD and a specially designed psychological battery are the primary end points. This is a 4-year study where a central committee assesses patient data when the investigators feel a patient has converted – in an attempt to standardize the end point. Baseline data analysis has shown significant scores on the NPI in this MCI patient group – particularly anxiety and depression (Feldman *et al.*, 2003). Galantamine is being evaluated versus placebo in amnesic MCI, again using traditional cognitive and functional outcomes, this time supported with volumetric MRI. A combination of delayed clinical conversion to AD and slower rates of atrophy on MRI would support a disease-modifying effect. Final results from these studies are expected in late 2005.

The trial findings will be interesting as the instruments being used are, in the main, those used in AD, and, perhaps with the exception of the clinical dementia rating (CDR) scale (Morris, 1993), their performance in MCI is not clearly understood. For example the Alzheimer Disease Assessment Scale – Cognitive Scale (ADAS-cog) (Rosen *et al.*, 1984) has a fairly flat early course, so a one-point separation from placebo may actually be clinically significant but not deemed so by licensing authorities. Additions to the ADAS-cog have

been made, but no instrument has, as yet, been specifically validated for use in any individual domain or global assessment of MCI.

25.3.7 Antidepressants

With the use of Petersen criteria (Petersen *et al.*, 1999), depression excludes the use of the terminology 'MCI', as depression itself causes mild impairments in cognition. Notwithstanding this, selective serotonergic reuptake inhibitors (SSRIs) are frequently used during MCI (Devanand *et al.*, 2003), as anxiety and depression are commonly identified symptoms; and both respond to this class in the general population. The aetiology of depression at this stage is not likely to be coincidental, as most cognitively impaired patients do not report a prior history of depressive disorder (Zubenko *et al.*, 2003). Therefore treatment of the underlying condition may be the best treatment (Rabins *et al.*, 1999) – perhaps with ChEIs (Minger *et al.*, 2000). However, the best pathological post-mortem correlation with depression in AD is loss of neurones in the locus caeruleus (noradrenergic) (Zweig *et al.*, 1988), with weaker evidence of raphe neuronal loss (serotonergic) (Forstl *et al.*, 1992). These findings may not be applicable at the MCI stage, but using an antidepressant with noradrenergic as well as serotonergic effects may make a more rational choice than an SSRI alone. Apathy is also a relatively common finding in MCI and represents a key differential diagnosis of depression (Landes *et al.*, 2001). Apathy is a common finding in neuropsychiatric disorder and seems to be a marker for frontal lobe dysfunction (Cummings, 1993). Both cholinergic (Cummings and Back, 1998) and dopaminergic (Gilley *et al.*, 1991) pathways are implicated in this dysfunction, so again treatment with ChEIs may be an option (Boyle and Malloy, 2004), or perhaps dopamine stabilizing agents. One particular SSRI, sertraline, has inherent dopamine reuptake inhibition, making it a theoretically attractive option – but a combination study of donepezil and sertraline in AD did not show any advantage with the addition of sertraline (Raskind and Peskind, 2001). To date, no systematic studies have been performed with any antidepressant in MCI for depression or apathy, so any treatment is empirical, with no one antidepressant or class having been demonstrated as superior to another. Avoidance of antidepressants with anticholinergic side effects, such as tricyclics, would be practical – given the proposed cholinergic basis of several dementia subtypes.

25.3.8 Antiglutamatergic agents

Over activity of the excitatory amino acid glutamate is recognized as a cause of neurotoxicity (Dean and Lipton, 2001). For some time, strategies to block its binding site on the *N*-methyl-D-aspartate (NMDA) receptor have been tried to reduce this excitotoxicity; which is known to increase tau phosphorylation, and consequent tangle formation

(Couratier *et al.*, 1996). One NMDA receptor, memantine, has been licensed for use in moderate to severe AD (Reisberg *et al.*, 2003). It has not yet undergone studies in MCI, but suggestions of neuroprotection (Steig *et al.*, 1999) make it an obvious target. Other compounds acting on the AMPA glutamatergic receptors, as well as the NMDA, are in development, some already being considered for MCI studies.

25.3.9 Reducing medications that have intrinsic anticholinergic activity

Aside from neuroleptics, many of the commonly prescribed drugs given to older people have anticholinergic activity (Mintzer and Burns, 2000). These include warfarin, digoxin, frusemide, cimetidine and prednisolone. This anticholinergic toxicity can be measured in serum (Mulsant *et al.*, 2003) and has been shown to be a predictor of delirium (Tune, 2000) and a possible confounder in response to cholinesterase inhibitors. This is not a routine investigation yet. Chronic exposure to such toxicity is associated with poor outcomes in AD (Lu and Tune, 2003). Reversible cognitive impairments can also be induced with high levels of these anticholinergic compounds in the serum (Mulsant *et al.*, 2003). This means that as part of the review of drug treatments that occurs for any person with cognitive impairment, replacing the more anticholinergic compounds where possible with less harmful choices (for example, bumetanide instead of frusemide) is an essential step.

25.3.10 Future treatments

Whether any of the current compounds currently being studied in MCI prove to have any effect, it is likely to be mostly symptomatic. What is really needed when symptoms are minimal is an intervention that is disease modifying, either by preventing, delaying or slowing the progression of disease (Scorer, 2001). Strategies to reduce or alter amyloid production, such as secretase inhibition (Moore *et al.*, 2000), chelating agents (Finefrock *et al.*, 2003), and anti-aggregants (Gervais *et al.*, 2001) are all in development for AD, but would be sensibly employed at the MCI stage if effective. The best known study of this type involved immunization with amyloid itself (Schenk *et al.*, 1999). The trials were halted early because of side effects, but in the one case that has undergone post mortem to date, a significant reduction in the expected numbers of amyloid plaques in the brain was found (Niccoll *et al.*, 2003). However, it is by no means clear that patients in the immunization studies benefited cognitively, and further worries about the supremacy of the amyloid hypothesis comes from findings in transgenic animals that behavioural symptoms develop before amyloid deposition occurs (Moechars *et al.*, 1999). This is a reminder that intervention in tau hyperphosphorylation is also a valid treatment option, especially as tangle distribution correlates more to the AD symptomatology (Ohm *et al.*, 2003). Blockade of glycogen synthase

3- β (GSK 3- β) and cyclin dependent kinase 5 are current targets for study (Lovestone *et al.*, 1999).

However, abnormal amyloid and tau production may be the result of loss of neuronal plasticity (Mesulam, 1999). Nerve growth factor (NGF) has been postulated to regulate this plasticity by controlling neurotransmission and neuritic outgrowth (Seiler and Schwab, 1984). No definitive way has been found to effectively introduce NGF, other than through highly invasive techniques (Eriksdotter-Johnagen *et al.*, 1998). If oral compounds could produce similar effect, then this would be an avenue to explore in MCI.

25.3.11 Non-pharmacological interventions

Attention to diet and alterations in life style, for example smoking cessation and stress reduction, may have some minor effects after the MCI stage has been reached. Exercise has also been repeatedly associated with cognitive preservation (Verghese *et al.*, 2003). Both being involved in a social network (Fratiglioni *et al.*, 2000) or participating in cognitively stimulatory activity have been associated with a reduced risk of AD (Wilson *et al.*, 2002) and a slowing in the rate of cognitive decline (Coyle, 2003). One controlled study looking at memory enhancement and relaxation training for older people with MCI has shown that memory trained individuals had significantly better memory appraisals and a trend towards better recall (Rapp *et al.*, 2002). Such techniques may prove to work well in MCI, either singly or in combination with other agents. Previously, when used in AD, there seemed a point when memory training appeared to have detrimental effects – reinforcing disability rather than helping adapt to it. Targeted cognitive training could now have some positive effect, and studies to test this assumption are underway.

25.4 CONCLUSION

Early treatment opportunities in dementia, before significant losses have occurred, have to remain a long-term desire for all who work with patients with dementia. Many current and potential options are emerging as putative treatments for use in this early stage of MCI; but the main question still remains as to whether MCI is a real entity, or whether, even now, a lot of the cases being called MCI for the purpose of clinical studies are already diagnosable AD or a related disorder. Being diagnosed with dementia has dramatic social consequences in some countries, including the USA. Having a prodementia nosology can resolve certain powerful political dilemmas, but then provide a difficult problem when interpreting data. Many of the MCI subjects have associated executive function abnormalities, if looked for, and when they are questioned have subtle functional changes. This satisfies the criteria for dementia and so this diagnosis may be possible against existing research criteria (American Psychiatric Association, 1994).

If this is accepted, this current crop of MCI studies aimed at treating a new indication are perhaps superfluous. What must therefore be guarded against is the continued support of an unnecessary nosology, driven by either social prejudice or the need to market an indication.

However, patients with MCI are already attending clinics, asking advice about possible treatments. Responses to such requests vary. Ethically the important thing is to do no harm, rather than feel obliged to do something that may be inappropriate. Explaining the stage of MCI to patients and allowing them to make informed choices is the best practice – bearing in mind that being told that you have a significant problem that may or may not lead to dementia is anxiety provoking in its own right. Patients need time to ask questions and must have longitudinal follow up in order to detect both progression and remission. This is a large service commitment, especially in services still trying to manage the increased numbers of mild to moderate AD.

MCI should be regarded as a potential warning of incipient brain dysfunction, and the opportunity to attempt simple preventative measures in those who come forward should not be missed. In the absence of early biomarkers, the emphasis should be preservation of cognitive wellness rather than treatment of a disease. Simple treatment options are available. Certainly lifestyle changes, including dietary advice and relaxation, can be advised; while mental and physical exercises are also non-invasive techniques that may provide benefit. Correction of any blood pressure or cholesterol abnormality is relevant at any time – whether cognitive impairment is there or not. Pharmacologically, vitamin E is currently perhaps the most appropriate drug intervention, and many US physicians are already advising its use. Further research is needed to provide clearer information regarding optimal pharmacological and non-pharmacological management of MCI.

26.1 GENERAL

26.1.1 History

Alois Alzheimer (1898) felt that senile dementia was the most frequent neuropsychiatric disorder. Alzheimer and several other authors knew that a small proportion of patients developed signs of a 'senium praecox' (Gowers 1902). He stated: 'In some people a premature ageing or degeneration occurs, preferably affecting the central nervous system.' When Alzheimer published his famous first case of 'Alzheimer's disease' (AD) he was intrigued by the early onset of a dementia syndrome and the abundant intraneuronal neurofibrillary tangles in the patient's neocortex, which had never been seen before in a patient with such early onset of illness. In this patient, the clinical course and the neuropathological changes, particularly the neuronal loss in the superficial layers of the neocortex were excessively severe. Kraepelin (1910) decided that this presenile form of degenerative dementia with plaques and neurofibrillary tangles should bear Alzheimer's name. Initially this term was reserved for severe forms of presenile dementia with abundant plaques and neurofibrillary tangles, until a number of researchers felt that the clinical and neuropathological differences between the presenile and the senile manifestations of primary degenerative dementia were insufficient to define separate diagnostic entities (Albert, 1963; Lauter and Meyer, 1968; Corsellis, 1969). This new unitarian concept had a number of important implications. The concept of Alzheimer's disease, originally having a narrow focus, now became extended and softened. Senile dementia could no longer be accepted as the inevitable consequence of normal ageing, but became a disease. The number of patients with AD increased enormously. The economic burden and

obligation became obvious. The main risk factor was identified: age.

26.1.2 The size of the problem

Decreased mortality has led to a larger number of elderly people in our society, and decreased fertility has contributed to the higher proportion of old people. As age is the single most important demographic risk factor for AD, considerations of demographic changes are relevant for the single most important mental health problem in our ageing society. The growing importance of AD in the basic and clinical sciences is reflected by the growing number of publications. The exponential increase in publications on AD is unparalleled by research on other forms of dementia.

26.2 CLINICAL DEFINITION OF ALZHEIMER'S DISEASE

26.2.1 Diagnostic criteria

Clinically AD is a pure dementia syndrome without clinical evidence of another underlying specific disease relevant to the observed cognitive impairment. In the last decades, the cognitive paradigm of dementia has prevailed. Common elements of different diagnostic criteria for a dementia syndrome are: (1) secondary, (2) severe and (3) cognitive deficits. The deficits must not be pre-existent. They have to be severe enough to cause a significant impairment of the usual activities of daily living (ADL). This secondary impairment must not be explained by physical handicaps, but has to be related

to the cognitive deficits. Most diagnostic guidelines consider amnesic deficits as a core feature of the dementia syndrome. A common and critical basic dilemma of all guidelines is the definition of clear thresholds for the distinction between near normal and already pathological cognitive problems. There is an obvious, decisive and unresolved difficulty regarding the measurement of intellectual and behavioural disturbances, which usually develop over long periods and on the basis of rather variable levels of premorbid functioning. Erkinjuntti *et al.* (1997) demonstrated that different diagnostic criteria yield highly inconsistent results in the definition of the dementia syndrome in elderly individuals. These differences cannot be explained exclusively by different sensitivities of the examined criteria. This general difficulty is particularly pertinent in AD where the major defining criterion is the dementia syndrome. The criteria suggested by McKhann *et al.* (1984), the ICD-10 (World Health Organization, 1993) and the DSM-IV criteria (American Psychiatric Association, 1994) are given in Boxes 26.1 and 26.2. The daily use of such criteria and diagnostic categories misleads us to believe that they stand for natural facts, for nosological entities. However, the authors of these operational guidelines clearly stated that they are tentative and in need of further revisions. Their major drawback is a focus on the dementia syndrome instead of the underlying neurobiological disease process. Their advantage is that they state exactly what I have to describe in this chapter.

26.2.2 Clinical symptoms

AD frequently follows a typical clinical course which reflects the underlying neuropathology. The length of the prodementia phase cannot be reliably established with current clinical research tools. Theoretical considerations based on neuropathological and molecular biological findings suggest that this subclinical stage of illness extends over several decades. The clinical stages outlined in the present chapter overlap, and patients gradually progress from the mildest to the most severe manifestations of illness.

26.2.3 The prodementia stages/mild cognitive impairment

Meticulous neuropsychological investigation may reveal mild cognitive impairment 5 years before the clinical diagnosis of a dementia syndrome can be established according to contemporary diagnostic standards. The pattern of the subdiagnostic difficulties includes mild impairment in acquiring new information. Other demanding cognitive tasks, including the ability to plan or to access the semantic memory store, can also be compromised causing similar cognitive problems. The differentiation between incipient AD and a reversible condition (e.g. dementia syndrome of depression)

Box 26.1 Diagnostic criteria for research (DCR-10) for dementia in Alzheimer's disease (ICD-10: WHO, 1993)

- A. The general criteria (G1-G4) must be met.
- B. There is no evidence from the history, physical examination or special investigations for any other possible cause of dementia (e.g. cerebrovascular disease, HIV disease, Parkinson's disease, Huntington's disease, normal pressure hydrocephalus), a systemic disorder (e.g. hypothyroidism, vitamin B₁₂ or folic acid deficiency, hypercalcaemia), or alcohol or drug abuse.

F00.0 Dementia in Alzheimer's disease with early onset (G30.0)

1. The criteria for dementia for dementia in Alzheimer's disease (F00) must be met, and the age at onset must be below 65 years.
2. In addition, at least one of the following requirements must be met:
 - (a) evidence of a relatively rapid onset and progression;
 - (b) in addition to memory impairment, there must be aphasia (amnesic or sensory), agraphia, alexia, acalculia or apraxia (indicating the presence of temporal, parietal and /or frontal lobe involvement).

F00.1 Dementia in Alzheimer's disease with late onset (G30.1)

1. The criteria for dementia in Alzheimer's disease (F00) must be met and the age at onset must be 65 years or more.
2. In addition, at least one of the following requirements must be met:
 - (a) evidence of a very slow, gradual onset and progression (the rate of the latter may be known only retrospectively after a course of 3 years or more);
 - (b) predominance of memory impairment.

G1 (1) over intellectual impairment

G1 (2) (see general criteria for dementia)

F00.2 Dementia in Alzheimer's disease, atypical or mixed type (G.30.8)*

F00.9 Dementia in Alzheimer's disease, unspecified (G30.9)

*Atypical dementia, Alzheimer's type. This term and code should be used for dementias that have important atypical features or that fulfil criteria for both early- and late-onset types of Alzheimer's disease. Mixed Alzheimer's and vascular dementia is also included here

or benign, non-progressive memory impairment is unreliable. At the prodementia stage of AD, patients do not show a significant deterioration in ADL. At this stage, individuals may take advantage of memory aids and of other supportive strategies to overcome or compensate for their cognitive deficits. The performance of complex work tasks may be

Box 26.2 *DSM-IV criteria for dementia of the Alzheimer's type (American Psychiatric Association, 1994)*

- A.** The development of multiple cognitive deficits manifested by both
- (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
 - (2) one (or more) of the following cognitive disturbances:
 - (a) aphasia (language disturbance)
 - (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
 - (c) agnosia (failure to recognize or identify objects despite intact sensory function)
 - (d) disturbance in executive functioning (i.e. planning, organizing, sequencing, abstracting)
- B.** The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C.** The course is characterized by gradual onset and continuing cognitive decline.
- D.** The cognitive deficits in criteria A1 and A2 are not due to any of the following:
- (1) other central nervous system conditions that cause progressive deficits in memory and cognition (e.g. cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural haematoma, normal pressure hydrocephalus, brain tumour);
 - (2) systemic conditions that are known to cause dementia (e.g. hypothyroidism, vitamin B₁₂ or folic acid deficiency, niacin deficiency, hypercalcaemia, neurosyphilis, HIV infection);
 - (3) substance-induced conditions.
- E.** The deficits do not occur exclusively during the course of a delirium.
- F.** The disturbance is not better accounted for by another Axis I disorder (e.g. major depressive disorder, schizophrenia).
- With early onset: at age 65 or below**
- 290.11 With delirium:** if delirium is superimposed on the dementia.
- 290.12 With delusions:** if delusions are the predominant feature.
- 290.13 With depressed mood:** if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.
- 290.10 Uncomplicated:** if none of the above predominates in the current clinical presentation.
- With late onset: after age of 65 years**
- 290.3 With delirium:** if delirium is superimposed on the dementia.
- 290.20 With delusions:** if delusions are the predominant feature.
- 290.21 With depressed mood:** if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.
- 290.0 Uncomplicated:** if none of the above predominates in the current clinical presentation.

reduced. Patients tend to avoid difficult challenges and downplay or dissimulate their problems. In addition, non-cognitive alterations of behaviour, including social withdrawal and depressive dysphoria, may be present 5 years before a clinical diagnosis is made. Patients with more severe alterations of cerebrospinal fluid tau- and βA_4 -concentration and those developing more extensive functional brain changes will convert to dementia (Riemenschneider *et al.*, 2002; Drzezga *et al.*, 2003).

26.2.4 Mild dementia stage

In most patients, a significant impairment of learning and memory is the outstanding clinical feature. In some individuals, however, aphasic or visuoconstructional deficits may prevail. Working memory, old declarative memories from the patient's earlier years and implicit memory are affected to a much lesser degree than the declarative recent memory.

Memory impairment usually interferes with various cognitive domains and usually plays a key role in the patient's difficulties with ADL. The patient's reduced ability to plan, judge and organize may not only show in complex tasks, but also in more difficult household chores (e.g. managing bank account, preparing meals). Communication may begin to suffer from shrinking vocabulary, decreasing word fluency and less precise expressive language, even though a patient may still appear eloquent, 'fluent' and even verbose on casual inspection. An impairment of object naming and semantic difficulties with word generation can be demonstrated by means of neuropsychological tests. Constructional apraxia can be revealed on drawing tasks. Spatial disorientation frequently causes major problems in driving, as patients are less capable of estimating distances and speed. Because they have an increased risk of accidents, patients with a diagnosis of AD should be carefully assessed for driving ability, regulations for which vary between countries. At the mild stage of AD, patients may still be able to live independently for most of the time, but owing to the

significant cognitive difficulties in several domains, they will need support with a variety of organizational matters. If a patient wishes to remain at home, arrangements for a support system should be made at this stage before a more intensive or permanent supervision is necessary.

Non-cognitive disturbances in AD are more frequent than previously thought. Symptoms of depression may prevail in the early stage of illness (Burns *et al.*, 1990). These emotional disturbances are typically mild and fluctuating, but also full-blown depressive episodes can occur. They may partly represent understandable emotional reactions to reduced cognitive and ADL skills or to reduced social contacts while the patient's insight is, at least, partly retained. Patients with severe depressive disturbances may show reduced cell counts in the locus caeruleus and other aminergic brain-stem nuclei (Zubenko *et al.*, 1989; Förstl *et al.*, 1992). A reduced dorsofrontal blood flow has been demonstrated in patients with severe apathy. Subtle impairment of complex motor tasks may remain unnoticed on standard neurological examination.

26.2.5 Moderate dementia stage

Due to the severe impairment of recent memory, patients may appear to 'live in the past'. Logical reasoning, planning and organizing significantly deteriorate at this stage. Language difficulties become more obvious as word finding difficulties, paraphasia and circumstantiality increase. Reading skills deteriorate and the comprehension of texts can be incomplete. Writing becomes increasingly insecure with an increasing number of mistakes and omissions. Patients become distractible and gradually lose insight into their condition. Longer (ideomotor) sequences of action can no longer be organized, until finally the skills of using household appliances, dressing and eating are lost. The patient's spatial disorientation increases. Cortical visual agnosia is often present and can include the inability to recognize familiar faces (prosopagnosia). One-third of patients with AD at this stage develop illusionary misidentifications and other delusional symptoms, which are triggered by their cognitive deficits but also by the underlying disease process (Reisberg *et al.*, 1996). Up to 20 per cent of the patients develop hallucinations, mostly of visual quality, which may be associated with a particularly severe cholinergic deficit (Lauter, 1968; Perry *et al.*, 1990). At this stage, anosognosia prevails, but residues of insight may contribute to 'catastrophic reactions' following minor distress. Patients often lose emotional control and develop temper tantrums, which may be accompanied by physical or verbal aggression. Aimless and restless activities like wandering or hoarding are common (Devanand *et al.*, 1997).

Patients in this moderate state of illness cannot survive in the community without close supervision. They are incapable of managing financial or legal matters. Household gas or electrical appliances are a constant source of danger to patients and also their carers. Hospital or nursing home admission may be delayed or even avoided, if a closely knit support system is in

place. During this phase, there is a maximum strain on partners and other carers because of the patient's non-cognitive behavioural problems and somatic symptoms. Restlessness, aggression, disorientation and incontinence are the most frequent factors that precipitate the breakdown of family support. Sphincter control is insufficient and can be aggravated by 'pseudo-incontinence' as a consequence of spatial disorientation and clumsy handling of clothes. Many patients are at an increased risk of falls provoked by a hesitant, festinating gait and a stooped posture (Förstl *et al.*, 1992).

26.2.6 Severe dementia stage

Specific modular cognitive deficits cannot be teased apart at that late stage of illness, when almost all cognitive functions are severely impaired. Even early biographical memories can be lost. Language is reduced to simple phrases or even single words. Patients are increasingly unable to articulate the most simplest of needs. However, many patients can receive and return emotional signals long after the loss of language skills. This emotional receptiveness has to be remembered while the patient is completely dependent on comprehensive nursing care.

Patients often misunderstand and misinterpret nursing interventions, and this may lead to aggressive reactions. Subgroups of patients may develop stereotyped motor programmes as yelling or wandering. Restlessness and aggression may also be an expression of pain or the consequence of a profoundly disturbed circadian rhythm. A large proportion of patients show extreme apathy and exhaustion. Patients need support while eating, and even the most basic motor functions (chewing and swallowing) may be impaired as an expression of extreme apraxia. Double incontinence is frequent. Other motor disturbances (e.g. rigidity and primitive reflexes) may interfere with provision of nursing support. Extrapyramidal motor symptoms are usually due to a comorbidity with Parkinson's disease. Snouting and grasping reactions are the most frequent primitive reflexes and are associated with frontal lobe atrophy. Myoclonus and epileptic seizures can be observed in a smaller proportion of patients with severe AD, but are more frequent as compared with the general elderly population. Many bedridden patients develop decubitus ulcerations, contractions and infections. Pneumonia followed by myocardial infarction and septicaemia are the most frequent causes of death in AD.

26.3 BASIC DEFINITION OF ALZHEIMER'S DISEASE

26.3.1 Neurophysiology and neuroimaging

Neither cranial computed tomography (CT) nor magnetic resonance tomography (MRT) or single photon emission

computed tomography (SPECT), nor positron emission tomography (PET), not even electroencephalography (EEG) and its quantitative analysis (qEEG) are appropriate tools for diagnosing AD. Each of these methods can, however, contribute to a clinical diagnosis:

- by excluding other specific causes of dementia that are incompatible with AD, and
- by documenting functional and morphological changes that are characteristic of AD.

26.3.1.1 EEG

Hans Berger's original observation of a slowed background activity in the EEG of demented patients was repeatedly confirmed with modern quantitative methods. This slowing exceeds the changes observed in elderly individuals without cognitive changes, but is significantly less severe than in patients with reversible confusional states or other types of brain changes underlying cognitive impairment. The decrease of α power and the increase of slow θ and δ activity are correlated with the severity of illness. The dimensional complexity and the synchronicity (coherence) of the EEG signals are significantly reduced in clinically manifest AD. A statistical discrimination of patients from elderly controls can be achieved in more than 80 per cent (Besthorn *et al.*, 1997).

26.3.1.2 SPECT AND PET

Numerous SPECT studies demonstrated a typical asymmetric temporoparietal hypoperfusion in a large proportion of patients with AD. A decrease of temporoparietal perfusion is an important sign of AD and this typical perfusion pattern represents a valuable aid for the differentiation of AD from forms of dementia with a strong vascular component and from frontal or frontotemporal brain degenerations. PET methods are possibly more sensitive for the early observation of characteristic functional changes. The correlations between reduced perfusion or reduced metabolism with cognitive deficits, stage or duration of illness are statistically significant (Bartenstein *et al.*, 1997). Similar to qEEG, SPECT and PET allow a statistical discrimination of patients with AD from elderly controls in more than 80 per cent.

26.3.1.3 CT/MRT

The intracranial cerebrospinal fluid spaces show an age-related increase. A significant AD-associated atrophy is superimposed on this age-related effect. The corresponding decrease of brain volume is significantly correlated with the decrease of cognitive performance. As the hippocampus is an early target for neurofibrillary tangles, neuronal and gross volume loss, it should be visualized accurately at the first occasion for a thorough clinical and neuroradiological examination. The demonstration of an increasing volume loss in the mediotemporal cortex is of diagnostic importance. Similar to qEEG, SPECT and PET, planimetric and volumetric estimates of brain atrophy permit

a statistical discrimination between patients with AD and elderly controls in more than 80 per cent – which is not necessarily of great clinical importance.

26.3.2 Neuropathology

Some authors have argued that plaques and neurofibrillary tangles could also be found in the brains of non-demented persons who appeared clinically intact until their death and that their pathophysiological significance was, therefore, doubtful (e.g. Rothschild, 1937). Blessed *et al.* (1968) established a statistical correlation between the severity of cortical plaque depositions and the ADL and also of cognitive performance. This approach reintroduced reason, or at least commonsense, into the scientific investigation of the mind-brain relationship of dementing patients. Brun and Gustafson (1976) pointed out the typical distribution of cerebral degeneration in AD, which is usually most pronounced in the mediotemporal limbic area, the posterior inferior temporal areas, adjoining parieto-occipital lobes and posterior cingulate gyrus. The frontal lobes are less severely involved. The primary sensory projection areas are frequently spared in typical AD. Braak and Braak (1991) elaborated a topographic distribution of neurofibrillary tangles, neuritic plaques and neuropil threads, including non-demented individuals in their studies. In stages I and II, the transentorhinal cortex is affected; the neurofibrillary tangles extend into the entorhinal cortex in stages III and IV, the hemispherical isocortex shows neurofibrillary and plaque depositions in stages V and VI, when patients usually develop clinical deficits. The clinical validity of Braak and Braak's staging has been confirmed in several studies (e.g. Delacourte *et al.*, 1998).

26.3.3 Diagnostic confirmation

According to the clinicopathological paradigm, a histopathological confirmation of clinically suspected AD is still considered the gold standard. The clinical diagnosis of AD can be confirmed by the neuropathological work-up in 80 per cent of the cases or more, similar to qEEG, SPECT, PET, CT and MRI studies. This high percentage is often mistaken as a proof of our clinical skills and may mislead to undue complacency. It must not be forgotten that the *a priori* probability of choosing the right diagnosis is higher than 60 per cent, simply because of the high prevalence of AD. The probability that a patient who satisfies clinical diagnostic criteria for AD will also satisfy neuropathological criteria for Alzheimer's disease is – according to Bayes' theory – directly proportional to the prevalence of AD (i.e. critical levels of plaques and neurofibrillary tangles according to standard neuropathological criteria) in the study population. In dealing with prevalent brain changes, highly sensitive – and highly unspecific – diagnostic criteria will inevitably lead to a frequent diagnostic confirmation. Numerous selection

Box 26.3 *Likelihood of dementia due to AD, shown by plaques and neurofibrillary tangles (according to Hyman and Trojanowski, 1997)*

- **Low:** Limited severity and distribution according to Braak stages I and II
- **Intermediate:** Moderate neocortical neuritic plaques and limbic neurofibrillary tangles according to Braak stages III and IV
- **High:** Frequent neocortical neuritic plaques and neurofibrillary tangles according to Braak stages V and VI

mechanisms lead to strongly biased patient samples in memory clinics and in scientific long-term studies that lead to these high, impressive validation rates. The patients have usually undergone repeated examinations; many reached a severe stage of illness before death; cases difficult to examine and with evidence of mixed pathology had been eliminated from these studies at an earlier stage. Such samples have little to do with the normal clinical situation and the diagnostic difficulties at early and mild stages of illness when diagnostic certainty is much lower. Recent studies, using operational, clinical and neuropathological criteria, have shown that the presence of Alzheimer-type changes in the brains of demented patients can be predicted with a rather high reliability (owing to their prevalence), but that the admixture of other pathologies is not infrequent (Bowler *et al.*, 1998; Holmes *et al.*, 1998). Modern neuropathological criteria (Hyman and Trojanowski 1997) do not offer a categorical 'yes-or-no' decision for the verification of AD, but yield an estimate for the likelihood that the observed plaque – and tangle counts and their distribution – explain the clinical deficits (Box 26.3).

It remains questionable whether it is appropriate for clinicians to speculate about the exclusive presence of Alzheimer-type plaques and tangles in their patients' brains, or whether it would be more adequate to aim at identifying as many treatable pathogenic cofactors as possible.

26.4 THE FUNCTIONAL NEUROANATOMY OF ALZHEIMER'S DISEASE

26.4.1 Corticocortical disconnection

Blessed *et al.* (1968) confirmed a relationship between the isocortical plaque density and the clinical deficits. This is illustrated by the severity and extension of primarily temporoparietal hypoperfusion and hypometabolism in SPECT and PET studies. Brun and Gustafson (1976) pronounced the plausible correlation between the pattern of neuropsychological deficits and the topographical pattern of the brain changes. Delacourte *et al.* (1998) observed that cognitive

deficits are inevitably associated with neurofibrillary changes in the polymodal isocortical association areas. Neurofibrillary and plaque depositions in the isocortical layers III and V are associated with a degeneration of glutamatergic pyramidal cells responsible for corticocortical and corticosubcortical projections (Pearson *et al.*, 1985; Arendt *et al.*, 1999). Up to 50 per cent of the neocortical neurones can be lost (Gomez-Isla *et al.*, 1997). This leads to a functional impairment of feed-forward loops from the lower to the higher association areas, and of feedback systems from higher to lower association areas. Its cognitive consequence is an increased noise from disturbed amplification and filtering of information. A decreased EEG coherence can be considered as a neurophysiological result of this disconnection. A callosal atrophy is evidence for corticocortical axons. The cortical localization of the process can be associated with the clinical symptoms: a disruption of cortical pathways mediating visuospatial cognition is associated with constructional apraxia; damage of high order visual association areas with apperceptive agnosia.

26.4.2 Hippocampal de-afferentiation and de-efferentiation

Hyman *et al.* (1984) demonstrated an isolation of the hippocampal formation due to a cell-specific pathology in layers II and IV of entorhinal cortex and the subiculum, normally responsible for the connection with basal forebrain, thalamus, hypothalamus and association cortices. This leads to a perforant pathway destruction with consecutive glutamate depletion in the dentate gyrus (Hyman *et al.*, 1987). It is now well known that the transentorhinal followed by the entorhinal regions are early targets of neurofibrillary tangle formation and neuronal degeneration in AD (Braak and Braak, 1991; Delacourte *et al.*, 1998). Intact hippocampal pyramidal cells ('index neurones') are part of extensive hippocampal-neocortical neuronal networks and represent essential prerequisites for the storage and retrieval of declarative memories in adult individuals. Deficits of recent episodic memory are frequent presenting symptoms in AD. According to Ribot's law, recent declarative memory functions are more severely impaired than older episodic and semantic memories, which are affected in the course of illness. The volume of the amygdala-hippocampus complex is positively correlated with the performance on memory tasks and inversely correlated with the severity of dementia (Fama *et al.*, 1997; Mori *et al.*, 1997; Pantel *et al.*, 1997). There is a close association between the severity of mediotemporal lobe atrophy and hypoperfusion or hypometabolism of the temporoparietal neocortex (Lavenex *et al.*, 1997; Yamaguchi *et al.*, 1997). The severity of mediotemporal degeneration increases while the disease process extends over the isocortex. The individual contribution of the archicortical and isocortical changes to the clinical deficits are, therefore, difficult to disentangle. The situation is further complicated by severe alterations in the upper brain stem.

26.4.3 Cholinergic denervation

As explained in other chapters of this volume, the basal nucleus of Meynert and other cholinergic nuclei in the basal forebrain are the only sources of acetylcholine for the isocortex and the hippocampus. Acetylcholine in the neocortex reduces the potassium resting potential, thereby increasing neuronal excitability, and also stimulates the activity of GABAergic interneurons allowing a focused cortical excitation. In addition, acetylcholine reduces the activity of thalamic pacemaker neurons. This is how acetylcholine increases attention and allows the organized processing of information in the neocortex and limbic system (Arendt, 2002). In summary, acetylcholine reduces the resistance in hippocamponeocortical oscillating circuits responsible for the formation and retrieval of memories. Acetylcholinesterase inhibitors temporarily reduce the resistance in these circuits.

26.4.4 Heterogeneity

There are presenile and senile, sporadic and familial forms of AD. The patients are examined at different stages of illness; and the topographic patterns – reflected by the clinical symptoms – may show some heterogeneity and deviate from the standard course of illness described above. Most of these heterogeneous patterns are not sufficiently distinctive and stable over time to warrant the definition of meaningful subtypes of AD. Few patients have been described in whom an atypical pattern of deficit, related to plaque and tangle pathology, persisted over a longer period of time, e.g. in progressive biparietal atrophy. As mentioned above, Alzheimer pathology does not protect against other forms of neuropathological change. In old age, the admixture of other pathologies, e.g. of vascular changes, Lewy bodies, etc., is not infrequent. Some neuropathological changes would be extremely difficult to detect under the cover of plaques and tangles, e.g. brain degenerations with focal cortical onset, lacking distinctive histopathology.

26.5 DIFFERENTIAL DIAGNOSES

26.5.1 What is (probably) not Alzheimer's disease

'AD' should not be considered as a synonym for normal ageing. Also, AD is not a synonym for dementia; this is often forgotten, even in diagnostic guidelines. AD is not just the clinical Alzheimer dementia syndrome, but the underlying neurodegenerative process together with its typical clinical manifestation. AD is not (only) a presenile, but also a senile form of degenerative dementia. AD is more severe than age-associated memory impairment, benign senescent forgetfulness and the like. AD is more than an amnesic syndrome, even if deficits of episodic memory may frequently represent the core symptom of AD. AD is not a confusional state, but a

confusional state may represent a first transient manifestation of a subclinical cholinergic deficit and the threshold for confusional states is reduced in patients who are cholinergically challenged due to Lewy body and/or plaque and tangle pathology in the basal forebrain nuclei.

AD is different from other forms of dementia with specific features that satisfy standard clinical and neuropathological criteria, e.g. so-called vascular dementia, dementia with Lewy bodies, Pick-complex diseases and other brain degenerations with focal cortical onset and characteristic histopathological hallmarks, Creutzfeldt–Jakob disease, AIDS-related complex, Huntington's disease, alcohol-related cognitive impairment, cognitive impairment and schizophrenia, the dementia syndrome of depression or other uncommon forms dementia.

26.5.2 What may be (come) Alzheimer's disease

As mentioned earlier, patients satisfying clinical criteria for the diseases listed above may still have critical numbers of plaques and neurofibrillary tangles, and a cholinergic deficit, and may, therefore, benefit from cholinergic and other anti-dementia treatment with efficacy demonstrated for typical AD. To date, there is no method for ruling out significant numbers of plaques and neurofibrillary tangles in the patients' brains with sufficient certainty during their lifetime, but there may be features that make the presence of significant Alzheimer pathology, or comorbidity, more likely, e.g.

- a slow onset of cognitive impairment before a stroke;
- a continuous progression of dementia after treatment for normal pressure hydrocephalus;
- hippocampal atrophy;
- temporoparietal and more extensive hypoperfusion and hypometabolism (Drzezga *et al.*, 2003);
- a family history of Alzheimer dementia;
- a molecular-genetic risk or diagnostic factor; or
- increased tau and decreased βA_4 in the cerebrospinal fluid (Riemenschneider *et al.*, 2002).

Double pathology decreases the threshold for the manifestation of deficits. Less severe vascular changes would be required for the manifestation of dementia, if a moderate amount of plaques and neurofibrillary tangles is already present. This appears to be confirmed by observations from pivotal landmark studies (MRC-CFAS 2001; Snowdon *et al.*, 1997). Therefore a clinical deficit unexplained by the severity and extension of a single type of specific brain changes suggests the presence of cerebral multimorbidity.

Clinically, any mild cognitive impairment, amnesic syndrome, confusional state, depression, etc. may represent an early preclinical stage of AD. Pathophysiologically, a low α power, a discrete temporoparietal hypoperfusion or hypometabolism, early molecular cerebrospinal fluid alterations may herald incipient AD. Morphologically, anyone with mild brain atrophy, any person with subthreshold

counts of plaques and neurofibrillary tangles would be a candidate for AD. Genetically, asymptomatic carriers of dominant mutations or risk factors are disposed to developing AD.

26.5.3 Alzheimer-Plus

There is nearly no senile dementia without relevant Alzheimer pathology (MRC-CFAS 2001). Cognition (C) should therefore be considered as the difference between initial intellectual capability (I) and the cumulative effects of the severity (S) and extension (e) of different types of brain changes, neurofibrillary tangles (NFT), plaques (PL), Lewy bodies (LB), frontotemporal (Pi), micro- (MIC), macroangiopathic (MAC), etc.:

$$C = I - (S_{NFT} \cdot e_{NFT} + S_{PL} \cdot e_{PL} + S_{LB} \cdot e_{LB} + S_{Pi} \cdot e_{Pi} + S_{mic} \cdot e_{mic} + S_{MAC} \cdot e_{MAC} + \dots)$$

The correlations between individual morphological features and specific symptoms are not as clear cut as in other neuropsychiatric syndromes observed in younger patients. The relationship between neuropathological changes and clinical deficits appears more fuzzy due to the variabilities of severity, extensions and admixtures (NFT – learning, declarative recent memory, hippocampal atrophy, increased tau concentrations; plaques – ‘higher’ neocortical neuropsychological deficits, neocortical atrophy, decreased βA_4 concentration; Lewy bodies – motivational, affective and extrapyramidal motor symptoms, pigmented nuclei pathology; Pick-complex – behavioural and language deficits, frontotemporal atrophy, tau mutations; microangiopathy – slowing, gait apraxia, leukoaraiosis; macroangiopathy – see localization and extension of lesion).

26.5.4 Future diagnostic approaches

We are, presently, concentrating our diagnostic and therapeutic efforts on the epiphenomena of AD. It is now known,

that the disease process develops over many decades before it becomes clinically evident. It is hardly a rewarding exercise for patient and physician to establish the diagnosis of AD, once significant and irreversible brain changes have accrued. However, this will be the case as long as a diagnosis relies on the manifestation of a clinical dementia syndrome and does not aim at pathophysiological factors that could represent the targets of an early intervention. Cumulative incidence and morbidity suggest that everyone runs a remarkable risk of developing the symptoms of AD in old age. Therefore, risk or chance models should help to plan the timing and intensity of early interventions. Such models will include genetic, sociodemographic, somatic and environmental protective and risk factors together with the ‘early’ psychological and biological epiphenomena of illness (Figure 26.1). Most of these factors are discussed elsewhere in this volume. Genetic factors are currently frequently discussed. Several socio-demographic factors are of self-explanatory importance (age, life expectancy, cognitive reserve). The influence of somatic and environmental cofactors is usually disregarded because they are not considered part of the Alzheimer pathophysiology. Some of them are now getting increasing attention (oestrogen, cholesterol, cortisone; non-steroidal anti-inflammatory agents, homocysteine, vascular comorbidity). Subclinical changes that can occur in the course of the biological disease process and be discovered with special laboratory methods before the patient develops clinical symptoms can be considered as ‘early epiphenomena.’ These can be discrete cognitive, predominantly amnesic deficits, associated functional brain changes (Desgranges *et al.*, 1998), discrete morphological alterations in the mediotemporal lobe (Reiman *et al.*, 1998) and early alterations of cerebrospinal fluid. The gaps in Figure 26.1 need to be filled in the years to come in order to develop individualized risk profiles for early interventions preceding the medical manifestation of epiphenomena.

Risk factors for Alzheimer's disease

ANTHONY F JORM

27.1 Sociodemographic factors	369	27.6 Diet	372
27.2 Familial and genetic factors	370	27.7 Occupational and recreational factors	373
27.3 Premorbid cognitive and brain reserves	370	27.8 Preventive possibilities	373
27.4 Medical history and treatments	371	References	374
27.5 Health habits	372		

The study of risk factors for Alzheimer's disease (AD) was almost non-existent two decades ago, whereas today it is a flourishing area of research. This area is of considerable public health importance because of its potential implications for the prevention of AD by modification of risk factors.

This chapter will cover 'protection factors' as well as 'risk factors'. Although it is conventional to think of exposures in terms of increasing risk, it is sometimes more useful to invert the perspective and think of decreasing risk. We can equally validly think of a high level of factor X as increasing risk, or a low level of factor X as decreasing risk. It is simply a matter of choosing the most useful perspective. The chapter ends with a discussion of the potential for prevention through risk factor modification.

27.1 SOCIODEMOGRAPHIC FACTORS

27.1.1 Age

Old age is the most important risk factor for AD. Although the incidence rises steeply with age, there is dispute about what happens in very old age. One meta-analysis reported that incidence rises exponentially with age up to age 90 (Jorm and Jolley, 1998). These results are shown in Figure 27.1. However, another meta-analysis, involving a smaller number of studies, concluded that there is some levelling off in the rise of incidence in very old age (Gao *et al.*, 1998). If incidence continues to rise exponentially in very old age then everybody would develop AD if they lived long enough, whereas if incidence levels off some individuals may never develop the disease over a feasible life span.

Figure 27.1 Incidence of Alzheimer's disease across age groups: meta-analysis of data from three regions.

27.1.2 Sex

Although many studies have reported that women have a higher prevalence of AD than men, this difference could be due to either a higher incidence or longer survival after developing the disease. Incidence studies have not presented a consistent picture. One meta-analysis found that women tend to have a higher incidence in very old age, but not in the younger

old (Jorm and Jolley, 1998), whereas another concluded that women have a higher incidence overall (Gao *et al.*, 1998).

27.1.3 National and ethnic differences

If national or ethnic differences could be found, they would indicate important environmental or genetic differences. There might be major environmental differences between groups (e.g. in diet), which might not be discovered by research focusing on within-group differences. A comparison of incidence studies from different countries supports the possibility that incidence may be higher in some countries than others. One such comparison is shown in Figure 27.1. However, such effects can easily arise through methodological differences. What is needed are direct comparisons of different countries or ethnic groups using the same methodology. An important study of this sort has compared Nigerians with African Americans (Hendrie *et al.*, 2001). This study found that the incidence of AD was higher in African Americans, but the cause of the difference is not known.

27.2 FAMILIAL AND GENETIC FACTORS

27.2.1 Family history

A family history of dementia is an important risk factor. A meta-analysis of case-control studies found that risk for AD was around 3.5 times higher in individuals who had at least one first-degree relative with dementia (van Duijn *et al.*, 1991). Family history was stronger in those with early-onset AD compared with those with late-onset. Some families show an autosomal dominant pattern of inheritance for early-onset AD, but these are rare. A first-degree relative's actual percentage risk of developing AD will depend on their longevity. A large US study estimated the risk as 5 per cent up to age 70, 16 per cent up to age 80 and 33 per cent up to age 90 (Lautenschlager *et al.*, 1996).

27.2.2 Disease-causing mutations

There are a number of mutations which are sufficient in themselves to cause AD. These are mutations of the β -amyloid precursor protein gene on chromosome 21, and the presenilin genes on chromosome 1 and 14 (Lendon *et al.*, 1997). The discovery of these mutations has been of great theoretical importance for an understanding of AD disease, but from a public health perspective they account for very few cases.

27.2.3 ApoE genotype

Apolipoprotein E (ApoE) is a plasma protein involved in cholesterol transport and probably in neuronal repair. ApoE genotype alters risk for AD, but unlike the mutations

discussed above, does not in itself cause the disease. This gene, on chromosome 19, has three common alleles: $\epsilon 2$, $\epsilon 3$ and $\epsilon 4$. The $\epsilon 3$ allele is the most common in the population and the $\epsilon 2$ allele the least common. The $\epsilon 4$ allele is more common in Caucasians than in Japanese. The $\epsilon 4$ allele increases risk in a dose-dependent manner, while the $\epsilon 2$ allele decreases risk. A meta-analysis of relevant studies found that ApoE genotype is an important risk factor in all ethnic groups studied (Farrer *et al.*, 1997). Among Caucasians, for example, the $\epsilon 4/\epsilon 4$ genotype was associated with around 15 times the risk of AD compared with the common $\epsilon 3/\epsilon 3$ genotype, while the $\epsilon 3/\epsilon 4$ genotype was associated with around three times the risk. This increased risk was found for all ages between 40 and 90 years, but the effect diminished after age 70.

27.2.4 Other genetic risk factors

There are undoubtedly other polymorphisms which affect risk for AD. Although several have been proposed, subsequent research has not always been able to replicate the initial findings. For example, many studies have looked at polymorphisms in the regulatory region of the ApoE gene, but without consistent findings.

27.2.5 Down's syndrome

Virtually all people with Down's syndrome have the neuropathological features of AD by the age of 40 years. This pathology is due to having an extra copy of the amyloid precursor protein gene which is on chromosome 21. Nevertheless, the prevalence of dementia in people with Down's syndrome is much less than 100 per cent even by age 50 (Zigman *et al.*, 1996). The reason for this discrepancy between pathology and function is not understood. One study found that men with Down's syndrome were more likely to develop dementia than women and that those with an $\epsilon 4$ allele were at increased risk (Schupf *et al.*, 1998).

27.3 PREMORBID COGNITIVE AND BRAIN RESERVES

27.3.1 Education

Several studies have found that less educated individuals have a higher incidence of AD or cognitive decline (Stern *et al.*, 1994; White *et al.*, 1994; Farmer *et al.*, 1995), although not all studies show this. One hypothesis to explain this association is that better educated persons are able to compensate for any cognitive decline and the diagnosis of AD or dementia is therefore delayed (Mortimer, 1988). A clinical study of regional cerebral blood flow in AD patients has supported this hypothesis. When highly educated patients were matched to less educated patients for severity of dementia, the highly educated had a greater parietotemporal perfusion

deficit, implying that they were better able to compensate for the pathology (Stern *et al.*, 1992).

27.3.2 Premorbid intelligence

Education is correlated to intelligence, so it could be premorbid intelligence rather than education that is the protective factor. Indeed, one longitudinal study found that a reading vocabulary test was a better predictor of subsequent dementia than education (Schmand *et al.*, 1997). A clinical study of cerebral glucose metabolism in patients with AD showed greater hypometabolism in those with greater premorbid intelligence (Alexander *et al.*, 1997).

While the evidence on education and premorbid intelligence generally has been interpreted in terms of compensation for pathology, an epidemiological study of elderly nuns found evidence that verbal ability may directly influence AD pathology (Snowdon *et al.*, 1996). This study assessed verbal ability by analysing the autobiographies the nuns had written as young adults for density of ideas and grammatical complexity. Cognitive function was assessed approximately 58 years later and those nuns who subsequently died had a neuropathological examination. Not surprisingly, low idea density and grammatical complexity in young adulthood were associated with poorer cognitive functioning in old age. More surprising was the finding that low verbal ability early in life was related to AD pathology. Among the nuns who had died at follow up, all of those with neuropathologically confirmed AD had low verbal ability, compared with none of those without AD.

Even earlier premorbid intelligence differences have been reported in a Scottish study, which found that late-onset dementia was associated with lower intelligence test scores during childhood (Whalley *et al.*, 2000).

27.3.3 Brain reserve

The apparent protective effects of education and premorbid intelligence could be mediated by brain reserve (Schofield, 1999). Brain imaging studies have found that IQ is related to brain size and there is also some evidence that it is related to education (Jorm *et al.*, 1997). Several lines of evidence directly support the notion that brain reserve is protective. A neuropathological study found that individuals who had AD changes at autopsy, but were not demented during life, had bigger brains (Katzman *et al.*, 1988). Furthermore, individuals who have a larger brain on a scan or a larger head size appear to have a reduced risk of AD (Schofield, 1999).

27.4 MEDICAL HISTORY AND TREATMENTS

27.4.1 Head trauma

A meta-analysis of case-control studies found that a history of head trauma with loss of consciousness was associated

with a doubling of risk of AD in males, but no increased risk in females (Fleminger *et al.*, 2003). Supporting a role for head trauma as a risk factor, A β protein can be deposited extensively in the brain following severe head injury (Roberts *et al.*, 1991). This protein is one of the pathological hallmarks of AD. Unfortunately, in most of the risk factor studies, the incidence of head trauma was assessed retrospectively using reports from relatives who may be subject to biased reporting. Most prospective studies using objective medical records of head trauma have not supported an association with AD (Fleminger *et al.*, 2003). Some research has supported the hypothesis that head trauma is only a risk factor for individuals who carry the ApoE ϵ 4 allele (Mayeux *et al.*, 1995). However, other studies have not reported this effect.

27.4.2 Anti-inflammatory medication and arthritis

McGeer and colleagues (1990) have hypothesized that AD involves a chronic inflammatory state of the brain. They predicted that individuals taking anti-inflammatory drugs, or with diseases such as arthritis which are treated with such drugs, would be protected from AD. A meta-analysis of such studies provides some support for this prediction. Users of non-steroidal anti-inflammatory drugs (NSAIDs) were found to have 72 per cent of the risk of non-users (Etminan *et al.*, 2003). However, the appropriate dosage and duration of drug use was unclear. Randomized controlled trials of anti-inflammatory drugs are needed to confirm a preventive effect and are underway (Martin *et al.*, 2002; see also Chapter 37).

27.4.3 Oestrogen replacement

Animal studies have shown that oestrogen has multiple neuroprotective effects, including increased cerebral blood flow, stimulation of cholinergic activity, acting as a cofactor with nerve growth factors, prevention of neural atrophy and reversal of glucocorticoid damage (Burns and Murphy, 1996). Some epidemiological studies have suggested that oestrogen replacement therapy in post-menopausal women may have a protective effect. A meta-analysis pooling data from case-control and prospective studies found that oestrogen reduced the risk of AD by around 30 per cent (Yaffe *et al.*, 1998). A problem in interpreting these results is that better educated women are more likely to take oestrogen and, as discussed above, education may itself be protective. It is also possible that women tend to stop taking oestrogen if they begin to deteriorate cognitively. Randomized trials would provide the best evidence on the issue. However, data from a randomized controlled trial of oestrogen plus progestin involving over 4000 women found an increased incidence of dementia in those on medication (Shumaker *et al.*, 2003). This result has dashed the hope that oestrogen could be an important preventive intervention.

27.4.4 Vascular risk factors

AD has traditionally been thought of as separate from vascular dementia. However, in recent years, evidence has accumulated that vascular risk factors are involved. Several prospective studies show that both hypertension and diabetes increase risk for AD, although the evidence on these associations is not entirely consistent (Launer, 2002).

Another vascular risk factor receiving a lot of attention is plasma total homocysteine, which is thought to increase risk for stroke. Both case-control and prospective studies also support its role as a risk factor for AD (Morris, 2003).

Cholesterol may also have a role in AD. ApoE is the principal cholesterol carrier in the brain and, as described earlier, the $\epsilon 4$ allele of the ApoE gene increases risk for AD. There is some support for high cholesterol as a risk factor and for a protective effect of statins, a group of drugs that reduces cholesterol (Puglielli *et al.*, 2003).

How these vascular risk factors increase risk is not understood. One explanation is that they cause cerebrovascular disease that summates with AD pathology to produce dementia. However, a direct involvement in AD pathology is also possible.

27.4.5 History of depression

There is a general consensus that depression may be a prodromal feature of AD, but the interest lies in whether it could also be a risk factor. A meta-analysis of case-control studies and prospective studies found that a history of depression approximately doubles the risk of developing dementia (principally AD) (Jorm, 2001). There are several potential explanations of this association, the three most likely being:

- depression is a very early prodrome of AD;
- history of depression brings forward the clinical recognition of dementing diseases by adding in additional cognitive or motivational deficits; and
- depression leads to damage to the hippocampus through excessive glucocorticoid secretion (Jorm, 2001).

27.4.6 Herpes simplex virus

A neuropathological study has found that herpes simplex virus type 1 in the brain is a risk factor for AD in individuals who carry the ApoE $\epsilon 4$ allele (Itzhaki *et al.*, 1997). However, the virus was not a risk factor in individuals without the $\epsilon 4$ allele. The authors proposed that the virus is present in the brain in latent form and reactivates under certain conditions. ApoE genotype may affect the number of cells infected or the number of viruses released and hence the extent of any neuronal damage.

27.5 HEALTH HABITS

27.5.1 Alcohol consumption

A French prospective study found that wine drinking was protective for AD (Orgogozo *et al.*, 1997). Risk was reduced 80 per cent in moderate drinkers compared with abstainers. Subsequent work has found a protective effect for moderate drinking of alcohol in general (Huang *et al.*, 2002), although some work suggests the effect is greater for vascular dementia than for AD (Ruitenberg *et al.*, 2002).

27.5.2 Smoking

The evidence on smoking as a risk factor has been inconsistent. A meta-analysis of case-control studies found a reduced risk for AD in smokers, whereas prospective studies showed a slightly increased risk (Almeida *et al.*, 2002). Case-control studies may be affected by 'survivor bias' whereby smokers with AD are less likely to get included into studies because of early mortality.

27.6 DIET

27.6.1 Aluminium in drinking water

Early pathological research found increased concentrations of aluminium in the brains of AD cases, leading to the hypothesis that aluminium exposure plays a causative role. However, more recent research has disputed the initial finding, claiming that the aluminium was simply a contaminant in the pathologists' stains. Although aluminium exposure can produce an encephalopathy, this does not involve the pathological hallmarks of AD. Nevertheless, aluminium could play a contributing role in AD and epidemiological research on the topic has continued, centring particularly on aluminium in the water supply (Flaten, 2001). Although drinking water provides only around 2.5 per cent of dietary aluminium, the aluminium which is added as a flocculent during water treatment is in a soluble form, which might have greater bioavailability. Although the evidence is not consistent, several studies have found higher rates of AD in regions with high aluminium content in water, particularly where the water is acidic. Despite the weakness of the evidence, it might be prudent to keep the aluminium content of drinking water as low as practicable (Douglas, 1998).

27.6.2 Other dietary factors

Diet has received much less attention from researchers than many other factors. Nevertheless, there has been some interest in antioxidants as a protection factor, since these mop up free

radicals, which are believed to be a source of age-related neuronal degeneration. The evidence has been rather mixed, with some studies finding that vitamins C or E might be protective, but others finding no association (Luchsinger *et al.*, 2003).

In section 27.4.4, the role of homocysteine as a risk factor was mentioned. Homocysteine is increased by low levels of folate and vitamin B₁₂, leading to the expectation that dietary factors could be important. However, the potential protective effect of increasing dietary intake of folate and B₁₂ remains to be tested.

Several studies have found that fish consumption may be protective (Kalmijn *et al.*, 1997; Morris *et al.*, 2003). It has been proposed that fish is an important dietary source of *n*-3 polyunsaturated fatty acids, which are a primary component of membrane phospholipids in the brain.

Animal studies show that caloric restriction increases lifespan, presumably through decreased production of free radicals. Consistent with these findings, some epidemiological studies have found that higher caloric intake is associated either with AD or greater cognitive decline (Luchsinger *et al.*, 2002).

27.7 OCCUPATIONAL AND RECREATIONAL FACTORS

Findings on occupational hazards generally have been negative (Gun *et al.*, 1997). An exception may be exposure to electromagnetic fields. A series of case-control studies found that AD cases were more likely to have worked in occupations where exposure was high (Sobel *et al.*, 1996). These occupations involve working with electric motors very close to the body. Such occupations include carpenter, electrician, machinist and seamstress. It has been hypothesized that electromagnetic fields may upset intracellular calcium ion homeostasis which may promote the cleavage of amyloid precursor protein into A β (Sobel and Davanipour, 1996).

There is some evidence that recreational activities may be protective. A prospective study found that reading, playing board games, playing musical instruments and dancing were protective for AD and for vascular dementia (Verghese *et al.*, 2003). It is always possible that a lower level of these activities indicates preclinical dementia, but the association was also found when subjects in a possible preclinical state were excluded. There is also evidence that having an extensive social network may protect against dementia (Fratiglioni *et al.*, 2000). Again, a preclinical effect of AD is a possibility. With recreational and social activities, a randomized controlled trial would be required to demonstrate an unequivocal protective effect.

27.8 PREVENTIVE POSSIBILITIES

Ultimately, the prevention of AD will rest on an understanding of the biological processes involved. However, even without

such an understanding, public health efforts towards prevention are possible through modification of risk factors. At this stage of our knowledge there are only four risk factors that we could say are confirmed beyond reasonable doubt: old age, family history of dementia, Down's syndrome and ApoE genotype. None of these factors gives scope for preventive action through risk factor modification. Of the possible risk and protection factors reviewed above, the most relevant for preventive action are: head trauma, exposure to electromagnetic fields, anti-inflammatory medication, vascular risk factors, diet, an engaged lifestyle and education.

Prevention of head trauma is itself an important public health goal. There are already laws in many countries to require the wearing of seat belts and helmets. There are also restrictions on boxing. The possible association with AD should encourage such preventive efforts.

The research on electromagnetic fields is still in its infancy. However, it would be prudent to take action anyway. Sobel *et al.* (1996) have recommended that motors for industrial machines should be moved further from the body and be shielded by special metals.

Anti-inflammatory drugs have excited the most interest for prevention. The side effects of these drugs make them unsuitable for preventive use in the population as a whole. However, the risks may be outweighed by the potential benefits for high-risk individuals, such as those with a family history of AD. Current research, such as the Alzheimer's Disease Anti-Inflammatory Prevention Trial (ADAPT) (Martin *et al.*, 2002), will provide definitive answers.

Modification of vascular risk factors is feasible and has other potential benefits besides the prevention of AD. Antihypertensive treatment trials for the prevention of vascular diseases now generally include dementia or cognitive impairment as a secondary outcome. One trial, the Syst-Eur study, has found a preventive effect on AD (Forette *et al.*, 2002), but another trial, the SCOPE study, failed to find a preventive effect on dementia (Lithell *et al.*, 2003).

Diet provides another readily implementable approach to prevention. If homocysteine can be lowered by increasing folate intake, then food fortification could be carried out. Similarly, consumption of *n*-3 fatty acids could be encouraged through health promotion campaigns. However, randomized controlled trials of dietary interventions still need to be undertaken.

Having an engaged lifestyle is often advocated on the 'use it or lose it' principle and there is some epidemiological support for the benefits of having greater intellectual and social activity. While the evidence is not completely convincing in the absence of randomized controlled trials, there is minimal risk in a more engaged lifestyle, so encouraging such lifestyle change is justifiable.

If education and premorbid intelligence are protective, this has interesting implications for the future. Years of formal education are rising over successive cohorts in many developed countries, as are scores on IQ tests (Flynn, 1987).

Even brain weight has increased over the past century (Miller and Corsellis, 1977). These factors might lead to a lower incidence of AD in the future, although there is no evidence for a reduction in incidence over recent decades (Kokmen *et al.*, 1988), in spite of such changes.

The effect of any successful attempt at risk factor modification would probably be to delay onset rather than to completely avoid the disease. Nevertheless, it has been estimated that even a mean delay of 1 year could produce a large reduction in the number of cases in a population (Brookmeyer *et al.*, 1998). A delay of this magnitude may be quite feasible in the near future.

The natural history of Alzheimer's disease

JODY COREY-BLOOM AND ADAM S FLEISHER

28.1 Clinical features	376	28.5 Survival in Alzheimer's disease	381
28.2 Clinical utility of assessing change	377	28.6 Conclusions	383
28.3 Clinical predictors of rate of progression	379	References	383
28.4 Predicting nursing home placement in Alzheimer's disease	381		

Since the prevalence of Alzheimer's disease (AD) is expected to nearly quadruple in the next 50 years, it will undeniably continue to be an enormous public health problem in the elderly (Brookmeyer *et al.*, 1998). Knowledge of the clinical features and natural history of AD will facilitate planning in response to the increased demands on medical and social resources. In addition, this information will enable clinicians to provide patients and families with a more reliable prediction of the course of the disease. Furthermore, staging and monitoring AD is important in recruiting patients for clinical studies at definable levels of severity, and for measuring the value of interventions that may alter its course.

28.1 CLINICAL FEATURES

The diverse spectrum of symptoms of AD reflects dysfunction of widespread regions of the cerebral cortex. Symptoms begin insidiously, making it difficult to date the onset of cognitive and functional decline precisely. Progression is generally gradual and inexorable with occasional pauses; however, reliable measurement of disease progression in AD is difficult because of variability between and within subjects.

Memory loss is the cardinal and commonly presenting complaint in AD. Initially the patient has difficulty recalling new information such as names or details of conversation, while remote memories are relatively preserved. With progression, the memory loss worsens to include remote memory (Wilson *et al.*, 1983; Sullivan *et al.*, 1986; Bondi *et al.*, 1994; Cummings and Cole, 2002). Early in AD, judgement and abstraction are often impaired, suggesting involvement of the frontal lobes. Social comportment and interpersonal

skills are often strikingly preserved, and may remain relatively intact long after memory and insight have been lost.

Language is frequently normal early in AD, although reduced conversational output may be noted. As dementia progresses, many patients become more recognizably aphasic. Initially this manifests as dysnomia and mild loss of fluency, with paraphasic errors and relative preservation of repetition, a pattern resembling transcortical sensory aphasia (Cummings *et al.*, 1985; Cummings and Cole, 2002). At a later stage, language is obviously dysfluent and repetition impaired; terminally, a state of near-mutism may occur (Murdoch and Chenery, 1987).

Visuospatial impairment in AD results in symptoms such as misplacing objects or getting lost, and difficulty with tasks such as recognizing and drawing complex figures (Brouwers *et al.*, 1984; Kavcic and Duffy, 2003). Difficulty with calculation (affecting skills such as handling money), apraxia and agnosia are further problems that develop in AD. Apraxia may impair activities such as operating appliances or dressing; as might be expected, more complex skills tend to break down first, while highly overlearned motor tasks (e.g. playing a musical instrument, using tools) may be retained until relatively late in the course (Rapcsak *et al.*, 1989; Helmes and Ostbye, 2002). Agnosia develops in middle to late stages of AD, and includes features such as failing to recognize family members or spouses.

Psychiatric and behavioural symptoms occur frequently in AD. Over and above a general decline of activity and interest in virtually all AD patients, depressive symptoms occur in about 25 per cent, although severe depression is uncommon (Cummings *et al.*, 1987; Rosen and Zubenko, 1991; Becker *et al.*, 1994; Cummings and Cole, 2002). The frequency of significantly depressed mood in patients with AD ranged

from 0 to 87 per cent in 30 studies reviewed by Wragg and Jeste (1989) with higher rates reported from acute care facilities than in series from outpatient research sites. While many AD patients have depressive symptoms, most do not display enough features to meet DSM-IV criteria for major depressive disorders. The fact that vegetative symptoms such as sleep disturbance, weight gain, loss of libido, lack of interest and reduced motor activity are common to both AD and depression may account for the high rate of 'depression' found in some studies (Lazarus *et al.*, 1987; Becker *et al.*, 1994; Jost and Grossberg, 1996).

Delusions are common in AD, although they are rarely as systematized as in schizophrenia. They often have a paranoid flavour, with fears of personal harm, theft of personal property and marital infidelity. Misidentification syndromes also occur; whether these represent true delusions is unclear. The prevalence of psychotic symptoms in AD, the relationship of hallucinations and delusions to the severity of cognitive impairment, and the influence of psychosis on the rate of cognitive decline are controversial. Estimates of the prevalence of psychotic symptoms in AD range from 10 to 73 per cent, with most in the range of 28–38 per cent (Wragg and Jeste, 1989; Mega *et al.*, 1999). Delusions have been reported in 13–75 per cent of AD patients, and hallucinations, more commonly visual than auditory, in 3–50 per cent (Mayeux *et al.*, 1989; Becker *et al.*, 1994; Jost and Grossberg, 1996; Cook *et al.*, 2003). This substantial variation in frequencies is probably due to different methodologic approaches, especially in defining delusions and hallucinations, and to differences in the range of severity of AD in each series. Although psychotic symptoms may occur throughout the course of AD, they have their highest frequency at a moderate level of dementia (Drevets and Rubin, 1989).

In addition to depression and psychotic symptoms, AD patients show a wide range of behavioural abnormalities including agitation, wandering, sleep disturbances and disinhibition (Becker *et al.*, 1994; Jost and Grossberg, 1996; Lyketsos *et al.*, 2002). These often impose a significant burden on caregivers, and may precipitate nursing home placement. In contrast to psychotic symptoms, behavioural disturbances are more clearly associated with the degree of dementia (Teri *et al.*, 1988). Agitation includes physical aggression, verbal aggression and non-aggressive behaviours, such as motor restlessness and pacing (Reisberg *et al.*, 1987; Swearer *et al.*, 1988; Burns *et al.*, 1990; Hooker *et al.*, 2002). Wandering behaviour affects 3–26 per cent of AD outpatients. Insomnia and sleep disturbances are inconstant features of AD and sexual disinhibition has been reported in less than 10 per cent of patients (Burns *et al.*, 1990; Becker *et al.*, 1994). Thus, behavioural symptoms are a pervasive and poorly understood concomitant of cognitive deterioration in AD.

Excluding mental status testing, the neurologic examination is usually normal in AD, and the presence of significant or lateralizing abnormalities often suggests other diagnoses. Primitive reflexes (snout, glabellar, grasp),

impaired graphesthesia, and an abnormal response to double simultaneous stimulation (face–hand test) are frequently encountered in AD (Galasko *et al.*, 1990; Becker *et al.*, 1994). Variable features, including extrapyramidal signs (rigidity and bradykinesia), gait disturbances and myoclonus may occasionally be seen early in the course of AD, and increase in prevalence with the severity of the disease (Stern *et al.*, 1987). The frequency of extrapyramidal signs in patients with AD was as low as 12–14 per cent in some series (Galasko *et al.*, 1990; Burns *et al.*, 1991; Becker *et al.*, 1994), and as high as 28–92 per cent in others (Mayeux *et al.*, 1985; Molsa *et al.*, 1986; Bakchine *et al.*, 1989; Lopez *et al.*, 2000), depending on the severity of dementia in patients who were studied. In intermediate or advanced stages of dementia, patients often develop non-specific impairment of gait and balance, leading to an increased risk of falls. Myoclonus develops late in the course of AD and longitudinal studies report an increase in its frequency during follow up (Mayeux *et al.*, 1985; Hauser *et al.*, 1986; Tschampa *et al.*, 2001).

As neuronal degeneration progresses in AD, all of the above symptoms worsen, and eventually patients become uncommunicative, unable to care for themselves, walk, or maintain continence. They require total care, including feeding, and are often institutionalized.

28.2 CLINICAL UTILITY OF ASSESSING CHANGE

The course of AD and the combination of symptoms that manifest in each patient are markedly heterogeneous; however, there are several direct clinical applications of tracking change. First, in early cases of AD, where impairment is mild, documenting progression helps to confirm or establish the diagnosis of dementia. Clearly, progressive cognitive deterioration is incompatible with normal ageing, depression, delirium, or a static encephalopathy. The clinical follow up of patients who are initially classified as having AD greatly increases the accuracy of the diagnosis.

Second, progression to a greater degree than expected may prompt the physician to look for a superimposed factor that may be treatable, such as hypothyroidism, intercurrent infection, medication toxicity or depression.

Third, defining the anticipated course of AD in detail enables clinicians to provide patients and families with realistic expectations regarding the disease, and aids in making decisions for day care or institutionalization.

Longitudinal cognitive change may be fruitfully applied to several problems in clinical research. Change over time on mental status scores may be used to examine the influence of genetic/environmental factors or experimental treatment on the rate of dementia progression.

Attempts to refine the natural history of AD have used two basic methods: global staging systems and serial changes on psychometric test scores.

28.2.1 Measuring change with global staging systems

Staging systems for AD comprise information on intellectual, social and community functioning obtained by history rather than formal rating scales. Two widely used schemes are the Washington University Clinical Dementia Rating (CDR) scale (Hughes *et al.*, 1982; Morris 1997) and the Global Deterioration Scale (GDS) (Reisberg *et al.*, 1982, 1986), which divide AD into a succession of stages. These scales reflect an overall, indirect evaluation of cognition, primarily obtained from caregivers, rather than a direct assessment of the patient, but are able to assess the influence of cognitive loss on the ability to conduct everyday activities. They provide information about clinically meaningful function and behaviour and are less affected by the 'floor' and 'ceiling' effects commonly associated with psychometric tests.

The CDR incorporates information from patients and informants concerning six areas of mental function: memory, orientation, judgement and problem solving, community affairs, home and hobbies, and personal care. Each area is scored as 0 = normal, 0.5 = questionable, 1 = mild-, 2 = moderate-, or 3 = severe-impairment, and integrated to obtain an overall stage of dementia, using similar definitions of 0, 0.5, and 1–3. Interrater reliability is high, with a correlation of 0.91, and the CDR has been standardized for multi-centre use (Morris, 1997). Since the CDR includes cognitive items and activities of daily living (ADL), it is not surprising that it correlates well with the cognitive Blessed Information-Memory-Concentration (BIMC) scale ($r = 0.55$) and with the ADL-based Blessed Dementia Scale (BDS) ($r = 0.53$) (Berg *et al.*, 1988). Putting the CDR into practice, these authors followed a cohort of 43 initially mild AD patients (CDR 1) for 90 months. Over 67 per cent of patients progressed to CDR 3 (severe dementia) by 50 months, and over 80 per cent by 66 months. Many patients in this CDR 1 group reached end points: 50 per cent of patients were institutionalized by 40 months, and 80 per cent by 60 months. Thirty per cent of patients died by 40 months, and 40 per cent by 72 months. Although the CDR is clearly a useful staging instrument (Morris, 1997) and has become widely accepted in the clinical setting as a reliable and valid global assessment measure for AD, it is not as sensitive a measure of annual or short-term rate of change, as movement from one stage to the next may take several years (Storandt *et al.*, 2002).

The GDS divides AD into a succession of seven major, clinically distinguishable stages (further subdivided into 16) ranging from normal cognition (GDS 1) to severe dementia (GDS 7) (Reisberg *et al.*, 1982). Criteria for many of the stages combine history (initially of memory decline, later of functional impairment, progressing to loss of self-care, language and gait), and mental status examination. Stages defined by this integration of history, ADL and cognition should show high correlations with mental state screening tests: indeed, the GDS correlates well with the Mini-Mental State Examination (MMSE) ($r = 0.9$; $P < 0.001$) and the BIMC

($r = 0.8$, $P < 0.001$) (Reisberg *et al.*, 1989). GDS stages 1 and 2 correspond to CDR 0, representing normal ageing, and GDS 3 is equivalent to CDR 0.5. In a longitudinal study, only 5 per cent of GDS 2 subjects became demented over 3–4 years, whereas 15 per cent of GDS 3 subjects progressed to more advanced stages of dementia.

The GDS has similar virtues and drawbacks to the CDR, namely difficulty in defining a natural history over periods shorter than a year or two. The primary use of these staging systems may be in research settings and in following patients longitudinally over extended periods, since the transitions from one stage to the next occur over relatively long intervals.

28.2.2 Measuring change by rate of decline on cognitive tests

As a more flexible longitudinal index of brain function, studies have measured the annual rate of change (ARC) of mental status test scores in AD. Longitudinal data exist for ARC on five mental status tests in common use: the BIMC, the MMSE, the Dementia Rating Scale (DRS), the Cambridge Cognitive Examination (CAMCOG) (Roth *et al.*, 1986), and the Alzheimer's Disease Assessment Scale (ADAS) (Rosen *et al.*, 1984). Unfortunately, although these rates of decline are available, their generalizability is uncertain.

Katzman *et al.* (1988) compared four groups of subjects with AD on the BIMC, with follow up over 1 year. These cohorts differed substantially with regard to age, education, sex and severity of dementia, and included community-dwelling and institutionalized subjects. The mean rate of change on the BIMC did not differ significantly among the four groups for subjects who initially made 24 or fewer errors (out of a possible 33). In those patients, the ARC on the BIMC was 4.4 errors per year, and did not vary with age, education or place of residence. Among demented subjects with an initial BIMC score of more than 24 errors, the rate of change was lower, presumably because the test had reached a floor. A similar overall rate of progression for the BIMC was found in a group of outpatients with AD (Ortof and Crystal, 1989). Subjects lost an average of 4.1 points per year, regardless of age of onset, duration of illness, or family history of dementia. Two further studies observed a comparable ARC in community-dwelling AD patients (Thal *et al.*, 1988; Salmon *et al.*, 1990). In all of these studies, the standard deviation was slightly less than the mean ARC over 1 year and the range of ARC varied widely. Significant variation in the mean ARC on the BIMC has been observed, however, by other investigators. For example, Lucca *et al.* (1993) noted a change of only 2.6 (± 4.9) points on the BIMC over 1 year in a group of 56 patients with AD comprising outpatients and inpatients at geriatric institutions. Using data from the California Alzheimer's Disease Diagnostic and Treatment Centers, we observed an annual rate of change of 2.8 points on the BIMC (Corey-Bloom *et al.*, 1993).

For the MMSE, a number of studies have reported a mean ARC in AD ranging from 1.8 to 4.2 points. Of these studies,

the one with the lowest ARC entered patients at a very mild stage of AD (Becker *et al.*, 1988). Studies with the highest ARC had more severely impaired subjects at entry (Yesavage *et al.*, 1988; Burns *et al.*, 1991), while the remaining studies showed an intermediate ARC (about 2.5 points per year) in patients with a moderate initial level of impairment (Uhlman *et al.*, 1986; Salmon *et al.*, 1990; Teri *et al.*, 1990; Corey-Bloom *et al.*, 1993; Aguero-Torres *et al.*, 1998; Swanwick *et al.*, 1998; Thal *et al.*, 2000; Winblad *et al.*, 2001). This illustrates that rate of change on the MMSE is affected by the severity of cognitive impairment even before the test reaches a floor.

Few studies of longitudinal cognitive change in AD have used extended follow-up periods. In a study distinguished by 7 years of follow up, Aguero-Torres *et al.* (1998) found a mean ARC of 2.8 points on the MMSE during their first period of evaluation (entry–3 years) and 3.0 points thereafter (3–7 years). Salmon *et al.* (1990) compared the BIMC, MMSE and DRS in 55 community-dwelling patients with AD over 2 years. Each subject's scores on the three tests were highly intercorrelated at entry and after 1 and 2 years. Over the study period, patients lost a mean of 3.2 points on the BIMC, 2.8 points on the MMSE and 11.4 points on the DRS per year. In general, the group declined to a greater degree on all three scales in the second year than in the first, but this was statistically significant only for the DRS. For individuals, however, the ARC of mental status scores in the first year did not predict the next year's rate of decline.

Two somewhat longer instruments, similar to the DRS, have been used for serial assessment, the CAMCOG and the ADAS. The CAMCOG is the cognitive component of the Cambridge Mental Disorders of the Elderly Examination (CAMDEX), an instrument designed for assessing dementia. It has sections testing memory, language, praxis, orientation, attention, calculation, abstraction and perception, with a maximum total score of 107. In a survey of 110 patients spanning a wide spectrum of severity of AD, Burns *et al.* found a significant decline over one year in the overall score (12.3 points), and in virtually every subsection (Burns *et al.*, 1991). Group scores for memory, orientation, attention and abstraction were close to 'floor' on initial evaluation, and declined further over 1 year. The initial mean MMSE for this group was 10 (± 5.9), lower than in studies cited above, and changed by an average of 3.5 points. A more recent study by Swanwick *et al.* (1998) of 95 less demented subjects reported an annual decline on the CAMCOG of 9.4 (± 9.5) points.

The ADAS includes a cognitive portion, with a maximum of 70 points, and a non-cognitive subscale scored out of 40. Kramer-Ginsberg *et al.* (1988) (and Mohs, personal communication) found an average ARC on the ADAS of 9.3 points in 60 AD patients. Yesavage *et al.* (1988) reported a similar ARC on the ADAS of 8.3 points in 30 patients with AD, and additionally noted a high intercorrelation between selected subscales of the ADAS and the MMSE. More recently, Thal *et al.* (2000) reported an ARC of 7.5 points in a larger group of 102 AD patients participating in the acetyl-L-carnitine (ALCAR)

clinical trial. It should be noted that rates of decline in clinical trials are generally lower than those reported for natural history studies, likely owing to inherent selection biases. Clinical trial participants are hand-selected with regard to concomitant comorbidities and medications, and may represent a population that tends to have better overall health care and more involved caregivers.

Unfortunately, while mean ARC for each of the above cognitive scales was reasonably consistent between studies, the standard deviations were fairly large, roughly equal to the means, indicating substantial individual variability. Some patients' scores did not decline, and even improved over 1–2 years of follow up. This variability has several possible explanations. First, AD may not progress uniformly, since patients with early dementia may enter a 'plateau' phase with relatively slow deterioration. Second, performance on these cognitive tests probably does not decline in a linear fashion. Third, test–retest variability is influenced by patients' mood, attention and motivation and many other issues that have an impact on day-to-day mental performance, adding a further element of uncertainty to ARC calculations. A fourth possibility is that a number of biological and clinical factors may modify the rate of progression of AD. These include demographic characteristics such as age at onset, gender, and education; genetic features such as apolipoprotein (ApoE) status; and clinical factors such as concomitant cerebrovascular disease, presence of psychosis or extrapyramidal signs (EPS), and use of vitamins, oestrogen, lipid lowering agents, or non-steroidal anti-inflammatory drugs.

28.3 CLINICAL PREDICTORS OF RATE OF PROGRESSION

As noted above, a number of factors have been identified that appear to affect the rate of decline in AD; however, this is a thorny issue since variables thought to have independent prognostic significance may simply be markers of the level of disease severity (Drachman *et al.*, 1990).

For example, using a large well-characterized sample of CERAD subjects, Morris *et al.* (1993) found that dementia progression may be non-linear, that rate-of-change determinations were less reliable when the observation period was 1 year or less, and that rate of progression in AD was determined by the severity of cognitive impairment: the less severe the dementia, the slower the rate of decline. Similarly, Teri *et al.* (1995), using a community-based sample of 156 probable AD patients followed for up to 5 years, found that average rate of decline in cognitive function, as measured by the MMSE and Mattis DRS, becomes more rapid as the disease progresses. This has been confirmed by a more recent study by Storandt *et al.* (2002) who, using a large cohort of mildly demented subjects, found that initial dementia severity was the most significant predictor of annual rate of progression on composite psychometric testing, with increasingly steeper

slopes as severity increased. In addition, these authors found that the rates of decline were highly variable from person to person and between groups as well. There was limited evidence for any systematic predictors of cognitive decline, including combined psychometric measures.

Several studies investigating age at onset as a predictor of deterioration have reported a significant association between earlier age at onset and greater rate of cognitive or functional worsening (Lucca *et al.*, 1993; Jacobs *et al.*, 1994; Teri *et al.*, 1995; Mungas *et al.*, 2001; Backman *et al.*, 2003). This is not supported, however, by one study of 95 subjects with AD attending an outpatient memory clinic (Swanwick *et al.*, 1998).

Gender was not seen to influence cognitive decline in several studies of AD (Reisberg *et al.*, 1986; Drachman *et al.*, 1990; Burns *et al.*, 1991; Mortimer *et al.*, 1992; Jacobs *et al.*, 1994; Storandt *et al.*, 2002) but this was not the case for others that reported slower (Heston *et al.*, 1981; Lucca *et al.*, 1993; Aguero-Torres *et al.*, 1998) and faster (Swanwick *et al.*, 1998) rates of progression in men as compared with women.

Level of education has also been examined as a predictor of decline in several studies (Fillee *et al.*, 1985; Katzman *et al.*, 1988; Drachman *et al.*, 1990; Teri *et al.*, 1995; Storandt *et al.*, 2002); however, because minimally educated subjects were not included in most of these investigations, the effect of education requires further examination.

The ApoE $\epsilon 4$ allele is associated with both a high likelihood of developing AD and an earlier age of onset; nonetheless, there have been conflicting results with regard to the influence of ApoE genotype on the course of cognitive decline in AD. Gomez-Isla *et al.* (1996) in a prospective longitudinal study of 359 AD patients, found that the ApoE $\epsilon 4$ allele was not associated with any change in rate of progression of dementia (Gomez-Isla *et al.*, 1996). Likewise, Growdon *et al.* (1996) reported that rate of decline did not vary significantly across ApoE genotype on any neuropsychological test administered to 66 probable AD patients over a span of up to 5.5 years. Kurz *et al.* (1996) noted no association between $\epsilon 4$ status and rate of cognitive decline over 3 years on the CAMCOG or MMSE in 64 clinically diagnosed AD subjects. Furthermore, Frisoni *et al.* (1995) reported a slower rate of progression with increasing $\epsilon 4$ gene dose in a retrospective examination of 62 sporadic AD patients. These latter findings were similar to those of Stern *et al.* (1997) who noted a slower rate of decline on the modified MMSE among patients with ApoE $\epsilon 4$ alleles compared with patients with other genotypes. On the other hand, Craft *et al.* (1998) reported an accelerated rate of decline on the DRS in ApoE $\epsilon 4$ homozygotes with probable AD, and Hirono *et al.* (2003) reported a similar accelerated rate of decline on the ADAS-cog, even after controlling for age, gender, education, test interval and baseline scores.

Concomitant cerebrovascular disease has not been shown to significantly increase rate of cognitive decline in AD (Lee *et al.*, 2000; Storandt *et al.*, 2002). However, one longitudinal study with autopsy follow up of 50 patients with AD and

strokes, compared with 218 AD patients without strokes, showed a slight increase in rate of decline on MMSE scores in the comorbid stroke group for subjects over the age of 80 (Mungas *et al.*, 2001).

Although it has been suggested that patients who develop EPS have a faster rate of decline, many of the earlier studies probably included patients on neuroleptics and those with dementia with Lewy bodies (DLB) (Miller *et al.* 1991; Mortimer *et al.*, 1992; Chui *et al.*, 1994; Stern *et al.*, 1994). It is now clear that there is a pathological subset of dementia patients with α -synuclein positive cortical Lewy bodies (LBs) either in isolation or in addition to typical AD pathology (Olichney *et al.*, 1998). A recent retrospective study by Lopez *et al.* (2000) compared clinical characteristics of 185 autopsy-proven AD and 60 autopsy-proven DLB subjects. These authors found no differences in rate of cognitive decline between the two, although DLB subjects developed EPS earlier (Lopez *et al.*, 2000).

Whether neuropsychiatric symptoms superimposed on AD influence cognitive deterioration has been examined by several authors. Initial reports suggested that AD patients reached end points on a modified MMSE or BDS score more rapidly when psychotic symptoms were present (Mayeux *et al.*, 1985; Stern *et al.*, 1987; Drevets and Rubin 1989; Stern *et al.*, 1990). However, these investigations did not match patients for their level of dementia. Controlling for severity of AD, several studies were unable to replicate these findings (Reisberg *et al.*, 1986; Huff *et al.*, 1990; Chen *et al.*, 1991), although two additional investigations have confirmed psychosis as a robust predictor of cognitive decline (Chui *et al.*, 1994; Stern *et al.*, 1994). One cross-sectional study reported that AD patients with depression had more ADL impairment than those without (Pearson *et al.*, 1989); however, other longitudinal studies found no effect of depression on rate of decline (Lopez *et al.*, 1990; Storandt *et al.*, 2002). Lopez *et al.* (1999) examined the effect of psychiatric symptoms and medications on progression in 179 mild to moderate probable AD patients, followed for a mean of 49.5 ± 27.4 months. These authors found that the presence of psychiatric symptoms and the use of psychiatric medications were associated with increased rate of functional but not cognitive decline.

Whether vitamins, oestrogen, lipid lowering agents, or non-steroidal anti-inflammatory drugs (NSAIDs) affect progression of AD is actively being investigated. High dose vitamin E has been shown to slow disease progression in a double-blind, placebo-controlled, trial of moderately severe AD patients (Sano *et al.*, 1997). Although several observational studies have suggested that oestrogen replacement therapy may have a beneficial effect on cognitive performance in women with AD, many have substantial methodologic problems (Haskell *et al.*, 1997; Yaffe *et al.*, 1998). Furthermore, a recent study of the association between serum oestradiol and oestrone levels in 120 hysterectomized women taking hormone replacement therapy found no significant association between hormone levels and cognitive functioning after either

2 or 12 months of treatment (Thal *et al.*, 2003). Although large cohort analyses have demonstrated decreased prevalence of AD with use of various lipid lowering agents (Rockwood, 2002), the effect of these compounds on progression of cognitive decline in AD will only be answered by the large multi-centre placebo-controlled trials currently underway. Similarly, there have been conflicting results with regard to the effect of NSAIDs on AD progression. Analysis of longitudinal changes over 1 year on measures of verbal fluency, spatial recognition and orientation revealed less decline among AD patients taking NSAIDs than among non-NSAID patients (Rich *et al.*, 1995). On the other hand, a randomized placebo-controlled trial of naproxen and rofecoxib showed no effect on cognitive decline in 351 patients with mild to moderate AD (Aisen *et al.*, 2003).

28.4 PREDICTING NURSING HOME PLACEMENT IN ALZHEIMER'S DISEASE

Most patients with AD reside in nursing homes late in the course of the illness. The interval between the diagnosis of AD and the need for institutional placement has much practical and clinical importance, but is not easy to predict. Dementia severity is usually cited as the most important predictor (Storandt *et al.*, 2002; Figure 28.1); however, behavioural symptoms such as agitation, wandering or aggression may pre-empt nursing home placement, regardless of the level of cognitive impairment. Other variables that greatly influence the decision to institutionalize a demented patient are social support and caregiver burden.

A large population-based historical cohort study by Eaker *et al.* (2002) suggests, not surprisingly, that the presence of dementia increases the overall risk of institutionalization. In their study the adjusted hazard ratio of being admitted to a nursing home for AD cases compared with controls was 5.44 (95 per cent CI 3.68, 8.05), independent of comorbid conditions.

Several studies have examined predictors of institutionalization in AD. As expected, the predictive factors are complex and vary greatly among studies. One investigation of 14 married men with AD found that urinary or faecal incontinence, inability to speak coherently and loss of skills needed for bathing and grooming were major determinants of institutionalization (Hutton *et al.*, 1985). In a 5-year study of 92 patients who developed AD before the age of 70, lower mental status scores or aphasia were more common in those who were institutionalized (Heyman *et al.*, 1987). In most instances nursing home placement occurred because the patients had become almost completely helpless and required 24-hour supervision; for 10 patients the decision was prompted by death or serious illness of their caregivers.

A prospective study of 101 initially community-dwelling AD patients found that 12 per cent with 'mild AD' were in nursing homes after 1 year, and 35 per cent after 2 years

Figure 28.1 Progression to nursing home placement in non-demented (CDR of 0) and demented (CDR 0.5 incipient, 0.5 dementia of the Alzheimer type (DAT), and CDR 1) groups. (Reproduced with permission from Storandt *et al.*, 2002.)

(Knopman *et al.*, 1988). For 'advanced AD', the figures were 39 per cent at 1 year and 62 per cent at 2 years. Total ADL scores were significantly related to institutionalization, while incontinence, irritability, inability to walk, wandering, hyperactivity and nocturnal behavioural problems were the leading reasons for placement cited by caregivers. The importance of disruptive behaviours such as aggressiveness, sleep disturbances and wandering have also been cited as important predictors of institutionalization among AD patients by other authors (Haupt and Kurz, 1993; Bianchetti *et al.*, 1995; Tariot *et al.*, 1995; Lopez *et al.*, 1999).

A CERAD analysis, comprising 20 university medical centres, found that the median time from enrolment to nursing home placement was 3.1 years, with significantly reduced times (2.1 years) for males who were unmarried (Heyman *et al.*, 1997). The major predictors of time to admission were measures of dementia severity upon entry into the study, including the degree of cognitive impairment, functional disability, and overall stage. Age at entry and marital status (men only) also predicted time to nursing home admission. Similar findings with regard to marital status have been reported by others (Haupt and Kurz, 1993).

Finally, a recent large multiregional, prospective study distinguished by an extremely large number of patients ($n = 3944$), found that specific caregiver traits (including age ≥ 80 , low income, poor health and high perceived burden as a result of caregiving) predicted earlier placement for care recipients (Gaugler *et al.*, 2003).

28.5 SURVIVAL IN ALZHEIMER'S DISEASE

Length of survival in AD is highly variable, although an excess mortality has consistently been reported (Katzman, 1976; Jorm *et al.*, 1987; Aevansson *et al.*, 1998). Although

mean survival after symptom onset may range from 2 to >16 years, the observed survival rate among AD populations is generally significantly less than the expected rate, based on life expectancy tables (Walsh *et al.*, 1990). Depending on the study, survival at 5 years ranges from 10 to 40 per cent in different AD populations. Of course, the most favourable survival rates were seen in mild cohorts followed up in outpatient settings, with lowest survival rates reported in relatively severely demented subjects from hospital series. The median duration of survival among CERAD patients from time of study entry was 5.9 years (Heyman *et al.*, 1996), which compared favourably to the 5.3 years reported by Walsh *et al.* (1990), the 5.7 years noted by Molsa *et al.* (1986), and the 5.8 years described by Jost and Grossberg (1995). Three other studies found shorter median periods of survival of 3.4 years (Schoenberg *et al.*, 1987), 3.5 years (Barclay *et al.*, 1985), and 4.3 years (Claus *et al.*, 1998), possibly due to inclusion of more severe subjects.

The shortened survival of AD patients results from complications due to severe mental decline. Malnutrition, dehydration, pneumonia and other infections occur frequently in the terminal stages when patients are bed-bound, incontinent and unable to communicate or feed themselves. Compared with other elderly individuals, AD patients are not especially predisposed to cancer, cerebrovascular or cardiovascular disease (Molsa *et al.*, 1986).

Probably not surprisingly, the most consistent predictors of mortality in AD patients are age, gender and severity of dementia. Age was significantly associated with survival time in a large sample of patients with AD, drawn from throughout the state of California (Moritz *et al.*, 1997). Increasing age has also been related to shorter survival in several additional studies (Hier *et al.*, 1989; Walsh *et al.*, 1990; van Dijk *et al.*, 1991; Heyman *et al.*, 1996; Reisberg *et al.*, 1996; Aguero-Torres *et al.*, 1998; Claus *et al.*, 1998; Gambassi *et al.*, 1999; Ueki *et al.*, 2001). Although two reports have indicated that survival rates of patients with early-onset AD are considerably less than those of late-onset AD (Heyman *et al.*, 1987; McGonigal *et al.*, 1992), this finding has not been confirmed by others (Walsh *et al.*, 1990; Bracco *et al.*, 1994; Corder *et al.*, 1995; Bowen *et al.*, 1996; Heyman *et al.*, 1996).

Most investigators have reported shorter survival times for men than women (Schoenberg *et al.*, 1987; Berg *et al.*, 1988; Burns *et al.*, 1991; van Dijk *et al.*, 1991; Corder *et al.*, 1995; Jagger *et al.*, 1995; Molsa *et al.*, 1995; Stern *et al.*, 1995; Bowen *et al.*, 1996; Heyman *et al.*, 1996; Reisberg *et al.*, 1996; Moritz *et al.*, 1997; Claus *et al.*, 1998; Gambassi *et al.*, 1999; Lapane *et al.*, 2001; Ueki *et al.*, 2001), although this has not been the case for a few studies (Hier *et al.*, 1989; Walsh *et al.*, 1990; Becker *et al.*, 1994). Furthermore, it has been suggested by some that predictors may differ by gender. For example, Moritz *et al.* (1997) found that among men, but not women, survival times were negatively associated with selected neurological symptoms, particularly aphasia and apraxia. Among women, but not men, a history of cardiovascular conditions was associated with poorer survival. Lapane *et al.* (2001) on

Figure 28.2 Progression to the end point of death in non-demented (CDR of 0) and demented (CDR 0.5 incipient, 0.5 dementia of the Alzheimer type (DAT), and CDR 1) groups. (Reproduced with permission from Storandt *et al.*, 2002.)

the other hand, found that the most important predictors of mortality for men were severity of dementia and the occurrence of delirium. For women, death was associated with impairment of ADL, presence of pressure sores, malnutrition and comorbidity.

Patients with more severe cognitive impairment at study entry have consistently been reported to have shorter durations of survival (Walsh *et al.*, 1990; Burns *et al.*, 1991; Evans *et al.*, 1991; Jagger *et al.*, 1995; Heyman *et al.*, 1996; Moritz *et al.*, 1997; Claus *et al.*, 1998; Ueki *et al.*, 2001; Storandt *et al.*, 2002; Figure 28.2). In addition, functional disability has been shown to decrease survival time in AD (Martin *et al.*, 1987; Bianchetti *et al.*, 1995; Heyman *et al.*, 1996; Ueki *et al.*, 2001).

Additional variables that may influence survival time in patients with AD have not been well established, including level of education (Becker *et al.*, 1994; Stern *et al.*, 1995; Geerlings *et al.*, 1997), medical comorbidity (White *et al.*, 1996; Moritz *et al.*, 1997; Aguero-Torres *et al.*, 1998; Gambassi *et al.*, 1999; Lopez *et al.*, 1999), and psychiatric or behavioural symptoms (Barclay *et al.*, 1985; Molsa *et al.*, 1986; Walsh *et al.*, 1990; Stern *et al.*, 1994; Samson *et al.*, 1996), among others.

Survival in AD appeared to be unrelated to ApoE $\epsilon 4$ gene dose in a study by Corder *et al.* (1995). However, Tilvis *et al.* (1998) noted increased mortality in elderly demented patients with the $\epsilon 4$ allele, a finding supported, at least for men, in a recent study of 92 autopsy confirmed AD cases (Dal Forno *et al.*, 2002). On the other hand, Stern *et al.* (1997) found that the presence of at least one $\epsilon 4$ allele was associated with a less aggressive form of AD and a decreased risk of mortality in 99 patients with probable AD followed for up to 6 years.

EPS appeared to be an important predictor of mortality in a population-based study of 198 patients with probable early-onset AD (Samson *et al.*, 1996). EPS at entry was also associated with a higher relative risk of death in 236 patients with mild AD followed semiannually by Stern *et al.* (1994).

Figure 28.3 Survival differences by the presence of extrapyramidal signs (EPSs) and Lewy bodies (LBs) from a life-table analysis. (Reproduced with permission from Haan et al., 2002.)

A recent study of 379 AD patients found similar heightened mortality for EPS and reported that individuals with EPS were three times more likely to have LBs at autopsy (Haan et al., 2002; Figure 28.3). Both EPS and LBs were associated with earlier age at death. This was not the case for a study by Lopez et al. (2000) who reported no differences between AD and DLB with regard to survival.

28.6 CONCLUSIONS

Despite an abundance of observations about the natural history of AD, the variability of its clinical features and rate of progression has not been explained, and the validity of 'subtypes' of AD has not been proven. Overall, the most consistent predictor of more rapid deterioration and death in AD appears to be the degree of cognitive and functional disability. Because of the relatively low prevalence of additional clinical features such as EPS, depression and psychosis at early stages of the disease, larger studies, carefully controlled for the potential confounding effect of dementia severity, are needed to clarify their effect on prognosis.

Neurochemistry of Alzheimer's disease

NICHOLAS A CLARKE AND PAUL T FRANCIS

29.1 Acetylcholine	387	29.4 Treatment strategies based on glutamatergic neurotransmission	390
29.2 Glutamate	389	29.5 Conclusion	390
29.3 Interactions between cholinergic and glutamatergic systems	390	References	391

The known neurochemistry of Alzheimer's disease (AD) has, to date, been characterized by cholinergic neurotransmission dysfunction. Human anticholinergic drug studies (Drachman and Leavitt, 1974), the demonstration of first choline acetyltransferase (ChAT) activity and then acetylcholine (ACh) deficits in people with AD (Bowen *et al.*, 1976), and the subsequent development of the cholinesterase inhibitor (ChEI) class of drug, are now matters of historical record.

Present neurochemical understanding in AD touches, at its limits, upon how early the cholinergic deficit develops and whether it occurs in so-called mild cognitive impairment (MCI). Other basic science research, now informed by therapeutic drug use, assesses the ubiquitous glutamatergic neurotransmitter systems, the workhorse of the brain. Anatomical studies suggest interconnectivity between these two systems, but their exact role in AD will require further elucidation. Just as cholinergic and glutamatergic disruption may be additive in their effect, so may pharmacological replacement therapy be synergistic (Francis *et al.*, 1993).

The mistreatment of tau and amyloid proteins described elsewhere (see Chapters 31 and 32) offers the most upstream knowledge of the AD pathological cascade. Neurotransmitter deficits, neuronal loss and (aberrant) synapse proliferation and subsequent decline suggest possible windows of influence upon the disease. Refinement of neurotransmitter influence on protein mistreatment and other cell level dysfunction is likely to follow. A recent example is the description of beneficial effects of a cholinergic agonist, specific to the muscarinic M1 receptor, upon 'healthy' amyloid precursor protein metabolism (Nitsch *et al.*, 2000).

Recent findings with long-term ChEI treatment show delays to nursing home placements, but not time to reach a specific point of cognitive decline or death (Lopez *et al.*,

2002; Geldmacher *et al.*, 2003). Future research may yet give substance to hopes that disease modification is possible by neurotransmitter manipulation in AD.
